The behavior of the resistance coefficient in nonuniform flow is qualitatively similar to that observed for uniform flow (Fig 2). However, the Λ vs Re curves are shifted to much higher values of resistance coefficient, and to lower values of Reynolds number. This behavior is caused by the nonuniformity of the flow. The values of Λ represented in Fig 2 were calculated by considering a superficial velocity based on the total available cross-sectional area of the porous medium. Rodríguez et al (1993) have argued that, in the nonuniform flow case, the su---ficial velocity of the fluid is not constant over th... ...ow section, and therefore there are regions ... fluid velocity which contribute to increas... ...re drop and to decrease the Reynolds number for the onset of inertial and non-Newtonian effects. Rodríguez et al were able to show by means of a quantitative analysis of the data in Fig. 2 that the addition of polymer modifies the macroscopic flow field and that that flow modification effect is enhanced with increases in polymer concentration.

One of the most important aspects of the results shown in Fig 2 is the fact that, despite the flow modifications induced by the polymer in the nonuniform flow case, there is still a large increase in resistance coefficient with respect to the Newtonian value. We will now explore how the magnitude of this increase compares with the increase observed in uniform flow. For this purpose, we will quantify the increase corresponding to the plateau levels by normalizing the plateau resistance coefficient with respect to the Newtonian and water values.

Let Λ_p be the plateau value of the resistance coefficient. First we will express this value in terms of the shear viscosity of the solution. Consider the ratio of solution to solvent shear viscosities, defined by

$$x = \frac{\eta_{sln}}{\eta_s} \tag{4}$$

The parameter x should also be equal to the ratio between the resistance coefficients of solution and solvent as $Re \to 0$, since, in the viscous limit (Darcian regime), the pressure drop is proportional to the shear viscosity of the fluid.

The value of the plateau resistance coefficient that takes into account shear viscosity effects; i.e., the value of Λ_p calculated by using in Eq 1 the shear viscosity of the solution instead of that of the solvent, is given by

$$\Lambda_x = \frac{\Lambda_p}{x} \tag{5}$$

Let Λ_0 be the resistance coefficient of the solvent (water) at the Reynolds number at which the plateau is reached. Then, the ratio Λ_p/Λ_0 represents the maximum excess resistance coefficient caused by the presence of polymer, regardless of flow distribution effects. One might expect the curves Λ_p/Λ_0 vs C to be the same for uniform and nonuniform flow. These curves are presented in Fig 3. Notice that the maximum excess resistance coefficient is very close between uniform and nonuniform flow for low concentrations, but the nonuniform flow values are appreciably higher at high concentrations. This is caused by the fact that, in the nonuniform flow case, the solution is subjected to point velocities that are substantially higher than the superficial velocity. These high velocities lead to strong elongational flow fields in the pores, that yield a macroscopic pressure drop that exceeds that obtained in uniform flow. This analysis shows that the changes in rheological properties of the solution caused by the elongational flow field result in a higher friction at the pore level, instead of a drastic change in the flow distribution. These results have special relevance in the simulation of non-Newtonian flow in petroleum reservoirs, where the flow distribution is three dimensional.

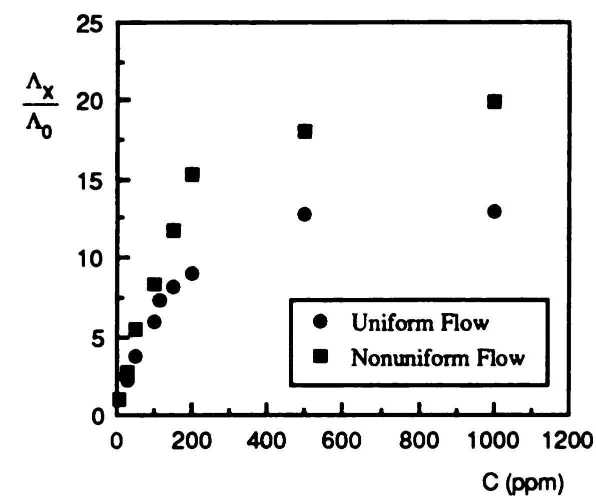

FIG 3. Effect of flow distribution on excess Λ values.

Flow-induced degradation

In order to investigate the mechanical degradation induced by the flow, two PEO (M_v=3E06) solutions (C=100 and 1000 ppm) were repeatedly passed through the uniform-flow porous medium at a constant flow rate while the pressure drop was being recorded.

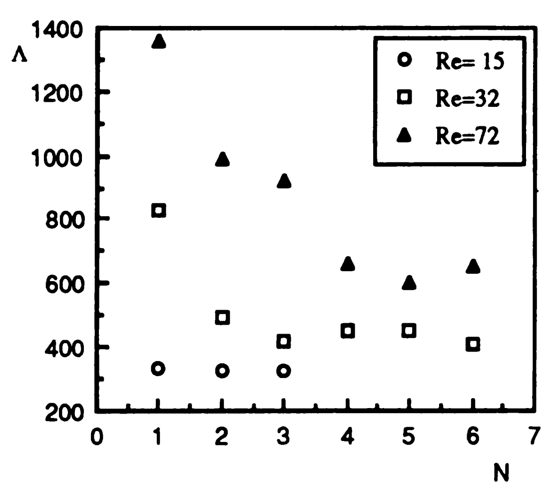

FIG 4. Decrease in resistance coefficient during mechanical degradation of the solution (C=100 ppm).

Figures 4 and 5 show the variation of the resistance coefficient with the number of passes (N) at constant Reynolds number. It can be seen that, at the lowest Reynolds number, there is no appreciable variation in the value of Λ with the number of passes (Fig 4). At higher Reynolds numbers the value of Λ rapidly decreases with N, achieving a nearly constant value after 3 to 4 passes. The decrease in the value of Λ at constant Reynolds number indicates that the solution is being degraded at a particular average strain rate, which is proportional to Reynolds number. Such strain rate for fracture is expected to be dependent on the polymer molecular weight (Odell et al, 1992). Hence when most of the molecules that can be broken at that particular strain rate have been degraded the resistance coefficient will become constant.

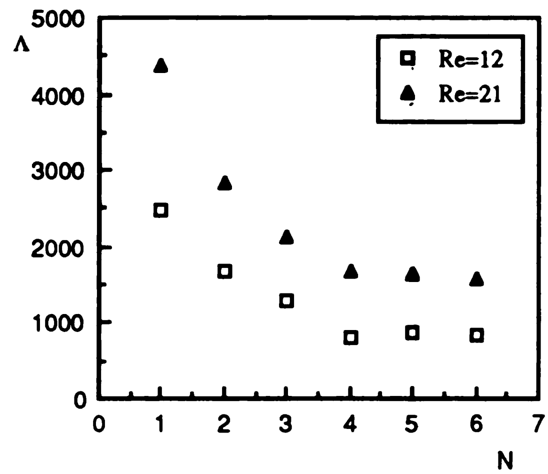

FIG 5. Decrease in resistance coefficient during mechanical degradation of the solution (C=1000 ppm).

The flow induced degradation can also be assessed by the relative displacement of the Λ versus Re curves measured after the solution was circulated at constant Reynolds number. Figures 6 and 7 show how the degradation of the polymer affects the Λ versus Re curves in the whole range of Reynolds number in which the polymer induces a non-Newtonian effect. The onset of non-Newtonian behavior of the solution is shifted to higher values of Reynolds number after degradation occurs. The increase in onset Reynolds number (Re_0) can be interpreted as an increase in the critical strain rate for chain extension or for the onset of transient entanglement network formation, depending on the theory used to explain the sudden increase in flow resistance (Müller et al, 1988). These theories predict that the onset strain rates are proportional to the longest relaxation time of the chain or to the disentanglement time of the molecule, respectively, and both quantities are proportional to the molecular length. Any increase in onset Reynolds number will therefore indicate a decrease in the average molecular weight of the polymer if the same porous medium is used and the solution concentration remains constant.

Figures 6 and 7 also show that the solution is significantly degraded only if the Reynolds number at which it is circulated through the porous medium is higher that the original Re_0 of the undegraded solution. In fact, the value of onset Reynolds number after degradation is close to the Reynolds number at which the solution was degraded. This result implies that most of the molecules break once they are in the stretched state either in isolation or as part of a transient entanglement network. A similar conclusion has been reported in idealized elongational flow experiments (Odell et al, 1990).

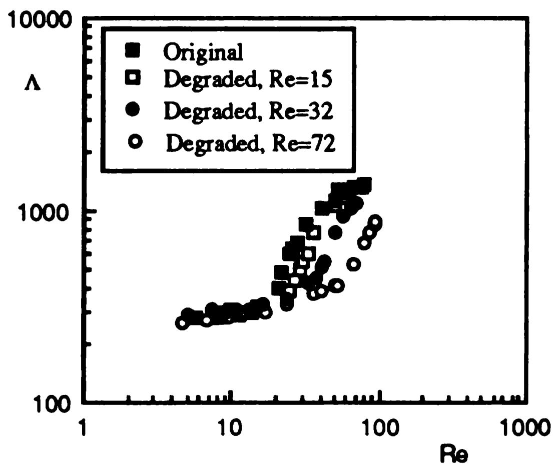

FIG 6. Resistance coefficients of original and degraded solutions, C=100 ppm.

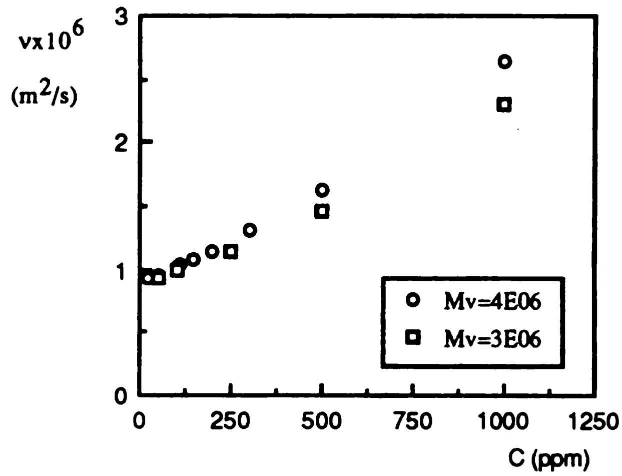

FIG 8. Kinematic viscosity as a function of polymer concentration.

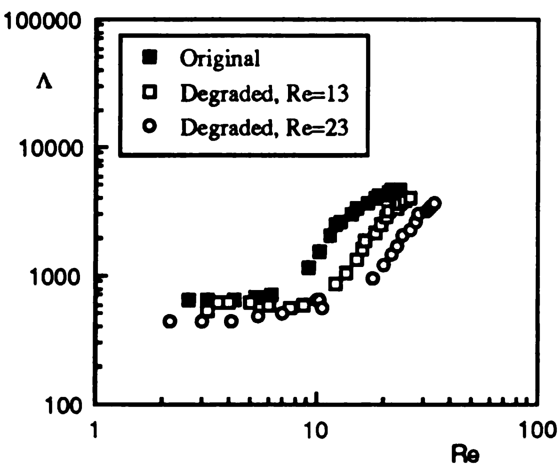

FIG 7. Resistance coefficients of original and degraded solutions, C=1000 ppm.

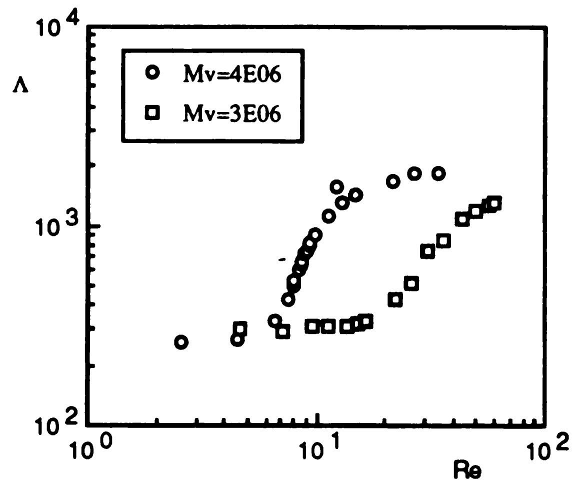

FIG 9. Resistance coefficient vs Reynolds number for 100 ppm PEO solutions.

Molecular weight effects

The effects of molecular weight on the resistance coefficient of polymer solutions in uniform flow were investigated by using two different PEOs (M_v=3E06 and 4E06). Figure 8 presents kinematic viscosity data (ν) as a function of concentration for solutions of both polymers. It can be seen that the shear viscosities do not differ much at low concentrations and it is only beyond 500 ppm where the lower molecular weight PEO exhibits lower viscosities than the higher molecular weight one. However, Figs 9 to 11 show that the porous media flow behavior of these polymer solutions is substantially different even at low concentrations.

Figures 9 to 11 show that the onset Reynolds number is higher for the lower molecular weight polymer. This trend is clearly seen in Fig 12, where the onset Reynolds number is plotted as a function of concentration for the solutions of both polymers. The fact that the drop in Re_0 with C observed is substantial has been used as an argument in favor of transient entanglement network formation as the most likely explanation of the non-Newtonian increases in flow resistance encountered in porous media flow (Rodríguez et al, 1993). Figure 12 also shows that the log-log representation of Re_0 vs C is nearly a straight line, whose slope is independent of molecular weight. Both curves are well fitted by the following relation

$$Re_0 = K\,C^{-0.6} \tag{6}$$

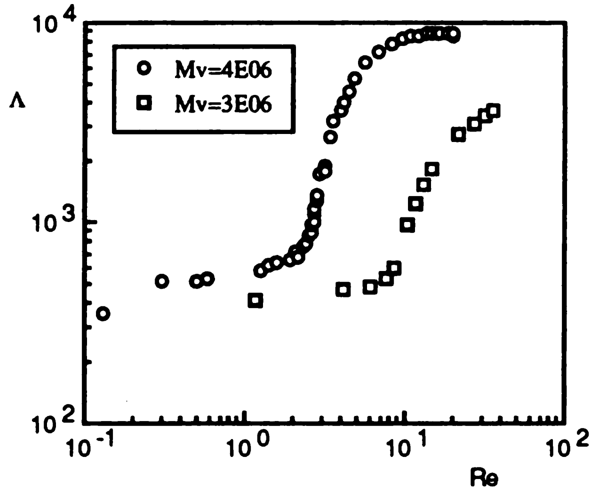

FIG 10. Resistance coefficient vs Reynolds number for 500 ppm PEO solutions.

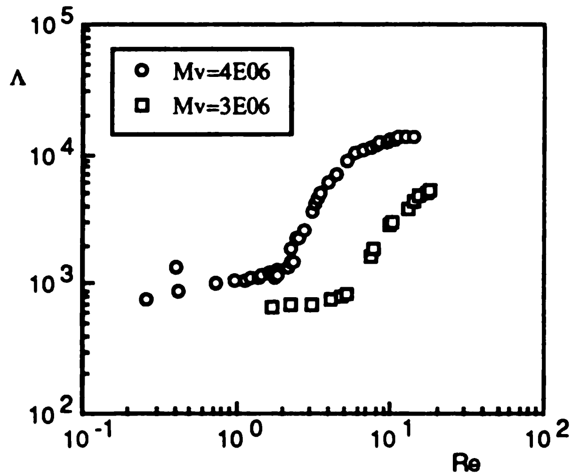

FIG 11. Resistance coefficient vs Reynolds number for 1000 ppm PEO solutions.

This is an interesting observation since it reflects a behavior that is independent of molecular weight. However, this result would have to be validated with the use of better characterized polymer samples such as closely monodisperse standards.

It should be noted that the two 100 ppm solutions used in Fig 9 have identical shear viscosities (see Fig 8); this is also indicated by the fact that the two values of resistance coefficients at very low Reynolds numbers are identical. When higher concentrations are used, the curves corresponding to the two polymers differ from the lowest Re numbers (see Figs 10 and 11). The difference in the saturation value of Λ (Λ_p) is evident from the lowest concentrations: the lower molecular weight polymer causes a lower increase in flow resistance as it is expected.

Due to the nature of the flow field in the porous medium the resistance coefficient should be proportional to the shear viscosities of the polymer solution, at low Reynolds numbers (both viscosities should be equal in this regime). Since no appreciable chain extension would be expected below the onset Reynolds number, the contribution of the elongational viscosity to the value of Λ at low Re would be constant with Reynolds number (Newtonian behavior). However, the value of Λ at high Re (after the sudden increase in Λ) should be influenced by two opposing effects: the shear viscosity of the solution might decrease with increasing shear rate (PEO/water solutions are known to be shear thinning, and this effect is more noticeable at moderate concentrations and it also depends on the molecular weight of the polymer, Dauben and Menzie, 1967) and the elongational viscosity increases with increasing strain rate. It is clear by the shape of the curves in Figs 9 to 11 that the increase in shear viscosity upon increasing solution concentration is responsible for the differences observed in the Λ values at low Reynolds number (Newtonian regime), while the elongational viscosity is dominating the behavior of the resistance coefficient at Reynolds numbers larger than the onset value.

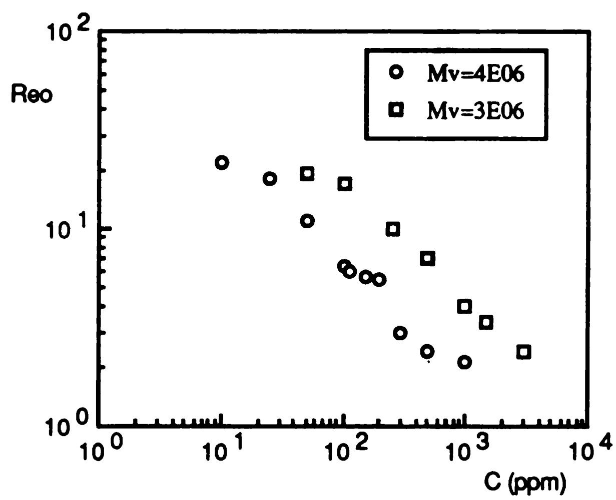

FIG 12. Concentration dependence of the onset Reynolds number for aqueous PEO solutions.

Other important aspects of comparing Λ versus Re curves of the two different molecular weight polymers used here can be appreciated in Figs 13 and 14. In Fig 13 two different concentrations have been deliberately chosen for which the two polymer solutions exhibit the same resistance coefficient plateau (which should be proportional to the elongational viscosity), approximately the same onset Reynolds number and different low Reynolds number resistance coefficients (which should be proportional to the shear viscosity). The case presented in Fig 13 illustrates that two solutions exhibiting very different shear viscosities might produce the same thickening action in porous media flow. Fig 14, on the other hand, depicts another possible case in which the shear viscosities of both polymer solutions are identical but their elongational response varies according to the molecular weight of the polymer. These results lead to conclude that the importance of the elongational viscosity should not be overlooked if polymers are to be selected for applications that involve complex flow situations like porous media flow (encountered, for instance, in enhanced oil recovery). Figs 13 and 14 clearly show that the selection should not be based exclusively on the shear flow behavior.

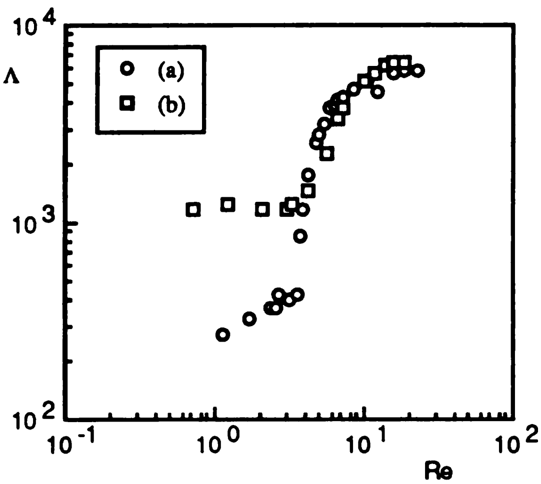

FIG 13. Comparison of resistance coefficient for: (a) M_V=4E06, C=300 ppm; (b) M_V=3E06, C=1500 ppm.

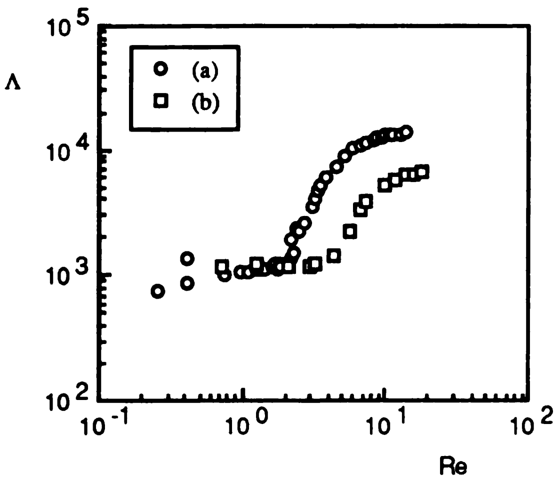

FIG 14. Comparison of resistance coefficient for: (a) M_V=4E06, C=1000 ppm; (b) M_V=3E06, C=1500 ppm.

CONCLUSIONS

We have investigated the effects of flow distribution, polymer degradation, and polymer molecular weight on the fluid dynamics of poly(ethylene oxide) aqueous solutions flowing through porous media. The addition of polymer induces a change in the macroscopic flow distribution within the porous medium. However, the characteristic non-Newtonian increases in flow resistance observed in uniform flow are also present in nonuniform flows. In uniform flows, the polymer molecules are significantly degraded only when non-Newtonian effects are present. An increase in polymer molecular weight results in a substantial reduction of the Reynolds number at which the non-Newtonian effects set in. An important conclusion is that the magnitude of increase in flow resistance caused by the polymer is not exclusively determined by the shear viscosity of the solution. The elongational viscosity plays a more important role at this respect.

Analysis of cylindrically curved panels based on a two field variable variational principle

Maher N Bismarck-Nasr

Divisão de Engenharia Aeronáutica, Instituto Tecnológico de Aeronáutica
Centro Técnico Aeroespacial, São José dos Campos, SP, 12228-900, Brazil

A variational formulation of thin cylindrically curved panels having transverse displacement and Airy stress function as field variable is presented. Euler-Lagrange equations and boundary conditions are obtained. A finite element based on this variational principle preserving $C^{(1)}$ continuity is formulated. Applications for free vibrations, buckling, and supersonic panel flutter analyses are given. Several numerical calculations are presented. The results obtained are discussed and are compared with previous analytical solutions, numerical calculations, and experimental findings.

INTRODUCTION

Structural analysis of plates and shells using two field variables, the transverse displacement w and the Airy stress function F, has been investigated by several authors. Donnell[9], Marguerre[17], and von Kármán[29] made the major contributions in obtaining the differential equations for static analysis. Reissner[23] introduced a variational principle with w and F being the field variables. Based on an order of magnitude analysis to justify the omission of the inplane inertias, Reissner[24] extended the application to dynamic analysis of shallow shells. In spite of the simplifications it introduces, Reissner's two filed variables principle is scarcely used in finite element applications. The main reason is attributed to the complications introduced for the application of the boundary conditions on Airy stress function[12-13].

In Ref 5, starting from Reissner's variational equation for free vibration of thin cylindrically curved panels, the Euler-Lagrange equations governing the problem and the boundary conditions were obtained. It was shown that the boundary conditions on F are as simple and direct to apply as on w. The variational principle was used to derive a C^1 continuity rectangular finite element and numerical results of free vibration for freely supported square curved panels were presented. In Ref 6, the formulation was extended to the buckling analysis of cylindrically curved panels and numerical results were presented for various classical end conditions and for different aspect ratios of the panel. In Ref 7, the formulation was applied to the supersonic flutter of cylindrically curved panels. Numerical results were presented for square panels with flow in the meridional direction for clamped, simply supported, and freely supported end conditions.

The present paper generalizes the formulation and amplifies the results of Refs 5-7. Several numerical results are presented and are compared with previous analytical solutions, numerical calculations, and experimental findings.

PROBLEM FORMULATION

The variational equation of thin cylindrically curved shallow shells, Fig 1, neglecting inplane inertias[24], considering the effect of the work done by an external non-stationary aerodynamic load[7], and the initial inplane prestress[6] can be expressed as,

$$\begin{aligned}\delta(\Pi^*) = \delta\Big\{ & \frac{1}{2}\int_A \rho\, h\, w_{,t}^2\, dA \\ & - \frac{D}{2}\int_A \left[w_{,xx}^2 + w_{,yy}^2 + 2\nu w_{,xx} w_{,yy} + 2(1-\nu) w_{,xy}^2\right] dA \\ & + \frac{1}{2Eh}\int_A \left[F_{,xx}^2 + F_{,yy}^2 - 2\nu F_{,xx} F_{,yy} + 2(1+\nu) F_{,xy}^2\right] dA \\ & - \int_A \frac{w}{R} F_{,xx}\, dA + \int_A w\,\Delta p\, dA \\ & - \frac{1}{2}\int_A \left[N_{xx} w_{,x}^2 + N_{yy} w_{,y}^2 + 2 N_{xy} w_{,x} w_{,y}\right] dA \Big\} = 0 \end{aligned} \tag{1}$$

The functions subjected to variation in Eq (1) are the transverse displacement w and the Airy stress function F. In Eq (1) ρ is the material mass density per unit of area, h is the shell thickness, $D = Eh^3/12(1-\nu^2)$ is the shell flexural rigidity, ν is Poisson's ratio, E is Young's modulus, R is the shell radius, Δp is the non-stationary aerodynamic pressure difference, and N_{xx}, N_{yy}, and N_{xy} are the initial prestresses. Using the quasi-static aerodynamic theory, the relationship between Δp and w can be written as[4]

$$\Delta p = -\frac{2Q}{\sqrt{M^2-1}}\left[\cos\Lambda \frac{\partial w}{\partial x} + \sin\Lambda \frac{\partial w}{\partial y}\right] \tag{2}$$

where $Q = \rho V^2/2$ is the dynamic pressure, M is the free stream Mach number, V is the velocity of the unperturbed external flow, and Λ is the angle between the free stream direction and the x-direction.

Performing the variational operation, grouping terms, and through application of Green's theorem, the variational equation (1) reads

$$
\begin{aligned}
&- \int_A \delta w \left[D\nabla^4 w + \frac{1}{R} F_{,xx} + \rho h w_{,tt} \right] dA \\
&+ \int_A \delta F \left[\frac{1}{Eh} \nabla^4 F - \frac{1}{R} w_{,xx} \right] dA \\
&- \int_C \delta w \left[M_{x,x} + 2 M_{xy,y} \right] dy + \int_C \delta w \left[M_{y,y} + 2 M_{xy,x} \right] dx \\
&+ \int_C \delta w_{,x} M_x \, dy - \int_C \delta w_{,y} M_y \, dx + \int_C \left[M_{xy} \delta w \right]_{,y} dy \\
&- \int_C \left[M_{xy} \delta w \right]_{,x} dx + \int_C \delta F u_{,yy} \, dy \\
&- \int_C \delta F v_{,xx} \, dx + \int_C \delta F_{,x} v_{,y} \, dy - \int_C \delta F_{,y} u_{,x} \, dx \\
&+ \frac{1+\nu}{Eh} \int_C \left[\delta F \cdot F_{,xy} \right]_{,y} dy - \frac{1+\nu}{Eh} \int_C \left[\delta F \cdot F_{,xy} \right]_{,x} dx \\
&+ \frac{2Q}{\sqrt{M^2-1}} \int_A \left[\cos\Lambda \, w_{,x} + \sin\Lambda \, w_{,y} \right] \delta w \, dA \\
&+ \int_A \left[N_{xx} w_{,xx} + N_{yy} w_{,yy} + 2 N_{xy} w_{,xy} \right] \delta w \, dA = 0 \quad (3)
\end{aligned}
$$

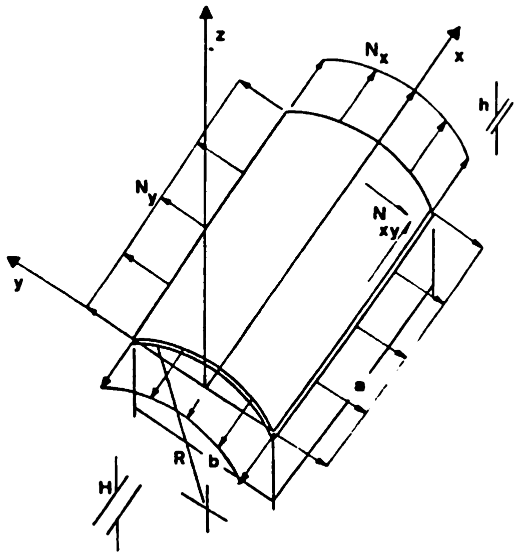

FIG 1. Shell geometry and notations.

Using Eq (3), the Euler-Lagrange equations governing the problem read,

$$
\begin{aligned}
&D\nabla^4 w + \frac{1}{R} F_{,xx} + \rho h w_{,tt} \\
&- \frac{2Q}{\sqrt{M^2-1}} \int_A \left[\cos\Lambda \, w_{,x} + \right.
\end{aligned}
$$

$$- N_{xx} w_{,xx} - N_{yy} w_{,yy} - 2 N_{xy} w_{,xy} = 0 \qquad (4)$$

$$\nabla^4 F - \frac{Eh}{R} w_{,xx} = 0 \qquad (5)$$

and the boundary conditions are given by

1. On $x =$ constant
   - w is prescribed or $M_{x,x} + 2 M_{xy,y} = 0$
   - $w_{,x}$ is prescribed or $M_x = 0$
   - F is prescribed or $u_{,yy} = 0$
   - $F_{,x}$ is prescribed or $v_{,y} = 0$
2. On $y =$ constant
   - w is prescribed or $M_{y,y} + 2 M_{xy,x} = 0$
   - $w_{,y}$ is prescribed or $M_y = 0$
   - F is prescribed or $v_{,xx} = 0$
   - $F_{,y}$ is prescribed or $u_{,x} = 0$
3. At a corner (discontinuity in C) $M_{xy} = 0$ (equivalent to $w_{,xy} = 0$) if w is not prescribed; and $F_{,xy} = 0$, if F is not prescribed.

The first conditions are the forced or geometrical conditions, and the second ones are the free or natural conditions. When using a variational formulation for a boundary value problem, the admissible functions should satisfy only the forced boundary conditions. Therefore, using the above conditions, we can write the classical boundary conditions on an edge say, $\nu =$ constant, as

1. Clamped edges $w = w_{,\nu} = 0$, and at the corner $F_{,\nu\eta} = 0$
2. Free edges $F = F_{,\nu} = 0$, and at the corner $M_{,\nu\eta} = 0$ ($i.e., w_{,\nu\eta} = 0$)
3. Simply supported edges $w = 0$ and at the corner $F_{,\nu\eta} = 0$
4. Freely supported edges $w = F = 0$

A finite element solution for the problem at hand can be performed using rectangular elements preserving C^1 continuity based on the functional given in Eq (1). Thus, we can write

$$
\begin{aligned}
z(x,y) = \sum_{i=1}^{2} \sum_{j=1}^{2} &\left[H_{0i}(x) H_{0j}(y) z_{ij} + H_{1i}(x) H_{0j}(y) z_{,x_{ij}} \right. \\
&\left. + H_{0i}(x) H_{1j}(y) z_{,y_{ij}} + H_{1i}(x) H_{1j}(y) z_{,xy_{ij}} \right] \qquad (6)
\end{aligned}
$$

where z stands for w or F, and H_{mn} are first order Hermitian polynomials; other notations are as given in Ref 3. Using the standard finite element technique we obtain for each element a set of two equations cast in the form below:

$$
\begin{aligned}
&[k_{ww}]\{w\} + [k_{wF}]\{F\} + [m]\{\ddot{w}\} + \lambda [a]\{w\} + \\
&\left[N_{xx}\left[k_{G_{N_{xx}}}\right] + N_{yy}\left[k_{G_{N_{yy}}}\right] + N_{xy}\left[k_{G_{N_{xy}}}\right] \right]\{w\} = \{0\} \qquad (7a) \\
&[k_{Fw}]\{w\} + [k_{FF}]\{F\} = \{0\} \qquad (7b)
\end{aligned}
$$

where $\lambda = 2Q/\sqrt{M^2-1}$ is the dynamic pressure parameter. The elements of the stiffness matrix $[k_{ww}]$, the compatibility matrix $[k_{FF}]$, the coupling matrix $[k_{wF}]$, the mass matrix $[m]$, the geometrical stiffness matrices $[k_G]$, and the aerodynamic matrix $[a]$ can be calculated as given in Refs 3, 4, and 5. Using the finite element standard assembly technique and applying the appropriate boundary conditions, the whole structure matrix equations read,

$$[K_{ww}]\{w\} + [K_{wF}]\{F\} + [M]\{\ddot{w}\} + \lambda[A]\{w\} + \left[N_{xx}\left[K_{G_{N_{xx}}}\right]\{w\} + N_{yy}\left[K_{G_{N_{yy}}}\right]\{w\} + N_{xy}\left[K_{G_{N_{xy}}}\right]\right]\{w\} = \{0\} \tag{8a}$$

$$[K_{Fw}]\{w\} + [K_{FF}]\{F\} = \{0\} \tag{8b}$$

The degrees of freedom $\{F\}$ can be eliminated using the compatibility equation (8*b*), reducing the problem to,

$$[K_{eq}]\{w\} + [M]\{\ddot{w}\} + \lambda[A]\{w\}$$
$$\left[N_{xx}\left[K_{G_{N_{xx}}}\right] + N_{yy}\left[K_{G_{N_{yy}}}\right] + N_{xy}\left[K_{G_{N_{xy}}}\right]\right]\{w\} = \{0\} \tag{9}$$

where

$$[K_{eq}] = [K_{ww}] - [K_{wF}][K_{FF}]^{-1}[k_{Fw}]$$

An examination of Eq (9) reveals that the computational effort required for the solution of the problem is equivalent to that of a flat plate problem when the present formulation is used. Further, the inplane boundary conditions are applied on F, $F_{,x}$, $F_{,y}$, and $F_{,xy}$, and are all nodal degrees of freedom.

APPLICATIONS

In this section three sets of applications are presented, namely, free vibration analysis, buckling analysis, and supersonic panel flutter analysis. Several numerical calculations are given and are discussed and compared with previous analytical solutions, numerical calculations, and experimental findings.

Free vibration analysis

The first series of calculations performed are for cylindrically curved panels freely supported on all edges. These calculations were made in order to compare the results obtained using the present formulation with the exact analytical solution of Reissner's equation[24]. It is anticipated that for the curved panels, with the increase of the curvature, higher modes will become the critical modes for buckling and supersonic flutter conditions. Therefore, the finite element model used must maintain a good precision for a wide range of the lower part of the frequency spectrum.

To study the convergence of the present method two meshes were used, namely, a 2x2 mesh and a 4x4 mesh. The numerical results showed that convergence to the exact solution was quite rapid and that the 4x4 mesh solution practically coincides with the exact solution. Fig 2 presents the results obtained for the first natural frequency parameter $\Omega = \omega(\rho h a^4/D\pi^4)^{1/2}$, where ω is the natural frequency, versus the shell rise parameter H/h,

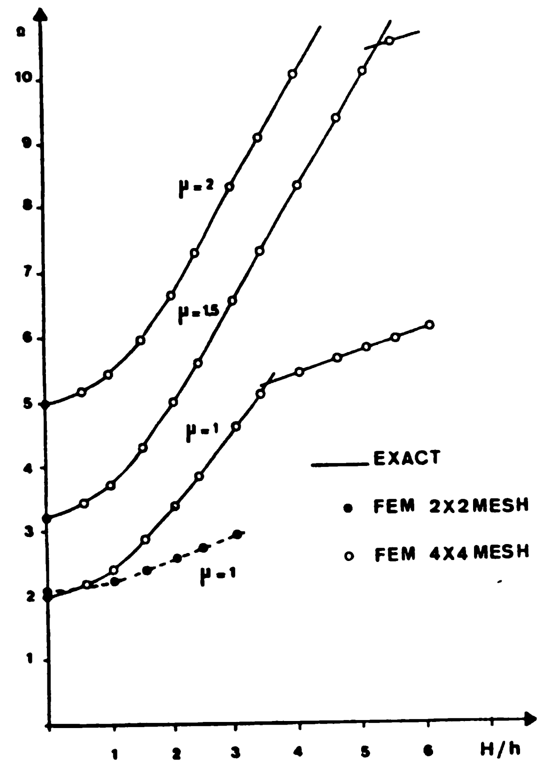

FIG 2. First natural frequency parameter versus curvature parameter.

for different aspect ratios $\mu = a/b$. The results are compared with Reissner's exact solution. Table I compares the results obtained using the present formulation and Reissner's solution for the first fifteen modes for $\mu = 1$ and $\alpha = 12(1-\nu^2)a^4/h^2R^2 = 734.64$ for a 4x4 mesh. The precision achieved using the present formulation was considered sufficient enough in order to proceed for further calculations where no exact solutions exist using a 4x4 mesh.

mode	m, n	Exact solution	Present analysis
1	1,1	2.426	2.426

Table I. Natural frequency parameter Ω for freely supported cylindrically curved panels of aspect ratio 1 and curvature parameter $\alpha = 734.64$.

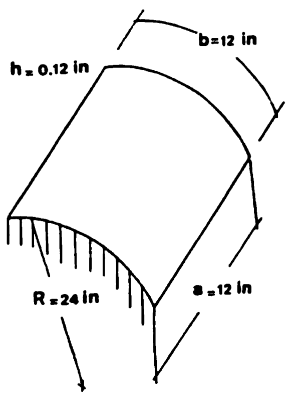

FIG 3. Cantilever thin cylindrically curved panel.

The second series of calculations were performed for the cantilever shallow shell depicted in Fig 3. The shell has dimensions $R = 24$ in, $h = 0.102$ in, and $a = b = 12$ in, and is of steel material.

This example has been chosen because it has a part of the boundary clamped whereas the rest of the boundary is free and, therefore, will present a good test for the application of the Airy function boundary conditions for these cases. This model has been extensively used in the literature for comparison purposes between various finite element models performance and analytical solutions. Further, experimental results for the model are available.

The results obtained are shown in Table II and are compared with previous solutions and experimental findings. Olson and Lindberg solution [22] is a finite element solution using a conforming, doubly curved shallow shell triangular element having 38 degrees of freedom. Walker solution[32] is also a finite element solution using a doubly curved quadrilateral helicoidal shell element with 40 degrees of freedom. Leissa solution[16] is a Rayleigh-Ritz solution using algebraic polynomials as trial functions. The experimental findings are due to Olson and Lindberg[22].

Table II. Natural frequencies in Hz of the cantilever cylindrical shell panel.

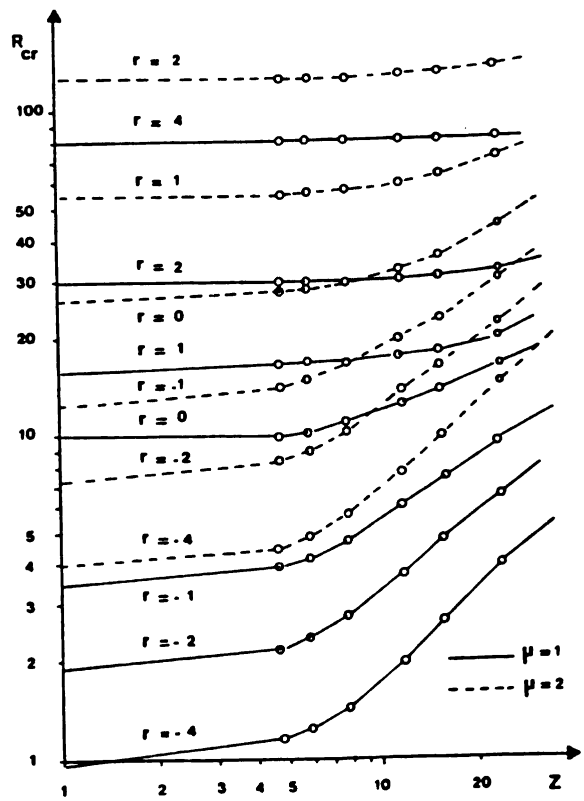

FIG 4. Combined shear and axial stress buckling parameter for all edges freely supported.

Table II presents two columns for the present formulation. In the first column was taken the value 3x10^6 psi for the Young's modulus E, as is commonly used in academic solutions and as was made in Refs 16, 22, and 32. In the second column was taken the value 3.1x10^6 psi for E in order to compare the results of the computations with the experimental results. Obviously, the two columns bear a constant ratio. The results show that good achievements have been obtained using the present formulation.

Buckling analysis

In Ref 6, buckling analysis of curved sheet panels under the action of pure shear and pure axial compression using the present formulation were presented for different aspect ratios and boundary conditions. In this section some of the results obtained for buckling of curved panels under the action of combined shear and axial loads are given.

The first series of calculations are performed for curved sheet panels with freely supported end conditions. The results of the computations are shown in Fig 4. The curves are plotted for the buckling stress resultant versus the curvature parameter z, $\left(z = b^2(1-\nu^2)^{1/2}/Rh\right)$ and is a length-curvature parameter commonly used in the buckling analysis of curved plates and axisymmetric shells[14]. In this figure, two sets of curves are given, one set for aspect ratio $\mu = 1$ and the other set for $\mu = 2$. For each aspect ratio set, the calculations have been done for ratios of axial stress to shear stress, $\sigma_{xx}/\sigma_{x\theta} = 0, 1, 2,$ and 4. The curves labelled with negative values are for compressive axial loads.

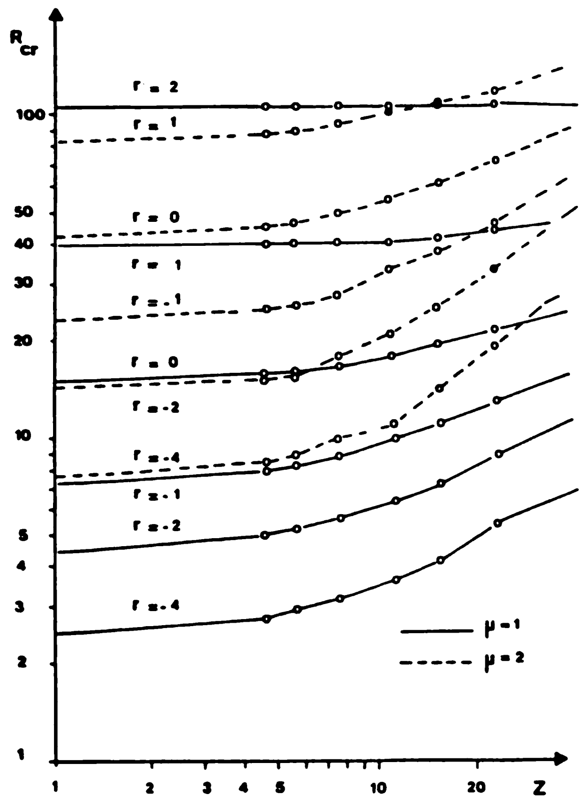

FIG 5. Combined shear and axial stress buckling parameter for all edges clamped.

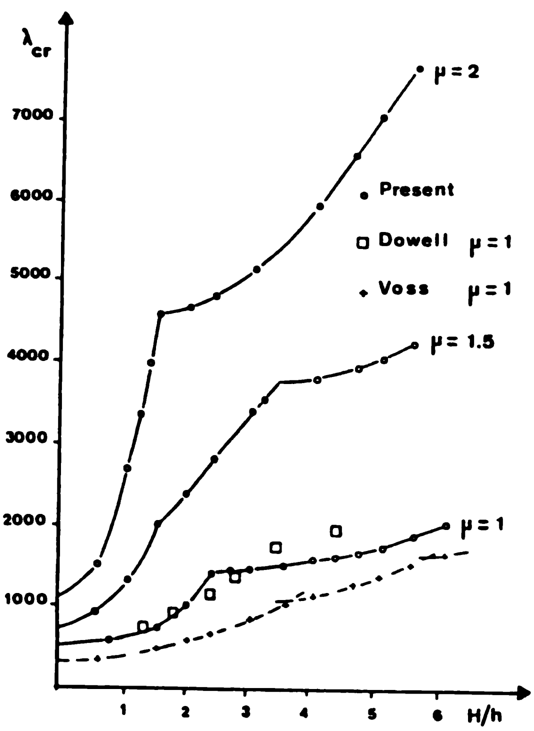

FIG 6. Flutter dynamic pressure parameter versus shell rise for flow in the x-direction and all edges freely supported.

The next set of computations was performed for curved panels with all edges clamped and for the same loading cases and aspect ratios as for the previous calculation set. The results are shown in Fig 5.

From the results of Figs 4 and 5, the following conclusions can be drawn:

- A curved panel under the action of inplane compression or shear is expected to buckle essentially as a flat plate when the curvature is small and to buckle in the same manner as a cylinder when the plate curvature is large. Between the two limits there is a transition region from one type of behavior to the other.

- The buckling loads depend not only on the geometry, but also on the boundary conditions. For the freely supported case the curves are smoother in the transition region if compared with the clamped end condition cases. Further, the buckling loads in the transition region are more affected for values of aspect ratio near unity.

- As the length-curvature parameter z increases, it is expected that the buckling load changes characterizing the flat plate behavior with buckling occurring with the first number of half waves to the cylinder behavior characterized by a large number of waves or a diamond-buckle-pattern deflection. In the transition region, it is, therefore, expected to find cups in the curves as the critical waves change by integer values.

Supersonic flutter analysis

Flutter characteristics determination of shallow shells is of prime importance in supersonic aircraft and launch vehicles designs. The first analytical research on supersonic flutter of thin cylindrically curved panels was made by Voss[30], who used Reissner's shallow shell equations, quasi-static aerodynamic theory, and the Galerkin method for the solution of freely supported ends boundary conditions. Nonlinear flutter analysis of two-dimensional[10] and three-dimensional[11] curved panels were performed by Dowell using a quasi-static aerodynamic theory. Dowell's investigations showed that the inplane edge restraints had a great influence on the flutter boundaries and this was attributed to the frequency spectrum of the shells analyzed. The effect of edge restraints was again investigated by Matsuzaki[18] using the Galerkin method for the solution of the problem.

Since the introduction of the aerodynamic matrix concept by Olson[20], many authors exploited the application of the finite element method in the field of supersonic panel flutter. The application of Olson's concept has been extended to three-dimensional plates[15,21,25], coupled plates[2], circular cylindrical shells[1], and conical shells[8,28]. Finite element flutter formulations with structural nonlinearities were studied by Mei[19], Rao and Rao[26] for flat plates and Ueda[27] for conical shells. Yang[31] introduced in the formulation of the aerodynamic matrix a numerical integration technique in order to obtain more accurate results tending to the exact linearized flow theory

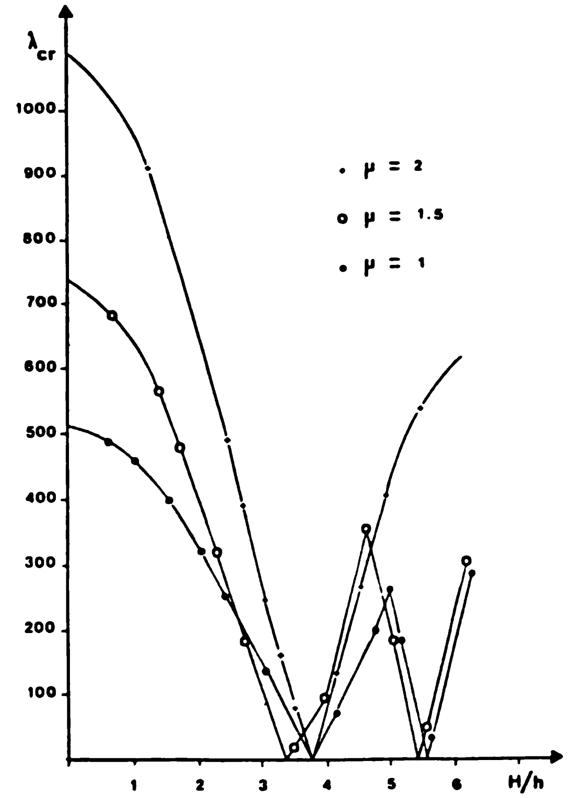

FIG 7. Flutter dynamic pressure parameter versus shell rise for flow in the y-direction and all edges freely supported.

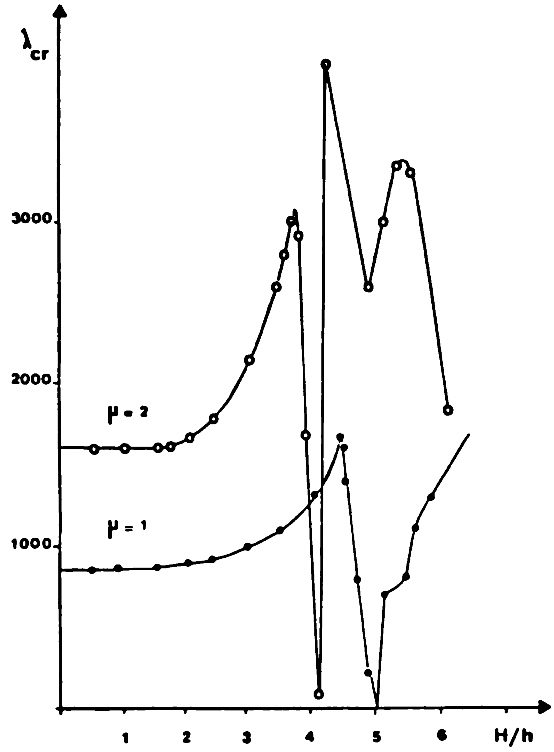

FIG 8. Flutter dynamic pressure parameter versus shell rise for flow in the x-direction and all edges clamped.

case of high order frequencies. Except for Ref 25, where the problem was formulated using a hybrid element coupled with the classical modal superposition technique for the solution of the flutter problem, all other formulations were performed based on the total potential energy principle with the displacements taken as field variables. In Ref 7 finite element analysis of the supersonic flutter of cylindrically curved panels based on Reissner's two field variable variational principle was presented and several numerical results were given. In this section further results not given in Ref 7 are presented, namely, the effect of aspect ratio is analyzed and the flow condition parallel to the y-axis is solved.

Figures 6 to 9 summarize the results obtained in the present investigation. Figure 6 presents the critical flutter parameter λ_{cr} versus the shell rise H/h, where H is the maximum shell height and h the shell thickness, for different values of the panel aspect ratio μ of rectangular freely supported panels. The results are compared with the two mode Galerkin's solution of Voss[30] and Dowell's solution[11].

Dowell's solution is a six chordwise mode Galerkin approximation with a half-sine wave in the cross-stream direction. Dowell's solution practically coincides with the present finite element solution for the part of the curve where $n = 1$ are the critical modes for instability. Voss' two mode solution, despite being conservative, shows the same trend as the present finite element solution with increasing values of n_{cr} as the [illegible] parameter H/h increases.

Figure 7 presents the results of freely supported panels with flow in the y-direction and for different aspect ratio of the panels. In Figs 8 and 9, the same cases analyzed in Figs 6 and 7 are repeated for panels clamped on all edges.

Observing the results of Figs 6 to 9, the following conclusions can be made:

- For flows parallel to the x-direction, the critical modes of flutter are for $n = 1$ and are for the first spanwise modes. In this region the curvature effect is stabilizing in the sense that the critical dynamic pressure increases with the increase of the curvature. With further increase of the curvature, the panel passes through a transition region characterized from a flat plate behavior to a deep shell behavior. This region is characterized by the dips, knees, and cups observed in the dynamic pressure parameter versus curvature effect, and is explained by the coalescence of successive higher modes to produce the first critical flutter condition. After this transition region, with further increase in the curvature, the panel behaves as a deep shell and the critical flutter modes are those with an elevated number of waves in the cross stream direction and the first spanwise modes. In this part the shallow shell theory is no longer adequate and deep shell theory must be used. The present shallow shell theory is, therefore, limited to the flat plate and the transition part behavior of the curved panels.

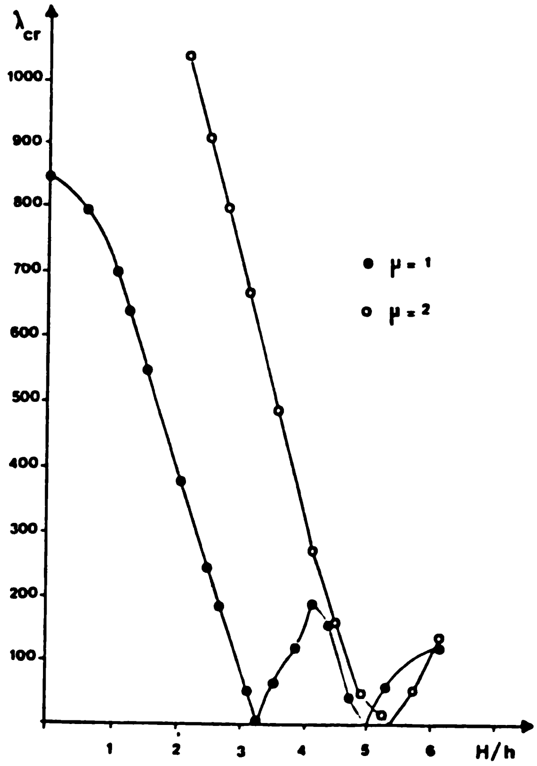

FIG 9. Flutter dynamic pressure parameter versus shell rise for flow in the y-direction and all edges clamped.

- For flow parallel to the y-direction, as can be seen from the results obtained in Figs 6 to 9, the curvature effect is destabilizing in the sense to decrease the flutter dynamic pressure with the increase of curvature. Again, this is explained by the frequency spectrum of the panel. In the transition region the panel is characterized by the same behavior demonstrated in the x-direction flow case and coalescence for successive values of n_{cr} occur.

- For clarity of the exposition, as was made in Ref 7, no damping effect, whether of structural or aerodynamic nature has been incorporated in the present formulation. If a constant viscous type structural damping and/or aerodynamic damping term pf the potential flow theory are used in the analysis, it can be shown that their effect is always stabilizing (see discussion of Ref 4) in the sense to increase the critical dynamic parameter. The effect of such dampings is small in the flat plate behavior and deep shell regions. In the transition region such dampings have a greater influence on the panel stability and remove the sharp minima or dips observed in the critical dynamic pressure parameter, which are due to coalescence of modes with nearly identical frequencies and small aerodynamic coupling.

CONCLUSIONS

Free vibration, buckling, and supersonic panel flutter analyses of cylindrically curved panels have been presented. The analyses are based on Reissner's two field variable variational principle. It is shown that the boundary conditions on Airy stress function are as simple and direct to apply as for the boundary conditions on the transverse displacement. The element used in the analyses is characterized by its high precision and direct application of the boundary conditions.

New theoretical developments in aeroacoustics and aerodynamics

Mauricio Pazini Brandão

Aeronautical Engineering Division, Instituto Tecnológico de Aeronáutica
Centro Técnico Aeroespacial, 12228-900 São José dos Campos SP Brazil

The Acoustic Analogy is studied regarding its application to Aerodynamics. The concept of generalized derivatives is reviewed and extended. As consequences, new versions of the generalized continuity, momentum, energy, and energy momentum conservation equations are presented. These conservation laws form a basis for theoretical ideas regarding three-dimensional, linear and non-linear, potential and non-potential, steady and unsteady flows of incompressible and compressible, inviscid and viscous fluids. Extensions made in the definition of generalized derivatives relate fluid properties to new surface terms linked to tangential flow. In integral form, some of these relations recall the classical circulation and downwash integrals of Aerodynamics. An iterative solution technique of the resulting singular integral equations is proposed.

INTRODUCTION

In *On Sound Generated Aerodynamically, Part I – General Theory*, (1952) and *Part II – Turbulence as a source of sound*, (1954) Lighthill introduced a new theory in Acoustics. This theory, later summarized in Lighthill (1962), came to be known as *Acoustic Analogy*. Its main result may be represented by an inhomogeneous wave equation for the perturbation pressure generated by turbulence. This equation results from an exact algebraic fusion of the continuity and momentum equations. The forcing term, called quadrupole, translates into Mathematics the physical effect of fluid acting on itself as a mechanism of noise generation.

Since its introduction, the *Acoustic Analogy* has been useful not only in Aeroacoustics (see, for example, Ffowcs Williams (1984)), but also in determining the structural loading created by noise in rockets (see, for example, Ahuja (1973)). And many other applications have appeared in the pertinent literature.

The development of Lighthill was extended by Ffowcs Williams and Hawkings (1969) to include the effect of moving surfaces. Two new source terms, named in the literature monopole and dipole, appeared in this work on the right hand side of Lighthill's equation. The result allowed for the inclusion in the theory of physical mechanisms like those due to thickness displacement and pressure relaxation into the medium. Since its appearance, this analytical tool has been used to study the noise produced by the motion in the air of bodies of complicated geometry, like helicopters and prop-fans (see, for example, Farassat (1986)).

The result of Ffowcs Williams and Hawkings may be represented by an equation which combines in a single mathematical statement boundary conditions with the continuity and momentum equations. This result is in linear interpretation a wave equation for the perturbation pressure produced by bodies moving through fluids. Therefore, it has received wide acceptation among aeroacousticians.

Since aerodynamic noise is a pressure perturbation propagating through the air, with careful considerations the *Acoustic Analogy* can be applied to other contexts where pressure is the variable of interest. With this perception, Long (1983) and (1985) developed the first work in which this theory was applied to Aerodynamics. The objective was then to determine the pressure on the surface of moving bodies, something which should be realized as a limiting process in both Physics and Mathematics. This work opened a possibility of unification in the treatment of aeroacoustic and aerodynamic problems.

Long's formulation was simplified from the general context by considering the fluid inviscid and by neglecting the nonlinear quadrupole term. His results were not satisfactory, for the pressure distribution did not capture the full expansion on the surface of bodies of large thickness and some lifting effects appeared only after the adoption of *ad-hoc* computational schemes. These applications were restricted to small perturbation problems.

Brandão (1988*a*) tried in his thesis to improve on Long's results by incorporating in the interpretation of the fluid velocity vector the unknown components induced by thickness and lifting effects. The outcome of this attempt appeared in summarized form in Brandão (1989), showing that it was possible to obtain an increase in robustness of the associated computational schemes, as well as an improvement on the physical understanding of the role played by basic elements of the approach. However, this reference also showed a persistence of the above mentioned failures, indicating that the remedy for the problem was not then at hand.

Along the same line, Lee and Yang (1990) established a parallel between *Acoustic Analogy* and *Potential Aerodynamics*. With the clear admission that the equation of Ffowcs Williams and Hawkings lacked a lifting mechanism, they chose to work with a linear and inhomogeneous wave equation for the velocity potential ϕ. The results, though, continued to show the same traces of incompleteness in the description of the flow physics.

Brentner (1988) presented preliminary results of a research where lifting effects were captured with the inclusion in the formulation of the *non-linear* quadrupole term. A full account of this research can be found in his thesis (Brentner (1990)). However, his results were obtained only in the case of motion inside an incompressible fluid and need to be generalized. Furthermore, there are possibilities in which *linear* formulations may yield equivalent results. This feeling, still not proved, resulted from several recent attempts of the author (see, for example, Brandão (1991)) in investigating *non-linear* versions of the formulation, including the so-called quadrupole source term for compressible fluids. These attempts were developed in the quest for finding explanations for the previously described difficulties. Physical reasoning has led the author to the conclusion that something *basic, linear,* is missing in the formulation that might solve the problem. What has been missing should be linked to tangential flow and circulation around the body, elements which have been disregarded in previous works following this line of thought.

A more complete theory is necessary for applications to more general contexts and, perhaps, for explaining the previously mentioned failures. A wishful theory would possibly increase the number of linear sources in the Ffowcs Williams and Hawkings equation, so that linear versions of the mathematical model could still provide useful results regarding large perturbation and lifting problems. An extension to the existing theory is possible by reviewing the concept of generalized derivatives, an idea which constitutes an elegant tool for incorporating boundary conditions to differential equations. This revision appears to have reached the desired objectives.

In this paper we start by presenting new definitions on the concept of time and space generalized derivatives. From these definitions, inhomogeneous forms of the continuity, momentum, energy, and energy momentum equations are obtained. Connections between potential and non-potential theories of Aerodynamics and Aeroacoustics are then established. Finally, integral transformations of the new results are obtained and possibilities of applications are discussed.

This work intends to present recent theoretical results concerning the aeroacoustic approach to Aerodynamics. The approach may be regarded as an alternate analytical method in unsteady fluid dynamics, akin to a mixed boundary-volume element technique, which might prove useful for demanding applications in aeroelasticity.

A BRIEF REVIEW

Lighthill's acoustical equation can be obtained from an exact algebraic manipulation of the continuity and momentum equations. This equation appeared in Lighthill (1952) and reads

$$\Box^2\left[c^2(\rho-\rho_o)\right]=\frac{\partial^2\mathcal{T}_{ij}}{\partial x_i\partial x_j}$$

where

$$\Box^2=\frac{1}{c^2}\frac{\partial^2}{\partial t^2}-\frac{\partial^2}{\partial x_i\partial x_i}$$

is the D'Alembertian or wave operator,

$$\mathcal{T}_{ij}=\mathcal{P}_{ij}+\rho\, u_i u_j-\left[p_o+c^2(\rho-\rho_o)\right]\delta_{ij}$$

is the so-called Lighthill stress tensor, and c is the sound speed in the reference condition. The right hand side of this wave equation is the quadrupole term.

If the same derivation steps used to obtain Lighthill's equation are repeated, this time using the concept of generalized derivatives, the result is a more complete inhomogeneous wave equation for Lighthill's variable $c^2(\rho-\rho_o)$. This equation appeared in Ffowcs Williams and Hawkings (1969) and reads

$$\bar{\Box}^2\left[c^2(\rho-\rho_o)\right]=\frac{\bar{\partial}}{\partial t}\left[\rho_o v_n|\nabla f|\,\delta(f)\right]-\frac{\bar{\partial}}{\partial x_i}\left[\tilde{\mathcal{P}}_{ij}n_j|\nabla f|\,\delta(f)\right]+\frac{\bar{\partial}^2\mathcal{T}_{ij}}{\partial x_i\partial x_j}$$

where $\bar{\Box}^2$ stands for the generalized D'Alembertian operator. Comparing both wave equations, on the right hand side of the latter two new forcing terms appear. They are called monopole and dipole, respectively.

It can be shown (see, for example, Brandão (1991)) that in linear approximation Lighthill's variable is equivalent to the perturbation pressure p. Therefore, both equations can describe the propagation in the air of pressure waves generated by the physical mechanisms on their right hand sides.

It should be remarked that the equation of Ffowcs Williams and Hawkings, although considering information generated on the surface of a body moving in a fluid, is expressed in terms of a coordinate system fixed to the *immovable* fluid. This is not the common case in Aerodynamics, where variables of interest are usually described as viewed from a reference system fixed to the moving body. Finally, it can be observed that the surface terms are concerned only with mechanisms which act normally to the surface. Our interest here is to investigate the inclusion of tangential mechanisms of noise generation.

GENERALIZED DERIVATIVE - CONCEPT

Consider an infinite domain of quiescent fluid in standard conditions (pressure p_o, specific mass ρ_o, and temperature T_o), and an associated Cartesian coordinate system fixed to the fluid at rest. Consider inside this domain a body made out of fluid in the same standard conditions and delimited by a closed and impenetrable surface $f=0$. Therefore, except for a hypothetical surface of negligible thickness, the whole domain of interest in the problem is composed by fluid.

Note that the surface $f=0$ is in general represented by a mathematical function of space and time, and that this function can be defined uniquely, except for a multiplicative constant. This function is established so that inside the body $f<0$, and outside the body $f>0$. Thus, the gradient of f is normal to the surface and points towards the outer side of the surface, a fact which is used to construct vectors normal and tangent to the surface.

If this body moves with respect to the fixed fluid coordinate system and by hypothesis the internal fluid conditions are kept unchanged, fluid properties like pressure, density, velocity components, and temperature suffer finite jumps as we go through the surface, coming from inside. These property jumps have their greatest amplitudes close to the surface. Physical reasoning dictates that a gradual decrease in these amplitudes happens as increases the distance from the body and that disturbances should dye out completely far from the body.

Instead of considering two different domains of fluid separated by the surface $f = 0$, the idea of generalized derivative is to automatically handle these jumps by adding to the regular derivative terms valid only on the surface. Thus, a single mathematical formulation can be used to link information between the two distinct regions of fluid.

Let us consider a general fluid field property denoted by $\mathcal{F}(x_i, t)$, with $i = 1,2,3$. The generalized derivative of this function with respect to time has been defined previously (see, for example, Farassat (1977)) as

$$\frac{\bar{\partial}\mathcal{F}}{\partial t} = \frac{\partial \mathcal{F}}{\partial t} + \Delta\mathcal{F}\frac{\partial f}{\partial t}\delta(f) \tag{1}$$

where $\Delta\mathcal{F}$ represents the property jump through f, which is dictated by physical reasoning, and $\delta(f)$ stands for the Dirac delta function of the surface f. Note that the regular time derivative is recovered for all field points not on $f = 0$.

The difficulty here is that definition (1) is not unique, depending on a multiplicative constant contained implicitly inside the function f. This definition can be made unique as follows:

$$\frac{\bar{\partial}\mathcal{F}}{\partial t} = \frac{\partial \mathcal{F}}{\partial t} + \frac{\Delta\mathcal{F}}{|\nabla f|}\frac{\partial f}{\partial t}\delta(f) \tag{2}$$

because the gradient of f is defined in the whole domain and carries also the same multiplicative constant. Therefore, definition (2) is more rigorous than (1), and will be used whenever necessary in this paper.

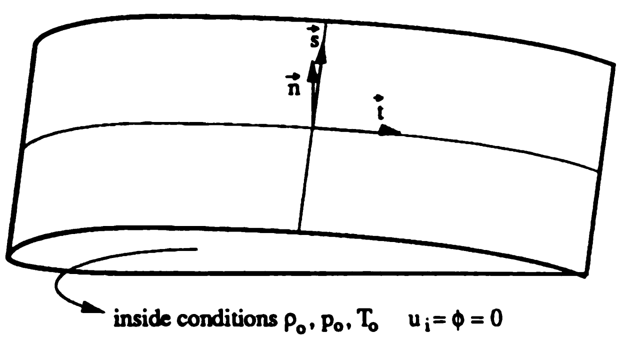

FIG 1. Definition of geometry and jump conditions.

Consider now a right-handed triad of unit vectors sitting on a point of the surface f, as depicted in Fig 1. This triad has a unit vector normal to the surface, here denoted by $\vec{n}$, and two mutually perpendicular tangential unit vectors, represented respectively by $\vec{t}$ and $\vec{s}$. Note that the directions of $\vec{t}$ and $\vec{s}$ are left free, being defined according to the problem at hand.

The generalized derivative of the fluid property $\mathcal{F}$ with respect to the spatial coordinate x_i, $i = 1,2,3$ has been defined previously (see, for example, Farassat (1977)) as

$$\frac{\bar{\partial}\mathcal{F}}{\partial x_i} = \frac{\partial \mathcal{F}}{\partial x_i} + \Delta\mathcal{F}\frac{\partial f}{\partial x_i}\delta(f) \tag{3}$$

Again, the first difficulty here is that this definition is not unique. Besides, the definition accounts only for property jumps normal to the surface.

It should be observed that a scalar property, like density, may present only normal jump across the surface. However, vector and tensor properties, like velocities and stresses, may present jumps in directions other than the normal to the surface.

To solve the problems pointed above, we propose the following alternative definition for this generalized derivative:

$$\frac{\bar{\partial}\mathcal{F}}{\partial x_i} = \frac{\partial \mathcal{F}}{\partial x_i} + \Delta\mathcal{F}\,(n_i + t_i + s_i)\,\delta(f) \tag{4}$$

Here, as before, $\Delta\mathcal{F}$ represents the fluid property jump across the surface. Furthermore,

$$n_i = \frac{1}{|\nabla f|}\frac{\partial f}{\partial x_i}$$

is the i-th component of the unit vector $\vec{n}$ normal to the surface at the point considered. The two remaining unit vectors can be obtained from the relations of orthonormality.

Note that if in this definition $\mathcal{F}$ is a vector or tensor property, from the Dirac delta term we obtain projections of these properties along the normal and tangential directions defined as shown in Fig 1.

The advantages of using definition (4) instead of (3) may be described as follows: first, the new proposition is established without ambiguity regarding surface definition; and second, it also accounts for property jumps occurring along the two tangential directions orthogonal to the normal defined at a point *on the body surface*. As we shall see, important effects may be introduced in the physics of the problem due to this extension on the concept of generalized derivatives.

CONSERVATION EQUATIONS

In Computational Fluid Dynamics it is common to work with homogeneous conservation equations, with later inclusion of forcing boundary conditions. The purpose of working with generalized derivatives is to include inhomogeneities at the very beginning of the mathematical fluid flow modeling, so that we do not have to worry about them later. Therefore, the goal of this section is to use definitions (2) and (4) to obtain generalized versions of first principles of Fluid Mechanics. Here, these principles will involve conservations of mass, momentum, energy, and energy momentum.

Continuity Equation

The equation of conservation of mass has its regular conservative form displayed as

$$\frac{\partial \rho}{\partial t} + \frac{\partial}{\partial x_i}(\rho u_i) = 0 \tag{5}$$

Here, ρ is the fluid particle specific mass (or density, according to the aerodynamicist usual parlance) in the perturbed state and u_i is the i-th component of the perturbed velocity vector related to the immovable reference system of coordinates. This is a single partial differential equation for four unknowns, namely, ρ and u_i, with $i = 1,2,3$.

If the time and space derivatives appearing in Eq (5) are generalized according to definitions (2) and (4) respectively, we obtain the following result, after collecting terms in suitable form:

$$\frac{\bar\partial \rho}{\partial t} + \frac{\bar\partial}{\partial x_i}(\rho u_i) = \left[\frac{\partial \rho}{\partial t} + \frac{\partial}{\partial x_i}(\rho u_i)\right] + \frac{\rho}{|\nabla f|}\left[\frac{\partial f}{\partial t} + u_i\frac{\partial f}{\partial x_i}\right]\delta(f) + \left[-\frac{\rho_o}{|\nabla f|}\frac{\partial f}{\partial t} + \rho\, u_i\,(t_i + s_i)\right]\delta(f) \qquad (6)$$

Above, the first square bracket on the right hand side is null because it is the regular continuity equation, which is equal to zero for all field points where it is valid. The second square bracket on the right hand side is also null due to Lamb's non-penetration condition (see Lamb (1945)). If this condition is applied again in the treatment of the third square bracket, there results

$$\frac{\bar\partial \rho}{\partial t} + \frac{\bar\partial}{\partial x_i}(\rho\, u_i) = [\rho_o\, v_n + \rho\,(v_t + v_s)]\,\delta(f) \qquad (7)$$

Here, v_n, v_t, and v_s are projections of the fluid particle velocity over the directions of the unit vectors normal and tangent to the body surface. If the body moves with velocity $\vec V$ with respect to the reference system of coordinates, due to the non-slip condition $\vec u$ is null and $\vec v = \vec V$ on the surface. However, for an inviscid fluid the projections appearing in Eq (7) are given by

$$v_n = V_i\, n_i = V_n \qquad v_t = (V_i + u_i)\, t_i = V_t + u_t$$

$$v_s = (V_i + u_i)\, s_i = V_s + u_s \qquad (8a-c)$$

because $u_n = u_i\, n_i = 0$. Thus, in any case, v_n is totally known from the motion alone, whereas in the inviscid case v_t and v_s include the unknown perturbation velocities generated by the motion.

Equation (7) is, in the present context, a generalized form of the continuity principle which presents new mechanisms of "mass generation" at the boundary $f = 0$.

Momentum Equation

The regular momentum equation in conservative form and in the absence of body forces is given by

$$\frac{\partial}{\partial t}(\rho\, u_i) + \frac{\partial}{\partial x_j}(\mathcal{P}_{ij} + \rho\, u_i\, u_j) = 0 \qquad (9)$$

Here,

$$\mathcal{P}_{ij} = p_s\, \delta_{ij} + \mathcal{E}_{ij}$$

is the compressive stress tensor which includes in its diagonal the static pressure p_s of a fluid element in the perturbed state, indicated by the Kronecker delta δ_{ij}, as well as the viscous stress tensor $\mathcal{E}_{ij}$. For a Newtonian fluid, (see Thompson (1972)) this tensor depends on the empirical viscosity coefficients μ and μ_v, called shear and bulk or volume coefficients, respectively, and on velocity gradients and divergent, as shown below:

$$\mathcal{E}_{ij} = -\mu\left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i}\right) + \left(\frac{2}{3}\mu - \mu_v\right)\frac{\partial u_k}{\partial x_k}\,\delta_{ij}$$

Therefore, except for given viscosity coefficients, $\mathcal{E}_{ij}$ does not introduce in Eq (9) any new variables beyond those already used to describe the flow kinematics.

Equation (9) is a concise representation of three partial differential equations, each of them giving the equilibrium of momentum in the direction of one of the axes of the reference system. Together with Eq (5), Eqs (9) form a set of 4 equations with 5 unknowns, yielding a hint of the mathematical incompleteness which ultimately leads to the closure problem.

The generalization of the derivatives of Eq (9) according to Eqs (2) and (4) yields the following result after a proper algebraic arrangement:

$$\frac{\bar\partial}{\partial t}(\rho\, u_i) + \frac{\bar\partial}{\partial x_j}(\mathcal{P}_{ij} + \rho\, u_i\, u_j) = \left[\frac{\partial}{\partial t}(\rho\, u_i) + \frac{\partial}{\partial x_j}(\mathcal{P}_{ij} + \rho\, u_i\, u_j)\right] + \left[\frac{\rho\, u_i}{|\nabla f|}\left(\frac{\partial f}{\partial t} + u_j\frac{\partial f}{\partial x_j}\right)\right]\delta(f) + \left[\tilde{\mathcal{P}}_{ij}\, n_j + \left(\tilde{\mathcal{P}}_{ij} + \rho\, u_i\, u_j\right)(t_j + s_j)\right]\delta(f) \qquad (10)$$

where

$$\tilde{\mathcal{P}}_{ij} = \mathcal{P}_{ij} - p_o\delta_{ij}$$

is the perturbed compressive stress tensor, with the perturbation pressure $p = p_s - p_o$ in its diagonal.

On the right hand side of Eq (10), the first two square brackets contain the regular momentum equation and Lamb's non-penetration condition, respectively. Since both brackets vanish, we are left with

$$\frac{\bar\partial}{\partial t}(\rho\, u_i) + \frac{\bar\partial}{\partial x_j}(\mathcal{P}_{ij} + \rho\, u_i\, u_j) = \left[\tilde{\mathcal{P}}_{ij}\, n_j + \left(\tilde{\mathcal{P}}_{ij} + \rho\, v_i\, v_j\right)(t_j + s_j)\right]\delta(f) \qquad (11)$$

Equation (11) is the generalized version of the momentum equation obtained within the focus of the present work. Note that surface terms of tangential nature appear inside the equation as new "sources of momentum".

Energy Equation

In the absence of body forces, a hypothesis commonly adopted in Aerodynamics, the regular energy equation in conservative form reads

$$\frac{\partial e}{\partial t} + \frac{\partial}{\partial x_i}(e\, u_i + q_i + \mathcal{P}_{ij}\, u_j) = 0 \qquad (12)$$

Here,

$$e = \rho\, c_v\, T + \frac{1}{2}\rho\, u^2$$

is the total energy (internal plus kinetic) of a fluid element per unit of volume, c_v is the specific heat at constant volume, T is the absolute temperature of a fluid element in the perturbed state, and q_i is the i-th component of the heat flux vector.

Like the continuity equation (5), Eq (12) is another single partial differential equation involving several fluid properties. This equation introduces the temperature T

as a new variable in the set to be investigated. In addition, it accounts formally for heat transfer processes like conduction, convection, and radiation by means of the vector $\vec{q}$, which will be left undefined here because it is beyond the scope of the paper to discuss this specific subject further.

If we generalize the derivatives of Eq (12) according to the rules given by Eqs (2) and (4), we obtain

$$\frac{\bar{\partial} e}{\partial t} + \frac{\bar{\partial}}{\partial x_i}(e\,u_i + q_i + \mathcal{P}_{ij}\,u_j) =$$
$$\left[\frac{\partial e}{\partial t} + \frac{\partial}{\partial x_i}(e\,u_i + q_i + \mathcal{P}_{ij}\,u_j)\right]$$
$$+ \left[\frac{e}{|\nabla f|}\left(\frac{\partial f}{\partial t} + u_i\frac{\partial f}{\partial x_i}\right)\right]\delta(f)$$
$$+ (e_o\,v_n + q_n + \mathcal{P}_{ij}\,u_j\,n_i)\,\delta(f)$$
$$+ (e\,u_i + q_i + \mathcal{P}_{ij}\,u_j)(t_i + s_i)\,\delta(f)$$

Again, the two square brackets on the right hand side vanish. Therefore, we are left with

$$\frac{\bar{\partial} e}{\partial t} + \frac{\bar{\partial}}{\partial x_i}(e\,u_i + q_i + \mathcal{P}_{ij}\,u_j) =$$
$$[e_o\,v_n + e\,(v_t + v_s) + q_n + q_t + q_s]\,\delta(f)$$
$$+ \mathcal{P}_{ij}\,v_j\,(n_i + t_i + s_i)\,\delta(f) \qquad (13)$$

In this result, $e_o = \rho_o\,c_v\,T_o$ is the internal energy of the fluid in the reference state. This is also the *total* energy of reference, because the fluid does not move. Furthermore, $q_n = q_i\,n_i$ is the projection of the heat flux vector onto the direction normal to the body surface and similar projections are defined in the two tangential directions.

Note the similarity of structure between Eqs (7) and (13), which are two scalar equations with normal and tangential forcing terms. This similarity has sparked the question whether there would be other similarity to be established between the momentum equation, which is of vectorial nature, and other equation of interest to Fluid Mechanics. The answer to this question is discussed in the next subsection.

Energy Momentum Equation

The continuity equation can be understood as the conservation of a fluid physical property which is a moment of order zero of the fluid element mass with respect to its velocity. Thus, *mass* is a scalar property. Along this line of thought, the fluid physical property *momentum* can be regarded as a moment of first order of the fluid element mass with respect to its velocity. The momentum equation is, therefore, the mathematical statement of the physical relation between momentum and forces, being of vectorial nature. Similarly, *energy* can be considered as a second order moment of the fluid element mass with respect to its velocity. This scalar physical property has also a relation with other physical processes, involving heat and work, known as the energy equation. The question that naturally arises from this paragraph is whether there are moments of higher order which might be useful in establishing relationships among physical properties of interest in Fluid Mechanics.

The response to the question is not easily found in texts of Fluid Mechanics. In studies of turbulence (see, for example, Monin and Yaglom (1975)) we can find transport relationships of third or higher order. However, they relate fluid velocities in two or three different points, whereas here we are interested in these moments for a single fluid point. Moments of higher order of this type appear frequently in studies of Plasma Physics. See, for example, Shkanofsky and Johnston (1966) and Bernstein (1974). Here, we will limit the discussion to the third order moment, which will be denoted by eu_i and will be called *energy momentum*.

In the absence of other physical processes, which may not be of interest in problems of Fluid Mechanics, at least for low-speed flow regimes, we can state the conservation of this physical property as follows: *the rate of change of the material volume energy momentum is equal to the sum of the directional power of surface and body forces and the directional heat flux through the volume boundary.*

By directional power we should understand the power associated to a fluid element (a scalar property) animated by the corresponding fluid velocity vector. Therefore, directional power is a vectorial property. Similar understanding should be taken for the directional heat flux, by replacing the power by the normal component of the heat flux vector q_n. Mathematically, the statement of conservation, which can be viewed as a relation for the *energy acceleration*, can be written as follows:

$$\frac{d}{dt}\int_{\mathcal{V}} e\,u_i\,d\mathcal{V} = \int_{\mathcal{V}} \rho\,G_j\,u_j\,u_i\,d\mathcal{V}$$
$$+ \int_{\mathcal{S}} T_j\,u_j\,u_i\,d\mathcal{S} - \int_{\mathcal{S}} q_j\,n_j\,u_i\,d\mathcal{S} \qquad (14)$$

Here, $\rho\,G_j$ represents the j-th component of the body forces per unit of volume acting on any fluid element within the volume $\mathcal{V}$. Moreover, T_j denotes the j-th component of the surface forces per unit of area acting on the boundary $\mathcal{S}$ of the volume $\mathcal{V}$.

If we use the theorems of Reynolds and Gauss (see, for example, Thompson (1972)) together with the traditional expedient of the arbitrariness of size of the material volume, the integral conservation statement (14) can be transformed into the following differential one:

$$\frac{\partial}{\partial t}(eu_i) + \frac{\partial}{\partial x_j}(eu_iu_j) = \rho\,G_j\,u_j\,u_i$$
$$- \frac{\partial}{\partial x_j}(\mathcal{P}_{jk}\,u_k\,u_i) - \frac{\partial}{\partial x_j}(q_j\,u_i) \qquad (15)$$

In the absence of body forces, a simplification which is traditionally admitted as true in Aerodynamics, Eq (15) is reduced to

$$\frac{\partial}{\partial t}(eu_i) + \frac{\partial}{\partial x_j}(eu_iu_j + \mathcal{P}_{jk}\,u_k\,u_i + q_j\,u_i) = 0 \qquad (16)$$

This is the expression for the regular equation of energy momentum in conservative form. Rates of change of energy momentum are related to its transport, power of shear and normal forces, and heat transfer processes. Note the resemblance between the structure of Eqs (9) and (16), which are both of vectorial nature.

If we now transform the regular derivatives of Eq (16) into generalized ones, according to Eqs (2) and (4), we obtain

$$\frac{\bar{\partial}}{\partial t}(eu_i) + \frac{\bar{\partial}}{\partial x_j}(eu_iu_j + \mathcal{P}_{jk}\,u_k\,u_i + q_j\,u_i) =$$

$$\left[\frac{\partial}{\partial t}(eu_i) + \frac{\partial}{\partial x_j}(eu_iu_j + \mathcal{P}_{jk}\,u_k\,u_i + q_j\,u_i)\right]$$
$$+ \left[\frac{eu_i}{|\nabla f|}\left(\frac{\partial f}{\partial t} + u_j\,\frac{\partial f}{\partial x_j}\right)\right]\,\delta(f)$$
$$+ (q_n\,u_i + \mathcal{P}_{jk}\,u_k\,u_i\,n_j)\,\delta(f)$$
$$+ (eu_iu_j + q_ju_i + \mathcal{P}_{jk}u_ku_i)\,(t_j + s_j)\,\delta(f)$$

Deleting the two square brackets on the right hand side, based on the same arguments given before, there results

$$\frac{\bar{\partial}}{\partial t}(eu_i) + \frac{\bar{\partial}}{\partial x_j}(eu_iu_j + \mathcal{P}_{jk}\,u_k\,u_i + q_j\,u_i) =$$
$$[ev_i\,(v_t + v_s) + v_i\,(q_n + q_t + q_s)]\,\delta(f)$$
$$+ \mathcal{P}_{jk}\,v_k\,v_i\,(n_j + t_j + s_j)\,\delta(f) \qquad (17)$$

As expected, Eq (16) can be retrieved from Eq (17) if there are no surfaces of discontinuity in the flow. Equation (17) is the generalized form of the energy momentum equation derived within the present focus. This inhomogeneous partial differential equation states that changes of energy momentum are forced by boundary mechanisms which act normally and tangentially to the discontinuity surface. This idea, presented in preliminary form by Brandão (1988*b*), is here extended to a more general context.

A comparison between the generalized conservation equations here displayed with their previous counterparts shows that the inhomogeneous normal terms are now uniquely defined and that tangential terms are added as sources of mass, momentum, energy, and energy momentum. These results are consequences of the new definitions of the generalized derivatives with respect to time and space.

As a final remark, it may be observed that the conservation laws here presented are also valid for problems involving multiple bodies. In a wind tunnel, for example, the surface f may incorporate the body-fluid boundary of a testing model, as well as of the testing section walls. This possibility was successfully explored by Medeiros and Brandão (1991). For high-speed flows, shock surfaces may also be considered as additional sources of discontinuity, as described by Farassat (1987). Therefore, the generality of the present approach allows application of these results to both external and internal flows, ranging from the incompressible to the supersonic case.

POTENTIAL FLOW CONNECTIONS

A general approach should allow its reduction to simpler contexts. This approach is called *non-potential* because it makes no use of hypotheses of potentiality and also, because viscosity effects appear explicitly within the tensors $\mathcal{E}_{ij}$ and $\mathcal{P}_{ij}$. Here, we explore the [illegible] ally the simplification of the method to the w[illegible] ential theory framework, for the case of inc[illegible] d compressible fluids.

Incompressible fluids

Equation (5), when specialized for an incompressible fluid, reads simply

$$\frac{\partial u_i}{\partial x_i} = 0 \qquad (18)$$

If now we admit the existence of a potential function ϕ whose gradient yields the perturbation velocity vector, Eq (18) becomes the classical Laplacian equation

$$\frac{\partial^2\phi}{\partial x_i\partial x_i} = 0 \qquad (19)$$

The idea here is to generalized the derivatives of this equation.

If we consider that by hypothesis the velocity potential ϕ is equal to zero in the reference condition, as shown in Fig 1, according to definition (4), the first generalized derivative of the velocity potential with respect to the spatial coordinate x_i is given by

$$\frac{\bar{\partial}\phi}{\partial x_i} = \frac{\partial\phi}{\partial x_i} + \phi\,(n_i + t_i + s_i)\,\delta(f)$$

The second generalized derivative then yields

$$\frac{\bar{\partial}^2\phi}{\partial x_i\partial x_i} = \frac{\bar{\partial}}{\partial x_i}\left[\frac{\partial\phi}{\partial x_i} + \phi\,(n_i + t_i + s_i)\,\delta(f)\right]$$
$$= \frac{\partial^2\phi}{\partial x_i\partial x_i} + \left[\frac{\partial\phi}{\partial x_i}(n_i + t_i + s_i)\right]\delta(f)$$
$$+ \frac{\bar{\partial}}{\partial x_i}[\phi\,(n_i + t_i + s_i)\,\delta(f)]$$

If we now use Eq (19) and the velocity potential definition, the generalized Laplacian equation which governs the mass effects in incompressible fluids reads as follows:

$$\frac{\bar{\partial}^2\phi}{\partial x_i\partial x_i} = (v_n + v_t + v_s)\,\delta(f)$$
$$+ \frac{\bar{\partial}}{\partial x_i}[\phi\,(n_i + t_i + s_i)\,\delta(f)] \qquad (20)$$

This is a Poisson equation which incorporates normal and tangential boundary conditions. As it stands, the equation does not allow an immediate analytical or computational treatment due to the presence of Dirac delta terms of the surface function f on its right hand side. An integral transformation of the equation is required *a priori* to permit this objective to be achieved.

According to Morse and Feshbach (1953), the basic solution to the Poisson problem

$$\nabla^2\mathcal{G} = \frac{\partial^2\mathcal{G}}{\partial x_i\partial x_i} = \delta\left(\vec{X}(x_i,t) - \vec{Y}(x_i,t)\right)$$

reads

$$\mathcal{G}\left(\vec{X},\vec{Y},t\right) = -\frac{1}{4\pi r} \qquad (21)$$

where r is the distance between a source point at position $\vec{Y}(x_i,t)$ and the observer point at position $\vec{X}(x_i,t)$, that is, $r = |\vec{X}(x_i,t) - \vec{Y}(x_i,t)|$. This is the basic Green's function of Laplace's equation for the unbounded domain $\mathcal{V}$.

From here, a formal solution for Eq (20) can be constructed as follows:

$$\phi = -\frac{1}{4\pi}\int_{\mathcal{V}} \frac{v_n + v_t + v_s}{r}\,\delta(f)\,d\mathcal{V} - \frac{1}{4\pi}\frac{\bar{\partial}}{\partial x_i}\int_{\mathcal{V}} \frac{\phi\,(n_i + t_i + s_i)}{r}\,\delta(f)\,d\mathcal{V} \qquad (22)$$

The element of volume $d\mathcal{V}$ which appears in Eq (22) may be expressed in various forms. Among them, the most convenient to our purpose is the one which considers elements of distance conformed to the body surface and centered on the source point, as depicted in Fig 2, that is,

$$d\mathcal{V} = d\eta\, d\xi\, d\zeta = d\eta\, dS$$

Here, $d\eta$ is an element of distance along $\vec{n}$ from the surface source, whereas $d\xi$ and $d\zeta$ are elements of distance along the curvilinear coordinate axes locally tangent to $\vec{t}$ and $\vec{s}$ respectively, so that their product yields an element of area dS of the body surface.

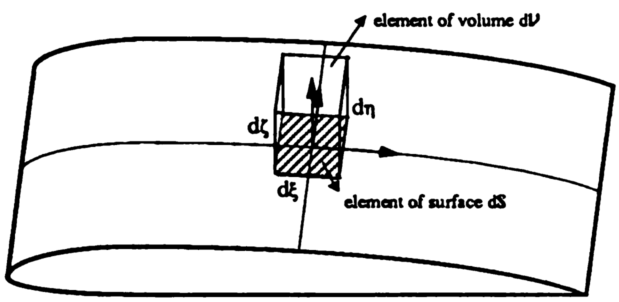

FIG 2. Body-fitted volume element.

With this geometrical set-up, Eq (22) assumes the following form:

$$\phi = -\frac{1}{4\pi}\int_{f=0}\int_0^{\infty} \frac{v_n + v_t + v_s}{r}\,\delta(f)\,dS\,d\eta - \frac{1}{4\pi}\frac{\bar{\partial}}{\partial x_i}\int_{f=0}\int_0^{\infty} \frac{\phi\,(n_i + t_i + s_i)}{r}\,\delta(f)\,dS\,d\eta \qquad (23)$$

Since the domain of integration on η contains the surface $f = 0$, which is equivalent to the lower bound $\eta = 0$, an operational property of the Dirac delta function of f allows us to reduce Eq (23) to

$$\phi = -\frac{1}{4\pi}\int_{f=0} \frac{v_n + v_t + v_s}{r}\,dS - \frac{1}{4\pi}\frac{\bar{\partial}}{\partial x_i}\int_{f=0} \frac{\phi\,(n_i + t_i + s_i)}{r}\,dS \qquad (24)$$

One could choose to solve this integro-differential equation for the velocity potential. The unknown variable ϕ appears independently and also inside both integrands on the right hand side. A numerical solution is possible by iteration, having as starting condition the known motion of the body with respect to the reference coordinate system, as well as a reasonable guess for the unknown velocity potential ϕ on the body surface. Note that Eq (24), although driven by surface information only, as it should, is valid for all field points.

One could also choose to differentiate Eq (24) to obtain a governing equation for the perturbation velocity component u_i. This choice may be motivated by the fact that is physically more appealing to work with velocities than with potentials. Then, if we take the gradient of ϕ in Eq (24), we obtain the following result:

$$u_i = -\frac{1}{4\pi}\frac{\partial}{\partial x_i}\int_{f=0} \frac{v_n + v_t + v_s}{r}\,dS - \frac{1}{4\pi}\frac{\partial\bar{\partial}}{\partial x_i \partial x_j}\int_{f=0} \frac{\phi\,(n_j + t_j + s_j)}{r}\,dS \qquad (25)$$

This equation relates a perturbed velocity component u_i to integrals on the surface of the moving body, having the motion kinematics as major information. If we replace v_n, v_t, and v_s by their expanded inviscid versions given by Eqs $(8a - c)$ and we keep on the left hand side what is unknown, the Eq (25) above can be expressed as the following integro-differential equation:

$$4\pi u_i + \frac{\partial}{\partial x_i}\int_{f=0} \frac{u_t + u_s}{r}\,dS + \frac{\partial\bar{\partial}}{\partial x_i \partial x_j}\int_{f=0} \frac{\phi\,(n_j + t_j + s_j)}{r}\,dS = -\frac{\partial}{\partial x_i}\int_{f=0} \frac{V_n + V_t + V_s}{r}\,dS \qquad (26)$$

where the meaning of the five velocity projections is now intuitive. Taking the velocity component u_i as reference, a result like this is known in the mathematical nomenclature as an integral equation of the Fredholm type, of the second kind, because the unknown u_i appears independently and inside one integrand on the left hand side. However, Eq (26) is a little bit more complicated than that, in the sense that it also includes another unknown, namely, the velocity potential ϕ.

If the body surface is smooth, we are allowed to replace the generalized derivatives of the surface integrals by regular ones and to commute the differential and integral operators. Then, we can rewrite Eq (26) symbolically as

$$4\pi u_i + \int_{f=0} \bar{\mathcal{K}}_{u_i}\,dS + \int_{f=0} \bar{\mathcal{K}}_{\phi_i}\,dS = -\int_{f=0} \bar{\mathcal{K}}_{V_i}\,dS \qquad (27)$$

where

$$\bar{\mathcal{K}}_{u_i} = \frac{\partial}{\partial x_i}\left[\frac{u_t + u_s}{r}\right]$$

$$\bar{\mathcal{K}}_{\phi_i} = \frac{\partial^2}{\partial x_i \partial x_j}\left[\frac{\phi\,(n_j + t_j + s_j)}{r}\right]$$

$$\bar{\mathcal{K}}_{V_i} = \frac{\partial}{\partial x_i}\left[\frac{V_n + V_t + V_s}{r}\right]$$

Note that Eq (27) represents a set of three linear equations for four unkonwns, namely, the three velocity components u_i and the velocity potential ϕ. Numerical solutions of this set can be obtained in an iterative fashion. To start the process, the unknown integrals on the left hand side can be ignored and the equations solved only for the known input on the right hand side. In the next iteration, the solution of the previous iteration can be plugged into the unknown integrals, and the process assessed with respect to convergence. To speed up the process, reasonable guesses for the perturbed velocity field and its potential can be prescribed in the first iteration in order to render known the integrands $\mathcal{K}_{u_i}$ and $\mathcal{K}_{\phi_i}$. Once a solution is achieved, the field pressure distribution can be obtained by means of a steady or unsteady version of Bernoulli's equation.

The success of these propositions are still to be evaluated with practical applications. However, since perturbation velocities are small compared to the velocity of reference, the greatest input in the process is already known and appears as the driving term on the right hand side of Eq (27). Perturbation techniques in Aerodynamics have long suffered when the starting point was a homogeneous equation. Here, the starting point is the solution of an inhomogeneous equation and, hopefully, closer to the final answer.

An important remark to be made here is that, for a two-dimensional problem, the surface integrals appearing in Eq (27) become closed line integrals along the cross section boundary. In this case, the integral with the tangential velocity term is linked to the classical circulation integral (see, for example, Karamchetti (1973)), whereas the other integral on ϕ may be connected to the classical downwash integral (see, for example, Mangler (1951)). Therefore, known lifting mechanisms have been introduced in the formulation and this inclusion is evident at its simplest framework. The validity of this statement wil be checked in future applications of this approach.

Compressible fluids

It is known in Compressible Aerodynamics that a sequence of derivation steps involving the regular continuity and momentum equations, with the help of a thermodynamic relation between pressure and density, leads to the so-called full-potential equation. Linearization of the complete, non-linear equation yields the convected wave equation for an observer on the body surface or the acoustical wave equation for an observer in the fixed fluid frame of reference. If exactly the same ingredients are used in the recipe, but now under generalized form, a new result can be obtained. However, in complete form the result is lengthy and cumbersome. In order to show connections between the present approach and already established theories, here we will choose to study the simplified framework of small perturbation problems.

The governing equation now is the wave equation

$$\Box^2\phi = \frac{1}{c^2}\frac{\partial^2\phi}{\partial t^2} - \frac{\partial^2\phi}{\partial x_i \partial x_i} = 0 \tag{28}$$

The generalized version of the Laplacian operator is given by Eq (20). According to Eq (2), the first generalized derivative of ϕ with respect to time is given by

$$\frac{\bar\partial\phi}{\partial t} = \frac{\partial\phi}{\partial t} + \frac{\phi}{|\nabla f|}\frac{\partial f}{\partial t}\,\delta(f)$$

Then, the second generalized derivative yields

$$\frac{\bar\partial^2\phi}{\partial t^2} = \frac{\bar\partial}{\partial t}\left[\frac{\partial\phi}{\partial t} + \right. \qquad =$$

$$\frac{\partial^2\phi}{\partial t^2} + \left[\frac{\partial\phi}{\partial t}\frac{1}{|\nabla f|}\frac{\partial f}{\partial t}\right]\delta(f) + \frac{\bar\partial}{\partial t}\left[\frac{\phi}{|\nabla f|}\frac{\partial f}{\partial t}\,\delta(f)\right]$$

$$= -\frac{\partial\phi}{\partial t}\,v_n\,\delta(f) - \frac{\bar\partial}{\partial t}\left[\phi\, v_n\,\delta(f)\right]$$

with the help of Eq (28) and Lamb's non-penetration condition. If we join this result accordingly with Eq (20), we obtain

$$\bar\Box^2\phi = -(v_n + v_t + v_s)\,\delta(f) - \frac{\bar\partial}{\partial x_i}\left[\phi\,(n_i + t_i + s_i)\,\delta(f)\right]$$

$$-\frac{1}{c^2}\left\{\frac{\partial\phi}{\partial t}\,v_n\,\delta(f) + \frac{\bar\partial}{\partial t}\left[\phi\,v_n\,\delta(f)\right]\right\} \tag{29}$$

Note that Eq (20), the incompressible limit of Eq (29), is recovered if we let the sound speed c go to infinity.

According to Morse and Feshbach (1953), the basic solution of the wave problem in unbounded domain

$$\Box^2\mathcal{G} = \frac{1}{c^2}\frac{\partial^2\mathcal{G}}{\partial t^2} - \frac{\partial^2\mathcal{G}}{\partial x_i x_i} = \delta(t-\tau)\,\delta\left(\vec{X}(x_i,t) - \vec{Y}(x_i,\tau)\right)$$

is given by

$$\mathcal{G}\left(\vec{X},\vec{Y},t,\tau\right) = \frac{\delta(g)}{4\pi r} \tag{30}$$

In this solution, $\delta(g)$ is the Dirac delta function of a sphere $g = t - \tau - r/c = 0$ of information triggered at a source position $\vec{Y}(x_i,\tau)$ at retarded time $\tau = t - r/c$ and received at an observer position $\vec{X}(x_i,t)$ at actual time t. In addition, $r = |\vec{X}(x_i,t) - \vec{Y}(x_i,\tau)|$ is the distance traveled by the information with constant speed c. As we can see, this model reproduces what happens in nature with propagation of perturbations in compressible fluids.

The application of the solution (30) to the governing equation (29) yields the following transformation:

$$4\pi\phi = -\int_{-\infty}^{t}\int_{\mathcal{V}}\frac{v_n + v_t + v_s}{r}\,\delta(f)\,\delta(g)\,d\mathcal{V}\,d\tau$$

$$-\frac{\bar\partial}{\partial x_i}\int_{-\infty}^{t}\int_{\mathcal{V}}\frac{\phi\,(n_i + t_i + s_i)}{r}\,\delta(f)\,\delta(g)\,d\mathcal{V}\,d\tau$$

$$-\frac{1}{c^2}\int_{-\infty}^{t}\int_{\mathcal{V}}\frac{\partial\phi}{\partial t}\frac{v_n}{r}\,\delta(f)\,\delta(g)\,d\mathcal{V}\,d\tau$$

$$-\frac{1}{c^2}\frac{\bar\partial}{\partial t}\int_{-\infty}^{t}\int_{\mathcal{V}}\frac{\phi\,v_n}{r}\,\delta(f)\,\delta(g)\,d\mathcal{V}\,d\tau$$

The integration on τ yields (see Brandão (1989))

$$4\pi\phi = -\int_{\mathcal{V}}\left[\frac{v_n + v_t + v_s}{r}(1 + M_r)\right]_{\text{ret}}\delta(f)\,d\mathcal{V}$$

$$-\frac{\bar\partial}{\partial x_i}\int_{\mathcal{V}}\left[\frac{\phi\,(n_i + t_i + s_i)}{r}(1 + M_r)\right]_{\text{ret}}\delta(f)\,d\mathcal{V}$$

$$-\frac{1}{c^2}\int_{\mathcal{V}}\left[\frac{\partial\phi}{\partial t}\frac{v_n}{r}(1 + M_r)\right]_{\text{ret}}\delta(f)\,d\mathcal{V}$$

$$-\frac{1}{c^2}\frac{\bar\partial}{\partial t}\int_{\mathcal{V}}\left[\frac{\phi\,v_n}{r}(1 + M_r)\right]_{\text{ret}}\delta(f)\,d\mathcal{V}$$

where $M_r = v_r/c = (v_i r_i)/(cr)$ is the source Mach vector projected onto the direction of propagating information (from source to observer). Here, for the purpose of demonstration only, it is admitted that the entire flowfield is subsonic. Moreover, the subscript "ret" means that during the convolution the information coming from a source and arriving at time t at the observer should be taken as having been emitted at the corresponding retarded time τ. If we now consider the volume integration as performed in the last subsection, we obtain

$$\begin{aligned}4\pi\phi = &-\int_{f=0}\left[\frac{v_n + v_t + v_s}{r}(1+M_r)\right]_{\text{ret}} dS \\ &-\frac{\bar{\partial}}{\partial x_i}\int_{f=0}\left[\frac{\phi(n_i+t_i+s_i)}{r}(1+M_r)\right]_{\text{ret}} dS \\ &-\frac{1}{c^2}\int_{f=0}\left[\frac{\partial\phi}{\partial t}\frac{v_n}{r}(1+M_r)\right]_{\text{ret}} dS \\ &-\frac{1}{c^2}\frac{\bar{\partial}}{\partial t}\int_{f=0}\left[\frac{\phi\, v_n}{r}(1+M_r)\right]_{\text{ret}} dS \qquad (31)\end{aligned}$$

One can choose to solve this integro-differential equation for the velocity potential ϕ or, as indicated for the incompressible case, to take its derivative and solve the result for the velocity component u_i. In the second case, if the body surface is smooth, we can rewrite Eq (31) in the following symbolic form:

$$\begin{aligned}4\pi u_i + \int_{f=0}\mathcal{K}_{u_i}\, dS + \int_{f=0}\mathcal{K}_{\phi_i}\, dS + \int_{f=0}\mathcal{K}_{\dot{\phi}M_i}\, dS \\ + \int_{f=0}\mathcal{K}_{\phi M_i}\, dS = -\int_{f=0}\mathcal{K}_{V_i}\, dS \qquad (32)\end{aligned}$$

where

$$\mathcal{K}_{u_i} = \frac{\partial}{\partial x_i}\left[\frac{u_t+u_s}{r}(1+M_r)\right]_{\text{ret}}$$

$$\mathcal{K}_{\phi_i} = \frac{\partial^2}{\partial x_i \partial x_j}\left[\frac{\phi(n_j+t_j+s_j)}{r}(1+M_r)\right]_{\text{ret}}$$

$$\mathcal{K}_{\dot{\phi}M_i} = \frac{\partial}{\partial x_i}\left[\frac{\partial\phi}{\partial t}\frac{M_n}{c\,r}(1+M_r)\right]_{\text{ret}}$$

$$\mathcal{K}_{\phi M_i} = \frac{\partial^2}{\partial x_i \partial t}\left[\frac{\phi\, M_n}{c\,r}(1+M_r)\right]_{\text{ret}}$$

$$\mathcal{K}_{V_i} = \frac{\partial}{\partial x_i}\left[\frac{V_n+V_t+V_s}{r}(1+M_r)\right]_{\text{ret}}$$

When comparing Eq (32) with its incompressible counterpart (Eq (27)), we observe that compressible effects appear in this mathematical model by means of

- the subsonic Doppler magnification factor $(1+M_r)$ shown inside all integrands;
- the consideration of the contents of all integrands at retarded time τ during integration; and
- the inclusion of the $\mathcal{K}_{\phi M_i}$ and $\mathcal{K}_{\dot{\phi}M_i}$ integrals in the equation.

As discussed for the incompressible model, the integro-differential equation (32) can be solved by iteration. To start the process, for a given motion the $\mathcal{K}_{V_i}$ integral is totally known and the $\mathcal{K}_{u_i}$, $\mathcal{K}_{\phi_i}$, $\mathcal{K}_{\phi M_i}$, and $\mathcal{K}_{\dot{\phi}M_i}$ can be estimated. Then, the velocity field can be computed and the answer compared to the estimate of the previous step. If convergence is not reached under a certain criterion, the process goes over another cycle and so on. From the velocity field we can proceed to compute pressure and temperature distributions.

Equation (29) and its integral solution (31) is more complete in terms of boundary sources than the one used by Lee and Yang (1990) to determine via a panel method the pressure distribution on the surface of rotating bodies and airfoils in the subsonic regime. Their governing equation can be obtained from Eq (29) if the v_t, v_s, t_i, and s_i terms are deleted.

The results obtained by Lee and Yang show a certain difficulty in capturing the full expansion on the surface of an ONERA rotor blade in the non-lifting case. The same difficulty is apparent for the pressure distribution on a NACA 0012 blade in a lifting condition. It is possible that they have experienced the same problems encountered by Long (1985) with large expansions and application of the Kutta condition to simulate viscosity effects. The new terms in Eq (29), linked to tangential information on the surface, may help in obtaining better correlation between theoretical and experimental results, thus, proving the adequacy of the approach for subsonic potential flows.

The incompressible model expressed by Eq (27), derived from the continuity equation, has no free-field contribution. The linear compressible model given by Eq (29), derived from the continuity and momentum equations, also has only surface contributions. Lee and Yang reported the adoption of dipoles in the wake to capture lift, a viable, though somewhat arbitrary measure. Had we considered the full potential equation as starting point, non-linear and well-defined volume and surface contributions would appear. Therefore, even better correlations can be obtained if the generalized version of the full potential equation is used. Besides, the applicability of the approach can then be extended into the transonic regime. An exploration of this issue is left for future studies regarding the present technique.

NON-POTENTIAL FLOW CONNECTIONS

The ultimate goal of the aerodynamicist is to solve the fluid mechanics about a body of given geometry in motion relative to the air, so that from this solution useful information can be extracted. Among what can be deemed useful certainly lies pressure and thermal loading, used to design the body shape and to analyze its performance in motion. When dealing with the concept of velocity potential, once a solution is obtained, we have to advance to velocity, then to pressure, and, finally, to temperature. In the last section we established connections of the present approach to the potential theory framework, so that a more direct formulation for velocity was obtained in the incompressible and compressible cases. The objective in this section is to proceed with these developments, now considering the complete physics given by the conservation laws. We will derive in this section two governing equations, one for pressure and another for energy propagation. There are no potential assumptions made in these derivations.

A governing equation for pressure

If exactly the same derivation steps leading to the equation of Ffowcs Williams and Hawkings are repeated, but, this time, using as major components the conservation laws (7) and (11), an even more complete governing equation can be obtained. The completeness here should be understood in the following senses:

- with respect to potential theory, the result includes fluid viscosity and should be regarded as a concise statement of the Navier-Stokes framework.
- with respect to the Ffowcs Williams and Hawkings equation, the result contains new source terms of tangential discontinuity and better definition of source terms of normal jump.

For the sake of completeness, the derivation of the governing equation occurs as described below:

1. Take the generalized time derivative of both sides of the continuity equation (7).
2. Take the generalized derivative of both sides of the momentum equation (11) with respect to x_i.
3. Subtract the result of the previous step from the result of step 1.
4. Subtract from both sides the term $c^2\,\bar{\nabla}^2\rho$.
5. Subtract from the result obtained in step 4 the following identity: $\bar{\Box}^2 c^2\rho_o = -\,c^2\,\bar{\nabla}^2\rho_o$.
6. Replace, where applicable, $\mathcal{P}_{ij}$ by $\tilde{\mathcal{P}}_{ij}$ in order to remove constants and work only with perturbations.

The result we are envisioning reads as follows:

$$\bar{\Box}^2\left[c^2(\rho-\rho_o)\right] = \frac{\bar{\partial}}{\partial t}\left[\rho_o v_n + \rho\,(v_t+v_c)\,\delta(f)\right] - \frac{\bar{\partial}}{\partial x_i}\left[\tilde{\mathcal{P}}_{ij}\,(n_j+t_j+s_j)\,\delta(f)\right] - \frac{\bar{\partial}}{\partial x_i}\left[\rho v_i\,(v_t+v_s)\,\delta(f)\right] + \frac{\bar{\partial}^2\mathcal{T}_{ij}}{\partial x_i\partial x_j} \tag{33}$$

With respect to the Ffowcs Williams and Hawkings equation, Eq (33) introduces two tangential mechanisms of perturbation generation which might be important in some problems of Fluid Mechanics. The new terms reinforce the monopole and dipole behaviors of sound directivity. Furthermore, the normal terms are now better defined, removing ambiguities created in the establishment of the surface function f.

The result represented by Eq (33) is quite general. It allows, among other possibilities, the limiting case where the fluid becomes incompressible. Letting c go to infinity, we obtain

$$\bar{\nabla}^2 p = -\frac{\bar{\partial}}{\partial t}\left[\rho_o\,(v_n+v_t+v_c)\,\delta(f)\right] - \frac{\bar{\partial}^2\bar{\mathcal{T}}_{ij}}{\partial x_i\partial x_j} + \frac{\bar{\partial}}{\partial x_i}\left\{\left[\tilde{\mathcal{P}}_{ij}\,(n_j+t_j+s_j)\qquad\right]\delta(f)\right\} \tag{34}$$

with

$$\bar{\mathcal{T}}_{ij} = \mathcal{E}_{ij} + \rho_o\,u_i\,u_j$$

This limit can find practical applications to low speed motions in air or to motions inside nearly incompressible fluids, like water.

Equations (33) and (34) involve boundary terms which can be handled more easily after integration processes. These mathematical operations are also useful to allow a practical interpretation of the $\delta(f)$ terms. If we make use of the Green's functions (30) and (21) for the wave and Laplace equations, respectively, and of other analytical tools applied in the last section, the integrated results are given by

$$\begin{aligned}4\pi c^2(\rho-\rho_o) + \frac{\bar{\partial}}{\partial x_i}\int_{f=0}\left[\frac{\tilde{\mathcal{P}}_{ij}(n_j+t_j+s_j)}{r}(1+M_r)\right]_{\text{ret}} d\mathcal{S} &= \frac{\bar{\partial}}{\partial t}\int_{f=0}\left[\frac{\rho_o v_n + \rho(v_t+v_s)}{r}(1+M_r)\right]_{\text{ret}} d\mathcal{S} \\ &\quad - \frac{\bar{\partial}}{\partial x_i}\int_{f=0}\left[\frac{\rho\,v_i(v_t+v_s)}{r}(1+M_r)\right]_{\text{ret}} d\mathcal{S} \\ &\quad + \frac{\bar{\partial}^2}{\partial x_i\partial x_j}\int_{\mathcal{V}}\left[\frac{\mathcal{T}_{ij}}{r}(1+M_r)\right]_{\text{ret}} d\mathcal{V}\end{aligned} \tag{35}$$

for the compressible case and

$$\begin{aligned}4\,\pi\,p + \frac{\bar{\partial}}{\partial x_i}\int_{f=0}\frac{\tilde{\mathcal{P}}_{ij}(n_j+t_j+s_j)}{r}\,d\mathcal{S} = {}& \frac{\bar{\partial}}{\partial t}\int_{f=0}\frac{\rho_o(v_n+v_t+v_s)}{r}\,d\mathcal{S} + \frac{\bar{\partial}^2}{\partial x_i\partial x_j}\int_{\mathcal{V}}\frac{\bar{\mathcal{T}}_{ij}}{r}\,d\mathcal{V} \\ &- \frac{\bar{\partial}}{\partial x_i}\int_{f=0}\frac{\rho_o v_i(v_t+v_s)}{r}\,d\mathcal{S}\end{aligned} \tag{36}$$

for the incompressible limit.

Now comes a critical issue. The Green's functions (21) and (30) are intrinsically singular. If derivatives of these solutions are taken, there result stronger singularities which cannot find interpretation in the ordinary sense, but can have meaning in the sense defined by Hadamard (1952). It is a matter of choice taking the derivatives before or after integration. Brandão (1987) and (1990) has shown that for better computing efficiency, which comprises both accuracy and time spent on numerical computations, it is always preferable to derive a singular integral and to handle its finite-part later than to compute the singular integral and to obtain later its numerical derivative.

With the singular integration issue in mind, Eq (35) can be written symbolically as

$$4\pi c^2(\rho-\rho_o) + \int_{f=0}\mathcal{K}^p_{\mathcal{S}}\,d\mathcal{S} = \int_{f=0}\mathcal{K}^v_{\mathcal{S}}\,d\mathcal{S} + \int_{\mathcal{V}}\mathcal{K}^v_{\mathcal{V}}\,d\mathcal{V} \tag{37}$$

This represents a *non-linear* integral equation for the perturbation pressure p, forced by velocity dependent boundary and volume integrals. Above, $\mathcal{K}^p_{\mathcal{S}}$ denotes a singular surface kernel for p, with a weak dependence on the velocity field. On the right hand side, $\mathcal{K}^v_{\mathcal{S}}$ symbolizes a singular surface kernel which depends on the velocity field only, whereas $\mathcal{K}^v_{\mathcal{V}}$ represents a singular volume kernel

INVISCID FLUIDS

The continuity equation (7) is valid for a compressible fluid and requires no specialization regarding viscosity. On the other hand, the momentum equation (11) for the inviscid case is reduced to

$$\frac{\bar{\partial}}{\partial t}(\rho u_i) + \frac{\bar{\partial}}{\partial x_j}(p\,\delta_{ij} + \rho\, u_i\, u_j) =$$

$$[p\,(n_i + t_i + s_i) + \rho\, v_i\,(v_t + v_s)]\,\delta(f) \tag{41}$$

From these four basic equations, a single wave equation can be obtained following the same steps described for the derivation of Eq (33). The result yields

$$\bar{\Box}^2\left[c^2(\rho - \rho_o)\right] = \frac{\bar{\partial}}{\partial t}\left[\rho_o v_n + \rho\,(v_t + v_c)\,\delta(f)\right]$$

$$-\frac{\bar{\partial}}{\partial x_i}\left[p\,(n_i + t_i + s_i)\,\delta(f)\right] + \frac{\bar{\partial}^2 t_{ij}}{\partial x_i \partial x_j}$$

$$-\frac{\bar{\partial}}{\partial x_i}\left[\rho v_i\,(v_t + v_s)\,\delta(f)\right] \tag{42}$$

where

$$t_{ij} = \rho\, u_i\, u_j + \left[p - c^2(\rho - \rho_o)\right]\delta_{ij} \tag{43}$$

is the inviscid version of Lighthill's stress tensor.

Equation (42) is a *non-linear* relation between the perturbation pressure p and several other fluid properties. The non-linearity is built inside Lighthill's variable $c^2(\rho - \rho_o)$ which also appears in the definition of t_{ij}, as given by Eq (43). For example, from a series expansion for Lighthill's variable given by Brandão (1991) we can rewrite this stress tensor as

$$t_{ij} \approx \rho\, u_i\, u_j + \frac{\gamma - 1}{2\,\rho_o\, c^2}\, p^2 \delta_{ij}$$

where $\gamma = c_p/c_v$ is the ratio between specific heat coefficients at constant pressure and volume. It is easily perceived that the non-linear pressure term is small in magnitude due to the squared perturbation pressure in its numerator and to the squared sound speed term in its denominator.

This non-linearity is equivalent, within compressible potential theory, to consider the sound speed c variable from point to point in the field, according to its thermodynamic state. This is *not* the case in the present approach, since here c is the speed of sound in the reference condition and, therefore, a constant. From this discussion, if the problem at hand excites only small perturbations, we are allowed to disregard this non-linearity and simplify Eq (42) to

$$\bar{\Box}^2 p = \frac{\bar{\partial}}{\partial t}\left[\rho_o v_n + \rho\,(v_t + v_c)\,\delta(f)\right] + \frac{\bar{\partial}^2 \rho u_i u_j}{\partial x_i \partial x_j}$$

$$-\frac{\bar{\partial}}{\partial x_i}\left\{\left[p\,(n_i + t_i + s_i) + \rho v_i\,(v_t + v_s)\right]\delta(f)\right\} \tag{44}$$

The addition of the hypothesis of incompressibility provides further reduction of Eq (44) to

$$\bar{\nabla}^2 p = -\frac{\bar{\partial}}{\partial t}\left[\rho_o\,(v_n + v_t + v_s)\,\delta(f)\right] - \frac{\bar{\partial}^2 \rho_o u_i u_j}{\partial x_i \partial x_j}$$

$$+\frac{\bar{\partial}}{\partial x_i}\left\{\left[p\,(n_i + t_i + s_i) + \rho_o v_i\,(v_t + v_s)\right]\delta(f)\right\} \tag{45}$$

Equation (42) should be considered as equivalent to the Euler equation in the Computational Fluid Dynamics parlance. The velocity potential ϕ does not appear there explicitly. During its derivation, the background is established in the sense that the fluid is inviscid, and nothing else in terms of hypotheses.

In integral form, Eq (42) assumes the same structure given by Eq (37), but with kernels given by

$$\mathcal{K}_S^p = \frac{\bar{\partial}}{\partial x_i}\left[\frac{p\,(n_i + t_i + s_i)}{r}(1 + M_r)\right]_{\text{ret}}$$

$$\mathcal{K}_S^v = \frac{\bar{\partial}}{\partial t}\left[\frac{\rho_o v_n + \rho\,(v_t + v_s)}{r}(1 + M_r)\right]_{\text{ret}}$$

$$-\frac{\bar{\partial}}{\partial x_i}\left[\frac{\rho\, v_i\,(v_t + v_s)}{r}(1 + M_r)\right]_{\text{ret}}$$

$$\mathcal{K}_\mathcal{V}^v = \frac{\bar{\partial}^2}{\partial x_i \partial x_j}\left[\frac{t_{ij}}{r}(1 + M_r)\right]_{\text{ret}}$$

Similarly, the incompressible limit (45) can be rewritten with the structure of Eq (38) but, this time, with the kernels simplified to

$$\bar{\mathcal{K}}_S^p = \frac{\bar{\partial}}{\partial x_i}\left[\frac{p\,(n_i + t_i + s_i)}{r}\right]$$

$$\bar{\mathcal{K}}_S^v = \frac{\bar{\partial}}{\partial t}\left[\frac{\rho_o\,(v_n + v_t + v_s)}{r}\right] - \frac{\bar{\partial}}{\partial x_i}\left[\frac{\rho_o\, v_i\,(v_t + v_s)}{r}\right]$$

$$\bar{\mathcal{K}}_\mathcal{V}^v = \frac{\bar{\partial}^2}{\partial x_i \partial x_j}\left[\frac{\rho_o u_i u_j}{r}\right]$$

As remarked previously, Eqs (42) and (45) are prototypes of general relations between pressure, density, and velocity for inviscid fluids. As such, these equations are single relations involving several variables. They cannot constitute solutions themselves, but can be used as mother-equations in iterative schemes already tested in simplified form (see Brandão (1989)) as well as others presently in development.

SUMMARY AND CONCLUSIONS

Results of theoretical nature have been presented concerning the application of an aeroacoustic approach to Aerodynamics. These results cover general issues, like non-linear, viscous, three-dimensional, unsteady, and compressible flows, as well as related simplifications. These simplifications have been discussed in order to construct parallels between the new governing equations and well-established mathematical models of Fluid Mechanics. Therefore, the discussion here has explored from the Navier-Stokes to the Laplacian context, passing through the Euler, full-potential, and linearized potential frameworks.

The inclusion of boundary conditions as source terms of partial differential equations is a characteristic of modern boundary element methods. This mathematical task can be accomplished with the help of the concept of generalized derivatives. In the approach, this trend of incorporating boundary conditions to the governing equations which depends heavily on the velocity field and weakly on the pressure field. For smooth surfaces, these kernels are given explicitly by

$$\mathcal{K}_S^p = \frac{\bar{\partial}}{\partial x_i}\left[\frac{\tilde{\mathcal{P}}_{ij}\,(n_j + t_j + s_j)}{r}\,(1 + M_r)\right]_{\text{ret}}$$

$$\mathcal{K}_S^v = \frac{\bar{\partial}}{\partial t}\left[\frac{\rho_o v_n + \rho\,(v_t + v_s)}{r}\,(1 + M_r)\right]_{\text{ret}} - \frac{\bar{\partial}}{\partial x_i}\left[\frac{\rho\, v_i\,(v_t + v_s)}{r}\,(1 + M_r)\right]_{\text{ret}}$$

$$\mathcal{K}_V^v = \frac{\bar{\partial}^2}{\partial x_i \partial x_j}\left[\frac{\mathcal{T}_{ij}}{r}\,(1 + M_r)\right]_{\text{ret}}$$

Similarly, Eq (36) can be represented concisely as

$$4\pi p + \int_{f=0} \bar{\mathcal{K}}_S^p\, d\mathcal{S} = \int_{f=0} \bar{\mathcal{K}}_S^v\, d\mathcal{S} + \int_{\mathcal{V}} \bar{\mathcal{K}}_V^v\, d\mathcal{V} \qquad (38)$$

with the following simplified kernels

$$\bar{\mathcal{K}}_S^p = \frac{\bar{\partial}}{\partial x_i}\left[\frac{\tilde{\mathcal{P}}_{ij}\,(n_j + t_j + s_j)}{r}\right]$$

$$\bar{\mathcal{K}}_S^v = \frac{\bar{\partial}}{\partial t}\left[\frac{\rho_o\,(v_n + v_t + v_s)}{r}\right] - \frac{\bar{\partial}}{\partial x_i}\left[\frac{\rho_o\, v_i\,(v_t + v_s)}{r}\right]$$

$$\bar{\mathcal{K}}_V^v = \frac{\bar{\partial}^2}{\partial x_i \partial x_j}\left[\frac{\bar{\mathcal{T}}_{ij}}{r}\right]$$

Equations (37) and (38) are single integral equations involving several unknowns. As before, an iterative solution technique is recommended to obtain the pressure field. This solution starts with a reasonable guess for the velocity field, which can be constructed taking as basis the known motion of the body with respect to the reference system at rest. This guess allows estimation of the $\mathcal{K}_S^v$ and $\mathcal{K}_V^v$ integrals, the driving input for pressure determination. Once one cycle is completed, the momentum equation can be used to yield a better distribution for the unknown perturbation velocity field. Then, the pressure can be recomputed and convergence evaluated. Further details on this solution algorithm have been provided by Brandão (1991). There are reasons to believe that convergence can be reached within a few cycles because iterations begin with an input very close to the converged solution. However, applications are necessary to demonstrate this point.

A governing equation for energy

It is known that for high speed air flows, the temperature of the fluid near or on the body surface becomes an important issue. Since Eq (33) is mostly concerned with pressure propagation generated by motion, no temperature information can be obtained from this equation. Therefore, studies regarding this objective are required. Here we explore a theoretical possibility, integrating into a single statement the physics of the energy and energy momentum equations, so that we can have access to temperature distributions in the field, as well as to mechanisms of energy propagation through the flow.

A new governing equation [illegible] tends the *Acoustic Analogy* into this issue, car[illegible] llowing the steps below, in complete simila[illegible] tion of Eq (33):

1. Take the generalized time derivative of both sides of the energy equation (13).
2. Take the generalized derivative of both sides of the energy momentum equation (17) with respect to x_i.
3. Subtract the result of the previous step from the result of step 1.
4. Divide the whole equation by c^2.
5. Subtract from both sides of the previous step the term $\bar{\nabla}^2 e$.

The result of this process yields

$$\bar{\Box}^2 e = \frac{1}{c^2}\left\{\frac{\bar{\partial}}{\partial t}\left[\mathcal{M}\;\delta(f)\right] - \frac{\bar{\partial}}{\partial x_i}\left[\mathcal{D}_i\;\delta(f)\right] - \frac{\bar{\partial}^2 \mathcal{Q}_{ij}}{\partial x_i \partial x_j} - \frac{\bar{\partial}^2}{\partial t \partial x_i}\left(q_i + \mathcal{P}_{ij} u_j\right)\right\} \qquad (39)$$

where we define

$$\mathcal{M} = e_o v_n + e\,(v_t + v_s) + (\mathcal{P}_{ij} v_j + q_i)\,(n_i + t_i + s_i)$$

$$\mathcal{D}_i = e v_i\,(v_t + v_s) + v_i\left(\tilde{\mathcal{P}}_{jk} v_k + q_j\right)(n_j + t_j + s_j)$$

and

$$\mathcal{Q}_{ij} = e u_i u_j + \mathcal{P}_{jk} u_k u_i + u_i q_j + c^2 e\,\delta_{ij}$$

as the energetic monopole scalar, dipole vector, and quadrupole tensor, respectively.

Equation (39) is a wave equation for the total fluid element energy e driven by two surface and two volume source terms of different natures. The surface terms, in the order given, have the behavior of the traditional monopole and dipole. The first volume term is a free-field quadrupole, like in Lighthill's equation. Finally, the second volume term is a free-field contributor of mixed nature, still to be interpreted.

If we now consider the incompressible limit of Eq (39), the following identity results:

$$\bar{\nabla}^2 e = \frac{\bar{\partial}^2 e}{\partial x_i \partial x_j}\,\delta_{ij} \qquad (40)$$

which gives no useful information. However, a result like this was expected because the energy equation introduces new effects in the flow physics only in the compressible case. The "locking phenomenon" is well-known in Computational Fluid Dynamics for low Mach number flows. The reduction of Eq (39) to identity (40) is just an equivalent manifestation of the same phenomenon.

Like the other governing equations before in this paper, Eq (39) can now the integrated and solved numerically by an iterative scheme. However, these details will be omitted here for reasons of brevity and to allow time for maturation of the concept.

Equations (33) and (39) are the most sophisticated results presented in this contribution. Together, they form a mathematical model within the Navier-Stokes environment of modern Computational Fluid Dynamics. For the sake of completeness, now we can simplify the context with the hypothesis of motion inside inviscid fluids, which places the mathematical model inside the Euler equations framework.

started with Ffowcs Williams and Hawkings (1969), as an outgrowth of Lighthill's *Acoustic Analogy*. Applications of the approach to Aerodynamics resulted in an incomplete description of the flow physics, which can be summarized by

- underevaluation of expansions;
- overevaluation of compressions; and
- difficulty in capturing circulation.

This incompleteness suggested to the author that what was missing in the earlier mathematical model could be related to its boundary conditions. The challenge then consisted not only on having a perception for the lacking information, but also on devising a logical mathematical device for its inclusion in the model.

With the objective of attempting corrections in these theoretical deficiencies, the concept of generalized derivatives has been revisited and extended, removing ambiguities of definition of surface functions and allowing for property jumps along tangential directions on the discontinuity surfaces. As results, new generalized versions of the continuity, momentum, energy, and energy momentum equations have been derived. Connections with potential flow theory have been presented for both incompressible and compressible fluids. In the second case, a new linear formulation has been derived which is more complete than the one used by Lee and Yang (1990). Integral transformations of the governing equations have been provided and possibilities of obtaining solutions via iteration have been presented.

By following the path which leads to the Ffowcs Williams and Hawkings equation, a new formulation relating pressure and velocity has been obtained for non-potential flows. This formulation presents new mechanisms of noise generation related to tangential flow, which may be important in aerodynamic applications. A similar relation between several fluid properties has been derived for the energy propagating from a moving body. The inviscid and incompressible limits of these relations have been made explicit to emphasize the generality of the approach. The corresponding integral transformations of these equations have been supplied and their solution algorithm given in very broad terms.

Although the association between circulation and vorticity is practically unavoidable in Aerodynamics, the word *vorticity* does not appear in this paper before this paragraph. The main issue raised by this contribution is the development of a mathematical model with correct and well-defined boundary conditions which, together with free-field effects, can reproduce experimental results in Fluid Mechanics. In discussing this issue, the author believes that the concept of vorticity, as established in the classical literature, is not necessary. However, this concept might be invoked to serve as reference or to correct the present model if it is proven incomplete.

The results shown here are based on logical assumptions. It is expected that studies based on the theory presented might help in the development of the aeroacoustic approach to Aerodynamics and in the clarification of the quoted unresolved issues. The theory is now established and ready to be checked in its validity. Future studies should include benchmark applications and comparisons of results with well-known experimental and/or theoretical data.

ACKNOWLEDGEMENTS

The Brazilian Ministry of Aeronautics, Fundação Casimiro Montenegro Filho, and Fundação de Amparo à Pesquisa do Estado de São Paulo provided support concerning the development and presentation of this research in technical meetings.

This paper is concerned with some new aspects of the theory of anholonomic components of tensors of single and double fields. Consistent definitions of these components are given. As applications, the geometrically nonlinear equations of elasticity and shells referred to general curvilinear coordinates are written in terms of anholonomic components of vectors and tensors involved.

INTRODUCTION

Historically, the notion of physical components of vectors was first introduced by Ricci and Levi-Civita in a memoir published in 1901. Thirring, as early as 1925, had noticed the connection existing between physical and tensorial components. Cissotti (1928) introduced the concept of physical components of covariant tensors of order n. An entirely satisfactory theory of physical components in orthogonal curvilinear coordinates was presented by McConnell (1931). For more details in early developments of the theory of physical components, see, for example, Truesdell (1953), Ericksen (1960), and Altman and Oliveira (1982).

With respect to non-orthogonal coordinate systems, different authors, e.g. Green and Zerna (1968), Sedov (1965), Synge and Schield (1949), and Truesdell (1953), produced distinct definitions of physical components of tensors. Usually, to avoid any ambiguity in these definitions, the tensor components are transformed to refer to an orthogonal coordinate system in order to allow the use of McConnell's concept of physical components. Truesdell (1953) dealt with mixed components and in (1954) pointed out the connection between his method and the theory of anholonomic coordinates (Schouten, 1951; Ericksen, 1960). A theory developed by Altman and Oliveira (1977, 1982) and Oliveira and Altman (1978), which includes all physical components (mixed, covariant, and contravariant), shows the compatibility and relationship among some of those definitions. In this context, each tensor is seen as a linear transformation between two vector spaces properly chosen. The concept of physical components depends fundamentally on this linear transformation and on the unit bases of the mentioned vector spaces. In the light of the work of Altman and Oliveira (1977), the connection between physical and anholonomic components, viewed as an isomorfism between vectorial spaces, is implicitly contained in the definition of physical components of tensors.

The purpose of this article is to present some new aspects of the theory of anholonomic components of tensors of single and double fields and to demonstrate their applications to representative problems in Solid Mechanics.

Convected coordinates were utilized by Altman and Bevilacqua (1991) in order to obtain the equations of motion in a Lagrangian description. The resulting equations, after being referred to a local orthogonal coordinate system, were written in terms of physical components of tensors. Here, in the description of the motion of a continuous body, the undeformed state is defined by curvilinear coordinates and the deformed state by either a new set of curvilinear coordinates or by its convected coordinates. The components of the first Piola-Kirchhoff stress tensor and of the deformation gradient, which enter into the equations of motion, are components of tensors of double field. A study of anholonomic components of second order tensors of single and double fields is provided in order to express the set of governing equations of a body in terms of these components.

As applications of the above mentioned theory, the geometrically nonlinear equations of elasticity and shells referred to general curvilinear coordiantes are written in terms of anholonomic components of the vectors and tensors involved.

Finally, in the last section of this paper, some comments about the suitability and generality of the theory of anholonomic components here presented are made.

PRELIMINARIES

Consider the body C, occupying in the undeformed state a region C that consists of the material volume $\mathcal{V}$ and its surface $\mathcal{S}$. The position of a point P in this region is denoted by a curvilinear coordinate system X^J $(J = \mathrm{I}, \mathrm{II}, \mathrm{III})$. In the deformed state, the material points of the region C go into a region c, consisting of a volume v and its surface s. A point in the deformed state may be represented by a new set of curvilinear coordinates x^j $(j = 1, 2, 3)$.

The covariant and contravariant base vectors at each point in $\mathcal{C}$ and at each one in c, are denoted by $\left(\left\{\vec{G}_J\right\},\left\{\vec{G}^J\right\}\right)$ and $(\{\vec{g}_j\},\{\vec{g}^j\})$, respectively. The base vectors and the corresponding metrics (G_{IJ},G^{IJ}) and (g_{ij},g^{ij}), are defined by

$$\vec{G}_J = \vec{R}_{,J} \quad , \quad (J = \mathrm{I},\mathrm{II},\mathrm{III}) \tag{1a}$$

$$G_{IJ} = \vec{G}_I \cdot \vec{G}_J \quad , \quad G_{IK}\, G^{JK} = \delta_I^J \quad ,$$
$$\vec{G}^I = G^{IJ}\,\vec{G}_J \tag{1b-d}$$

and

$$\vec{g}_j = \vec{r}_{,j} \quad , \quad (j = 1,2,3) \tag{2a}$$

$$g_{ij} = \vec{g}_i \cdot \vec{g}_j \quad , \quad g_{ik}\, g^{jk} = \delta_i^j \quad , \quad \vec{g}^i = g^{ij}\,\vec{g}_j \tag{2b-d}$$

where

$$\vec{R} = \vec{R}\left(X^{\mathrm{I}},X^{\mathrm{II}},X^{\mathrm{III}}\right) \quad , \quad \vec{r} = \vec{r}\left(x^1,x^2,x^3\right) \tag{3a,b}$$

are the position vectors of a point in $\mathcal{C}$ and of one in c, $\left(\delta_I^J,\delta_i^j\right)$ are the Kronecker symbols referred to the coordinates systems X^I and x^i, and the indices after a comma indicate derivatives with respect to X^J when they are majuscules and with respect to x^j when they are minuscules.

The displacement vector $\vec{u}$ is defined as the vector that extends from a material point in the undeformed body to the same material point in the deformed body. This vector will have components $\mathcal{U}^I$ referred to X^I and u^i referred to x^i, i.e.,

$$\vec{u} = \mathcal{U}^I\,\vec{G}_I = \mathrm{u}^i\,\vec{g}_i \tag{4a,b}$$

The displacement vector $\vec{u}$ may also be expressed in terms of its covariant components $\mathcal{U}_I$ and u_i as follows

$$\vec{u} = \mathcal{U}_I\,\vec{G}^I = \mathrm{u}_i\,\vec{g}^i \tag{4c,d}$$

Furthermore, the partial derivatives of $\vec{u}$ with respect to X^J and x^j, can be written as

$$\vec{u}_{,J} = \mathcal{U}^I_{;J}\,\vec{G}_I = \mathcal{U}_{I;J}\,\vec{G}^I \tag{4e,f}$$

$$\vec{u}_{,j} = \mathrm{u}^i_{;j}\,\vec{g}_i = \mathrm{u}_{i;j}\,\vec{g}^i \tag{4g,h}$$

where the symbols $(\ )_{;J}$ and $(\ )_{;j}$ denote the covariant derivatives with respect to X^J and x^j, respectively.

The motion of the body is expressed by

$$x^i = x^i\left(X^I,t\right) \quad \text{or} \quad X^I = X^I\left(x^i,t\right) \tag{5a,b}$$

Each point p in c at time t comes from a point P in $\mathcal{C}$ at time $t = 0$. It is assumed that the mappings $(5a,b)$ are single-valued and have continuous partial derivatives with respect to their arguments up to any order required. Each expression of $(5a,b)$ is the unique inverse of the other. Thus, since the transformations are reversible, the determinants (Jacobians)

$$\left|\frac{\partial x^i}{\partial X^I}\right| \quad \text{or} \quad \left|\frac{\partial X^I}{\partial x^i}\right|$$

are not zero.

ANHOLONOMIC COMPONENTS OF VECTORS

The physical dimensions of the covariant and contravariant components $\mathcal{V}_K$ and $\mathcal{V}^K$ of the same vector

$$\vec{V} = \mathcal{V}_K\,\vec{G}^K = \mathcal{V}^K\,\vec{G}_K \quad (K = \mathrm{I},\mathrm{II},\mathrm{III}) \tag{6a,b}$$

are different, since the vectors of their bases are not generally of unit length. The need of finding components of vectors, whose dimensions coincide with those of the vectors themselves, is accomplished by constructing the unit bases

$$\vec{U}_K = \frac{\vec{G}_K}{\sqrt{G_{KK}}} \quad \text{and} \quad \vec{U}^K = \frac{\vec{G}^K}{\sqrt{G^{KK}}} \tag{7a,b}$$

and their reciprocal bases

$$\underline{\vec{U}}^K = \sqrt{G_{KK}}\,\vec{G}^K \quad \text{and} \quad \underline{\vec{U}}_K = \sqrt{G^{KK}}\,\vec{G}_K \tag{7c,d}$$

respectively. Expanding the vector $\vec{V}$ with respect to these bases one obtains

$$\vec{V} = \left[\mathcal{V}^K\right]_U \vec{U}_K = [\mathcal{V}_K]_{U^*}\,\vec{U}^K =$$
$$[\mathcal{V}_K]_{\underline{U}}\,\underline{\vec{U}}^K = \left[\mathcal{V}^K\right]_{\underline{U}^*}\,\underline{\vec{U}}_K \tag{8a-d}$$

where $K = \mathrm{I},\mathrm{II},\mathrm{III}$ and

$$\left[\mathcal{V}^K\right]_U = \sqrt{G_{KK}}\,\mathcal{V}^K \quad , \quad [\mathcal{V}_K]_{U^*} = \sqrt{G^{KK}}\,\mathcal{V}_K \tag{8e,f}$$

$$[\mathcal{V}_K]_{\underline{U}} = \frac{\mathcal{V}_K}{\sqrt{G_{KK}}} \quad , \quad \left[\mathcal{V}^K\right]_{\underline{U}^*} = \frac{\mathcal{V}^K}{\sqrt{G^{KK}}} \tag{8g,h}$$

are called physical (Ericksen, 1960; Altman and Oliveira, 1982) or anholonomic components of $\vec{V}$ relative to the bases $U = \left\{\vec{U}_K\right\}$, $U^* = \left\{\vec{U}^K\right\}$, $\underline{U} = \left\{\underline{\vec{U}}^K\right\}$, and $\underline{U}^* = \left\{\underline{\vec{U}}_K\right\}$ respectively.

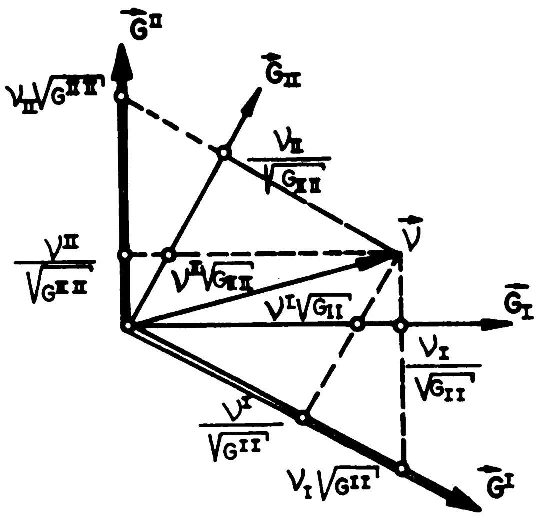

FIG 1. Physical or anholonomic components of a vector.

As it can be seen from Figure 1, the components defined by formulas $(8e,f)$ are the parallel projections of the vector $\vec{V}$ onto the directions $\vec{G}_K$ and $\vec{G}^K$, respectively, while the components $(8g, h)$ are the orthogonal projections over the same directions, respectively. Ricci and Levi-Civita (1901), had already introduced these four sets of components.

Observe that the double indices in the metric symbols do not contribute to the summation convention. For the deformed state, similar formulas as the preceding ones can be obtained by substituting the uppercase indices and letters which enter in the above expressions by lowercase ones.

ANHOLONOMIC COMPONENTS OF TENSORS OF DOUBLE FIELD

A second order tensor of double field $\mathcal{T}$ can be defined as linear combinations of tensor products of the type $\vec{\underset{\sim}{U}} \otimes \vec{\underset{\sim}{u}}$ (or $\vec{\underset{\sim}{u}} \otimes \vec{\underset{\sim}{U}}$), where $\vec{\underset{\sim}{U}}$ and $\vec{\underset{\sim}{u}}$ are elements that belong to one of the bases of the sets $\{U, \underline{U}, U^*, \underline{U}^*\}$ and $\{u, \underline{u}, u^*, \underline{u}^*\}$, respectively. For example, the expressions

$$\mathcal{T} = \sum_{M,m} [T^{Mm}]_{\mathcal{B}}\, \vec{\underline{U}}_M \otimes \vec{u}_m = \sum_{M,m} T^{Mm}\, \vec{G}_M \otimes \vec{g}_m \qquad (9a,b)$$

represent a covariant second order tensor of double field, where $\mathcal{B} = \underline{U}^* \otimes u$ is a basis of the considered tensorial space and the notation $[T^{Mm}]_{\mathcal{B}}$ denotes the anholonomic components of the tensor of double field referred to the basis $\mathcal{B}$. Taking into account the identity $(9a, b)$ and the expressions of $\vec{\underline{U}}_M$ and $\vec{u}_m$ as functions of $\vec{G}_M$ and $\vec{g}_m$, respectively, one obtains

$$[T^{Mm}]_{\mathcal{B}} = \frac{\sqrt{g_{mm}}}{\sqrt{G^{MM}}}\, T^{Mm} \qquad (9c)$$

where $M = \mathrm{I}, \mathrm{II}, \mathrm{III}$ and $m = 1, 2, 3$. Similarly, fifteen more anholonomic components of $\mathcal{T}$ can be obtained.

A third order tensor of double field can be defined as linear combinations of tensor products of anyone of the following types: $\vec{\underset{\sim}{U}}_1 \otimes \vec{\underset{\sim}{u}}_1 \otimes \vec{\underset{\sim}{u}}_2$, $\vec{\underset{\sim}{u}}_1 \otimes \vec{\underset{\sim}{U}}_1 \otimes \vec{\underset{\sim}{u}}_2$, $\vec{\underset{\sim}{u}}_1 \otimes \vec{\underset{\sim}{u}}_2 \otimes \vec{\underset{\sim}{U}}_1$, $\vec{\underset{\sim}{u}}_1 \otimes \vec{\underset{\sim}{U}}_1 \otimes \vec{\underset{\sim}{U}}_2$, $\vec{\underset{\sim}{U}}_1 \otimes \vec{\underset{\sim}{u}}_1 \otimes \vec{\underset{\sim}{U}}_2$, and $\vec{\underset{\sim}{U}}_1 \otimes \vec{\underset{\sim}{U}}_2 \otimes \vec{\underset{\sim}{u}}_1$, where $\vec{\underset{\sim}{U}}_i$ and $\vec{\underset{\sim}{u}}_i$ $(1 = 1, 2)$ are elements that belong to one of the bases of the sets $\{U, \underline{U}, U^*, \underline{U}^*\}$ and $\{u, \underline{u}, u^*, \underline{u}^*\}$, respectively. Similarly as above, the expressions

$$\mathcal{T} = \sum_{M,m,L} [T^{Mm}{}_L]_{\mathcal{B}}\, \vec{\underline{U}}_M \otimes \vec{u}_m \otimes \vec{U}^L = \sum_{M,m,L} T^{Mm}{}_L\, \vec{G}_M \otimes \vec{g}_m \otimes \vec{G}^L \qquad (10a,b)$$

represent a mixed third order tensor of double field, where $\mathcal{B} = \underline{U}^* \otimes u \otimes U^*$ is a basis of the considered tensorial space. The substitution of the vectors $\vec{\underline{U}}_M$, $\vec{u}_m$, and $\vec{U}^L$ as given by formulas (7) into expressions $(10a, b)$ leads to

$$[T^{Mm}{}_L]_{\mathcal{B}} = \frac{\sqrt{g_{mm}}}{\sqrt{G^{MM}}} \sqrt{G^{LL}}\, T^{Mm}{}_L \qquad (11)$$

which is the expression of the anholonomic components of a third order tensor of double field referred to the basis $\mathcal{B} = \underline{U}^* \otimes u \otimes U^*$.

It should be observed that since the covariant derivatives of the vectorial and tensorial components have also a tensorial character, the above theory can be utilized to obtain their anholonomic counterparts. For instance, utilizing formula (11) for the covariant derivative of the first Piola-Kirchhoff stress tensor with respect to X^L, denoted by $\hat{S}^{Kk}{}_{;L}$, one obtains

$$\left[\hat{S}^{Kk}{}_{;L}\right]_{\underline{U}^* \otimes u \otimes U^*} = \frac{\sqrt{g_{kk}}}{\sqrt{G^{KK}}} \sqrt{G^{LL}}\, \hat{S}^{Kk}{}_{;L} \qquad (12)$$

which is the expression of the anholonomic components of $\hat{S}^{Kk}{}_{;L}$, referred to the basis $\underline{U}^* \otimes u \otimes U^*$.

As a particular case, the anholonomic components of tensors of single field (Oliveira and Altman, 1981) can be obtained from the preceding theory by making $U = u$, $\underline{U} = \underline{u}$, $U^* = u^*$, and $\underline{U}^* = \underline{u}^*$. In this context the anholonomic components of the displacement gradient $\mathcal{U}^I_{;J}$ and $\mathcal{U}_{I;J}$ referred to the bases $U \otimes \underline{U}$ and $\underline{U} \otimes \underline{U}$, respectively, can be determined from the expressions

$$\sum_{I,J} [\mathcal{U}^I_{;J}]_{U \otimes \underline{U}}\, \vec{U}_I \otimes \vec{\underline{U}}^J = \sum_{I,J} \mathcal{U}^I_{;J}\, \vec{G}_I \otimes \vec{G}^J \qquad (13a)$$

and

$$\sum_{I,J} [\mathcal{U}_{I;J}]_{\underline{U} \otimes \underline{U}}\, \vec{\underline{U}}^I \otimes \vec{\underline{U}}^J = \sum_{I,J} \mathcal{U}_{I;J}\, \vec{G}^I \otimes \vec{G}^J \qquad (13b)$$

leading to

$$[\mathcal{U}^I_{;J}]_{U \otimes \underline{U}} = \frac{\sqrt{G_{II}}}{\sqrt{G_{JJ}}}\, \mathcal{U}^I_{;J} \qquad (13c)$$

and

$$[\mathcal{U}_{I;J}]_{\underline{U} \otimes \underline{U}} = \frac{1}{\sqrt{G_{II}}\sqrt{G_{JJ}}}\, \mathcal{U}_{I;J} \qquad (13d)$$

Furthermore, note that in the case of single field tensors, formula $(9c)$ coincides with Green and Zerna's physical components of the stress tensor.

Expressions (9) to (13) will be needed in the sequel.

DIMENSIONAL ANALYSIS OF ANHOLONOMIC COMPONENTS

In this section it will be proved the dimensional invariance of the anholonomic components of a second order tensor of double field, under transformation of coordinates.

Firstly, it should be observed that the dimension of $\sqrt{G_{II}}dX^I$ and of $\sqrt{g_{ii}}dx^i$ is L, where L denotes the dimension of length. This follows from the Riemannian metrics

$$dS^2 = G_{IJ}\, dX^I\, dX^J \quad , \quad ds^2 = g_{ij}\, dx^i\, dx^j \qquad (14a,b)$$

The dimensions of G^{II} and g^{ii} can be calculated as functions of G_{II} and g_{ii}, respectively, by observing that if $G_I = \dim(G_{II})$ and $g_i = \dim(g_{ii})$, then

$$\dim G = G_I\, G_J\, G_K \quad , \quad \dim g = g_i\, g_j\, g_k \qquad (15a,b)$$

where

$$G = \det[G_{IJ}] \quad , \quad g = \det[g_{ij}] \qquad (15c,d)$$

The substitution of expressions $(15a, b)$ into

$$G^I = \frac{\dim A_{II}}{\dim G} \quad , \quad g^i = \frac{\dim a_{ii}}{\dim g} \tag{15e, f}$$

where

$$\dim A_{II} = G_J\, G_K \quad , \quad \dim a_{ii} = g_j\, g_k \tag{15g, h}$$

lead to

$$G^I = \frac{1}{G_I} \quad , \quad g^i = \frac{1}{g_i} \tag{15i, j}$$

The dimension of a tensor of double field $\mathcal{T}$, which is denoted by dim $\mathcal{T}$, can be defined as being the dimension of its components in orthonormal cartesian systems (Y^M, y^m), $(M = \mathrm{I}, \mathrm{II}, \mathrm{III}\ ;\ m = 1,2,3)$. It can be proved that the dimension of the anholonomic components of $\mathcal{T}$ in any coordinate systems (X^K, x^k), where $K = \mathrm{I}, \mathrm{II}, \mathrm{III}$ and $k = 1,2,3$ is invariant and equal to dim $\mathcal{T}$. Let the contravariant components $\bar{T}^{Kk}$ be chosen to represent the double tensor field of second order in the coordinate systems (X^K, x^k) and T^{Mm} its components in the orthonormal cartesian systems (Y^M, y^m). From the formulas for changing coordinates

$$\bar{T}^{Kk}(X, x) = T^{Mm}(Y, y)\, \frac{\partial X^K}{\partial Y^M}\, \frac{\partial x^k}{\partial y^m} \tag{16}$$

one can write

$$\dim \bar{T}^{Kk} = \dim (X^K)\, L^{-1} \cdot \dim (x^k)\, L^{-1} \dim T^{Mm} \tag{17a}$$

or

$$\dim \bar{T}^{Kk} = \dim (X^K) \cdot \dim (x^k)\, L^{-2} \dim \mathcal{T} \tag{17b}$$

where

$$\dim T^{Mm} = \dim \mathcal{T} \tag{17c}$$

and dim (X^K) and dim (x^k) are the dimensions of the X^K and x^k coordinates, respectively. From formula $(9c)$, where $\mathcal{B} = \underline{U}^* \otimes u$, it can be written

$$\dim \left[\bar{T}^{Kk}\right]_{\mathcal{B}} = \dim \left(\sqrt{\frac{g_{kk}}{G^{KK}}}\right) \dim \bar{T}^{Kk} \tag{18a}$$

After substituting formula $(17b)$ into expression $(18a)$, one obtains

$$\dim \left[\bar{T}^{Kk}\right]_{\mathcal{B}} = \left[\sqrt{g_k}\, \dim(x^k)\right] \cdot \left[\sqrt{G_K}\, \dim(X^K)\right] L^{-2} \dim \mathcal{T} \tag{18b}$$

or

$$\dim \left[\bar{T}^{Kk}\right]_{\mathcal{B}} = \dim \mathcal{T} \tag{18c}$$

since

$$\sqrt{g_k} \dim (x^k) = \sqrt{G_K} \dim (X^K) = L \tag{18d}$$

By the same reasoning, it can be shown that the dimensions of the anholonomic counterparts of the covariant and mixed components of a double tensor field are also equal to dim $\mathcal{T}$. Furthermore, this theorem can be extended for higher order tensors of double field.

ELASTICITY EQUATIONS IN TERMS OF ANHOLONOMIC COMPONENTS

As an application of the preceding theory, the nonlinear elasticity equations of a continuous body will be written in terms of anholonomic components of vectors and tensors involved.

Equations of motion

Consider Cauchy's first law of motion expressed in terms of the reference state (Eringen, 1962)

$$\hat{S}^{Kk}{}_{:K} + P^k = \rho_o\, a^k \quad (k = 1,2,3) \tag{19a}$$

and the boundary conditions

$$\nu_K\, \hat{S}^{Kk} = F^k \quad (k = 1,2,3) \tag{19b}$$

where

$$\hat{S}^{Kk}{}_{:K} = \hat{S}^{Kk}{}_{,K} + \hat{S}^{Km}\, \Gamma^k_{ml}\, x^l_{,K} + \hat{S}^{Kk}\, \Gamma^L_{LK} \tag{19c}$$

In these expressions, $\hat{S}^{Kk}$ are the components of the first Piola-Kirchhoff stress tensor; Γ^R_{IS} and Γ^r_{is} are the Christoffel symbols in the reference state and in the deformed state, respectively; $x^l = x^l(X^K, t)$ express the motion of the body which carries various material points through various spatial positions; ρ_o is the mass density in the reference state; P^k and F^k are contravariant components in the directions $\vec{g}_k$ of the body force and prescribed surface traction referred to the unit volume and unit area before deformation, respectively; a^k are contravariant components of the acceleration in the directions $\vec{g}_k$; and finally, ν_K are the covariant components of the exterior normal in the directions $\vec{G}^K$, $(K = \mathrm{I}, \mathrm{II}, \mathrm{III})$.

Based on formula $(9c)$, the anholonomic components of $\hat{S}^{Kk}$ relative to the basis $\mathcal{B} = \underline{U}^* \otimes u$, denoted by $\hat{\sigma}^{Kk}$, reads

$$\hat{\sigma}^{Kk} = \left[\hat{S}^{Kk}\right]_{\mathcal{B}} = \frac{\sqrt{g_{kk}}}{\sqrt{G^{KK}}}\, \hat{S}^{Kk} \tag{20a}$$

Substituting expression $(20a)$ into equations $(19a, b)$ and taking the anholonomic components of P^k, F^k, a^k, ν_K as

$$p^k = \left[P^k\right]_u = \sqrt{g_{kk}}\, P^k \quad ,$$

$$f^k = \left[F^k\right]_u = \sqrt{g_{kk}}\, F^k \tag{21b-d}$$

$$\alpha^k = \left[a^k\right]_u = \sqrt{g_{kk}}\, a^k \quad ,$$

$$\eta_K = [\nu_K]_{U^*} = \sqrt{G^{KK}}\, \nu_K \tag{21e-h}$$

one obtains

$$\sqrt{g_{kk}} \left[\frac{\sqrt{G^{KK}}}{\sqrt{g_{kk}}}\, \hat{\sigma}^{Kk}\right]_{:K} + p^k = \rho_o\, \alpha^k \tag{22a}$$

and

$$\nu_K\, \hat{\sigma}^{Kk} = f^k \tag{22b}$$

which are the desired equations. Observe that if $L = K$, then formula (12) (where the symbol (;) was replaced by (:)) reduces to

$$\left[\hat{S}^{Kk}{}_{:K}\right]_u = \sqrt{g_{kk}}\, \hat{S}^{Kk}{}_{:K} \tag{23a}$$

or taking into account expression (20a)

$$\left[\hat{S}^{Kk}{}_{:K}\right]_u = \sqrt{g_{kk}}\left[\frac{\sqrt{G^{KK}}}{\sqrt{g_{kk}}}\,\hat{\sigma}^{Kk}\right]_{:K} \qquad (23b)$$

The latter expression gives the anholonomic components of the covariant derivative of the first Piola-Kirchhoff stress tensor directly in terms of the derivatives of its anholonomic components. The substitution of formulas (23b) and (21) into equations (22), yield

$$\left[\hat{S}^{Kk}{}_{:K}\right]_u + \left[P^k\right]_u = \rho_o\left[a^k\right]_u \qquad (24a)$$

$$[\nu_K]_{U^\bullet}\left[\hat{S}^{Kk}\right]_{\underline{U}^\bullet\otimes u} = \left[F^k\right]_u \qquad (24b)$$

which shows that the anholonomic components in equations (24a,b) are related just in the same way as their tensorial components in equations (19a,b).

Some authors prefer the use of convected coordinates which can be obtained from the foregoing coordinates by equating the numerical value of the coordinate x^k of a given point as to that of X^K. For these coordinates the following relation

$$\hat{S}^{KI} = (\delta^I_R + \mathcal{U}^I_{;R})\,S^{KR} \qquad (25a)$$

holds true, where the notations $\mathcal{U}^I_{;R}$, $\hat{S}^{KI}$, and S^{KR}, for $I, R, K = \mathrm{I}, \mathrm{II}, \mathrm{III}$, denote the displacement gradient tensor components, the first and second Piola-Kirchhoff stress tensors components, respectively. In this case equations (19) reduce to

$$\left[(\delta^I_R + \mathcal{U}^I_{;R})\,S^{KR}\right]_{;K} + P^I = \rho_o\,\ddot{\mathcal{U}}^I \qquad (25b)$$

$$\nu_K\,(\delta^I_R + \mathcal{U}^I_{;R})\,S^{KR} = F^I \qquad (25c)$$

where

$$\hat{S}^{KI}{}_{;K} = \hat{S}^{KI}{}_{,K} + \hat{S}^{KM}\,\Gamma^I_{KM} + \hat{S}^{KI}\,\Gamma^L_{LK} \qquad (25d)$$

In terms of anholonomic components equations (25b,c) can be written in the form

$$\sqrt{G_{II}}\left[\frac{\sqrt{G^{KK}}}{\sqrt{G_{II}}}\,(\sigma^{KI} + \mu^I_R\,\sigma^{KR})\right]_{;K} + p^I = \rho_o\,\ddot{u}^I \qquad (26a)$$

$$\eta_K\,(\sigma^{KI} + \mu^I_R\,\sigma^{KR}) = f^I \qquad (26b)$$

where the formulas

$$\ddot{\mu}^I = \left[\ddot{\mathcal{U}}^I\right]_U = \sqrt{G_{II}}\,\ddot{\mathcal{U}}^I\ ,$$

$$\mu^I_J = [\mathcal{U}^I_{;J}]_{U\otimes\underline{U}} = \frac{\sqrt{G_{II}}}{\sqrt{G_{JJ}}}\,\mathcal{U}^I_{;J}$$

$$\mu_{IJ} = [\mathcal{U}_{I;J}]_{\underline{U}\otimes\underline{U}} = \frac{\mathcal{U}_{I;J}}{\sqrt{G_{II}\,G_{JJ}}}\ ,$$

$$\sigma^{IJ} = [S^{IJ}]_{\underline{U}^\bullet\otimes U} = \frac{\sqrt{G_{JJ}}}{\sqrt{G\cdots}}\,S^{IJ}$$

$$p^I = [P^I]_U = \sqrt{G\cdots}$$

$$f^I = [F^I]_U = \sqrt{G_{II}}\,F^I \qquad (27a-l)$$

relate the vectorial and tensorial components which enter into equations (25b,c) to their anholonomic counterparts. The anholonomic components of $\mathcal{U}^I_{;J}$ and $\mathcal{U}_{I;J}$ can also be expressed as

$$\mu^I_J = \frac{\sqrt{G_{II}}}{\sqrt{G_{JJ}}}\left[\left(\frac{\mu^I}{\sqrt{G_{II}}}\right)_{,J} + \sum_{K=\mathrm{I}}^{\mathrm{III}}\frac{\mu^K}{\sqrt{G_{KK}}}\,\Gamma^I_{JK}\right] \qquad (28a)$$

$$\mu_{IJ} = \frac{1}{\sqrt{G_{II}}\sqrt{G_{JJ}}}\left[\left(\mu_I\sqrt{G_{II}}\right)_{,J} + \sum_{K=\mathrm{I}}^{\mathrm{III}}\sqrt{G_{KK}}\,\mu_K\,\Gamma^K_{IJ}\right] \qquad (28b)$$

by substituting into expressions (27d) and (27f) the following formulas

$$\mathcal{U}^I_{;J} = \left(\frac{\mu^I}{\sqrt{G_{II}}}\right)_{,J} + \sum_{K=\mathrm{I}}^{\mathrm{III}}\frac{\mu^K}{\sqrt{G_{KK}}}\,\Gamma^I_{JK} \qquad (28c)$$

$$\mathcal{U}_{I;J} = \left(\sqrt{G_{II}}\,\mu_I\right)_{,J} + \sum_{K=\mathrm{I}}^{\mathrm{III}}\mu_K\sqrt{G_{KK}}\,\Gamma^K_{IJ} \qquad (28d)$$

Kinematic and linear constitutive equations

The expression of Green strain tensor components

$$E_{IJ} = e_{IJ} + \frac{1}{2}\mathcal{U}_{M;I}\,\mathcal{U}^M_{;J} \qquad (29a)$$

when written in terms of anholonomic components, reads

$$\epsilon_{IJ} = \varepsilon_{IJ} + \frac{1}{2}\bar{\mu}_{MI}\,\mu^M_J \qquad (29b)$$

In these formulas

$$e_{IJ} = \frac{1}{2}(\mathcal{U}_{I;J} + \mathcal{U}_{J;I})$$

$$\epsilon_{IJ} = [E_{IJ}]_{U^\bullet\otimes\underline{U}} = \sqrt{\frac{G^{II}}{G_{JJ}}}\,E_{IJ}$$

$$\varepsilon_{IJ} = [e_{IJ}]_{U^\bullet\otimes\underline{U}} = \sqrt{\frac{G^{II}}{G_{JJ}}}e_{IJ} = \frac{1}{2}\sqrt{\frac{G^{II}}{G_{JJ}}}(\mathcal{U}_{I;J} + \mathcal{U}_{J;I})$$

$$\bar{\mu}_{MI} = [\mathcal{U}_{M;I}]_{\underline{U}\otimes U^\bullet} = \sqrt{\frac{G^{II}}{G_{MM}}}\,\mathcal{U}_{M;I}$$

$$\mu^M_J = [\mathcal{U}^M{}_{;J}]_{U\otimes\underline{U}} = \sqrt{\frac{G_{MM}}{G_{JJ}}}\,\mathcal{U}^M_{;J} \qquad (29c-l)$$

where $\mathcal{U}_{I;J}$ is given by Eq (28d) and

$$\mathcal{U}_{J;I} = \left(\sqrt{G_{JJ}}\,\mu_J\right)_{,I} + \sum_{K=\mathrm{I}}^{\mathrm{III}}\mu_K\sqrt{G_{KK}}\,\Gamma^K_{JI} \qquad (29m)$$

Furthermore, taking into account the last formula (and substituting J by M), the expression (29i) can be written as

$$\bar{\mu}_{MI} = \sqrt{\frac{G^{II}}{G_{MM}}}\left[\left(\sqrt{G_{MM}}\,\mu_M\right)_{,I} + \sum_{K=\mathrm{I}}^{\mathrm{III}} \sqrt{G_{KK}}\,\mu_K\,\Gamma^K_{MI}\right] \tag{30}$$

and the expression for μ^M_J is given by formula (28a) by making $M = I$.

In order to obtain the linear constitutive equations expressed in terms of anholonomic components, consider the following stress-strain relation

$$S^{IJ} = C^{IJKL}\,E_{KL} \tag{31}$$

where C^{IJKL} are the elastic coefficients. They depend on the metric of the undeformed body and on its physical properties. From the symmetries of the second Piola-Kirchhoff stress tensor S^{IJ} and Green's strain tensor E_{IJ}, it follows that $C^{IJKL} = C^{JIKL}$ and $C^{IJKL} = C^{IJLK}$. Furthermore, it should be pointed out that since the elastic potential is invariant under transformation of coordinates, the sets of anholonomic components of S^{IJ} and E_{IJ} are chosen so as to have reciprocal bases, that is, the bases $\underline{U}^* \otimes U$ and $U^* \otimes \underline{U}$, respectively. Thus, the anholonomic components of C^{IJKL} can be obtained from

$$\sum_{I,J,K,L} [C^{IJKL}]_B\,\vec{\underline{U}}_I \otimes \vec{U}_J \otimes \vec{\underline{U}}_K \otimes \vec{U}_L = \sum_{I,J,K,L} C^{IJKL}\,\vec{G}_I \otimes \vec{G}_J \otimes \vec{G}_K \otimes \vec{G}_L \tag{32a}$$

yielding

$$c^{IJKL} = \left[C^{IJKL}\right]_{\underline{U}^*\otimes U \otimes \underline{U}^* \otimes U} = \frac{\sqrt{G_{JJ}}\,\sqrt{G_{LL}}}{\sqrt{G^{II}}\sqrt{G^{KK}}} \tag{32b}$$

The substitution of formulas (27h), (29c), and (32b) into relation (31), leads to

$$\left[S^{IJ}\right]_{\underline{U}^*\otimes U} = \left[C^{IJKL}\right]_{\underline{U}^*\otimes U\otimes \underline{U}^*\otimes U}\,\left[E_{KL}\right]_{U^*\otimes \underline{U}} \tag{33a}$$

or

$$\sigma^{IJ} = c^{IJKL}\,\epsilon_{KL} \tag{33b}$$

As it can be seen from this discussion, the difference between equations (33b) and (31) lies only on their bases of reference.

SHELL EQUATIONS IN TERMS OF ANHOLONOMIC COMPONENTS

As another application, the geometrically nonlinear equations of the first order shear deformation shell theory (Pietraszkiewicz, 1979; Schmidt and Reddy, 1988; Altman and Palmerio, 1991 and 1992) will be expressed in terms of anholonomic components of vectors and tensors. In order to carry out this, the formulas for the anholonomic components of vectors and tensors on a surface will be determined and the derivation of the needed tensorial equations, based on the work of Altman and Palmerio (1991,1992), will be outlined in the next subsections.

Notation and geometry of a surface

Let $\mathcal{V}$ be the volume of the undeformed body bounded by the upper $\mathcal{S}^+$ and lower $\mathcal{S}^-$ surfaces, which are equidistant from the midsurface Ω, and by a lateral surface $\mathcal{A}$. The distance between $\mathcal{S}^+$ and $\mathcal{S}^-$, denoted by h, is the thickness of the shell. Let $\mathcal{A}_s$ and $\mathcal{A}_u$, be the two parts of the lateral boundary surface $\mathcal{A}$, where the stresses and displacements are prescribed, respectively. In addition, let Γ_s and Γ_u be the intersections of $\mathcal{A}_s$ and $\mathcal{A}_u$ with Ω, respectively. To each point of $\mathcal{V}$, it is associated a set of curvilinear coordinates $(\theta^{\mathrm{I}}, \theta^{\mathrm{II}}, \theta^{\mathrm{III}})$ where $(\theta^{\mathrm{I}}, \theta^{\mathrm{II}})$ denotes the curvilinear surface coordinates of a point in Ω and θ^{III} the normal coordinate to Ω. The position vector $\vec{R}$ at a point $(\theta^{\mathrm{I}}, \theta^{\mathrm{II}}, \theta^{\mathrm{III}})$ of $\mathcal{V}$ can be written as

$$\vec{R} = \vec{R}_0\,(\theta^{\mathrm{I}}, \theta^{\mathrm{II}}) + \theta^{\mathrm{III}}\,\vec{N}\,(\theta^{\mathrm{I}}, \theta^{\mathrm{II}}) \tag{34a}$$

where $\vec{R}_0$ is the position vector of a point $(\theta^{\mathrm{I}}, \theta^{\mathrm{II}})$ in Ω and $\vec{N}$ is the unit vector normal to Ω at point $(\theta^{\mathrm{I}}, \theta^{\mathrm{II}})$. In what follows, Greek indices will have range I, II, while Latin indices will have the values I, II, III. At each point in the undeformed shell space the covariant and contravariant base vectors $(\vec{G}_I, \vec{G}^I)$ and the corresponding components of metric tensor (G_{IJ}, G^{IJ}) are given by

$$\vec{G}_\Gamma = \vec{R}_{,\Gamma} = \vec{R}_{0,\Gamma} + \theta^{\mathrm{III}}\,\vec{N}_{,\Gamma} \quad , \quad \vec{G}_{\mathrm{III}} = \vec{N} \quad ,$$

$$G_{\Gamma\Lambda} = \vec{G}_\Gamma \cdot \vec{G}_\Lambda \quad , \quad \vec{G}^I = G^{IJ}\,\vec{G}_J \quad ,$$

$$G_{IK}\,G^{JK} = \delta^J_I \quad , \quad G^{\Gamma\mathrm{III}} = G_{\Gamma\mathrm{III}} = 0 \quad ,$$

$$G^{\mathrm{III}\,\mathrm{III}} = G_{\mathrm{III}\,\mathrm{III}} = 1 \tag{34b-k}$$

Similarly, at each point on the midsurface, the base vectors and their associated metrics read

$$\vec{A}_\Gamma = \vec{R}_{0,\Gamma} \quad , \quad A_{\Gamma\Lambda} = \vec{A}_\Gamma \cdot \vec{A}_\Lambda \quad ,$$

$$\vec{A}^\Gamma = A^{\Gamma\Lambda}\vec{A}_\Lambda \quad , \quad A^{\Gamma\Lambda}A_{\Omega\Lambda} = \delta^\Gamma_\Omega \tag{35a-d}$$

$$A^{\Gamma\mathrm{III}} = A_{\Gamma\mathrm{III}} = 0 \quad , \quad A^{\mathrm{III}\,\mathrm{III}} = A_{\mathrm{III}\,\mathrm{III}} = 1 \tag{35e-h}$$

The base vectors $\left(\vec{G}_I, \vec{G}^I\right)$ and their corresponding metrics (G_{IJ}, G^{IJ}) are related to those of the midsurface as follows:

$$\vec{G}_\Gamma = \lambda^\Lambda_\Gamma \vec{A}_\Lambda \quad , \quad \vec{G}^\Gamma = \left(\lambda^{-1}\right)^\Gamma_\Lambda \vec{A}^\Lambda \tag{36a,b}$$

$$G_{\Gamma\Lambda} = \lambda^\Omega_\Gamma \lambda^\Theta_\Lambda A_{\Omega\Theta} \quad , \tag{36c}$$

$$G^{\Gamma\Lambda} = \left(\lambda^{-1}\right)^\Gamma_\Omega \left(\lambda^{-1}\right)^\Lambda_\Theta A^{\Omega\Theta} \tag{36d}$$

where the components of the shifter tensor and its inverse are given by (Naghdi, 1963)

$$\lambda^\Lambda_\Gamma = \delta^\Lambda_\Gamma - \theta^{\mathrm{III}} B^\Lambda_\Gamma \quad , \quad \lambda^\Lambda_\Gamma \left(\lambda^{-1}\right)^\Omega_\Lambda = \delta^\Omega_\Gamma \tag{36e,f}$$

The components of the curvature tensor are defined by

$$B_{\Gamma\Lambda} = -\vec{A}_\Gamma \cdot \vec{N}_{,\Lambda} = \vec{N} \cdot \vec{A}_{\Gamma,\Lambda} \tag{36g,h}$$

The following definitions and relationships are needed in the sequel:

$$d\mathcal{V} = \mu\,d\theta^{\mathrm{III}}\,d\Omega \quad , \quad d\mathcal{S} = \mu\,d\Omega \quad , \tag{37a,b}$$

$$A = \det(A_{\Gamma\Lambda}) \quad , \quad G = \det(G_{IJ}) \quad , \qquad (37c,d)$$

$$\mu = \sqrt{G/A} \qquad (37e)$$

where dV is the volume element and $d\Omega$ and dS are the area elements of the midsurface and of a surface $\theta^{\mathrm{III}} \neq 0$, respectively.

The relative displacement vector $\vec{u}$ of any point in the shell space, referred to the undeformed configuration of the body, may be represented as

$$\vec{u} = \mathcal{U}^I \vec{G}_I = \mathcal{U}_I \vec{G}^I \qquad (38a,b)$$

or

$$\vec{u} = U^\Gamma \vec{A}_\Gamma + U^{\mathrm{III}} \vec{N} = U_\Gamma \vec{A}^\Gamma + U_{\mathrm{III}} \vec{N} \qquad (38c,d)$$

where $(\mathcal{U}_I, \mathcal{U}^I)$ and (U_Γ, U^Γ) are the covariant and contravariant components of the vector $\vec{u}$ in the shell space and on the midsurface, respectively. The derivative of $\vec{u}$ with respect to θ^J is given by

$$\vec{u}_{,J} = \mathcal{U}_{I;J} \vec{G}^I = \mathcal{U}^I_{;J} \vec{G}_I \qquad (38e,f)$$

where the symbol $(\ )_{;J}$ denotes the covariant derivative with respect to θ^J. The covariant derivative with respect to the surface metric is designated by a stroke, e.g., $(\ )_{|\Lambda}$. It should be noted that $\theta^J = \theta^j$ and $\theta^{\mathrm{III}} = \theta^3$, since the system of coordinates is supposed to be convective.

Anholonomic components of tensors on a surface

The vector $\vec{V}$ given by formulas $(6a,b)$ can also be expressed in terms of the base vectors $\vec{A}_\Gamma$ and $\vec{N}$ in Ω as

$$\vec{V} = V^\Gamma \vec{A}_\Gamma + V^{\mathrm{III}} \vec{N} = V_\Gamma \vec{A}^\Gamma + V_{\mathrm{III}} \vec{N} \qquad (39a,b)$$

with $\Gamma = \mathrm{I}, \mathrm{II}$, where (V^Γ, V_Γ) denote the contravariant and covariant components of $\vec{V}$ in Ω. Similarly, as it was done before, the unit base vectors read

$$\vec{N}_\Gamma = \frac{\vec{A}_\Gamma}{\sqrt{A_{\Gamma\Gamma}}} \quad , \quad \vec{N}^\Gamma = \frac{\vec{A}^\Gamma}{\sqrt{A^{\Gamma\Gamma}}} \quad ,$$

$$\vec{A}_{\mathrm{III}} = \vec{A}^{\mathrm{III}} = \vec{N} \qquad (39c-f)$$

and their reciprocal bases

$$\underline{\vec{N}}^\Gamma = \sqrt{A_{\Gamma\Gamma}} \vec{A}^\Gamma \quad , \quad \underline{\vec{N}}_\Gamma = \sqrt{A^{\Gamma\Gamma}} \vec{A}_\Gamma \quad ,$$

$$\underline{\vec{A}}^{\mathrm{III}} = \underline{\vec{A}}_{\mathrm{III}} = \vec{N} \quad , \quad \Gamma = \mathrm{I}, \mathrm{II} \qquad (39g-j)$$

Expanding the vector $\vec{V}$ with respect to these bases, one obtains

$$\vec{V} = [V^\Gamma]_N \vec{N}_\Gamma + V^{\mathrm{III}} \vec{N} = [V_\Gamma]_{N^*} \vec{N}^\Gamma + V_{\mathrm{III}} \vec{N} \qquad (40a,b)$$

$$= [V_\Gamma]_{\underline{N}} \underline{\vec{N}}^\Gamma + V_{\mathrm{III}} \vec{N} = [V^\Gamma]_{\underline{N}^*} \underline{\vec{N}}_\Gamma + V^{\mathrm{III}} \vec{N} \qquad (40c,d)$$

where

$$[V^\Gamma]_N = \sqrt{A_{\Gamma\Gamma}} V^\Gamma \quad , \quad [V_\Gamma]_{N^*} = \sqrt{A^{\Gamma\Gamma}} V_\Gamma \quad ,$$

$$[V^{\mathrm{III}}]_N = [V_{\mathrm{III}}]_{N^*} = V^{\mathrm{III}} = V_{\mathrm{III}} \qquad (40e-i)$$

$$[V_\Gamma]_{\underline{N}} = \frac{V_\Gamma}{\sqrt{A_{\Gamma\Gamma}}} \quad , \quad [V^\Gamma \quad ,$$

$$[V_{\mathrm{III}}]_{\underline{N}} = [V^{\mathrm{III}}]_{\underline{N}^*} = V_{\mathrm{III}} = V^{\mathrm{III}} \qquad (40j-n)$$

are the physical or anholonomic components of $\vec{V}$ on the surface Ω relative to the bases $N = \{\vec{N}_I\}$, $N^* = \{\vec{N}^I\}$, $\underline{N} = \{\underline{\vec{N}}^I\}$, and $\underline{N}^* = \{\underline{\vec{N}}_I\}$, $I = \Gamma, \mathrm{III}$.

A second order tensor of single field $\mathcal{T}$ on a surface Ω can be defined as linear combinations of tensor products of the type $\underset{\sim}{N}_1 \otimes \underset{\sim}{N}_2$, where $\underset{\sim}{N}_1$ and $\underset{\sim}{N}_2$ are elements that belong to one of the bases of the set $\{N, N^*, \underline{N}, \underline{N}^*\}$. For example, the expressions

$$\mathcal{T} = \sum_{I,J} [T^{IJ}]_{\mathcal{B}} \vec{N}_I \otimes \vec{N}_J = \sum_{I,J} T^{IJ} \vec{A}_I \otimes \vec{A}_J \qquad (41a,b)$$

represent a covariant second order tensor of single field on the surface Ω, where $I, J = \Gamma, \mathrm{III}$, $\mathcal{B} = N \otimes N$ is a basis of the considered tensorial space, and the notation $[T^{IJ}]_{\mathcal{B}}$ denote the anholonomic components of the tensor of single field referred to the basis $\mathcal{B}$. Taking into account the identity $(41a,b)$ and the expressions of $\vec{N}_I$ and $\vec{N}_J$ as functions of $\vec{A}_I$ and $\vec{A}_J$, respectively, one obtains

$$[T^{IJ}]_{N \otimes N} = \sqrt{A_{II}} \sqrt{A_{JJ}}\, T^{IJ} \quad I, J = \Gamma, \mathrm{III} \qquad (41c)$$

where $A_{\mathrm{III}} = A^{\mathrm{III}} = 1$. This formula will be utilized in the sequel to obtain the anholonomic components of the stress tensor and also as a starting point to construct a compatible set of anholonomic components for the shell equations.

Strain-displacement relations

The kinematic equations of a shell are derived here from the Green-Lagrange strain tensor which can be written in terms of the displacement gradient components in the shell space as

$$E_{IJ} = \frac{1}{2} (\mathcal{U}_{I;J} + \mathcal{U}_{J;I} + \mathcal{U}_{M;I}\, \mathcal{U}^M_{;J}) \qquad (42a)$$

This relation, along with

$$\mathcal{U}^{\mathrm{III}}_{;\Gamma} = \mathcal{U}_{\mathrm{III};\Gamma} = \Phi_{\Gamma\mathrm{III}} = U_{\mathrm{III},\Gamma} + B^\Lambda_\Gamma U_\Lambda \quad ,$$

$$\mathcal{U}^\Lambda_{;\Gamma} = G^{\Omega\Lambda}\, \mathcal{U}_{\Omega;\Gamma} \quad , \quad \mathcal{U}_{\Lambda;\Gamma} = \lambda^\Omega_\Lambda\, \Phi_{\Omega\Gamma} \quad ,$$

$$\mathcal{U}_{\Omega;\Gamma}\, \mathcal{U}^\Omega_{;\Lambda} = \Phi_{\Omega\Gamma}\, \Phi^\Omega_{.\Lambda} \quad , \quad \mathcal{U}^\Lambda_{;\mathrm{III}} = (\lambda^{-1})^\Lambda_\Omega\, U^\Omega_{,\mathrm{III}} \quad ,$$

$$\Phi_{\Lambda\Gamma} = U_{\Lambda|\Gamma} - B_{\Lambda\Gamma}\, U_{\mathrm{III}} \quad , \quad \Phi^\Lambda_{.\Gamma} = U^\Lambda_{|\Gamma} - B^\Lambda_{.\Gamma}\, U_{\mathrm{III}} \quad ,$$

$$\mathcal{U}_{\Gamma;\mathrm{III}} = \lambda^\Omega_\Gamma\, U_{\Omega,\mathrm{III}} = U_{\Gamma,\mathrm{III}} - \theta^{\mathrm{III}}\, B^\Omega_\Gamma\, U_{\Omega,\mathrm{III}} \quad ,$$

$$\mathcal{U}_{\mathrm{III};\mathrm{III}}\, \mathcal{U}^{\mathrm{III}}_{;\mathrm{III}} = (U_{\mathrm{III},\mathrm{III}})^2 \quad , \quad \mathcal{U}_{\Gamma;\mathrm{III}}\, \mathcal{U}^\Gamma_{;\mathrm{III}} = U_{\Gamma,\mathrm{III}}\, U^\Gamma_{,\mathrm{III}} \quad ,$$

$$\mathcal{U}_{\mathrm{III};\Gamma}\, \mathcal{U}^{\mathrm{III}}_{;\Lambda} = \Phi_{\Gamma\mathrm{III}}\, \Phi_{\Lambda\mathrm{III}} \quad , \quad \mathcal{U}_{\Lambda;\Gamma}\, \mathcal{U}^\Lambda_{;\mathrm{III}} = \Phi_{\Lambda\Gamma}\, U^\Lambda_{,\mathrm{III}} \quad ,$$

$$\mathcal{U}_{\mathrm{III};\Gamma}\, \mathcal{U}^{\mathrm{III}}_{;\mathrm{III}} = \Phi_{\Gamma\mathrm{III}}\, U_{\mathrm{III},\mathrm{III}} \qquad (42b-q)$$

yield the following expressions for the strain components:

$$E_{\Gamma\Lambda} = e_{\Gamma\Lambda} + \frac{1}{2} (\Phi_{\Gamma\mathrm{III}}\, \Phi_{\Lambda\mathrm{III}} + \Phi_{\Omega\Gamma}\, \Phi^\Omega_{\Lambda}) \quad ,$$

$$E_{\Gamma\mathrm{III}} = e_{\Gamma\mathrm{III}} + \frac{1}{2} U^\Omega_{,\mathrm{III}}\, \Phi_{\Omega\Gamma} + \frac{1}{2} \Phi_{\Gamma\mathrm{III}}\, U^{\mathrm{III}}_{,\mathrm{III}} \quad ,$$

$$E_{\mathrm{III}\mathrm{III}} = e_{\mathrm{III}\mathrm{III}} + \frac{1}{2} U^{\Omega}_{,\mathrm{III}}\, U_{\Omega,\mathrm{III}}$$

where

$$2\,e_{\Gamma\Lambda} = \Phi_{\Gamma\Lambda} + \Phi_{\Lambda\Gamma} - \theta^{\mathrm{III}} \left(B^{\Omega}_{\Gamma}\, \Phi_{\Omega\Lambda} + B^{\Omega}_{\Lambda}\, \Phi_{\Omega\Gamma}\right) \quad ,$$

$$2\,e_{\Gamma\mathrm{III}} = U_{\Gamma,\mathrm{III}} + \Phi_{\Gamma\,\mathrm{III}} - \theta^{\mathrm{III}}\, B^{\Omega}_{\Gamma}\, U_{\Omega,\mathrm{III}} \quad ,$$

$$e_{\mathrm{III}\mathrm{III}} = U_{\mathrm{III},\mathrm{III}} \qquad (43a-f)$$

Introducing the following representation of the displacement components across the shell thickness

$$U_I\left(\theta^{\Gamma},\theta^{\mathrm{III}},t\right) = \overset{(0)}{U}_I\left(\theta^{\Gamma},t\right) + \theta^{\mathrm{III}}\, \overset{(1)}{U}_I\left(\theta^{\Gamma},t\right) \qquad (44)$$

into relations $(43a-f)$, one obtains

$$E_{\Gamma\Lambda} = \overset{(0)}{E}_{\Gamma\Lambda} + \theta^{\mathrm{III}}\, \overset{(1)}{E}_{\Gamma\Lambda} + \left(\theta^{\mathrm{III}}\right)^2 \overset{(2)}{E}_{\Gamma\Lambda} \qquad (45a)$$

$$E_{\Gamma\mathrm{III}} = \overset{(0)}{E}_{\Gamma\mathrm{III}} + \theta^{\mathrm{III}}\, \overset{(1)}{E}_{\Gamma\mathrm{III}} \quad , \quad E_{\mathrm{III}\mathrm{III}} = \overset{(0)}{E}_{\mathrm{III}\mathrm{III}} \qquad (45b,c)$$

where

$$\overset{(0)}{E}_{\Gamma\Lambda} = \overset{(0)}{e}_{\Gamma\Lambda} + \frac{1}{2}\left(\overset{(0)}{\Phi}_{\Gamma\mathrm{III}}\, \overset{(0)}{\Phi}_{\Lambda\mathrm{III}} + \overset{(0)}{\Phi}_{\Omega\Gamma}\, \overset{(0)}{\Phi}{}^{\Omega}_{\Lambda}\right)$$

$$\overset{(1)}{E}_{\Gamma\Lambda} = \overset{(1)}{e}_{\Gamma\Lambda} + \frac{1}{2}\left(\overset{(0)}{\Phi}_{\Gamma\mathrm{III}}\, \overset{(1)}{\Phi}_{\Lambda\mathrm{III}} \right.$$

$$\left. + \overset{(1)}{\Phi}_{\Gamma\mathrm{III}}\, \overset{(0)}{\Phi}_{\Lambda\mathrm{III}} + \overset{(0)}{\Phi}_{\Omega\Gamma}\, \overset{(1)}{\Phi}{}^{\Omega}{}_{\Lambda} + \overset{(1)}{\Phi}_{\Omega\Gamma}\, \overset{(0)}{\Phi}{}^{\Omega}_{\Lambda}\right)$$

$$\overset{(2)}{E}_{\Gamma\Lambda} = \overset{(2)}{e}_{\Gamma\Lambda} + \frac{1}{2}\left(\overset{(1)}{\Phi}_{\Gamma\mathrm{III}}\, \overset{(1)}{\Phi}_{\Lambda\mathrm{III}} + \overset{(1)}{\Phi}_{\Omega\Gamma}\, \overset{(1)}{\Phi}{}^{\Omega}_{\Lambda}\right)$$

$$\overset{(0)}{E}_{\Gamma\mathrm{III}} = \overset{(0)}{e}_{\Gamma\mathrm{III}} + \frac{1}{2}\left(\overset{(1)}{U}{}^{\Omega}\, \overset{(0)}{\Phi}_{\Omega\Gamma} + \overset{(1)}{U}_{\mathrm{III}}\, \overset{(0)}{\Phi}_{\Gamma\mathrm{III}}\right)$$

$$\overset{(1)}{E}_{\Gamma\mathrm{III}} = \overset{(1)}{e}_{\Gamma\mathrm{III}} + \frac{1}{2}\left(\overset{(1)}{U}{}^{\Omega}\, \overset{(1)}{\Phi}_{\Omega\Gamma} + \overset{(1)}{U}_{\mathrm{III}}\, \overset{(1)}{\Phi}_{\Gamma\mathrm{III}}\right)$$

$$\overset{(0)}{E}_{\mathrm{III}\mathrm{III}} = \overset{(0)}{e}_{\mathrm{III}\mathrm{III}} + \frac{1}{2}\left(\overset{(1)}{U}{}^{\Omega}\, \overset{(1)}{U}_{\Omega} + \overset{(1)}{U}_{\mathrm{III}}\, \overset{(1)}{U}{}^{\mathrm{III}}\right) \qquad (46a-f)$$

and

$$\overset{(0)}{e}_{\Gamma\Lambda} = \frac{1}{2}\left(\overset{(0)}{\Phi}_{\Gamma\Lambda} + \overset{(0)}{\Phi}_{\Lambda\Gamma}\right) \quad ,$$

$$\overset{(1)}{e}_{\Gamma\Lambda} = \frac{1}{2}\left(\overset{(1)}{\Phi}_{\Gamma\Lambda} + \overset{(1)}{\Phi}_{\Lambda\Gamma} - B^{\Omega}_{\Gamma}\, \overset{(0)}{\Phi}_{\Omega\Lambda} - B^{\Omega}_{\Lambda}\, \overset{(0)}{\Phi}_{\Omega\Gamma}\right) \quad ,$$

$$\overset{(2)}{e}_{\Gamma\Lambda} = -\frac{1}{2}\left(B^{\Omega}_{\Gamma}\, \overset{(1)}{\Phi}_{\Omega\Lambda} + B^{\Omega}_{\Lambda}\, \overset{(1)}{\Phi}_{\Omega\Gamma}\right) \quad ,$$

$$\overset{(0)}{e}_{\Gamma\mathrm{III}} = \frac{1}{2}\left(\overset{(0)}{\Phi}_{\Gamma\mathrm{III}} + \overset{(1)}{U}_{\Gamma}\right) \quad , \quad \overset{(0)}{e}_{\mathrm{III}\mathrm{III}} = \overset{(0)}{U}_{\mathrm{III}} \quad ,$$

$$\overset{(1)}{e}_{\Gamma\mathrm{III}} = \frac{1}{2}\left(\overset{(1)}{\Phi}_{\Gamma\mathrm{III}} - B^{\Omega}_{\Gamma}\, \overset{(1)}{U}_{\Omega}\right) \quad ,$$

$$\overset{(0)}{\Phi}_{\Gamma\mathrm{III}} = \overset{(0)}{U}_{\mathrm{III},\Gamma} + B^{\Omega}_{\Gamma}\, \overset{(0)}{U}_{\Omega} \quad , \quad \overset{(1)}{\Phi}_{\Gamma\mathrm{III}} = \overset{(1)}{U}_{\mathrm{III},\Gamma} + B^{\Omega}_{\Gamma}\, \overset{(1)}{U}_{\Omega}$$

$$\overset{(0)}{\Phi}_{\Gamma\Lambda} = \overset{(0)}{U}_{\Gamma|\Lambda} - B_{\Gamma\Lambda}\, \overset{(0)}{U}_{\mathrm{III}} \quad , \quad \overset{(1)}{\Phi}_{\Gamma\Lambda} = \overset{(1)}{U}_{\Gamma|\Lambda} - B_{\Gamma\Lambda}\, \overset{(1)}{U}_{\mathrm{III}}$$

$$\overset{(0)}{\Phi}{}^{\Gamma}_{.\Lambda} = \overset{(0)}{U}{}^{\Gamma}_{|\Lambda} - B^{\Gamma}_{.\Lambda}\, \overset{(0)}{U}_{\mathrm{III}} \quad ,$$

$$\overset{(1)}{\Phi}{}^{\Gamma}_{.\Lambda} = \overset{(1)}{U}{}^{\Gamma}_{|\Lambda} - B^{\Gamma}_{.\Lambda}\, \overset{(1)}{U}_{\mathrm{III}} \qquad (47a-l)$$

Since the elastic potential is invariant under transformation of coordinates, the anholonomic components of the stresses and strains will be chosen so as to have the following reciprocal bases $N \otimes N$ and $\underline{N} \otimes \underline{N}$, respectively. Taking into account formulas (40), and the expressions which define the anholonomic components of second order tensors relative to the bases $\underline{N} \otimes \underline{N}$ and $N \otimes \underline{N}$, it can be written

$$\overset{(n)}{u}{}^{\Gamma} = \left[\overset{(n)}{U}{}^{\Gamma}\right]_{N} = \sqrt{A_{\Gamma\Gamma}}\, \overset{(n)}{U}{}^{\Gamma} \quad ,$$

$$\overset{(n)}{u}_{\Gamma} = \left[\overset{(n)}{U}_{\Gamma}\right]_{\underline{N}} = \frac{1}{\sqrt{A_{\Gamma\Gamma}}}\, \overset{(n)}{U}_{\Gamma} \quad ,$$

$$\overset{(n)}{u}{}^{\mathrm{III}} = \left[\overset{(n)}{U}{}^{\mathrm{III}}\right] = \overset{(n)}{U}{}^{\mathrm{III}} \quad , \quad \overset{(n)}{u}{}^{\mathrm{III}} = \overset{(n)}{u}_{\mathrm{III}} = \overset{(n)}{U}_{\mathrm{III}} \quad ,$$

$$b^{\Gamma}_{.\Lambda} = \left[B^{\Gamma}_{.\Lambda}\right]_{N\otimes\underline{N}} = \frac{\sqrt{A_{\Gamma\Gamma}}}{\sqrt{A_{\Lambda\Lambda}}}\, B^{\Gamma}_{.\Lambda} \quad ,$$

$$b_{\Gamma\Lambda} = \left[B_{\Gamma\Lambda}\right]_{\underline{N}\otimes\underline{N}} = \frac{B_{\Gamma\Lambda}}{\sqrt{A_{\Gamma\Gamma}}\sqrt{A_{\Lambda\Lambda}}} \quad ,$$

$$\overset{(n)}{u}_{\Gamma\Lambda} = \left[\overset{(n)}{U}_{\Gamma|\Lambda}\right]_{\underline{N}\otimes\underline{N}} = \frac{1}{\sqrt{A_{\Gamma\Gamma}}\sqrt{A_{\Lambda\Lambda}}}\, \overset{(n)}{U}_{\Gamma|\Lambda} \quad ,$$

$$\overset{(n)}{u}{}^{\Gamma}{}_{\Lambda} = \left[\overset{(n)}{U}{}^{\Gamma}{}_{|\Lambda}\right]_{N\otimes\underline{N}} = \frac{\sqrt{A_{\Gamma\Gamma}}}{\sqrt{A_{\Lambda\Lambda}}}\, \overset{(n)}{U}{}^{\Gamma}{}_{|\Lambda} \quad ,$$

$$\overset{(n)}{\varphi}_{\Gamma\Lambda} = \left[\overset{(n)}{\Phi}_{\Gamma\Lambda}\right]_{\underline{N}\otimes\underline{N}} = \frac{1}{\sqrt{A_{\Gamma\Gamma}}\sqrt{A_{\Lambda\Lambda}}}\, \overset{(n)}{\Phi}_{\Gamma\Lambda} \quad ,$$

$$\overset{(n)}{\varphi}{}^{\Gamma}{}_{.\Lambda} = \left[\overset{(n)}{\Phi}{}^{\Gamma}{}_{.\Lambda}\right]_{N\otimes\underline{N}} = \frac{\sqrt{A_{\Gamma\Gamma}}}{\sqrt{A_{\Lambda\Lambda}}}\, \overset{(n)}{\Phi}{}^{\Gamma}{}_{.\Lambda} \quad ,$$

$$\overset{(n)}{\varphi}_{\Gamma\mathrm{III}} = \overset{(n)}{\varphi}_{\mathrm{III}\Gamma} = \overset{(n)}{\varphi}{}^{\mathrm{III}}{}_{.\Gamma} = \left[\overset{(n)}{\Phi}_{\Gamma\mathrm{III}}\right]_{\underline{N}} = \frac{1}{\sqrt{A_{\Gamma\Gamma}}}\, \overset{(n)}{\Phi}_{\Gamma\mathrm{III}} \qquad (48a-z)$$

where $n = 0, 1$. After substituting in these formulas

$$\overset{(n)}{U}_{\Gamma|\Lambda} = \overset{(n)}{U}_{\Gamma,\Lambda} - \overset{(n)}{U}_{\Omega}\, \Gamma^{\Omega}_{\Gamma\Lambda} = \left(\sqrt{A_{\Gamma\Gamma}}\, \overset{(n)}{u}_{\Gamma}\right)_{,\Lambda}$$

$$- \sum_{\Omega=\mathrm{I}}^{\mathrm{II}} \left(\sqrt{A_{\Omega\Omega}}\, \overset{(n)}{u}_{\Omega}\right) \Gamma^{\Omega}_{\Gamma\Lambda} \qquad (49a,b)$$

$$\overset{(n)}{U}{}^{\Gamma}{}_{|\Lambda} = \overset{(n)}{U}{}^{\Gamma}{}_{,\Lambda} - \overset{(n)}{U}{}^{\Omega}\,\Gamma^{\Gamma}_{\Omega\Lambda} = \left(\frac{\overset{(n)}{u}{}^{\Gamma}}{\sqrt{A_{\Gamma\Gamma}}}\right)_{,\Lambda} - \sum_{\Omega=\mathrm{I}}^{\mathrm{II}} \frac{\overset{(n)}{u}{}^{\Omega}}{\sqrt{A_{\Omega\Omega}}}\Gamma^{\Gamma}_{\Omega\Lambda} \qquad (49c,d)$$

$$\overset{(n)}{\Phi}{}_{\Gamma\Lambda} = \overset{(n)}{U}{}_{\Gamma|\Lambda} - B_{\Gamma\Lambda}\,\overset{(n)}{U}{}_{\mathrm{III}} = \left(\sqrt{A_{\Gamma\Gamma}}\,\overset{(n)}{u}{}_{\Gamma}\right)_{|\Lambda} - \sqrt{A_{\Gamma\Gamma}}\sqrt{A_{\Lambda\Lambda}}\,b_{\Gamma\Lambda}\,\overset{(n)}{u}{}_{\mathrm{III}} \qquad (49e,f)$$

$$\overset{(n)}{\Phi}{}^{\Gamma}{}_{\Lambda} = \overset{(n)}{U}{}^{\Gamma}{}_{|\Lambda} - B^{\Gamma}_{\Lambda}\,\overset{(n)}{U}{}_{\mathrm{III}} = \left(\frac{\overset{(n)}{u}{}^{\Gamma}}{\sqrt{A_{\Gamma\Gamma}}}\right)_{|\Lambda} - \frac{\sqrt{A_{\Lambda\Lambda}}}{\sqrt{A_{\Gamma\Gamma}}}\,b^{\Gamma}_{\Lambda}\,\overset{(n)}{u}{}_{\mathrm{III}} \qquad (49g,h)$$

$$\overset{(n)}{\Phi}{}_{\Gamma\mathrm{III}} = \overset{(n)}{U}{}_{\mathrm{III},\Gamma} + B^{\Omega}_{.\Gamma}\,\overset{(n)}{U}{}_{\Omega} = \left(\overset{(n)}{u}{}_{\mathrm{III}}\right)_{,\Gamma} + \sqrt{A_{\Gamma\Gamma}}\,b^{\Omega}_{.\Gamma}\,\overset{(n)}{u}{}_{\Omega} \qquad (49i,j)$$

where

$$\Gamma^{\Omega}_{\Gamma\Lambda} = g^{\Omega\Theta}\,\Gamma_{\Gamma\Lambda\Theta} = \frac{1}{2}g^{\Omega\Theta}\left(A_{\Gamma\Theta,\Lambda} + A_{\Lambda\Theta,\Gamma} - A_{\Gamma\Lambda,\Theta}\right) \qquad (49k,l)$$

it is obtained

$$\overset{(n)}{u}{}_{\Gamma\Lambda} = \frac{1}{\sqrt{A_{\Gamma\Gamma}}\sqrt{A_{\Lambda\Lambda}}}\left[\left(\sqrt{A_{\Gamma\Gamma}}\,\overset{(n)}{u}{}_{\Gamma}\right)_{,\Lambda} - \sum_{\Omega=\mathrm{I}}^{\mathrm{II}}\sqrt{A_{\Omega\Omega}}\,\overset{(n)}{u}{}_{\Omega}\,\Gamma^{\Omega}_{\Gamma\Lambda}\right] \qquad (50a)$$

$$\overset{(n)}{u}{}^{\Gamma}_{\Lambda} = \frac{\sqrt{A_{\Gamma\Gamma}}}{\sqrt{A_{\Lambda\Lambda}}}\left[\left(\frac{\overset{(n)}{u}{}^{\Gamma}}{\sqrt{A_{\Gamma\Gamma}}}\right)_{,\Lambda} - \sum_{\Omega=\mathrm{I}}^{\mathrm{II}}\frac{\overset{(n)}{u}{}^{\Omega}}{\sqrt{A_{\Omega\Omega}}}\,\Gamma^{\Gamma}_{\Omega\Lambda}\right] \qquad (50b)$$

$$\overset{(n)}{\varphi}{}_{\Gamma\Lambda} = \frac{1}{\sqrt{A_{\Gamma\Gamma}}\sqrt{A_{\Lambda\Lambda}}}\left[\left(\sqrt{A_{\Gamma\Gamma}}\,\overset{(n)}{u}{}_{\Gamma}\right)_{|\Lambda} - \sqrt{A_{\Gamma\Gamma}}\,\sqrt{A_{\Lambda\Lambda}}\,b_{\Gamma\Lambda}\,\overset{(n)}{u}{}_{\mathrm{III}}\right] \qquad (50c)$$

$$\overset{(n)}{\varphi}{}^{\Gamma}_{\Lambda} = \frac{\sqrt{A_{\Gamma\Gamma}}}{\sqrt{A_{\Lambda\Lambda}}}\left[\left(\frac{\overset{(n)}{u}{}^{\Gamma}}{\sqrt{A_{\Gamma\Gamma}}}\right)_{|\Lambda} - \frac{\sqrt{A_{\Lambda\Lambda}}}{\sqrt{A_{\Gamma\Gamma}}}\,b^{\Gamma}_{\Lambda}\,\overset{(n)}{u}{}_{\mathrm{III}}\right] \qquad (50d)$$

$$\overset{(n)}{\varphi}{}_{\Gamma\mathrm{III}} = \frac{1}{\sqrt{A_{\Gamma\Gamma}}}\left[\left(\overset{(n)}{u}{}_{\mathrm{III}}\right) \qquad \overset{(n)}{u}{}_{\Omega}\right] \qquad (50e)$$

Furthermore, taking into account that the anholonomic components of $\overset{(m)}{E}{}_{\Gamma\Lambda}$, $\overset{(m)}{e}{}_{\Gamma\Lambda}$, $\overset{(n)}{E}{}_{\Gamma\mathrm{III}}$, $\overset{(n)}{e}{}_{\Gamma\mathrm{III}}$, $\overset{(o)}{E}{}_{\mathrm{III}\mathrm{III}}$, $\overset{(o)}{e}{}_{\mathrm{III}\mathrm{III}}$, for $m = 0, 1, 2$ and $n = 0, 1$, are given by

$$\overset{(m)}{\epsilon}{}_{\Gamma\Lambda} = \left[\overset{(m)}{E}{}_{\Gamma\Lambda}\right]_{\underline{N}\otimes\underline{N}} = \frac{1}{\sqrt{A_{\Gamma\Gamma}}\sqrt{A_{\Lambda\Lambda}}}\overset{(m)}{E}{}_{\Gamma\Lambda} \quad ,$$

$$\overset{(m)}{\varepsilon}{}_{\Gamma\Lambda} = \left[\overset{(m)}{e}{}_{\Gamma\Lambda}\right]_{\underline{N}\otimes\underline{N}} = \frac{1}{\sqrt{A_{\Gamma\Gamma}}\sqrt{A_{\Lambda\Lambda}}}\overset{(m)}{e}{}_{\Gamma\Lambda} \quad ,$$

$$\overset{(n)}{\epsilon}{}_{\Gamma\mathrm{III}} = \left[\overset{(n)}{E}{}_{\Gamma\mathrm{III}}\right]_{\underline{N}} = \frac{1}{\sqrt{A_{\Gamma\Gamma}}}\overset{(n)}{E}{}_{\Gamma\mathrm{III}} \quad ,$$

$$\overset{(n)}{\varepsilon}{}_{\Gamma\mathrm{III}} = \left[\overset{(n)}{e}{}_{\Gamma\mathrm{III}}\right]_{\underline{N}} = \frac{1}{\sqrt{A_{\Gamma\Gamma}}}\overset{(n)}{e}{}_{\Gamma\mathrm{III}} \quad ,$$

$$\overset{(0)}{\epsilon}{}_{\mathrm{III}\mathrm{III}} = \left[E_{\mathrm{III}\mathrm{III}}\right] = E_{\mathrm{III}\mathrm{III}} \quad ,$$

$$\overset{(0)}{\varepsilon}{}_{\mathrm{III}\mathrm{III}} = \left[\overset{(0)}{e}{}_{\mathrm{III}\mathrm{III}}\right] = \overset{(0)}{e}{}_{\mathrm{III}\mathrm{III}} \qquad (51a-l)$$

the substitution of the vector and tensor components of expressions (46) and (47) in terms of their anholonomic counterparts given by formulas (48) and (51), leads to

$$\overset{(0)}{\epsilon}{}_{\Gamma\Lambda} = \overset{(0)}{\varepsilon}{}_{\Gamma\Lambda} + \frac{1}{2}\left(\overset{(0)}{\varphi}{}_{\Gamma\mathrm{III}}\,\overset{(0)}{\varphi}{}_{\Lambda\mathrm{III}} + \overset{(0)}{\varphi}{}_{\Omega\Gamma}\,\overset{(0)}{\varphi}{}^{\Omega}_{.\Lambda}\right)$$

$$\overset{(1)}{\epsilon}{}_{\Gamma\Lambda} = \overset{(1)}{\varepsilon}{}_{\Gamma\Lambda} + \frac{1}{2}\left(\overset{(0)}{\varphi}{}_{\Gamma\mathrm{III}}\,\overset{(1)}{\varphi}{}_{\Lambda\mathrm{III}} + \overset{(1)}{\varphi}{}_{\Gamma\mathrm{III}}\,\overset{(0)}{\varphi}{}_{\Lambda\mathrm{III}} + \overset{(0)}{\varphi}{}_{\Omega\Gamma}\,\overset{(1)}{\varphi}{}^{\Omega}_{\Lambda} + \overset{(1)}{\varphi}{}_{\Omega\Gamma}\,\overset{(0)}{\varphi}{}^{\Omega}_{\Lambda}\right)$$

$$\overset{(2)}{\epsilon}{}_{\Gamma\Lambda} = \overset{(2)}{\varepsilon}{}_{\Gamma\Lambda} + \frac{1}{2}\left(\overset{(1)}{\varphi}{}_{\Gamma\mathrm{III}}\,\overset{(1)}{\varphi}{}_{\Lambda\mathrm{III}} + \overset{(1)}{\varphi}{}_{\Omega\Gamma}\,\overset{(1)}{\varphi}{}^{\Omega}_{.\Lambda}\right)$$

$$\overset{(0)}{\epsilon}{}_{\Gamma\mathrm{III}} = \overset{(0)}{\varepsilon}{}_{\Gamma\mathrm{III}} + \frac{1}{2}\left(\overset{(1)}{u}{}^{\Omega}\,\overset{(0)}{\varphi}{}_{\Omega\Gamma} + \overset{(1)}{u}{}_{\mathrm{III}}\,\overset{(0)}{\varphi}{}_{\Gamma\mathrm{III}}\right)$$

$$\overset{(1)}{\epsilon}{}_{\Gamma\mathrm{III}} = \overset{(1)}{\varepsilon}{}_{\Gamma\mathrm{III}} + \frac{1}{2}\left(\overset{(1)}{u}{}^{\Omega}\,\overset{(1)}{\varphi}{}_{\Omega\Gamma} + \overset{(1)}{u}{}_{\mathrm{III}}\,\overset{(1)}{\varphi}{}_{\Gamma\mathrm{III}}\right)$$

$$\overset{(0)}{\epsilon}{}_{\mathrm{III}\mathrm{III}} = \overset{(0)}{\varepsilon}{}_{\mathrm{III}\mathrm{III}} + \frac{1}{2}\left(\overset{(1)}{u}{}^{\Omega}\,\overset{(1)}{u}{}_{\Omega} + \overset{(1)}{u}{}_{\mathrm{III}}\,\overset{(1)}{u}{}^{\mathrm{III}}\right) \qquad (52a-f)$$

and

$$\overset{(0)}{\varepsilon}{}_{\Gamma\Lambda} = \frac{1}{2}\left(\overset{(0)}{\varphi}{}_{\Gamma\Lambda} + \overset{(0)}{\varphi}{}_{\Lambda\Gamma}\right) \quad ,$$

$$\overset{(1)}{\varepsilon}{}_{\Gamma\Lambda} = \frac{1}{2}\left(\overset{(1)}{\varphi}{}_{\Gamma\Lambda} + \overset{(1)}{\varphi}{}_{\Lambda\Gamma} - b^{\Omega}_{\Gamma}\,\overset{(0)}{\varphi}{}_{\Omega\Lambda} - b^{\Omega}_{\Lambda}\,\overset{(0)}{\varphi}{}_{\Omega\Gamma}\right)$$

$$\overset{(2)}{\varepsilon}{}_{\Gamma\Lambda} = -\frac{1}{2}\left(b^{\Omega}_{\Gamma}\,\overset{(1)}{\varphi}{}_{\Omega\Lambda} + b^{\Omega}_{\Lambda}\,\overset{(1)}{\varphi}{}_{\Omega\Gamma}\right) \quad ,$$

$$\overset{(0)}{\varepsilon}{}_{\Gamma\mathrm{III}} = \frac{1}{2}\left(\overset{(0)}{\varphi}{}_{\Gamma\mathrm{III}} + \overset{(1)}{u}{}_{\Gamma}\right) \quad , \quad \overset{(0)}{\varepsilon}{}_{\mathrm{III}\mathrm{III}} = \overset{(1)}{u}{}_{\mathrm{III}}$$

$$\overset{(1)}{\varepsilon}_{\Gamma\blacksquare} = \frac{1}{2}\left(\overset{(1)}{\varphi}_{\Gamma\blacksquare} - b_{\Gamma}^{\Omega}\,\overset{(1)}{u}_{\Omega}\right) \qquad (53a-f)$$

where $\overset{(n)}{\varphi}_{\Gamma\Lambda}$, $\overset{(n)}{\varphi}{}^{\Gamma}{}_{\Lambda}$, and $\overset{(n)}{\varphi}_{\Gamma\blacksquare}$ are defined by formulas $(50c-e)$, respectively.

Equations of motion and boundary conditions

The equations of motion and the boundary conditions will be obtained by a variational approach. Consider the dynamic version of the principle of virtual displacements written in the form

$$0 = \int_0^T \left(-\int_{\mathcal{V}} \rho\, \dot{U}^I\, \delta\dot{U}_I\, d\mathcal{V} + \int_{\mathcal{V}} \mathcal{S}^{IJ} \delta E_{IJ}\, d\mathcal{V}\right.$$
$$\left. - \int_{\mathcal{V}} f^I\, \delta U_i\, d\mathcal{V} - \int_{\mathcal{A}_\circ} \hat{S}^I\, \delta U_I\, d\mathcal{A} - \int_{\mathcal{S}} P^I\, \delta U_I\, d\mathcal{S}\right) dt \qquad (54)$$

where ρ is the mass density, $\dot{U}_I$ is the time derivative of the displacement components U_I, $\mathcal{S}^{IJ}$ are the components of the second Piola-Kirshhoff stress tensor, f^I are the body forces per unit volume of the undeformed body, $\hat{S}^I$ and P^I are the components of the specified stress vectors, for the undeformed body: $\hat{S}^I$ act on the lateral surface and P^I on the upper and lower surfaces, $\mathcal{S}^+$ and $\mathcal{S}^-$. In order to derive the equations of motion it will be made use of the linear displacement representation (44) and of the following definitions:

$$R_{(n)}^{IJ} = \int_{-h/2}^{h/2} \mu\, \mathcal{S}^{IJ}\, (\theta^{\blacksquare})^n\, d\theta^{\blacksquare} \quad ,$$

$$I_i = \int_{-h/2}^{h/2} \mu\, \rho\, (\theta^{\blacksquare})^{i-1}\, d\theta^{\blacksquare} \quad ,$$

$$\overset{(n)}{F}{}^{\Gamma} = \int_{-h/2}^{h/2} \mu\, f^{\Gamma}\, (\theta^{\blacksquare})^n\, d\theta^{\blacksquare} \quad ,$$

$$\overset{(n)}{F}{}^{\blacksquare} = \int_{-h/2}^{h/2} \mu\, f^{\blacksquare}\, (\theta^{\blacksquare})^n\, d\theta^{\blacksquare} \quad ,$$

$$\overset{(n)}{P}{}^{I} = \left[(\theta^{\blacksquare})^n\, \mu\, P^I\right]_{-h/2}^{h/2}$$

$$\int_{\mathcal{A}_\circ} \hat{S}^I\, \delta U_I\, d\mathcal{A} = \sum_{n=0}^{N} \int_{\Gamma_\circ} \left[\hat{S}_{(n)}^{\Gamma}\, \delta\overset{(n)}{U}_{\Gamma} + \hat{S}_{(n)}^{\blacksquare}\, \delta\overset{(n)}{U}_{\blacksquare}\right] d\Gamma$$

$$\hat{S}_{(n)}^{\Gamma} = \int_{-h/2}^{h/2} \mu\, \mu_{\Omega}^{\Gamma}\, \hat{\mathcal{S}}^{\Lambda\Omega}\, \nu_{\Lambda}\, (\theta^{\blacksquare})^n\, d\theta^{\blacksquare} \quad ,$$

$$\hat{S}_{(n)}^{\blacksquare} = \int_{-h/2}^{h/2} \mu\, \hat{\mathcal{S}}^{\Lambda\blacksquare}\, \nu_{\Lambda}\, (\theta^{\blacksquare})^n\, d\theta^{\blacksquare} \qquad (55a-h)$$

where $n = 0, 1$ and $\hat{\mathcal{S}}^{\Gamma I}$ are the first Piola-Kirchhoff stress tensor components which have been defined by formula $(25a)$. Thus, expression (54) takes the form

$$0 = \int_0^T \int_{\Omega} \left[\left(I_1\, \overset{(0)}{\ddot{U}}{}^I + I_2\, \overset{(1)}{\ddot{U}}{}^I\right) \delta\overset{(0)}{U}_I\right.$$
$$+ \left(I_2\, \overset{(0)}{\ddot{U}}{}^I + I_3\, \overset{(1)}{\ddot{U}}{}^I\right) \delta\overset{(1)}{U}_I$$
$$+ \left(B_{\Lambda}^{\Gamma}\, \overset{(0)}{T}{}^{\blacksquare\Lambda}\right) \delta\overset{(0)}{U}_{\Gamma} + \left(B_{\Lambda}^{\Gamma}\, \overset{(1)}{T}{}^{\blacksquare\Lambda} + \overset{(0)}{Q}{}^{\Gamma\blacksquare}\right) \delta\overset{(1)}{U}_{\Gamma}$$
$$- B_{\Gamma\Lambda}\, \overset{(0)}{T}{}^{\Gamma\Lambda}\, \delta\overset{(0)}{U}_{\blacksquare} + \left(-B_{\Gamma\Lambda}\, \overset{(1)}{T}{}^{\Gamma\Lambda} + \overset{(0)}{Q}{}^{\blacksquare\blacksquare}\right) \delta\overset{(1)}{U}_{\blacksquare}$$
$$+ \overset{(0)}{T}{}^{\Gamma\Lambda}\, \delta\overset{(0)}{U}_{\Gamma|\Lambda} + \overset{(1)}{T}{}^{\Gamma\Lambda}\, \delta\overset{(1)}{U}_{\Gamma|\Lambda}$$
$$+ \overset{(0)}{T}{}^{\blacksquare\Lambda}\, \delta\overset{(0)}{U}_{\blacksquare,\Lambda} + \overset{(1)}{T}{}^{\blacksquare\Lambda}\, \delta\overset{(1)}{U}_{\blacksquare,\Lambda}$$
$$\left. - \overset{(0)}{F}{}^{I}\, \delta\overset{(0)}{U}_I - \overset{(1)}{F}{}^{I}\, \delta\overset{(1)}{U}_I\right] d\Omega\, dt$$
$$- \int_0^T \int_{\Gamma_\circ} \left[\hat{S}_{(0)}^{I}\, \delta\overset{(0)}{U}_I + \hat{S}_{(1)}^{I}\, \delta\overset{(1)}{U}_I\right] d\Gamma\, dt$$
$$- \int_0^T \int_{\Omega} \left[\overset{(0)}{P}{}^{I}\, \delta\overset{(0)}{U}_I + \overset{(1)}{P}{}^{I}\, \delta\overset{(1)}{U}_I\right] d\Omega\, dt \qquad (56)$$

where

$$\overset{(0)}{T}{}^{\Gamma\Lambda} = \overset{(0)}{L}{}_{\Omega}^{\Gamma}\, R_{(0)}^{\Omega\Lambda} + \overset{(1)}{\Phi}{}^{\Gamma}_{.\Omega}\, R_{(1)}^{\Omega\Lambda} - B^{\Gamma}_{.\Omega}\, R_{(1)}^{\Omega\Lambda} + \overset{(1)}{U}{}^{\Gamma}\, R_{(0)}^{\blacksquare\Lambda}$$

$$\overset{(1)}{T}{}^{\Gamma\Lambda} = \overset{(0)}{L}{}_{\Omega}^{\Gamma}\, R_{(1)}^{\Omega\Lambda} + \overset{(1)}{\Phi}{}^{\Gamma}_{.\Omega}\, R_{(2)}^{\Omega\Lambda} - B^{\Gamma}_{.\Omega}\, R_{(2)}^{\Omega\Lambda} + \overset{(1)}{U}{}^{\Gamma}\, R_{(1)}^{\blacksquare\Lambda}$$

$$\overset{(0)}{T}{}^{\blacksquare\Lambda} = \overset{(0)}{\Phi}{}_{\Omega}^{\blacksquare}\, R_{(0)}^{\Omega\Lambda} + \overset{(1)}{\Phi}{}^{\blacksquare}_{.\Omega}\, R_{(1)}^{\Omega\Lambda} + \left(1 + \overset{(1)}{U}{}^{\blacksquare}\right) R_{(0)}^{\blacksquare\Lambda}$$

$$\overset{(1)}{T}{}^{\blacksquare\Lambda} = \overset{(0)}{\Phi}{}_{\Omega}^{\blacksquare}\, R_{(1)}^{\Omega\Lambda} + \overset{(1)}{\Phi}{}^{\blacksquare}_{.\Omega}\, R_{(2)}^{\Omega\Lambda} + \left(1 + \overset{(1)}{U}{}^{\blacksquare}\right) R_{(1)}^{\blacksquare\Lambda}$$

$$\overset{(0)}{Q}{}^{\Gamma\blacksquare} = \overset{(0)}{L}{}_{\Omega}^{\Gamma}\, R_{(0)}^{\Omega\blacksquare} + \overset{(1)}{\Phi}{}^{\Gamma}_{.\Omega}\, R_{(1)}^{\Omega\blacksquare} - B^{\Gamma}_{.\Omega}\, R_{(1)}^{\Omega\blacksquare} + \overset{(1)}{U}{}^{\Gamma}\, R_{(0)}^{\blacksquare\blacksquare}$$

$$\overset{(0)}{Q}{}^{\blacksquare\blacksquare} = \overset{(0)}{\Phi}{}_{\Omega}^{\blacksquare}\, R_{(0)}^{\Omega\blacksquare} + \overset{(1)}{\Phi}{}^{\blacksquare}_{.\Omega}\, R_{(1)}^{\Omega\blacksquare} + \left(1 + \overset{(1)}{U}{}^{\blacksquare}\right) R_{(0)}^{\blacksquare\blacksquare}$$

$$\overset{(0)}{L}{}^{\Gamma}{}_{.\Omega} = \delta_{\Omega}^{\Gamma} + \overset{(0)}{\Phi}{}^{\Gamma}{}_{.\Omega} \quad ,$$

$$\overset{(n)}{\phi}_{\Gamma\blacksquare} = \overset{(n)}{\phi}_{\blacksquare\Gamma} = \overset{(n)}{\phi}{}^{\blacksquare}{}_{.\Gamma} \quad , \quad n = 0, 1 \qquad (57a-i)$$

Finally, performing the classical operations, the equations of motion are obtained as follows:

$$\overset{(0)}{T}{}^{\Gamma\Lambda}{}_{|\Lambda} - B_{\Lambda}^{\Gamma}\, \overset{(0)}{T}{}^{\blacksquare\Lambda} = I_1\, \overset{(0)}{\ddot{U}}{}^{\Gamma} + I_2\, \overset{(1)}{\ddot{U}}{}^{\Gamma} - \overset{(0)}{F}{}^{\Gamma} - \overset{(0)}{P}{}^{\Gamma}$$

$$\overset{(0)}{T}{}^{\blacksquare\Lambda}{}_{|\Lambda} + B_{\Gamma\Lambda}\, \overset{(0)}{T}{}^{\Gamma\Lambda} = I_1\, \overset{(0)}{\ddot{U}}{}^{\blacksquare} + I_2\, \overset{(1)}{\ddot{U}}{}^{\blacksquare} - \overset{(0)}{F}{}^{\blacksquare} - \overset{(0)}{P}{}^{\blacksquare}$$

$$\overset{(1)}{T}{}^{\Gamma\Lambda}{}_{|\Lambda} - B_{\Lambda}^{\Gamma}\, \overset{(1)}{T}{}^{\blacksquare\Lambda} - \overset{(0)}{Q}{}^{\Gamma\blacksquare} = I_2\, \overset{(0)}{\ddot{U}}{}^{\Gamma} + I_3\, \overset{(1)}{\ddot{U}}{}^{\Gamma} - \overset{(1)}{F}{}^{\Gamma} - \overset{(1)}{P}{}^{\Gamma}$$

$$\overset{(1)}{T}{}^{\blacksquare\Lambda}{}_{|\Lambda} + B_{\Gamma\Lambda}\overset{(1)}{T}{}^{\Gamma\Lambda} - \overset{(0)}{Q}{}^{\blacksquare\blacksquare} = I_2\,\overset{(0)}{\ddot{U}}{}^{\blacksquare}$$

$$+ I_3\,\overset{(1)}{\ddot{U}}{}^{\blacksquare} - \overset{(1)}{F}{}^{\blacksquare} - \overset{(1)}{P}{}^{\blacksquare} \qquad (58a-d)$$

and the natural and essential boundary conditions as

$$\overset{(0)}{T}{}^{\Gamma\Lambda}\,\nu_\Lambda - B^{\Gamma}_{(0)} = 0 \quad , \quad \overset{(0)}{T}{}^{\blacksquare\Lambda}\,\nu_\Lambda - B^{\blacksquare}_{(0)} = 0$$

$$\overset{(1)}{T}{}^{\Gamma\Lambda}\,\nu_\Lambda - B^{\Gamma}_{(1)} = 0 \quad , \quad \overset{(1)}{T}{}^{\blacksquare\Lambda}\,\nu_\Lambda - B^{\blacksquare}_{(1)} = 0 \quad (59a-d)$$

and

$$\overset{(0)}{U}_I = \overset{(0)}{\bar{U}}_I \quad , \quad \overset{(1)}{U}_I = \overset{(1)}{\bar{U}}_I \qquad (59e,f)$$

respectively, where $\overset{(n)}{\bar{U}}_I$, with $n = 0, 1$, are the specified displacements.

Based again on the preceding theory, one can write

$$\overset{(n)}{t}{}^{\Gamma\Lambda} = \left[\overset{(n)}{T}{}^{\Gamma\Lambda}\right]_{N\otimes N} = \sqrt{A_{\Gamma\Gamma}}\sqrt{A_{\Lambda\Lambda}}\,\overset{(n)}{T}{}^{\Gamma\Lambda} \quad ,$$

$$\overset{(n)}{t}{}^{\blacksquare\Lambda} = \left[\overset{(n)}{T}{}^{\blacksquare\Lambda}\right]_{N} = \sqrt{A_{\Lambda\Lambda}}\,\overset{(n)}{T}{}^{\blacksquare\Lambda} \quad , \quad n = 0, 1$$

$$\overset{(0)}{q}{}^{\Gamma\blacksquare} = \left[\overset{(0)}{Q}{}^{\Gamma\blacksquare}\right]_{N} = \sqrt{A_{\Gamma\Gamma}}\,\overset{(0)}{Q}{}^{\Gamma\blacksquare} \quad ,$$

$$\overset{(0)}{q}{}^{\blacksquare\blacksquare} = \left[\overset{(0)}{Q}{}^{\blacksquare\blacksquare}\right] \qquad (60a-g)$$

where $\overset{(n)}{t}{}^{\Gamma\Lambda}$, $\overset{(n)}{t}{}^{\blacksquare\Gamma}$, $\overset{(0)}{q}{}^{\Gamma\blacksquare}$, and $\overset{(0)}{q}{}^{\blacksquare\blacksquare}$ denote the anholonomic components of $\overset{(n)}{T}{}^{\Gamma\Lambda}$, $\overset{(n)}{T}{}^{\blacksquare\Gamma}$, $\overset{(0)}{Q}{}^{\Gamma\blacksquare}$, and $\overset{(0)}{Q}{}^{\blacksquare\blacksquare}$ relative to the bases above indicated, respectively. Substituting formulas $(48a-l)$ and $(60a-g)$ into equations (58) and (59), and taking the anholonomic components of $\overset{(n)}{P}{}^{\Gamma}$, $\overset{(n)}{F}{}^{\Gamma}$, $B^{\Gamma}_{(n)}$, and ν_Γ as

$$\overset{(n)}{p}{}^{\Gamma} = \left[\overset{(n)}{P}{}^{\Gamma}\right]_{N} = \sqrt{A_{\Gamma\Gamma}}\,\overset{(n)}{P}{}^{\Gamma} \quad , \quad \overset{(n)}{f}{}^{\Gamma} = \left[\overset{(n)}{F}{}^{\Gamma}\right]_{N} = \sqrt{A_{\Gamma\Gamma}}\,\overset{(n)}{F}{}^{\Gamma}$$

$$\overset{(n)}{p}{}^{\blacksquare} = \left[\overset{(n)}{P}{}^{\blacksquare}\right] = \overset{(n)}{P}{}^{\blacksquare} \quad , \quad \overset{(n)}{f}{}^{\blacksquare} = \left[\overset{(n)}{F}{}^{\blacksquare}\right] = \overset{(n)}{F}{}^{\blacksquare}$$

$$b^{\Gamma}_{(n)} = \left[B^{\Gamma}_{(n)}\right]_{N} = \sqrt{A_{\Gamma\Gamma}}B^{\Gamma}_{(n)} \quad , \quad b^{\blacksquare}_{(n)} = \left[B^{\blacksquare}_{(n)}\right] = B^{\blacksquare}_{(n)}$$

$$\eta_\Lambda = [\nu_\Lambda]_{\underline{N}} = \frac{1}{\sqrt{A_{\Lambda\Lambda}}}\,\nu_\Lambda \qquad (61a-n)$$

one obtains the equations of motion

$$\sqrt{A_{\Gamma\Gamma}}\left[\frac{1}{\sqrt{A_{\Gamma\Gamma}}\sqrt{A_{\Lambda\Lambda}}}\overset{(0)}{t}{}^{\Gamma\Lambda}\right]_{|\Lambda} - b^{\Gamma}_{\Lambda}\,\overset{(0)}{t}{}^{\blacksquare\Lambda} =$$

$$I_1\,\overset{(0)}{\ddot{u}}{}^{\Gamma} + I_2\,\overset{(1)}{\ddot{u}}{}^{\Gamma} - \overset{(0)}{f}{}^{\Gamma} - \overset{(0)}{p}{}^{\Gamma} \qquad (62a)$$

$$\left[\frac{1}{\sqrt{A_{\Lambda\Lambda}}}\overset{(0)}{t}{}^{\blacksquare\Lambda}\right]_{|\Lambda} + b_{\Gamma\Lambda}\,\overset{(0)}{t}{}^{\Gamma\Lambda} =$$

$$I_1\,\overset{(0)}{\ddot{u}}{}^{\blacksquare} + I_2\,\overset{(1)}{\ddot{u}}{}^{\blacksquare} - \overset{(0)}{f}{}^{\blacksquare} - \overset{(0)}{p}{}^{\blacksquare} \qquad (62b)$$

$$\sqrt{A_{\Gamma\Gamma}}\left[\frac{1}{\sqrt{A_{\Gamma\Gamma}}\sqrt{A_{\Lambda\Lambda}}}\overset{(1)}{t}{}^{\Gamma\Lambda}\right]_{|\Lambda} - b^{\Gamma}_{\Lambda}\,\overset{(1)}{t}{}^{\blacksquare\Lambda} - \overset{(0)}{q}{}^{\Gamma\blacksquare} =$$

$$I_2\,\overset{(0)}{\ddot{u}}{}^{\Gamma} + I_3\,\overset{(1)}{\ddot{u}}{}^{\Gamma} - \overset{(1)}{f}{}^{\Gamma} - \overset{(1)}{p}{}^{\Gamma} \qquad (62c)$$

$$\left[\frac{1}{\sqrt{A_{\Lambda\Lambda}}}\overset{(1)}{t}{}^{\blacksquare\Lambda}\right]_{|\Lambda} + b_{\Gamma\Lambda}\,\overset{(1)}{t}{}^{\Gamma\Lambda} - \overset{(0)}{q}{}^{\blacksquare\blacksquare} =$$

$$I_2\,\overset{(0)}{\ddot{u}}{}^{\blacksquare} + I_3\,\overset{(1)}{\ddot{u}}{}^{\blacksquare} - \overset{(1)}{f}{}^{\blacksquare} - \overset{(1)}{p}{}^{\blacksquare} \qquad (62d)$$

and the boundary conditions

$$\overset{(0)}{t}{}^{\Gamma\Lambda}\,\eta_\Lambda - b^{\Gamma}_{(0)} = 0 \quad , \quad \overset{(0)}{t}{}^{\blacksquare\Lambda}\,\eta_\Lambda - b^{\blacksquare}_{(0)} = 0$$

$$\overset{(1)}{t}{}^{\Gamma\Lambda}\,\eta_\Lambda - b^{\Gamma}_{(1)} = 0 \quad , \quad \overset{(1)}{t}{}^{\blacksquare\Lambda}\,\eta_\Lambda - b^{\blacksquare}_{(1)} = 0 \quad (63a-d)$$

$$\overset{(0)}{u}_I = \overset{(0)}{\bar{u}}_I \quad , \quad \overset{(1)}{u}_I = \overset{(1)}{\bar{u}}_I \qquad (63e,f)$$

written in terms of anholonomic components. Furthermore, relations (57) are expressed as follows:

$$\overset{(0)}{t}{}^{\Gamma\Lambda} = \overset{(0)}{l}{}^{\Gamma}_{\Omega}\,r^{\Omega\Lambda}_{(0)} + \overset{(1)}{\varphi}{}^{\Gamma}_{.\Omega}\,r^{\Omega\Lambda}_{(1)} - b^{\Gamma}_{.\Omega}\,r^{\Omega\Lambda}_{(1)} + \overset{(1)}{u}{}^{\Gamma}\,r^{\blacksquare\Lambda}_{(0)}$$

$$\overset{(1)}{t}{}^{\Gamma\Lambda} = \overset{(0)}{l}{}^{\Gamma}_{\Omega}\,r^{\Omega\Lambda}_{(1)} + \overset{(1)}{\varphi}{}^{\Gamma}_{.\Omega}\,r^{\Omega\Lambda}_{(2)} - b^{\Gamma}_{.\Omega}\,r^{\Omega\Lambda}_{(2)} + \overset{(1)}{u}{}^{\Gamma}\,r^{\blacksquare\Lambda}_{(1)}$$

$$\overset{(0)}{t}{}^{\blacksquare\Lambda} = \overset{(0)}{\varphi}{}^{\blacksquare}_{\Omega}\,r^{\Omega\Lambda}_{(0)} + \overset{(1)}{\varphi}{}^{\blacksquare}_{.\Omega}\,r^{\Omega\Lambda}_{(1)} + \left(1 + \overset{(1)}{u}{}^{\blacksquare}\right) r^{\blacksquare\Lambda}_{(0)}$$

$$\overset{(1)}{t}{}^{\blacksquare\Lambda} = \overset{(0)}{\varphi}{}^{\blacksquare}_{\Omega}\,r^{\Omega\Lambda}_{(1)} + \overset{(1)}{\varphi}{}^{\blacksquare}_{.\Omega}\,r^{\Omega\Lambda}_{(2)} + \left(1 + \overset{(1)}{u}{}^{\blacksquare}\right) r^{\blacksquare\Lambda}_{(1)}$$

$$\overset{(0)}{q}{}^{\Gamma\blacksquare} = \overset{(0)}{l}{}^{\Gamma}_{\Omega}\,r^{\Omega\blacksquare}_{(0)} + \overset{(1)}{\varphi}{}^{\Gamma}_{.\Omega}\,r^{\Omega\blacksquare}_{(1)} - b^{\Gamma}_{.\Omega}\,r^{\Omega\blacksquare}_{(1)} + \overset{(1)}{u}{}^{\Gamma}\,r^{\blacksquare\blacksquare}_{(0)}$$

$$\overset{(0)}{q}{}^{\blacksquare\blacksquare} = \overset{(0)}{\varphi}{}^{\blacksquare}_{\Omega}\,r^{\Omega\blacksquare}_{(0)} + \overset{(1)}{\varphi}{}^{\blacksquare}_{.\Omega}\,r^{\Omega\blacksquare}_{(1)} + \left(1 + \overset{(1)}{u}{}^{\blacksquare}\right) r^{\blacksquare\blacksquare}_{(0)}$$

$$\overset{(0)}{l}{}^{\Gamma}{}_{.\Omega} = \hat{\delta}^{\Gamma}_{.\Omega} + \overset{(0)}{\varphi}{}^{\Gamma}{}_{.\Omega} \qquad (64a-g)$$

where

$$r^{\Omega\Lambda}_{(n)} = \left[R^{\Omega\Lambda}_{(n)}\right]_{N\otimes N} = \sqrt{A_{\Omega\Omega}}\sqrt{A_{\Lambda\Lambda}}R^{\Omega\Lambda}_{(n)} \quad ,$$

$$r^{\blacksquare\Lambda}_{(n)} = \left[R^{\blacksquare\Lambda}_{(n)}\right]_{N} = \sqrt{A_{\Lambda\Lambda}}R^{\blacksquare\Lambda}_{(n)} \quad , \quad n = 0, 1, 2$$

$$\overset{(0)}{l}{}^{\Gamma}{}_{.\Lambda} = \left[L^{\Gamma}_{.\Lambda}\right]_{N\otimes\underline{N}} = \frac{\sqrt{A_{\Gamma\Gamma}}}{\sqrt{A_{\Lambda\Lambda}}}\,L^{\Gamma}_{.\Lambda} \quad ,$$

$$\hat{\delta}^{\Gamma}_{.\Lambda} = \left[\delta^{\Gamma}_{.\Lambda}\right]_{N\otimes\underline{N}} = \frac{\sqrt{A_{\Gamma\Gamma}}}{\sqrt{A_{\Lambda\Lambda}}}\,\delta^{\Gamma}_{.\Lambda} \qquad (64h-o)$$

Constitutive equations

The linear constitutive equations of an anisotropic shell having elastic symmetry with respect to the surface $\theta^3 = 0$ read (Librescu, 1987)

$$R_{(0)}^{\Gamma\Lambda} = B_0^{\Gamma\Lambda\Omega\Theta} \overset{(0)}{E}_{\Omega\Theta} + B_1^{\Gamma\Lambda\Omega\Theta} \overset{(1)}{E}_{\Omega\Theta} + B_2^{\Gamma\Lambda\Omega\Theta} \overset{(2)}{E}_{\Omega\Theta} + B_2^{\Gamma\Lambda\blacksquare\blacksquare} \overset{(0)}{E}_{\blacksquare\blacksquare} \tag{65a}$$

$$R_{(1)}^{\Gamma\Lambda} = B_1^{\Gamma\Lambda\Omega\Theta} \overset{(0)}{E}_{\Omega\Theta} + B_2^{\Gamma\Lambda\Omega\Theta} \overset{(1)}{E}_{\Omega\Theta} + B_3^{\Gamma\Lambda\Omega\Theta} \overset{(2)}{E}_{\Omega\Theta} + B_3^{\Gamma\Lambda\blacksquare\blacksquare} \overset{(0)}{E}_{\blacksquare\blacksquare} \tag{65b}$$

$$R_{(2)}^{\Gamma\Lambda} = B_2^{\Gamma\Lambda\Omega\Theta} \overset{(0)}{E}_{\Omega\Theta} + B_3^{\Gamma\Lambda\Omega\Theta} \overset{(1)}{E}_{\Omega\Theta} + B_4^{\Gamma\Lambda\Omega\Theta} \overset{(2)}{E}_{\Omega\Theta} + B_4^{\Gamma\Lambda\blacksquare\blacksquare} \overset{(0)}{E}_{\blacksquare\blacksquare} \tag{65c}$$

$$R_{(0)}^{\Gamma\blacksquare} = 2\, B_0^{\Gamma\blacksquare\Omega\blacksquare} \overset{(0)}{E}_{\Omega\blacksquare} + 2\, B_1^{\Gamma\blacksquare\Omega\blacksquare} \overset{(1)}{E}_{\Omega\blacksquare} \tag{65d}$$

$$R_{(1)}^{\Gamma\blacksquare} = 2\, B_1^{\Gamma\blacksquare\Omega\blacksquare} \overset{(0)}{E}_{\Omega\blacksquare} + 2\, B_2^{\Gamma\blacksquare\Omega\blacksquare} \overset{(1)}{E}_{\Omega\blacksquare} \tag{65e}$$

$$R_{(0)}^{\blacksquare\blacksquare} = B_0^{\blacksquare\blacksquare\Omega\Theta} \overset{(0)}{E}_{\Omega\Theta} + B_1^{\blacksquare\blacksquare\Omega\Theta} \overset{(1)}{E}_{\Omega\Theta} + B_2^{\blacksquare\blacksquare\Omega\Theta} \overset{(2)}{E}_{\Omega\Theta} + B_2^{\blacksquare\blacksquare\blacksquare\blacksquare} \overset{(0)}{E}_{\blacksquare\blacksquare} \tag{65f}$$

where

$$B_n^{IJKL} = \int_{-h/2}^{h/2} \mu\, C^{IJKL} \left(\theta^{\blacksquare}\right)^n \, d\theta^{\blacksquare} \tag{65g}$$

and C^{IJKL} are the components of the spatial tensor of elasticity (elastic coefficients).

Adding to the above set of anholonomic components

$$b_{(n)}^{IJKL} = \left[B_{(n)}^{IJKL}\right]_{N\otimes N\otimes N\otimes N} = \sqrt{A_{II}}\sqrt{A_{JJ}}\sqrt{A_{KK}}\sqrt{A_{LL}}\; B_{(n)}^{IJKL} \tag{66}$$

equations $(65a-f)$ can be written as

$$r_{(0)}^{\Gamma\Lambda} = b_0^{\Gamma\Lambda\Omega\Theta} \overset{(0)}{\epsilon}_{\Omega\Theta} + b_1^{\Gamma\Lambda\Omega\Theta} \overset{(1)}{\epsilon}_{\Omega\Theta} + b_2^{\Gamma\Lambda\Omega\Theta} \overset{(2)}{\epsilon}_{\Omega\Theta} + b_2^{\Gamma\Lambda\blacksquare\blacksquare} \overset{(0)}{\epsilon}_{\blacksquare\blacksquare} \tag{67a}$$

$$r_{(1)}^{\Gamma\Lambda} = b_1^{\Gamma\Lambda\Omega\Theta} \overset{(0)}{\epsilon}_{\Omega\Theta} + b_2^{\Gamma\Lambda\Omega\Theta} \overset{(1)}{\epsilon}_{\Omega\Theta} + b_3^{\Gamma\Lambda\Omega\Theta} \overset{(2)}{\epsilon}_{\Omega\Theta} + b_3^{\Gamma\Lambda\blacksquare\blacksquare} \overset{(0)}{\epsilon}_{\blacksquare\blacksquare} \tag{67b}$$

$$r_{(2)}^{\Gamma\Lambda} = b_2^{\Gamma\Lambda\Omega\Theta} \overset{(0)}{\epsilon}_{\Omega\Theta} + b_3^{\Gamma\Lambda\Omega\Theta} \overset{(1)}{\epsilon}_{\Omega\Theta} + b_4^{\Gamma\Lambda\Omega\Theta} \overset{(2)}{\epsilon}_{\Omega\Theta} + b_4^{\Gamma\Lambda\blacksquare\blacksquare} \overset{(0)}{\epsilon}_{\blacksquare\blacksquare} \tag{67c}$$

$$r_{(0)}^{\Gamma\blacksquare} = 2\, b_0^{\Gamma\blacksquare\Omega\blacksquare} \overset{(0)}{\epsilon}_{\Omega\blacksquare} + 2\, b_1^{\Gamma\blacksquare\Omega\blacksquare} \overset{(1)}{\epsilon}_{\Omega\blacksquare} \tag{67d}$$

$$r_{(1)}^{\Gamma\blacksquare} = 2\, b_1^{\Gamma\blacksquare\Omega\blacksquare} \overset{(0)}{\epsilon}_{\Omega\blacksquare} + 2\, b_2^{\Gamma\blacksquare\Omega\blacksquare} \overset{(1)}{\epsilon}_{\Omega\blacksquare} \tag{67e}$$

$$r_{(0)}^{\blacksquare\blacksquare} = b_0^{\blacksquare\blacksquare\Omega\Theta} \overset{(0)}{\epsilon}_{\Omega\Theta} + b_1^{\blacksquare\blacksquare\Omega\Theta} \overset{(1)}{\epsilon}_{\Omega\Theta} + b_2^{\blacksquare\blacksquare\Omega\Theta} \overset{(2)}{\epsilon}_{\Omega\Theta} + b_2^{\blacksquare\blacksquare\blacksquare\blacksquare} \overset{(0)}{\epsilon}_{\blacksquare\blacksquare} \tag{67f}$$

which are the desired anholonomic equations.

COMMENTS

The following comments are pertinent:

1. The method of anholonomic components as developed by Truesdell (1954) and Ericksen (1960) does not include all cases as Ericksen (1960) himself says: *"Possible a method sufficiently general as to cover every proposal which might appeal on some or another intuitive grounds could be constructed. In this connection we mention only that the method of anholonomic components, which appears quite general does not include Green and Zerna's definition."* Truesdell and Ericksen dealt only with anholonomic components of single field referred to the bases U and $\underline{U}$ of the undeformed (or u and $\underline{u}$ of the deformed) configuration of the body and, therefore, omitting the bases U^* and $\underline{U}^*$ (or u^* and $\underline{u}^*$). Otherwise, it can easily be shown that the expression of Green and Zerna's (1968) physical components of Cauchy's stress tensor τ^{ij}
$$\sigma^{ij} = \sqrt{\frac{g_{jj}}{g^{ii}}}\, \tau^{ij} \tag{68}$$
is equal to the expression of the anholonomic components of τ^{ij} referred to the basis $\mathcal{B} = \underline{u}^* \otimes u$. Since Truesdell and Ericksen omitted the basis $\underline{u}^*$, they could not include the anholonomic counterpart of Green and Zerna's definition in their method. The theory here developed is more general; it deals with all the above mentioned bases.

2. Some authors refer the physical components of the stress and strain tensors at a point of the body to different bases which are not reciprocal. This procedure is in disagreement with the invariance of the elastic potential of a body under transformation of coordinates. Thus, in order to satisfy this requirement, the bases of the anholonomic counterparts of those components should be chosen as to be reciprocal.

3. There are several anholonomic components which are suitable for each stress tensor component since all of them have similar physical significance. In fact, the decompositions of the stress tensor in terms of anholonomic components generate stress vectors $\overset{i}{\vec{T}}$ which depend on the chosen bases. For instance, consider the following stress vectors:
$$\overset{i}{\vec{T}}_{(G)} = \left[\tau^{ij}\right]_{\underline{u}^*\otimes u} \vec{u}_j \tag{69a}$$
and
$$\overset{i}{\vec{T}}_{(S)} = \left[\tau^{ij}\right]_{u\otimes \underline{u}^*} \vec{\underline{u}}_j \tag{69b}$$
where $\overset{i}{\vec{T}}_{(G)}$ and $\overset{i}{\vec{T}}_{(S)}$ denote Green and Zerna's (1968) and Sedov's (1965) stress vectors, respectively. In these expressions
$$\left[\tau^{ij}\right]_{\underline{u}^*\otimes u} = \frac{\sqrt{g_{jj}}}{\sqrt{g^{ii}}}\, \tau^{ij} \tag{70a}$$

and

$$[\tau^{ij}]_{u \otimes \underline{u}^*} = \frac{\sqrt{g_{ii}}}{\sqrt{g^{jj}}} \tau^{ij} \qquad (70b)$$

Taking into account formulas (8a) and (8d), it can be seen that the coefficients (70a,b) of expressions (69a,b) are the anholonomic components of the stress vectors $\overset{i}{\vec{T}}_{(G)}$ and $\overset{i}{\vec{T}}_{(S)}$ in the directions $\vec{u}_j$ and $\underline{\vec{u}}_j$, respectively. These and the remaining anholonomic components of the stress tensor have analogous physical interpretations to the one given by Green and Zerna (1968) for the physical counterparts of formulas (69a) and (70a). Thus, the use of one or another anholonomic component of the stress tensor is a matter of choice or of further convenience.

4. Finally, the theory and results given here can be extended in order to be applicable to any tensorial system of equations referred to general curvilinear coordinates.

ACKNOWLEDGEMENTS

The authors would like to express their appreciation to Professors Dewey H. Hodges and Marcos A. Ortega for their interest and stimulating discussions during the preparation of this paper.

Reduced constraint manifolds

Paulo Boulos and Nelson Achcar

Department of Structures and Foundation Engineering, Escola Politecnica Universidade de São Paulo, CP 61548, São Paulo, SP, Brazil

The formalization of the concept of internal constraint is usually done by means of restrictions on the deformation gradients, by imposing that they must stay on a submanifold of Lin^+. Our point of view is to impose restrictions on the right Cauchy-Green tensors, by imposing that they must stay on a submanifold of $Psym$, which we call reduced constraint manifold. We determine: all the constraint manifolds that are independent of the local reference configuration, a new formula for the reaction space, all the constraint manifolds whose reaction spaces are independent of the deformation gradient.

INTRODUCTION

An internal constraint is a limitation on the possible motions of a body point.The formalization of this concept can be achieved by specifying, for a fixed reference configuration, a regular submanifold $\mathcal{M}$ of Lin^+ (see section 2 for notation) called constraint manifold, to which must belong the deformation gradients at the point under consideration.One imposes that $\mathcal{M}$ be objective, that is, invariant under left action by the rotation group. This condition gives an equivalent way of imposing restrictions, namely, that the right Cauchy-Green tensor C must belong to a convenientely defined submanifold of $Psym$ called by us *reduced constraint manifold* (definition 3 (b)). In the present article we introduce the concept of reduced constraint manifold, we prove that there is a one to one correspondence between the set of reduced constraint manifolds and the set of the constraint manifolds and, through the new concept, we determine the constraint manifolds that are invariant relative to reference configurations (Theorem 8), and the ones whose reaction spaces are independent of the deformation imposed to the body (Theorem 15). This result uses a new formula for the reaction space (Proposition 12).

NOTATION

$\mathbf{R}, \mathbf{R}_*^+$: respectively,the field of real numbers,the set of positive reals.

$\mathbf{V}$: the vector space of translations associated to the affine space $\mathbf{E}$ of the points of Euclidean Geometry. The usual scalar product of the elements $\mathbf{v}$ and $\mathbf{w}$ of $\mathbf{V}$ will be denoted by $\mathbf{v} \cdot \mathbf{w}$.

Lin: the vector space of all (second order) tensors, viewed as linear operators of $\mathbf{V}$, provided with the following scalar product

$$A : B = tr(A^\top B)$$

($\top$ stands for transpose)

$\perp$ stands for orthogonal complement relative to the above scalar product, and $\perp_s$ stands for orthogonal complement relative to the scalar product induced on Sym.

$\mathbf{1}$ stands for the identity operator of $\mathbf{V}$.

$Lin^+ = \{F \in Lin \mid detF > 0\}$

$Sym = \{F \in Lin \mid F^\top = F\}$

$Skw = \{F \in Lin \mid F^\top = -F\}$

$Rot = \{R \in Lin^+ \mid R^\top = R^{-1}\}$

$Unim = \{F \in Lin^+ \mid detF = 1\}$

$Psym = \{C \in Sym \mid C \textit{ is positive definite}\}$

$Dev = \{C \in Sym \mid trC = 0\}$

$Sph = \mathbf{R}\mathbf{1}$

$\Sigma : Lin \to Sym$ is given by

$$\Sigma(F) = \frac{1}{2}(F + F^\top)$$

$\varphi : Lin^+ \to Psym$ is given by

$$\varphi(F) = F^\top F$$

$c_F : Lin \to Lin$, for each F in Lin, is given by

$$c_F(G) = FGF^\top$$

$u : Lin^+ \to Psym$ is given by

$$u(F) = U$$

where $F = RU$ is the right polar decomposition of F.

$dim\mathcal{N}$: the dimension of the (differentiable) manifold $\mathcal{N}$.

$\dot{\mathcal{N}}_X$: the tangent space to the manifold $\mathcal{N}$ at X.

$f_{*X} : \dot{\mathcal{M}}_X \to \dot{\mathcal{N}}_{f(X)}$: the differential at X of the differentiable mapping $f : \mathcal{M} \to \mathcal{N}$ between manifolds.

Proposition 1 *For every F in Lin^+ we have*
(i) $\varphi r_F = c_{F^T}\varphi$
(ii) $\varphi_{*F} = 2c_{F^T}\Sigma r_{F^{-1}}$
where $r_F : Lin^+ \to Lin^+$ *is given by* $r_F(G) = GF$.

Proof. From (i), whose proof is left to the reader, it follows that $\varphi = c_{F^T}\varphi r_{F^{-1}}$. By taking differentials, one obtains

$$\varphi_{*1} = (c_{F^T})_{*1}\varphi_{*1}(r_{F^{-1}})_{*F}$$

. Then (ii) follows by observing that $(c_{F^T})_{*1} = c_{F^T}$, $(r_{F^{-1}})_{*F} = r_{F^{-1}}$ and that

$$\varphi_{*1}(N) = 1^T N + N^T 1 = N + N^T = 2\Sigma(N)$$

Corollary 2 *φ is a submersion.*

Proof. It follows from (ii), since $r_{F^{-1}}$ is a diffeomorfism, and Σ and c_{F^T} are surjective.

INTERNAL CONSTRAINTS

Definition 3 *(a) A* constraint manifold *(Podio-Guidugli and Vianello, 1989) is a connected regular submanifold $\mathcal{M}$ of Lin^+ such that*

$$(i)\ Rot\mathcal{M} \subset \mathcal{M} \quad (ii)\ 1 \in \mathcal{M}$$

(b) A reduced constraint manifold *is a connected regular submanifold $\mathcal{C}$ of $Psym$ such that $1 \in \mathcal{C}$.*

Lemma 4 *If $\mathcal{M}$ is a constraint manifold then $\mathcal{M} \cap Psym$ is a reduced constraint manifold, whose dimension is $dim\mathcal{M} - 3$.*

Proof. Clearly $1 \in \mathcal{M} \cap Psym$.Now if we can prove that

$$(\ \dot{RotU}\ )_U \cap Sym = \{0\} \qquad (1)$$

for every U in $\mathcal{M} \cap Psym$, then it will follow that the sum $(\ \dot{RotU}\ )_U + Sym$ is direct, and since its dimension is 3+6=9, it must coincide with Lin.

Since

$$(\dot{RotU})_U \subset \dot{\mathcal{M}}_U,\ (\dot{Psym})_U = Sym,\ (\dot{Lin^+})_U = Lin,$$

we have

$$\dot{\mathcal{M}}_U + (\ \dot{Psym})_U\ = (\ \dot{Lin^+})_U$$

Accordingly, $\mathcal{M}$ and $Psym$ are transversal in each U of their intersection, so that (Varadarajan, 1974) such intersection is a regular submanifold of Lin^+.

To prove (1), we observe that an element of $(\dot{Rot})_U$ is of the form WU, with W in Skw. If WU is in Sym, then $-WU = UW$, so that if e is an eigenvector of U corresponding to the eingenvalue λ, one obtains

$$-\lambda W(e) = U(W(e))$$

so that W(e) must be zero, othe[illegible] would be eigenvalues of the positive de[illegible]. Since there is an ortonormal basis formed by eigenvectors of U, it follows that $W = 0$, so that (1) is proved.

The statement about the dimension follows from

$$dim\,\mathcal{M} + dim\,Psym = dim\,(\mathcal{M} \cap Psym) + dim\,Lin^+$$

Finally, since $\mathcal{M} \cap Psym = u(\mathcal{M})$, $\mathcal{M}$ is connected and u continuous, it follows that $\mathcal{M} \cap Psym$ is connected.

Proposition 5 *The mapping*

$$\mathcal{M} \mapsto \varphi(\mathcal{M})$$

is a bijection between the set of constraint manifolds and the set of reduced constraint manifolds, its inverse being given by

$$\mathcal{C} \mapsto \varphi^{-1}(\mathcal{C})$$

Forthermore, $dim\,\varphi(\mathcal{M}) = dim\,\mathcal{M} - 3$

Proof. Since $\mathcal{M}$ contains 1, and

$$\varphi(\mathcal{M}) = r^{-1}(\mathcal{M} \cap Psym) \qquad (2)$$

where $r : Psym \to Psym$ is the diffeomorphism given by $r(C) = C^{\frac{1}{2}}$, we can conclude by Lemma 4 that $\varphi(\mathcal{M})$ is a reduced constraint manifold.

On the other hand, if $\mathcal{C}$ is a reduced constraint manifold then $\varphi^{-1}(\mathcal{C})$ is a regular submanifold of Lin^+ for, according to Corollary 2, φ is a submersion.The relation

$$\varphi^{-1}(\mathcal{C}) = \bigcup_{C\in\mathcal{C}} \varphi^{-1}(C) = \bigcup_{C\in\mathcal{C}} Rot\,C^{\frac{1}{2}}$$

and the fact that $\mathcal{C}$ is connected allows us to conclude that $\varphi^{-1}(\mathcal{C})$ is connected. The same relation shows that condition(i) of Definition 3 is satisfied. Clearly condition (ii) is also satisfied, so that $\varphi^{-1}(\mathcal{C})$ is a constraint manifold.

Since φ is surjective we have $\varphi^{-1}(\varphi(\mathcal{C})) = \mathcal{C}$, and from (2)

$$\varphi^{-1}(\varphi(\mathcal{M})) = \varphi^{-1}(r^{-1}(\mathcal{M} \cap Psym)) = u^{-1}(\mathcal{M} \cap Psym) = \mathcal{M}$$

The statement about dimension follows from Lemma 4 and from (2).

CONFIGURATION INDEPENDENT CONSTRAINT MANIFOLDS

In (Podio-Guidugli and Vianello, 1989) it is proved that in order to a constraint manifold be independent of the (local) configuration at a body point it is necessary and sufficient that it be a subgroup of Lin^+. In this section we determine such constraint manifolds.

We shall need the following result, proved in (Podio-Guidugli, 1979), for which we give a new proof.

Proposition 6 *If W is a proper vector subspace of Sym invariant by c_R for all R in Rot, then W=Dev or W=Sph.*

Proof. (a) We claim that there is no proper vector subspace of Dev invariant under c_R for all R in Rot.

By a standard result of Group Representation Theory (Varadarajan, 1974), this will be proved if we can show that a linear operator T of Dev that commutes with $c_R|_{Dev}$ for all R in Rot must be a multiple of the identity. To see this, extend T to a linear operator $\tilde{T}$ of Sym by imposing it to be the identity in Sph. It is easy to see that $\tilde{T}$ commutes with c_R for all R in Rot, that is, $\tilde{T}$ is isotropic, so it is of the form (Gurtin, 1981)

$$\tilde{T}(A) = \alpha A + \beta tr A\, \mathbf{1}$$

Hence $T(A) = \alpha A$ for all A in Dev.

(b) Since c_R is an orthogonal operator of Sym, the fact that W is invariant under c_R implies that the same occurs with $W^{\perp\bullet}$. Clearly $W \cap Dev$ and $W^{\perp\bullet} \cap Dev$ are invariant under c_R. But we must have $W \cap Dev \neq \{0\}$ *or* $W^{\perp\bullet} \cap Dev \neq \{0\}$ (otherwise $dim W \leq 1$ and $dim W^{\perp\bullet} \leq 1$, which is impossible). In the former case we have by part (a) that $W \cap Dev = Dev$, so that $W \supset Dev$. Since $dim Dev = 5$ and W is a proper subspace of Sym, we must have $W = Dev$. The other case is treated similarly, to conclude that $W^{\perp\bullet} = Dev$, that is, $W = Sph$.

Lemma 7 *If $\mathcal{M}$ is a constraint manifold then*
(i) $SkwF \subset \dot{\mathcal{M}}_F$, for every F in $\mathcal{M}$.
(ii) $\varphi|_{\mathcal{M}}$ is a submersion.

Proof. (i) For W in Skw choose a curve $\alpha(t)$ in Rot such that $\alpha(0) = \mathbf{1}$, $\dot{\alpha}(0) = W$. Then the curve $\alpha(t)F$ is in $\mathcal{M}$, by Definition 3 (a)(i), passes by F at t=0, and has WF as tangent vector at this point, so that WF is in $\dot{\mathcal{M}}_F$.

(ii) By Proposition 1 (ii) we have $ker\, \varphi_{*F} = Skw\, F$, so that by part (i) $ker\, \varphi_{*F}$ is contained in $\dot{\mathcal{M}}_F$. Hence the kernels of φ_{*F} and $(\varphi|_{\mathcal{M}})_{*F}$ coincide. Using this we have

$$\begin{aligned} dim\, \mathcal{M} &= dim\, ker(\varphi|_{\mathcal{M}})_{*F} \\ &+ dim\,(\varphi|_{\mathcal{M}})_{*F}(\dot{\mathcal{M}}_F) \\ &= 3 + dim\, \varphi_{*F}(\dot{\mathcal{M}}_F) \end{aligned}$$

so that, in view of Proposition 5, we have

$$dim\, \varphi_{*F}(\dot{\mathcal{M}}_F) = dim\, \mathcal{M} - 3 = dim\, \varphi(\mathcal{M}).$$

Theorem 8 *Let $\mathcal{M}$ be a constraint manifold that is a subgroup of Lin^+. Then $\mathcal{M}$ is Rot, $\mathbf{R}^+_* Rot$, $Unim$, or Lin^+.*

Proof. Since $\mathcal{M}$ is a regular submanifold of Lin^+ as well as a subgroup, it is a Lie subgroup of Lin^+. Put $\mathcal{C} = \varphi(\mathcal{M})$. Then using Proposition 1, we have, for R in Rot,

$$c_R(\mathcal{C}) = \varphi\, r_{R^\top}(\mathcal{M}) = \varphi(\mathcal{M}) = \mathcal{C}$$

where we have used the fact that Rot is contained in the group $\mathcal{M}$.

From this relation it follows that for every R in Rot,

$$c_R(\dot{\mathcal{C}}_1) = \dot{\mathcal{C}}_1 \tag{3}$$

Case 1 : $\dot{\mathcal{C}}_1$ is a trivial vector subespace of Sym.

If $\dot{\mathcal{C}}_1 = 0$ we have $\mathcal{C} = \{\mathbf{1}\}$, and $\mathcal{M} = \varphi^{-1}\{\mathbf{1}\} = Rot$. If $\dot{\mathcal{C}}_1 = Sym$ then $\mathcal{C}$ is an open submanifold of $Psym$, so that $\mathcal{M} = \varphi^{-1}(\mathcal{C})$ is an open submanifold of Lin^+. This group is generated by any neighbourhood of $\mathbf{1}$ (Varadarajan, 1974), in particular by $\mathcal{M}$. Since $\mathcal{M}$ is a group, we have $\mathcal{M} = Lin^+$.

Case 2: $\dot{\mathcal{C}}_1$ is a non-trivial vector subspace of Sym.

By (3) and Proposition 6 we must have $\dot{\mathcal{C}}_1$ equal to Dev or Sph. Notice that

$$\varphi_{*\mathbf{1}}(\dot{\mathcal{M}}_1) = \dot{\mathcal{C}}_1, \quad \varphi_{*\mathbf{1}}(H) = H + H^\top \tag{4}$$

for every H in $\dot{\mathcal{M}}_1$, the first equality being granted by Lemma 7 (ii).

Now if $\dot{\mathcal{C}}_1 = Dev$ we must have by (4), that $H + H^\top$ belongs to Dev for every H in $\dot{\mathcal{M}}_1$, so $tr\, H = 0$. Hence $\dot{\mathcal{M}}_1$ is contained in the Lie algebra of the Lie group $Unim$. Since both are of dimension 8 ($dim\, \mathcal{M} = dim\, \mathcal{C} + 3$), they must coincide, so that $\mathcal{M}$ must be $Unim$.

Finally, if $\dot{\mathcal{C}}_1 = Sph$, we must have by (4) that $H + H^\top = \alpha\mathbf{1}$ for every H in $\dot{\mathcal{M}}_1$, where the scalar α depends on H. Noting that

$$H = \frac{\alpha}{2}\mathbf{1} + (H - \frac{\alpha}{2}\mathbf{1})$$

and that

$$\begin{aligned} (H - \frac{\alpha}{2}\mathbf{1})^\top &= H^\top - \frac{\alpha}{2}\mathbf{1} \\ &= \alpha\mathbf{1} - H - \frac{\alpha}{2}\mathbf{1} = -(H - \frac{\alpha}{2}\mathbf{1}) \end{aligned}$$

we see that $\dot{\mathcal{M}}_1$ is contained in $\mathbf{R1} + Skw$. Since both are of dimension 4, they must coincide, so $\mathcal{M}$ must equal the corresponding Lie group of the Lie algebra $\mathbf{R1} + Skw$, namely $\mathcal{M} = \mathbf{R}^+_* Rot$

REACTION SPACE

Definition 9 *(Podio-Guidugli, 1990) The* reaction space *at a point F of a constraint manifold $\mathcal{M}$ is the vector space*

$$\mathcal{R}(F) = (\dot{\mathcal{M}}_F F^{-1})^\perp$$

Clearly the dimension of $\mathcal{R}(F)$ is $9 - dim\mathcal{M}$.

Lemma 10 *(i) For any subset $\mathcal{L}$ of Lin we have*

$$\mathcal{L}^\perp \cap Sym = (\Sigma(\mathcal{L}))^{\perp\bullet}$$

(ii) For any subset $\mathcal{N}$ of Sym and any F in Lin we have

$$(F\mathcal{N}F^\top)^{\perp\bullet} = F^{-\top}\mathcal{N}^{\perp\bullet}F^{-1}$$

Proof. (i) It suffices to observe that for N in Sym and A in Lin the equality $N : A = 0$ is equivalent to $N : \Sigma(A) = 0$.

(ii) clearly $F\mathcal{N}F^\top$ is contained in Sym. Since

$$X : FNF^\top = F^\top XF : N$$

we see that a symmetric X is in $(F\mathcal{N}F^\top)^{\perp\bullet}$ if and only if $F^\top XF$ is in $\mathcal{N}^{\perp\bullet}$, that is, if and only if X is in $F^{-\top}\mathcal{N}^{\perp\bullet}F^{-1}$.

Lemma 11 *(i)* $\mathcal{R}(F) \subset Sym$
(ii) $\mathcal{R}(F) = \mathcal{D}(F)^{\perp\bullet}$ *where* $\mathcal{D}(F) = \Sigma(\dot{\mathcal{M}}_F F^{-1})$

Proof. The proof of (i) can be found in (Podio-Guidugli and Vianello, 1989), but follows easily from Lemma 7 (i), and (ii) follows from (i) and Lemma 7 (i) with $\mathcal{L} = \mathcal{M}_F F^{-1}$.

Proposition 12 *For F in the constraint manifold $\mathcal{M}$ we have*

$$\mathcal{R}(F) = F\dot{\mathcal{C}}^{\perp\bullet}_{F^\top F}F^\top$$

where $\mathcal{C} = \varphi(\mathcal{M})$.

Proof. Since $\mathcal{M}F^{-1}$ is a constraint manifold, then by Lemma 7 (ii) we can write

$$\varphi_{*1}(\dot{\mathcal{M}F^{-1}})_1 = (\dot{\varphi(\mathcal{M}F^{-1})})_1 \tag{5}$$

By Proposition 1 (ii) the left side of the above equality is equal to $\mathcal{D}(F)$ (as defined in Lemma 11). On the other hand, by part (ii) of the same proposition we have

$$\varphi(\mathcal{M}F^{-1}) = \varphi r_{F^{-1}}(\mathcal{M}) = c_{F^{-\top}}(\mathcal{C})$$

so that

$$\begin{aligned}\varphi((\dot{\mathcal{M}F^{-1}}))_1 &= (c_{F^{-\top}})_{*F^\top F}(\dot{\mathcal{C}}_{F^\top F}) \\ &= c_{F^{-\top}}(\dot{\mathcal{C}}_{F^\top F}) = F^{-\top}\dot{\mathcal{C}}_{F^\top F}F^{-1}\end{aligned}$$

(We have used the fact that $c_{F^{-\top}}|_{Psym}$ is a diffeomorphism).

Hence (5) becomes

$$\mathcal{D}(F) = F^{-\top}\dot{\mathcal{C}}_{F^\top F}F^{-1}$$

The result to be proved follows from this equality by using Lemma 11 (ii) and Lemma 10 (ii).

Examples 13

1. *Rigidity constraint*: $\mathcal{M} = Rot$, so $\mathcal{C} = \{\mathbf{1}\}$, $\dot{\mathcal{C}}_{\mathbf{1}} = \{0\}$. By using Proposition 12 we obtain $\mathcal{R}(F) = Sym$.

2. *Incompressibility constraint*: $\mathcal{M} = Unim$, $\mathcal{C} = Unim \cap Psym$, $\dot{\mathcal{C}}_{\mathbf{1}} = Dev$, $\dot{\mathcal{C}}_C = \dot{\mathcal{C}}_{\mathbf{1}}C = Dev\,C$. By proposition 12 we obtain $\mathcal{R}(F) = Sph$.

3. *Conformality constraint*: $\mathcal{M} =]\alpha, \beta[\,Rot$, with $0 \leq \alpha < 1 < \beta \leq +\infty$, so $\mathcal{C} =]\alpha^2, \beta^2[\,\mathbf{1}$, $\dot{\mathcal{C}}_C = Sph$. By using Proposition 12 we obtain $\mathcal{R}(F) = Dev$.

   The following examples appears in the litterature. They are handled in our approach by Lemma 14 to follow them.

4. *Constraint of inextensibility in diretion* e (e a unit vector):

$$\mathcal{M} = \{\, F \in Lin^+ \mid F(\mathrm{e}) \cdot F(\mathrm{e}) = 1\,\}$$

$$\mathcal{C} = \{\, C \in Psym \mid C : \mathrm{e} \otimes \mathrm{e} = 1\}$$

$$\mathcal{R}(F) = \mathbf{R}F(\mathrm{e} \otimes \mathrm{e})F^\top = \mathbf{R}F(\mathrm{e}) \otimes F(\mathrm{e})$$

5. *Constraint of inextensibility in the mean* :

$$\mathcal{M} = \{F \in Lin^+ \mid trF^\top F = 3\}$$

$$\mathcal{C} = \{C \in Psym \mid C : \mathbf{1} = 3\}$$

$$\mathcal{R}(F) = \mathbf{R}FF^\top$$

6. *Constraint that preserves area in a plane of normal* $\mathbf{n}$ ($\mathbf{n}$ a unit vector)

$$\mathcal{M} = \{F \in Lin^+ \mid F^*(\mathbf{n}) \cdot F^*(\mathbf{n}) = 1\}$$

   where $F^* = detF\, F^{-\top}$.

$$\mathcal{C} = \{C \in Psym \mid detC\, C^{-1} : \mathbf{n} \otimes \mathbf{n} = 1\}$$

$$\mathcal{R}(F) = \mathbf{R}(\mathbf{1} - F^*(\mathbf{n}) \otimes F^*(\mathbf{n}))$$

Lemma 14 *Let $\mathcal{H} = \{H \in Sym \mid H : A = a\}$ ($A \neq 0$ a fixed element of Sym) and $\zeta : Psym \to Psym$ a difeomorfism such that $\zeta(\mathbf{1}) \in \mathcal{H}$, and $\mathcal{C} = \zeta^{-1}(\mathcal{H} \cap Psym)$. Then*

$$\mathcal{R}(F) = \mathbf{R}F\zeta^\top_{*C}(A)F^\top$$

Proof. Since $\zeta(\mathcal{C}) = \mathcal{H} \cap Psym$ and ζ is a difeomorfism then

$$\zeta_{*C}(\dot{\mathcal{C}}_C) = (\dot{\mathcal{H} \cap Psym})_{\zeta(C)} = \dot{\mathcal{H}}_{\zeta(C)}$$

so that for H in $\dot{\mathcal{C}}_C$ we have $\zeta_{*C}(H) : A = 0$, that is, $H : \zeta^\top_{*C}(A) = 0$.This shows that $\zeta^\top_{*C}(A)$ is in $\dot{\mathcal{C}}^{\perp\bullet}$.Since $dim\mathcal{C} = dim\mathcal{H} = 5$, then $\dot{\mathcal{C}}^{\perp\bullet} = \mathbf{R}\zeta^\top_{*C}(A)$, and the proof follows now from Proposition 12.

Using this Lemma with ζ the identity map we obtain at once $\mathcal{R}(F)$ in the Examples 4 and 5 above. As to Example 6, where $\zeta(C) = detC\, C^{-1}$, a straightforward calculation gives

$$\zeta^\top_{*C}(\mathbf{n} \otimes \mathbf{n}) = C^{-1} - detC\, C^{-1}(\mathbf{n}) \otimes C^{-1}(\mathbf{n})$$

and $\mathcal{R}(F)$ follows from Lemma 14.

Theorem 15 *Let $\mathcal{M}$ be a constraint manifold such that $\mathcal{R}(F)$ is independent of F. Then $\mathcal{M}$ must be one of the following: a conformality constraint, the rigidity constraint, an open submanifold of Unim, an open submanifold of Lin^+.*

Proof. Put $\varphi(\mathcal{M}) = \mathcal{C}$. Since $\mathcal{R}(F)$ is independent of F, and on account of Proposition 12, we have

$$F\dot{\mathcal{C}}^{\perp\bullet}_{F^\top F}F^\top = \dot{\mathcal{C}}^{\perp\bullet}_{\mathbf{1}}$$

for every F in $\mathcal{M}$, so that, by Lemma 10 (ii) we have

$$F^{-\top}\dot{\mathcal{C}}_{F^\top F}F^{-1} = \dot{\mathcal{C}}_{\mathbf{1}} \tag{6}$$

for every F in $\mathcal{M}$.

Since $Rot \subset \mathcal{M}$ it follows that for every R in Rot we have

$$R\dot{\mathcal{C}}_{\mathbf{1}}R^\top = \dot{\mathcal{C}}_{\mathbf{1}} \tag{7}$$

so that according to Proposition 6 we are left with four possibilities for $\dot{\mathcal{C}}_1$, namely, Sph, Dev, 0, and Sym.

On the other hand, if C is in $\mathcal{C}$, choose F in $\mathcal{M}$ such that $\varphi(F) = C$. Then there is R in Rot such that the right polar decomposition of F is $F = RC^{\frac{1}{2}}$. Substituing in (6) we will obtain

$$\dot{\mathcal{C}}_C = C^{\frac{1}{2}} R^\top \dot{\mathcal{C}}_1 R C^{\frac{1}{2}} = C^{\frac{1}{2}} \dot{\mathcal{C}}_1 C^{\frac{1}{2}} \tag{8}$$

where use has been made of (7).

1. If $\dot{\mathcal{C}}_1 = Sph$ then by (8) we have $\dot{\mathcal{C}}_C = \mathbf{R}C$ It is not difficult to verify that in this case $\mathcal{C}$ is of the form $\mathcal{C} =]\gamma, \delta[\mathbf{1}$ with $0 \le \gamma < 1 < \delta \le +\infty$,so that $\mathcal{M} = \varphi^{-1}(\mathcal{C}) =]\gamma^{\frac{1}{2}}, \delta^{\frac{1}{2}}[Rot$, a conformality constraint.

2. Suppose $\dot{\mathcal{C}}_1 = Dev$. We claim that in this case $\mathcal{C}$ is contained in $Unim$. In effect, let C be in $\mathcal{C}$, and choose a differentiable curve in $\mathcal{C}$ such that $\alpha(0) = 1$ and $\alpha(1) = C$.Then

   $$\dot{\alpha}(t) \in \dot{\mathcal{C}}_{\alpha(t)} = \alpha(t)^{\frac{1}{2}}\, Dev\, \alpha(t)^{\frac{1}{2}}$$

   where use has been made of (8). Hence

   $$tr(\alpha(t)^{-\frac{1}{2}} \dot{\alpha}(t) \alpha(t)^{-\frac{1}{2}} = 0$$

   or

   $$tr(\alpha(t)^{-1} \dot{\alpha}(t)) = 0$$

   for every t in [0,1], which shows that the curve $t \mapsto \alpha(t)^{-1}\dot{\alpha}(t)$ is a curve in the Lie algebra of $Unim$. Therefore the product integration (Dollard and Friedman. 1987) of this curve is an element belonging to $Unim$, given by $\alpha(0)^{-1}\alpha(1)$, which is precisely C.

   By the above we have that $\mathcal{C}$ is contained in $Unim \cap Psym$. Since the dimensions of $\mathcal{C}$ and of $Unim \cap Psym$ are both equal to 5, $\mathcal{C}$ is an open submanifold of $Unim \cap Psym$, which in turn is equal to $\varphi(Unim)$. Hence $\mathcal{M} = \varphi^{-1}(\mathcal{C})$ is an open submanifold of $Unim$.

3. If $\dot{\mathcal{C}}_1 = \mathbf{0}$ then $\mathcal{C} = \{\mathbf{1}\}$ so that $\mathcal{M} = Rot$.

4. If $\dot{\mathcal{C}}_1 = Sym$, then $\mathcal{C}$ is an open submanifold of $Psym$, so $\mathcal{M} = \varphi^{-1}(\mathcal{C})$ is clearly an open submanifold of Lin^+.

A general FEM formulation of nonlinear dynamics applied to accessing the statical loading effect upon the dynamic response of planar frames

Reyolando M L R F Brasil and Carlos E N Mazzilli

Department of Structural and Foundation Engineering, Escola Politécnica
Universidade de São Paulo, CP 61548, 05424-970 São Paulo, SP, Brazil

This paper initially discusses the dynamics of discrete structural systems of geometricaly nonlinear behaviour costituted by linear elastic materials. Two formulations are derived, namely *global* and *incremental*. They are both suitable to general FE modelling, as the matrix equations of motion are written in explicit form. Matrices and vectors involved are characterized in terms of constraint equations defined within the continuum discretization. In principle, such formulations are applicable to any structural theory, as the theories of beams, plates and shells. As an example, the Bernoulli-Euler beam element is studied herewith. Both global and incremental formulations capture the effect geometrical nonlinearities have upon inertial and elastic forces alike. The ANDROS FEM program, developed by the authors, which is based upon the global formulation, has been successfully used in several nonlinear analyses. From this general background, the paper proceeds to consider the effect statical loading may have upon the free undamped vibration frequencies of a structure. It is shown that the tangent stiffness matrix of the incremental formulation should be used in the resultant eingenvalue problem. In some cases, axial forces are seen to have a strong influence on the internal resonance tuning. It is shown, in a sample structure thus tuned and subjected to dynamical loading, that a nonlinear regime may appear in the response.

A GENERAL FEM FORMULATION

Discrete structural systems of geometrically nonlinear behaviour constituted by linear elastic material are initially considered. The equations of motion in explicit form are investigated, retaining nonlinearities both in the elastic and in the inertial forces. The foregoing formulation is based on Mazzilli (1988) and is already in adequate form for application to the finite-element method, thus allowing the analysis of large engineering systems. The secant matrices of mass, equivalent damping – there included the inertial damping – and stiffness, as well as the equivalent load vector, are characterized within the global equations of motion. Alternatively, the tangent matrices of mass, damping and stiffness, and the incremental equivalent load vector are deduced within the incremental equations of motion. These latter may be eventually used for consideration of elastoplastic behaviour, interpreting it as hypoelasticity in each time increment. The formulation is able to tackle conservative and non-conservative applied loads, as well as translation and rotation support excitations.

As the starting point, the generalized Lagrange's equations are recast. For a system with n degrees of freedom $Q_1, Q_2, \dots, Q_n$, they are:

$$\frac{d}{dt}\left[\frac{\partial \mathcal{L}}{\partial \dot{Q}_r}\right] - \left[\frac{\partial \mathcal{L}}{\partial Q_r}\right] = N^r, \quad r = 1\,to\,n$$

the Lagrangian function $\mathcal{L}$ being given by the difference between the kinetic energy T and the total potential energy V. The generalized forces N^r retain the effects of the nonconservative forces. One can also define $\mathcal{L}$ as the difference between the kinetic energy and the strain energy U, so that N^r would then also include the effects of applied conservative forces. Holonomic constraints are assumed, so that the position vector of a generic volume element $d\Omega$ of the deformable system is supposed to be a known function of the generalized coordinates and the time:

$$\vec{R} = \vec{R}(Q_1, Q_2, \dots, Q_n, t)$$

If these functions are all linear in the generalized coordinates, geometrical nonlinearities will be lost. Therefore,

part of "MECHANICS PAN-AMERICA 1993" edited by MRM Crespo da Silva and CEN Mazzilli
Appl Mech Rev vol 46, no 11, part 2, November 1993

ASME Reprint No AMR134

extreme caution should be taken when the finite-element technique is introduced into the formulation. The usual hypothesis that the displacement field within a finite element is given by a linear combination of nodal displacements may be inadequate for the nonlinear analysis. Hence, at the Solid Mechanics level it is necessary that the underlying structural theory be consistently nonlinear and further that at the structural discretization level, via the finite-element technique, nonlinearities are not subtly lost within the matrix equations of motion.

The kinetic energy is:

$$T = \frac{1}{2}\int_{\Omega} \dot{\vec{R}} \cdot \dot{\vec{R}} \rho d\Omega$$

where Ω is the region occupied by the undeformed system and ρ the specific mass. The velocity vector is:

$$\dot{\vec{R}} = \frac{\partial \vec{R}}{\partial Q_r}\dot{Q}_r + \frac{\partial \vec{R}}{\partial t}$$

and consequently:

$$T = \frac{1}{2}A^{rs}\dot{Q}_r\dot{Q}_s + B^r\dot{Q}_r + \frac{1}{2}C$$

with:

$$A^{rs} = \int_{\Omega} \frac{\partial \vec{R}}{\partial Q_r} \cdot \frac{\partial \vec{R}}{\partial Q_s} \rho d\Omega;$$

$$B^{r} = \int_{\Omega} \frac{\partial \vec{R}}{\partial Q_r} \cdot \frac{\partial \vec{R}}{\partial t} \rho d\Omega;$$

$$C = \int_{\Omega} \frac{\partial \vec{R}}{\partial t} \cdot \frac{\partial \vec{R}}{\partial t} \rho d\Omega$$

Recasting Lagrange's equations, one gets:

$$\begin{aligned} A^{rs}\ddot{Q}_s + \left[\frac{\partial A^{rs}}{\partial Q_t} - \frac{1}{2}\frac{\partial A^{st}}{\partial Q_r}\right]\dot{Q}_s\dot{Q}_t \quad &+ \quad \frac{\partial A^{rs}}{\partial t}\dot{Q}_s + \\ \left[\frac{\partial B^r}{\partial Q_s} - \frac{\partial B^s}{\partial Q_r}\right]\dot{Q}_s \frac{\partial B^r}{\partial t} - \frac{1}{2}\frac{\partial C}{\partial Q_r} \quad &= \quad -\frac{\partial U}{\partial Q_r} + N^r \end{aligned}$$

A special though still rather general class of holonomic constraints is now considered. It is supposed that there exists a reference frame $Yy^1y^2y^3$, called "relative", with respect to which the system constraints are scleronomic. Support excitations are defined by rigid-body motion of the relative frame $Yy^1y^2y^3$ with respect to an inertial frame $Xx^1x^2x^3$. Calling $\vec{R}$ the position vector in the inertial frame, $\vec{r}$ the position vector in the relative frame and $\vec{S}$ the vector (Y-X), one writes:

$$\vec{R} = \vec{r} + \vec{S}; \quad \vec{S} = S^i\vec{e}_i; \quad \vec{r} = a^i_j y^j \vec{e}_i$$

where the matrix $[a^i_j]$ defines the relative frame rotation with respect to the inertial frame. It can be explicitly given in terms of the Euler angles (Mazzilli, 1988). For a planar problem, the matrix $[a^i_j]$ can be written in terms of the support rotation $\phi(t)$:

$$[a^i_j] = \begin{bmatrix} \cos\phi & -\sin\phi \\ \sin\phi & \cos\phi \end{bmatrix}$$

It was already observed that it is a feature of nonlinear structural theories to render nonlinear functions for the coordinates y^j in the variables $Q_1, Q_2, ..., Q_n$. Additionally, support excitations are defined by rotations through the matrix $[a^i_j(t)]$ or by translations through $S^i(t)$. Hence:

$$\vec{R} = [a^i_j(t)y^j(Q_1, Q_2, ..., Q_n) + S^i(t)]\vec{e}_i$$

Back into expressions for A^{rs}, B^r e C, and taking these into Lagrange's equations, one arrives at:

$$\begin{aligned} F^{rsjm}\delta_{jm}\ddot{Q}_s \quad &+ \\ \left(F^{rsjm}_{,t} - \frac{1}{2}F^{stjm}_{,r}\right)\delta_{jm}\dot{Q}_s\dot{Q}_t \quad &+ \\ (F^{rsjm} - F^{srjm})a^i_j\dot{a}^k_m\delta_{ik}\dot{Q}_s \quad &+ \\ H^{rj}a^i_j\ddot{S}^k\delta_{ik} \quad &+ \\ G^{rjm}a^i_j\ddot{a}^k_m\delta_{ik} \quad &= \quad -U_{,r} + N^r \end{aligned}$$

Notation $(.)_{,r}$ indicates partial differentiation with respect to Q_r, δ_{jm} being the Kronecker's symbol and:

$$\begin{aligned} F^{rsjm} \quad &= \quad \int_{\Omega} \frac{\partial y^j}{\partial Q_r}\frac{\partial y^m}{\partial Q_s}\rho d\Omega; \\ G^{rjm} \quad &= \quad \int_{\Omega} \frac{\partial y^j}{\partial Q_r} y^m \rho d\Omega; \\ H^{rj} \quad &= \quad \int_{\Omega} \frac{\partial y^j}{\partial Q_r}\rho d\Omega \end{aligned}$$

All terms dependent of F^{rsjm}, G^{rjm} e H^{rj} in the above equations of motion are inertial forces, there included the Coriolis forces:

$$(F^{rsjm} - F^{srjm})a^i_j\dot{a}^k_m\delta_{ik}\dot{Q}_s$$

and the centrifugal forces:

$$G^{rjm}a^i_j\ddot{a}^k_m\delta_{ik}$$

Since F^{rsjm}, G^{rjm} e H^{rj} may be functions of the generalized coordinates, it is clear that geometrical nonlinearities can in fact generate nonlinear inertial forces. The elastic force vector $U_{,r}$, on its turn, may also include nonlinear terms caused by geometrical nonlinearities, as it is well known even in Statics. It is supposed that the generalized force vector always include viscous damping:

$$N^r = P^r - \mu^{rs}\dot{Q}_s$$

The global nonlinear equations of motion can now be written in the compact form:

$$M^{rs}\ddot{Q}_s + D^{rs}\dot{Q}_s + U_{,r} = \mathcal{F}^r$$

where:

$$M^{rs} = F^{rsjm}\delta_{jm}$$

$$\begin{aligned} D^{rs} &= \mu^{rs} + (F^{rsjm} - F^{srjm})a^i_j \dot{a}^k_m \delta_{ik} \\ &+ \left(F^{rsjm}_{,t} - \frac{1}{2}F^{stjm}_{,r}\right)\delta_{jm}\dot{Q}_t \end{aligned}$$

$$\mathcal{F}^r = P^r - G^{rjm}a^i_j \ddot{a}^k_m \delta_{ik} - H^{rj}a^i_j \ddot{S}^k \delta_{ik}$$

It should be observed that the introduction of the stiffness matrix in the global equation of motion is, in some ways, arbitrary. In fact, what naturally appears there is the elastic force vector $U_{,r}$. Obviously, one could think of the secant stiffness matrix K^{rs}_S, as:

$$U_{,r} = K^{rs}_S Q_s$$

Nevertheless, several other matrices could be thought of, as the linear theory stiffness matrix, for example. Once a particular stiffness matrix K^{rs} has been chosen, one can add to both sides of the global equation of motion the term $K^{rs}Q_s$. Introducing now the definition:

$$\Delta\mathcal{F}^r = K^{rs}Q_s - U_{,r}$$

one finally gets for the global equations of motion:

$$M^{rs}\ddot{Q}_s + D^{rs}\dot{Q}_s + K^{rs}Q_s = \mathcal{F}^r + \Delta\mathcal{F}^r$$

In other words, the arbitrary choice of the stiffness matrix implies in adding to the load vector $\mathcal{F}^r$ a correcting term. It should be observed that, even in Statics, the global equilibrium equation:

$$U_{,r} = P^r$$

can well be written in the form:

$$K^{rs}Q_s = P^r + \Delta\mathcal{F}^r$$

and, in numerical nonlinear analysis, this latter suggests an iterative procedure equivalent to that of the modified Newton-Raphson method. In fact, choosing a particular matrix K^{rs} and supposing in the first iteration that $\Delta\mathcal{F}^r = 0$, one can obtain Q_s from the equilibrium equation. The new value for $\Delta\mathcal{F}^r$ would then come after its definition and so forth.

In a great number of cases it may be more convenient to work with the incremental equations of motion:

$$M^{rs}_T\delta\ddot{Q}_s + D^{rs}_T \quad \ldots \quad {}_s = \delta\mathcal{P}^r$$

where:

$$M^{rs}_T = M^{rs}$$

$$\begin{aligned} D^{rs}_T &= \mu^{rs} + (F^{rsjm} - F^{srjm})a^i_j \dot{a}^k_m \delta_{ik} \\ &+ (F^{rsjm}_{,t} + F^{rtjm}_{,s} - F^{stjm}_{,r})\delta_{jm}\dot{Q}_t \end{aligned}$$

$$\begin{aligned} K^{rs}_T &= U_{,rs} + G^{rjm}_{,s}a^i_j \ddot{a}^k_m \delta_{ik} + H^{rj}_{,s}a^i_j \ddot{S}^k \delta_{ik} \\ &+ F^{rtjm}_{,s}\delta_{jm}\ddot{Q}_t + \left(F^{rujm}_{,st} - \frac{1}{2}F^{utjm}_{,rs}\right)\delta_{jm}\dot{Q}_u\dot{Q}_t \\ &+ (F^{rtjm}_{,s} - F^{trjm}_{,s})a^i_j \dot{a}^k_m \delta_{ik}\dot{Q}_t + \mu^{rt}_{,s}\dot{Q}_t \end{aligned}$$

$$\begin{aligned} \delta\mathcal{P}^r &= \delta P^r - G^{rjm}(\delta a^i_j \ddot{a}^k_m + a^i_j \delta\ddot{a}^k_m)\delta_{ik} \\ &- H^{rj}(\delta a^i_j \ddot{S}^k + a^i_j \delta\ddot{S}^k)\delta_{ik} \\ &- (F^{rsjm} - F^{srjm})(\delta a^i_j \dot{a}^k_m + a^i_j \delta\dot{a}^k_m)\delta_{ik} \end{aligned}$$

A PLANAR STRUT FINITE ELEMENT

As an application example of the previous section general formulation, we consider now the 2-D strut finite element according to the Bernoulli-Euler theory (Mazzilli, 1990). From Figs 1a and 1b the following relations can be derived for the displacements u (local system $\bar{y}^1$ direction) and v (local system $\bar{y}^2$ direction) of the elemental mass dm situated in a cross section defined by the strut axis coordinate x and at a distance y from the cross section centroid:

$$\begin{aligned} u &= \bar{u} - y\sin\alpha \\ v &= \bar{v} + y(\cos\alpha - 1) \end{aligned}$$

where $\bar{u}$ and $\bar{v}$ are the u and v displacements of a material point on the strut axis and α is the cross-section rotation, for which rigorously:

$$\begin{aligned} \sin\alpha &= \frac{\bar{v}'}{\bar{\lambda}} \\ \cos\alpha &= \frac{1+\bar{u}'}{\bar{\lambda}} \\ \tan\alpha &= \frac{\bar{v}'}{1+\bar{u}'} \end{aligned}$$

Notation $(.)'$ denotes differentiation with respect to **x**. The axis stretching is:

$$\bar{\lambda} = \sqrt{(1+\bar{u}')^2 + (\bar{v}')^2}$$

Observe that the "local system" $Y\bar{y}^1\bar{y}^2$ is defined by a rotation θ, independent of time, with respect to the relative frame Yy^1y^2. In what follows here, the elemental

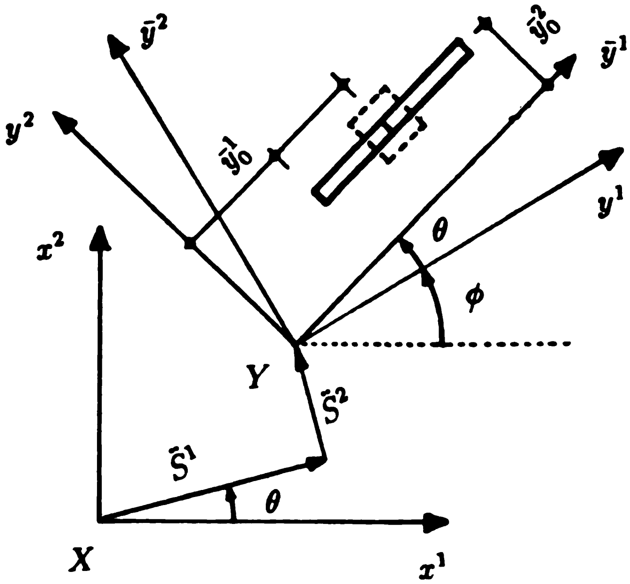

Fig 1a

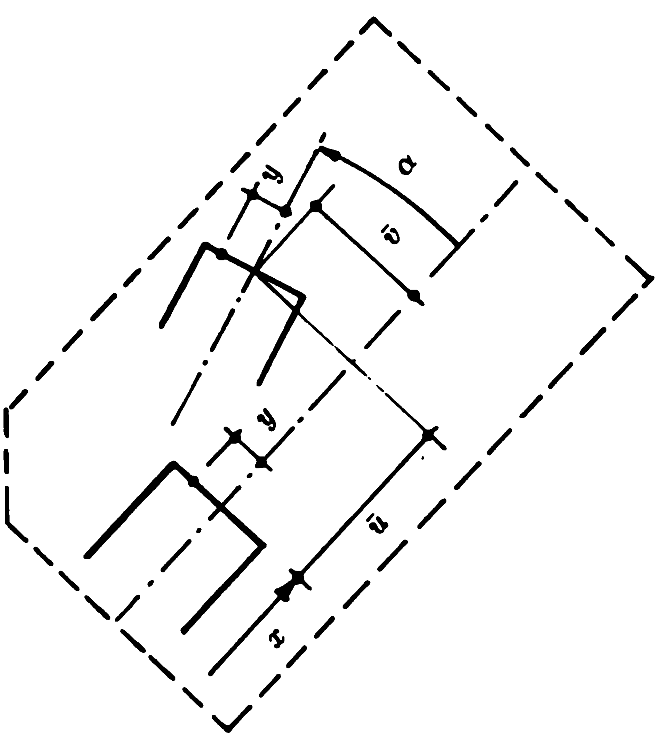

Fig 1b

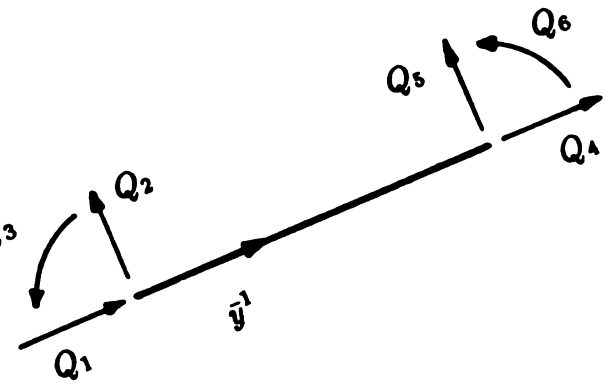

Fig 2

matrices and vectors will be defined for the local system. The constraint equations will then be:

$$
\begin{aligned}
\bar{y}^1 &= \bar{y}_0^1 + x + \bar{u} - y \sin\alpha \\
\bar{y}^2 &= \bar{y}_0^2 + \bar{v} + y \cos\alpha
\end{aligned}
$$

The following approximations will be assumed from now on:

$$\sin\alpha \approx \alpha \approx \tan\alpha \approx \bar{v}'$$

$$\cos\alpha \approx 1 - \frac{1}{2}(\bar{v}')^2$$

The Bernoulli-Euler strut does not allow for shear strain and the longitudinal strain ϵ can be defined as:

$$\epsilon = \bar{\epsilon} - y\alpha' \approx \bar{\epsilon} - y\bar{v}''$$

$$\bar{\epsilon} = \bar{\lambda} - 1 \approx \bar{u}' + \frac{1}{2}(\bar{v}')^2$$

To formulate the finite element it is necessary to introduce the discretization, that is, the displacement field within the element should be defined in terms of the nodal displacements, interpreted as generalized coordinates (Q_1 to Q_6) and indicated in Fig 2.

As in the standard applications of the finite-element method, one can think of stating that the transversal displacements $\bar{v}$ result from a **linear combination** of the nodal displacements:

$$\bar{v} = Q_i \Psi_i \text{ , } sum\ from\ 1\ to\ 6,\ where:$$

$$\Psi_1(x) = \Psi_4 = 0$$

$$\Psi_2(x) = 1 - 3\frac{x^2}{\ell^2} + 2\frac{x^3}{\ell^3}$$

$$\Psi_3(x) = x - 2\frac{x^2}{\ell} + \frac{x^3}{\ell^2}$$

$$\Psi_5(x) = 3\frac{x^2}{\ell^2} - 2\frac{x^3}{\ell^3}$$

$$\Psi_6(x) = -\frac{x^2}{\ell} + \frac{x^3}{\ell^2}$$

Nevertheless, if the longitudinal displacements $\bar{u}$ are also supposed to result from a **linear combination** of the nodal displacements, important geometrical nonlinearities will be lost. Instead, we shall follow here the simple hypothesis proposed by Souza Lima and Venancio Filho (1982) for Statics, that is, the **constancy** of normal forces N inside the element. It is interesting to remark that an equivalent hypothesis was recently proposed by Salami and Morley (1992), still in Statics.

$$\begin{aligned} N &= \frac{EA}{\ell}\int_0^\ell \bar{\epsilon}dx \\ &= \frac{EA}{\ell}\left[\bar{u}(\ell)-\bar{u}(0)+\frac{1}{2}\int_0^\ell(\bar{v}')^2dx\right] \\ &= \frac{EA}{\ell}\left[Q_4-Q_1+\frac{1}{2}\alpha_{ij}(\ell)Q_iQ_j\right] \end{aligned}$$

where EA is the axial stiffness and:

$$\alpha_{ij}(x)=\int_0^x \Psi_i'(z)\Psi_j'(z)dz$$

Therefore:

$$\bar{u}'=\frac{1}{\ell}(Q_4-Q_1)+\frac{1}{2\ell}Q_iQ_j\alpha_{ij}(\ell)-\frac{1}{2}Q_iQ_j\Psi_i'\Psi_j'$$

and, after integration in $\mathbf{x}$:

$$\bar{u}=Q_1+\left[\frac{1}{\ell}(Q_4-Q_1)+\frac{1}{2\ell}Q_iQ_j\alpha_{ij}(\ell)\right]x-\frac{1}{2}Q_iQ_j\alpha_{ij}(x)$$

or:

$$\bar{u}=Q_1\left(1-\frac{x}{\ell}\right)+Q_4\left(\frac{x}{\ell}\right)+\frac{1}{2}Q_iQ_j\left[\frac{x}{\ell}\alpha_{ij}(\ell)-\alpha_{ij}(x)\right]$$

It should be noted that the field of longitudinal displacements $\bar{u}$ has not resulted a linear function of the generalized coordinates!

The constraint equations can now be written in compact form as:

$$\bar{y}^j=\gamma^j(x,Q_1,Q_2,...,Q_6)+y\delta^j(x,Q_1,Q_2,...,Q_6)$$

where:

$$\gamma^1=\bar{y}_0^1+x+Q_i\Phi_i(x)+\frac{1}{2}Q_iQ_j\beta_{ij}(x)$$

$$\delta^1=-Q_i\Psi_i'$$

$$\gamma^2=\bar{y}_0^2+Q_i\Psi_i$$

$$\delta^2=1-\frac{1}{2}Q_iQ_j\Psi_i'\Psi_j'$$

In the above equations, $\Phi_i(x)$, $i=1,2,...,6$, are the standard interpolation functions of the linear analysis:

$$\Phi_1(x) \cdot$$

$$\Phi$$

$$\Phi_2(x)=\Phi_3(x)=\Phi_5(x)=\Phi_6(x)=0$$

and

$$\beta_{ij}(x)=\left[\frac{x}{\ell}\alpha_{ij}(\ell)-\alpha_{ij}(x)\right]$$

One is now ready to write in explicit form the elemental matrices and vectors used in the **global equations of motion**. In the local system, they are written as:

$$\bar{M}^{rs}=\rho A\int_0^\ell(\gamma^1_{,r}\gamma^1_{,s}+\gamma^2_{,r}\gamma^2_{,s})dx+\rho I\int_0^\ell(\delta^1_{,r}\delta^1_{,s}+\delta^2_{,r}\delta^2_{,s})dx$$

$$\begin{aligned} \bar{D}^{rs} &= \mu^{rs}-2\dot{\phi}\left[\rho A\int_0^\ell(\gamma^1_{,r}\gamma^2_{,s}-\gamma^1_{,s}\gamma^2_{,r})dx\right] \\ &+ \dot{Q}_i\rho A\int_0^\ell\left(\frac{1}{2}\gamma^1_{,ri}\gamma^1_{,s}+\gamma^1_{,r}\gamma^1_{,si}-\frac{1}{2}\gamma^1_{,sr}\gamma^1_{,i}\right)dx \\ &+ \dot{Q}_i\rho I\int_0^\ell\delta^2_{,si}\delta^2_{,r}dx \end{aligned}$$

$$\begin{aligned} \bar{U}_{,r} &= \frac{EA}{\ell}\left[\ell Q_i\Phi_i'+\frac{1}{2}\alpha_{ij}(\ell)Q_iQ_j\right][\ell\Phi_r'+Q_k\alpha_{kr}(\ell)] \\ &+ EIQ_i\int_0^\ell\Psi_i''(x)\Psi_r''(x)dx \end{aligned}$$

$$\begin{aligned} \bar{\mathcal{F}}^r &= \bar{K}^{rs}Q_s-\bar{U}_{,r}+\bar{P}^r \\ &+ \dot{\phi}^2\rho A\int_0^\ell(\gamma^1_{,r}\gamma^1+\gamma^2_{,r}\gamma^2)dx \\ &+ \dot{\phi}^2\rho I\int_0^\ell(\delta^1_{,r}\delta^1+\delta^2_{,r}\delta^2)dx \\ &+ \ddot{\phi}\rho A\int_0^\ell(\gamma^1_{,r}\gamma^2-\gamma^2_{,r}\gamma^1)dx \\ &+ \ddot{\phi}\rho I\int_0^\ell(\delta^1_{,r}\delta^2-\delta^2_{,r}\delta^1)dx \\ &- \rho A\ddot{S}^1\left[\cos\phi\int_0^\ell\gamma^1_{,r}dx+\sin\phi\int_0^\ell\gamma^2_{,r}dx\right] \\ &- \rho A\ddot{S}^2\left[-\sin\phi\int_0^\ell\gamma^1_{,r}dx+\cos\phi\int_0^\ell\gamma^2_{,r}dx\right] \end{aligned}$$

In the above equations $\phi(t)$ stands for the support rotation characterized by the imposed angle between the relative Yy^1 axis and the inertial Xx^1 axis.

The matrices and vectors of the **incremental formulation** are now explicitly written for the local system:

$$\bar{M}_T^{rs}=\rho A\int_0^\ell(\gamma^1_{,r}\gamma^1_{,s}+\gamma^2_{,r}\gamma^2_{,s})dx+\rho I\int_0^\ell(\delta^1_{,r}\delta^1_{,s}+\delta^2_{,r}\delta^2_{,s})dx$$

$$\begin{aligned} \bar{D}_T^{rs} &= \mu^{rs}-2\dot{\phi}\left[\rho A\int_0^\ell(\gamma^1_{,r}\gamma^2_{,s}-\gamma^1_{,s}\gamma^2_{,r})dx\right] \\ &+ 2\left[\rho A\int_0^\ell\gamma^1_{,r}\gamma^1_{,si}dx+\rho I\int_0^\ell\delta^2_{,r}\delta^2_{,si}dx\right]\dot{Q}_i \end{aligned}$$

$$
\begin{aligned}
\bar{U}_{,rs} &= \frac{EA}{\ell}[\ell\Phi'_s + \alpha_{is}(\ell)Q_i][\ell\Phi'_r + Q_j\alpha_{jr}(\ell)] \\
&+ \frac{EA}{\ell}\left[\ell Q_i\Phi'_i + \frac{1}{2}\alpha_{ij}Q_iQ_j\right]\alpha_{rs} \\
&+ EI\int_0^\ell \Psi''_r(x)\Psi''_s(x)dx
\end{aligned}
$$

$$
\begin{aligned}
\bar{K}_T^{rs} &= \bar{U}_{,rs} + \mu^{ri}_{,s}\dot{Q}_i \\
&- \dot{\phi}^2\rho A\int_0^\ell(\gamma^1_{,rs}\gamma^1 + \gamma^1_{,r}\gamma^1_{,s} + \gamma^2_{,r}\gamma^2_{,s})dx \\
&+ \dot{\phi}^2\rho I\int_0^\ell(\delta^1_{,r}\delta^1_{,s} + \delta^2_{,rs}\delta^2 + \delta^2_{,r}\delta^2_{,s})dx \\
&- \ddot{\phi}\rho A\int_0^\ell(\gamma^1_{,rs}\gamma^2 + \gamma^1_{,r}\gamma^2_{,s} - \gamma^2_{,r}\gamma^1_{,s})dx \\
&+ \ddot{\phi}\rho I\int_0^\ell(\delta^1_{,r}\delta^2_{,s} - \delta^2_{,rs}\delta^1 - \delta^2_{,r}\delta^1_{,s})dx \\
&+ \rho A\ddot{S}^1\left[\cos\phi\int_0^\ell\gamma^1_{,rs}dx + \sin\phi\int_0^\ell\gamma^2_{,rs}dx\right] \\
&+ \rho A\ddot{S}^2\left[-\sin\phi\int_0^\ell\gamma^1_{,rs}dx + \cos\phi\int_0^\ell\gamma^2_{,rs}dx\right] \\
&+ \ddot{Q}_i\rho A\int_0^\ell(\gamma^1_{,rs}\gamma^1_{,i} + \gamma^1_{,r}\gamma^1_{,si})dx \\
&+ \ddot{Q}_i\rho I\int_0^\ell(\delta^2_{,rs}\delta^2_{,i} + \delta^2_{,r}\delta^2_{,si})dx \\
&+ \left[\rho A\int_0^\ell\gamma^1_{,rs}\gamma^1_{,ij}dx + \rho I\int_0^\ell\delta^2_{,rs}\delta^2_{,ij}dx\right]\dot{Q}_i\dot{Q}_j \\
&- 2\dot{\phi}\left[\rho A\int_0^\ell(\gamma^1_{,rs}\gamma^2_{,i} - \gamma^1_{,is}\gamma^2_{,r})dx\right]\dot{Q}_i
\end{aligned}
$$

$$
\begin{aligned}
\delta\bar{P}^r &= \delta\bar{P}^r \\
&+ 2\dot{\phi}\rho A\left[\int_0^\ell(\gamma^1_{,r}\gamma^1 + \gamma^2_{,r}\gamma^2)dx\right]\delta\dot{\phi} \\
&+ 2\dot{\phi}\rho I\left[\int_0^\ell(\delta^1_{,r}\delta^1 + \delta^2_{,r}\delta^2)dx\right]\delta\dot{\phi} \\
&+ 2\rho A\left[\int_0^\ell(\gamma^1_{,r}\gamma^2_{,s} - \gamma^1_{,s}\gamma^2_{,r})dx\right]\delta\dot{\phi} \\
&+ 2\rho\left[I\int_0^\ell(\delta^1_{,r}\delta^2_{,s} - \delta^1_{,s}\delta^2_{,r})dx\right]\delta\dot{\phi} \\
&+ \rho A\left[\int_0^\ell(\gamma^1_{,r}\gamma^2 - \gamma^2_{,r}\gamma^1)dx\right]\delta\ddot{\phi} \\
&+ \rho I\left[\int_0^\ell(\delta^1_{,r}\delta^2 - \delta^2_{,r}\delta^1)dx\right[\delta\ddot{\phi} \\
&- \rho A\ddot{S}^1\left[-\sin\phi\int_0^\ell\gamma^1_{,r}dx + \cos\phi\int_0^\ell\gamma^2_{,r}dx\right]\delta\phi \\
&- \rho A\ddot{S}^2\left[-\cos\phi\int_0^\ell\gamma^1_{,r}dx - \sin\phi\int_0^\ell\gamma^2_{,r}dx\right]\delta\phi \\
&- \rho A\left[-\sin\phi\int_0^\ell\gamma^1_{,r}dx + \cos\phi\int_0^\ell\gamma^2_{,r}dx\right]\delta\ddot{S}^2 \\
&- \rho A\left[-\cos\phi\int_0^\ell\gamma^1_{,r}dx - \sin\phi\int_0^\ell\gamma^2_{,r}dx\right]\delta\ddot{S}^1
\end{aligned}
$$

Note that all matrices and vectors of both the global and the incremental equations of motion can be explicitly given in terms of the generalized coordinates, by considering the expressions for γ^1, γ^2, δ^1 and δ^2 previously written and the derivatives:

$$
\begin{aligned}
\gamma^1_{,r} &= \Phi_r + Q_i\beta_{ir} & \gamma^1_{,rs} &= \beta_{rs} \\
\gamma^2_{,r} &= \Psi_r & \gamma_{,rs} &= 0 \\
\delta^1_{,r} &= -\Psi'_r & \delta^1_{,rs} &= 0 \\
\delta^2_{,r} &= -Q_i\Psi'_i\Psi'_r & \delta^2_{,rs} &= -\Psi'_r\Psi'_s
\end{aligned}
$$

The authors implemented at the Computational Mechanics Laboratory of Escola Politécnica da Universidade de São Paulo, the ANDROS system of FEM programs to perform nonlinear dynamical analysis of structures, based upon the global formulation (Mazzilli and Brasil, 1992). It has been successfully used in several nonlinear analyses reported in a number of papers (Brasil and Mazzilli, 1991), (Brasil and Mazzilli, 1992).

INFLUENCE OF AXIAL FORCES ON UNDAMPED VIBRATION FREQUENCIES OF PLANAR FRAMED STRUCTURES

If a considerable level of static load is applied to planar framed structures, resulting in high axial forces in some members, their natural frequencies of undamped free vibration may change considerably. The undamped equation of motion for those (small) vibrations about the deformed configuration is:

$$
m_T^{rs}\,\delta\ddot{q}_s + k_T^{rs}\,\delta q_s = 0
$$

where k_T^{rs} stands for the coefficients of the tangent stiffness matrix for that level of static loading. The coefficients of the tangent mass matriz m_T^{rs} are those of m^{rs} and can usually be made equal to those of the linear theory mass matrix. These are the two matrices one should use in the eigenvalue problem solution to find the natural frequencies of free undamped vibrations for the statically loaded deformed structure.

One of the programs included in the ANDROS system performs a static nonlinear analysis of planar framed structures, via the Modified Newton-Raphson algorithm, to obtain the tangent stiffness matrix at a certain level of loading. The system also features a standard eigenvalues routine, based on Holseholder-QL algorithm, to give the frequencies of undamped free vibrations about the statically loaded deformed configuration of the structure.

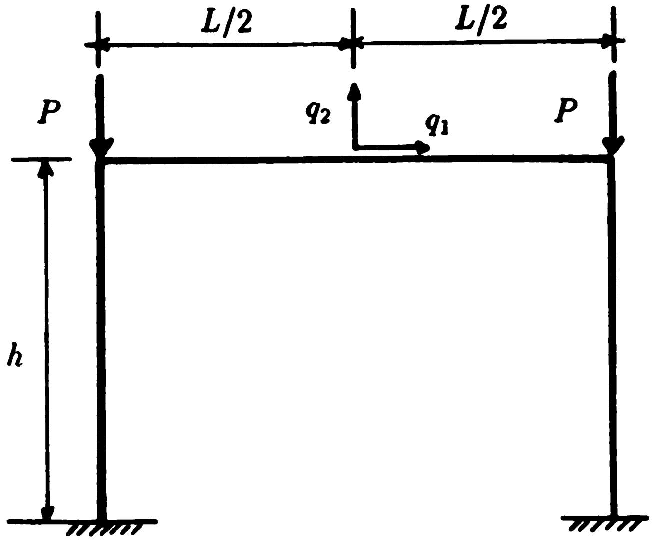

Fig 3

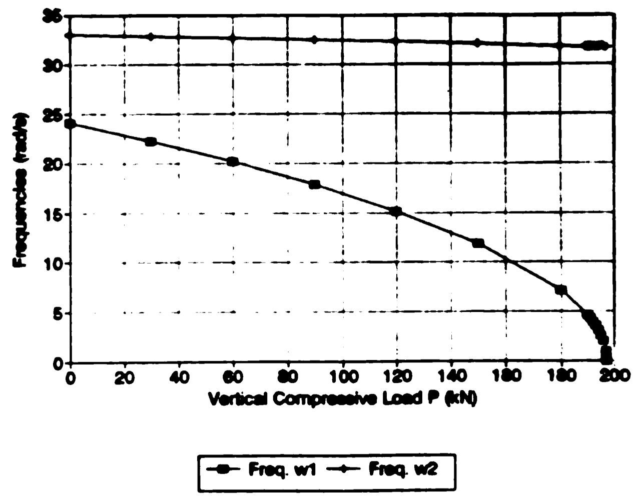

Fig 4

The simple portal frame of Fig 3 was analysed. It is constituted by a four-element horizontal beam and two three-element columns clamped in their bases. Two compressive vertical loads P are applied to the top of the columns. These forces could, as an example, be given by prestressing of the columns. The geometrical and material properties of the analysed model are:

$$A = 3.48 \times 10^{-3} m^2; \quad I = 1.55 \times 10^{-3} m^4;$$

$$L = 7.5m; \quad h = 3.0m;$$

$$E = 2.05 \times 10^{11} Pa; \quad \rho = 7.85 \times 10^3 kg/m^3$$

This structure was analysed for several levels of the P load. The values of its two lowest natural frequencies, namely: ω_1 (the sway mode frequency) and ω_2 (the first symmetrical mode frequency), are plotted in Fig 4 against the variation of P. One can see that ω_1 decreases according to a curve, reaching a zero value for the buckling load predicted by Timoshenko (1961), whereas ω_2 is nearly constant.

ANALYSIS OF A FRAME UNDER NEAR EXTERNAL AND INTERNAL RESONANCE CONDITIONS

As another example of the capabilities of the ANDROS FEM system, a full nonlinear dynamical analysis of a portal frame, with the same geometrical and material properties of the structure shown in Fig 3, is presented. When the load P is set to the value of 110 kN, one can see, in Fig 4, that the near internal resonance condition ($2\omega_1 \approx \omega_2$) is reached between the sway mode and the first symmetrical mode. It was considered a Rayleigh type viscous (linear) damping matrix to yield 0.5% damping rates for these first two modes.

In a forced motion analysis at this level of load, harmonic vertical support excitation was applied, of the form

$$\ddot{S}^2 = \ddot{S}_o \sin \Omega t$$

at near resonance with the symmetrical mode ($\Omega \approx \omega_2$).

For a better understanding of the effects of the geometrical nonlinearities, one should analyse Fig 5 where q_1 stationary amplitude is plotted. The ground acceleration amplitude $\ddot{S}_o$ is kept constant (equal to 0.25 g) while its frequency Ω varies around ω_2. These conditions of near internal and external resonances lead to the "saturation" of the symmetrical mode, through which the energy is pumped into the system, with consequent rapid growing of the lateral vibrations (which otherwise would be near null), due to transference of the surplus energy. Although these postcritical vibrations are found to be theoretically stable, the considerable amplitude of the sway movement may lead to structural damage or even to failure.

CONCLUDING REMARKS

This paper fits into a research line which starts with consistent and general formulations of analytical dynamics, having in mind a robust modelling. The next step would be its application to the finite-element method which would put at reach the analysis of complex engineering problems. Stationary basic solutions could then be surveyed, in special basic statical equilibrium configurations. It would follow a modal analysis considering small perturbations around the chosen basic state, which would give evidences of the relevant modes to be kept in a low-dimension version of the large-size problem. Here, intuitive engineering reasoning – such as the consideration of the energy imparted to the selected modes and the possibility of internal and external resonances –, together with computational techniques for location of in-

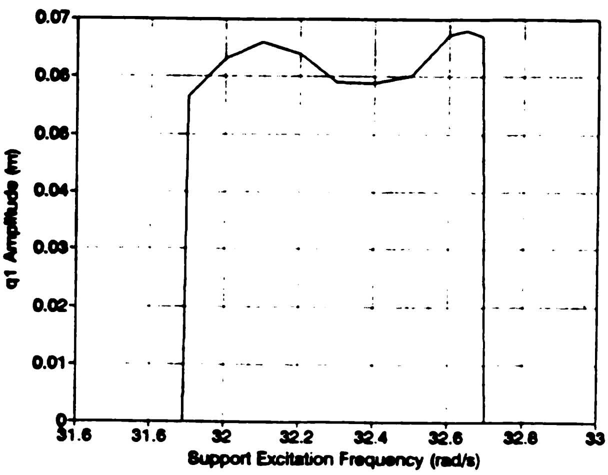

Fig 5

variant manifolds and their tangencies are required. Nonlinear parametric studies for the associated few-degree-of-freedom system would follow, supplying a valuable qualitative knowledge of alternative competing regimes. These studies would them be used to define the quantitative analysis to be performed in the original large-size system via the finite-element method. An effort in this way was made by Mazzilli and Brasil (1993). As a matter of fact, such a research line is already being pursued at LMC – Computational Mechanics Laboratory – of Escola Politécnica, University of São Paulo. At this moment, a general consistent formulation of analytical dynamics – which is part of the subject of this paper – is already available. Based upon it the ANDROS finite-element program was developed (Mazzilli and Brasil, 1992). ANDROS was capable of capturing in large systems the expected nonlinear phenomena after the study of associated simple systems.

Initial work is already under way on the condensation of multiple into few-degree-of-freedom systems, to which perturbation analyses can be applied in automatic fashion with the help of symbolic computation. So far this has been done following very much the intuitive engineering reasoning and considerable help is expected from the applied mathematicians in the more rigorous search of the invariant manifolds.

Geometrically exact analysis of spatial frames

Paulo M Pimenta and Takashi Yojo

Department of Structural and Foundation Engineering, Escola Politécnica
Universidade de São Paulo, CP 61548, 05424-970 São Paulo, SP, Brazil

A fully nonlinear, geometrically exact, finite strain rod model is derived from basic kinematical assumptions. The model incorporates shear distortion in bending and can take account of torsion warping. Rotation in 3D space is handled with the aid of the Euler-Rodrigues formula. The accomplished parametrization is simple and does not require update algorithms based on quaternions parameters. Weak and strong forms of the equilibrium equations are derived in terms of cross section strains and stresses, which are objective and suitable for constitutive description. As an example, an invariant linear elastic constitutive equation based on the small strain theory is presented. The attained formulation is very convenient for numerical procedures employing Galerkin projection like the finite element method and can be readily implemented in a finite element code. A mixed formulation of Hu-Washizu type is also derived, allowing for independent interpolation of the displacement, strain and stress fields within a finite element. An exact expression for the Fréchet derivative of the weak form of equilibrium is obtained in closed form, which is always symmetric for conservative loading, even far from an equilibrium state and is very helpful for numerical procedures like the Newton method as well as for stability and bifurcation analysis. Several numerical examples illustrate the usefulness of the formulation in the lateral stability analysis of spatial frames. These examples were computed with the code FENOMENA, which is under development at the Computational Mechanics Laboratory of the Escola Politécnica.

INTRODUCTION

The interest on geometrically nonlinear analysis of structures has increased in the recent few years. Besides the practical importance of nonlinear static and dynamic analysis of flexible rod and shell assemblages, the development of convenient geometrically exact models has contributed to this fact. These models show many benefits, which have been emphasized by many authors, as one can verify in a non-exhaustive list reproduced in the references.

This work derives a geometrically exact rod model from the kinematic assumption that cross sections, which are initially orthogonal to the axis, remain plane and undistorted during the deformation. The theory accommodates finite strains, large displacements and rotations, and accounts for shear distortion in bending. Torsion warping can be effortlessly acquainted for, provided elastic behavior is assumed. On the other hand, the introduction of elastic-plastic, visco-plastic and visco-elastic constitutive equations in terms of cross section generalized strains and stresses is straightforward. The consideration of cross section inertia is direct as well.

The accomplished formulation can be readily applied to the nonlinear analysis of spatial frames through the finite element method and presents the following advantages:

(a) rotations in 3D space are treated in a consistent but convenient way through the Euler-Rodrigues formula: update algorithms based on quaternion parameters are not required;
(b) there is no need of approximate strain-displacement relationships or additional assumptions like moderate rotations, small curvatures and small cross section dimensions;
(c) generalized cross section strains and stresses, which are energetically conjugate, can be consistently defined;
(d) generalized cross section displacements and external loadings, which are energetically conjugate, can be consistently defined;
(e) equilibrium and motion equations are consistently derived in weak form as well as in strong form;
(f) boundary conditions are obtained by variational arguments;

part of "MECHANICS PAN-AMERICA 1993" edited by MRM Crespo da Silva and CEN Mazzilli ASME Reprint No AMR134

(g) the issue of conservative external moments is completely elucidated;
(h) an exact expression for the Fréchet derivative of the weak form of equilibrium is obtained in closed form, which is always symmetric for conservative loadings, even far from an equilibrium state;
(i) objectivity requirements are exactly observed;
(j) conservation laws can be exactly satisfied;
(k) weak formulations of mixed type are easily obtained, that can be readily applied to formulation of reliable finite elements.

The developed rod model can be easily implemented in a nonlinear finite element code. Some simple numerical examples are shown at the end of the work as an illustration of the model usefulness.

Along the text, intensive use of vector and tensor calculus is made. Vectors are denoted by small case bold letters while tensors and matrices are denoted by bold capital letters. Summation convention over repeated Greek subscripts from 1 to 2 is adopted.

KINEMATICS

As reference configuration a straight rod with length ℓ is considered, as shown in figure 1. The domain occupied by it is denoted by $\mathcal{B}$. If needed, initial curved configurations can be mapped from $\mathcal{B}$. The boundary of $\mathcal{B}$ is here identified by $\mathcal{S} = \mathcal{S}_L \cup \mathcal{S}_E$, where $\mathcal{S}_L$ represents the lateral surface of the rod whereas $\mathcal{S}_E$ denotes its end surfaces.

A local orthogonal vector system $\{\boldsymbol{e}_1^r, \boldsymbol{e}_2^r, \boldsymbol{e}_3^r\}$, with $\boldsymbol{e}_3^r$ along the rod axis, is placed as shown in figure 1. Thus, a cross section lies on the plane defined by the vectors $\boldsymbol{e}_1^r$ and $\boldsymbol{e}_2^r$. Material points have their position in $\mathcal{B}$ given by the vector

$$\boldsymbol{\xi} = \boldsymbol{\zeta} + \boldsymbol{a}^r , \tag{1}$$

where $\boldsymbol{\zeta}$ describes the points on the rod axis while $\boldsymbol{a}^r$ describes the relative position of points on a cross section with respect to the axis. Local Cartesian coordinates are defined in the reference configuration by

$$x_\alpha = \boldsymbol{a}^r \cdot \boldsymbol{e}_\alpha^r \quad \text{and} \quad x_3 = \boldsymbol{\zeta} \cdot \boldsymbol{e}_3^r , \tag{2}$$

where the dot indicates the scalar product of two vectors. Thus, $\boldsymbol{a}^r$ can be represented by

$$\boldsymbol{a}^r = x_\alpha \boldsymbol{e}_\alpha^r . \tag{3}$$

The third local Cartesian coordinate is chosen here as the primary parameter and replaced by

$$\zeta = x_3 . \tag{4}$$

It is assumed that ζ lies in the interval $(0, \ell)$, i.e. $\zeta = 0$ at one end of the rod and $\zeta = \ell$ at the other end. Cross sections are identified by A whereas their contours are denoted by C.

During the rod motion, the position of the material points can be described by the mapping

$$\boldsymbol{x} = \hat{\boldsymbol{x}}(\boldsymbol{\xi}, t) , \tag{5}$$

where t is the time. $\boldsymbol{x}$ can be decomposed as follows

$$\boldsymbol{x} = \boldsymbol{z} + \boldsymbol{a} , \tag{6}$$

where

$$\boldsymbol{z} = \hat{\boldsymbol{z}}(\zeta, t) \tag{7}$$

describes the motion of points on the rod axis whilst $\boldsymbol{a}$ is a vector field indicated by

$$\boldsymbol{a} = \hat{\boldsymbol{a}}(\boldsymbol{\xi}, t) , \tag{8}$$

that describes the relative motion of the remaining points on a cross section.

The basic kinematic assumption states that cross sections remain plane and undistorted during the motion. Hence, $\boldsymbol{a}$ is given by

$$\boldsymbol{a} = \boldsymbol{Q}\boldsymbol{a}^r , \tag{8}$$

where

$$\boldsymbol{Q} = \hat{\boldsymbol{Q}}(\zeta, t) \tag{10}$$

is a rotation, i.e. an orthogonal tensor with positive determinant. A local orthogonal system attached to the cross sections, as displayed in the figure 1, can be defined by

$$\boldsymbol{e}_i = \boldsymbol{Q}\boldsymbol{e}_i^r , \quad (i = 1, 2, 3) . \tag{11}$$

$\boldsymbol{e}_3$ remains normal to the cross section during the rod motion while for $\boldsymbol{a}$ the following representation holds

$$\boldsymbol{a} = x_\alpha \boldsymbol{e}_\alpha , \tag{11}$$

i.e. $\boldsymbol{a}$ has constant components on the moving local basis $\{\boldsymbol{e}_1, \boldsymbol{e}_2, \boldsymbol{e}_3\}$ attached to the cross sections.

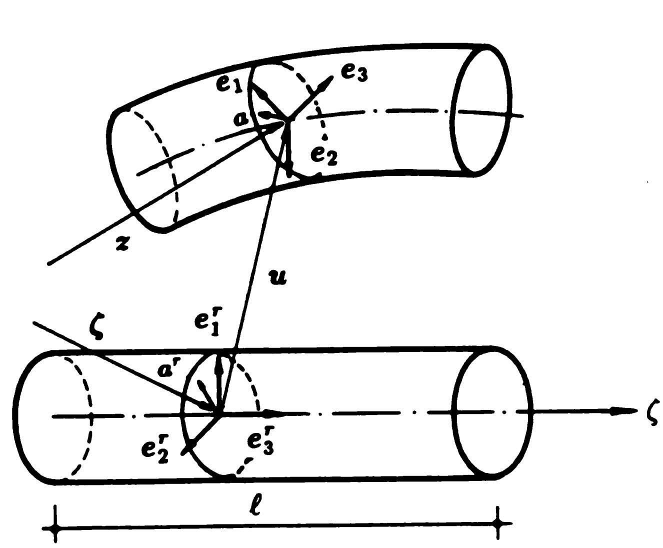

FIG 1. Rod deformation

The components of the axial displacement vector

$$u = z - \zeta\,, \tag{12}$$

are regarded as the cross section translational degrees of freedom. On the other hand, the rotation tensor Q can be expressed by the Euler-Rodrigues formula

$$Q = I + a\Theta + b\Theta^2\,, \tag{13}$$

where I is the identity tensor and Θ is a skew-symmetric tensor, whose axial vector is denoted by θ and

$$a = \frac{\operatorname{sen}\theta}{\theta} \quad \text{and} \quad b = \frac{1}{2}\frac{\operatorname{sen}^2(\theta/2)}{(\theta/2)^2} \tag{14}$$

are real continuous functions of θ. θ is the rotation angle given by the norm of θ, as follows

$$\theta = \|\theta\|\,. \tag{15}$$

We register here that $\theta = \theta e$, where e is the unit vector along the rotation axis with positive sense given by the right-hand rule. The components of θ are regarded as the cross section rotational degrees of freedom.

The deformation gradient

$$F = \hat{F}(\xi, t) \tag{16}$$

can be computed through

$$F = \frac{\partial z}{\partial x_\alpha} \otimes e^r_\alpha + z' \otimes e^r_3\,, \tag{17}$$

where the notation $(\cdot)'$ stands for the differentiation with respect to ζ and the notation $\otimes$ stands for the tensor product. After some manipulation, the deformation gradient can be expressed by

$$F = Q + (\eta + \kappa \times a) \otimes e^r_3\,, \tag{18}$$

where

$$\begin{aligned} \eta &= z' - e_3 \quad \text{and} \\ \kappa &= \Gamma\theta' \end{aligned} \tag{19}$$

can be regarded as generalized strains. In (19) the tensor

$$\Gamma = I + b\Theta + c\Theta^2 \tag{20}$$

has been introduced, where b is already defined in (14) and c is the continuous function of θ below

$$c = \frac{1-a}{\theta^2}\,. \tag{21}$$

We remark that κ is the axial ed from the skew-symmetric tensor

$$K = \tag{22}$$

where the notation $(\cdot)^T$ indicates the transposition of a tensor or matrix. Note that κ is not the curvature of the rod axis.

The generalized strains η and κ are affected by superposed rigid body motions. Hence, they are not convenient for constitutive description. The rotated strains

$$\eta^r = \hat{\eta}^r(\zeta, t) \quad \text{and} \quad \kappa^r = \hat{\kappa}^r(\zeta, t) \tag{23}$$

defined by

$$\begin{aligned} \eta^r &= Q^T\eta = Q^T z' - e^r_3 \quad \text{and} \\ \kappa^r &= Q^T\kappa = \Gamma^T\theta' \end{aligned} \tag{24}$$

are not affected by superposed rigid body motions. In $(24)_2$ the property

$$Q^T\Gamma = \Gamma^T \tag{25}$$

has been used. The deformation gradient can be expressed, with help from (24), by

$$F = Q\left[I + (\eta^r + \kappa^r \times a^r) \otimes e^r_3\right]. \tag{26}$$

Indicating the differentiation with respect to time by a superposed dot, as usual, the velocity of a material point is given by

$$\dot{z} = \dot{u} + \omega \times a\,, \tag{27}$$

where $\times$ stands for the vector product and ω is the cross section spin vector, which is the axial vector of

$$\Omega = \dot{Q}Q^T\,. \tag{28}$$

Similarly to $(19)_2$, ω can be computed through

$$\omega = \Gamma\dot{\theta}\,. \tag{29}$$

By time differentiation of (26), the following expression for the velocity gradient can be obtained

$$\dot{F} = \Omega F + Q\left[(\dot{\eta}^r + \dot{\kappa}^r \times a^r) \otimes e^r_3\right], \tag{30}$$

where

$$\begin{aligned} \dot{\eta}^r &= Q^T(\dot{u}' + z' \times \omega) \quad \text{and} \\ \dot{\kappa}^r &= Q^T\omega' \end{aligned} \tag{31}$$

are generalized strain rates. Alternative expressions for (31) are obtained by insertion of (29) in (31)

$$\begin{aligned} \dot{\eta}^r &= Q^T\left[\dot{u}' + z' \times (\Gamma\dot{\theta})\right] \\ \dot{\kappa}^r &= Q^T(\Gamma'\dot{\theta} + \Gamma\dot{\theta}') \end{aligned} \tag{32}$$

In $(32)_2$ one has, by differentiation of (20) with respect to ζ, the tensor

$$\begin{aligned} \Gamma' = b\Theta' &+ c(\Theta\Theta' + \Theta'\Theta) + \\ &+ d(\theta\cdot\theta')\Theta + e(\theta\cdot\theta')\Theta^2\,, \end{aligned} \tag{33}$$

where

$$d = \frac{a-2b}{\theta^2} \quad \text{and} \quad e = \frac{b-3c}{\theta^2} \tag{34}$$

are continuous real functions of θ.

The cross section displacement vector

$$\boldsymbol{d} = \hat{\boldsymbol{d}}(\zeta, t) \tag{35}$$

given by

$$\boldsymbol{d} = \begin{bmatrix} \boldsymbol{u} \\ \boldsymbol{\theta} \end{bmatrix} \tag{36}$$

is now introduced. The cross section strain vector

$$\boldsymbol{\epsilon} = \hat{\boldsymbol{\epsilon}}(\boldsymbol{d}) \tag{37}$$

given by

$$\boldsymbol{\epsilon} = \begin{bmatrix} \boldsymbol{\eta}^r \\ \boldsymbol{\kappa}^r \end{bmatrix}. \tag{38}$$

can also be introduced. The time differentiation of (38) leads to

$$\dot{\boldsymbol{\epsilon}} = \boldsymbol{B}\boldsymbol{\Delta}\dot{\boldsymbol{d}}, \tag{39}$$

where $\boldsymbol{\Delta}$ is the differential operator

$$\boldsymbol{\Delta} = \begin{bmatrix} \boldsymbol{I}\frac{\partial}{\partial\zeta} & \boldsymbol{O} \\ \boldsymbol{O} & \boldsymbol{I} \\ \boldsymbol{O} & \boldsymbol{I}\frac{\partial}{\partial\zeta} \end{bmatrix} \tag{40}$$

and $\boldsymbol{B}$ is the matrix given by

$$\boldsymbol{B} = \begin{bmatrix} \boldsymbol{Q}^T & \boldsymbol{O} \\ \boldsymbol{O} & \boldsymbol{Q}^T \end{bmatrix} \begin{bmatrix} \boldsymbol{I} & \boldsymbol{Z}'\boldsymbol{\Gamma} & \boldsymbol{O} \\ \boldsymbol{O} & \boldsymbol{\Gamma}' & \boldsymbol{\Gamma} \end{bmatrix}. \tag{41}$$

$\boldsymbol{O}$ and $\boldsymbol{Z}'$, that appear in (41), are the null tensor and the skew-symmetric tensor whose axial vector is

$$\boldsymbol{z}' = \boldsymbol{e}_3^r + \boldsymbol{u}'. \tag{42}$$

KINETICS

Introducing the notation : for the scalar product of two tensors, the internal power is given by

$$P_{int} = \int_0^\ell \int_A \boldsymbol{P} : \dot{\boldsymbol{F}}\, dA\, d\zeta, \tag{43}$$

where

$$\boldsymbol{P} = \hat{\boldsymbol{P}}(\boldsymbol{\xi}, t) \tag{44}$$

is the non-symmetric Piola stress tensor. $\boldsymbol{P}$ can be expressed by

$$\boldsymbol{P} = \boldsymbol{t}_\alpha \otimes \boldsymbol{e}_\alpha^r + \boldsymbol{\tau} \otimes \boldsymbol{e}_3^r. \tag{45}$$

Since the cross sections remain plane and undistorted, $\boldsymbol{\tau}$ is also the stress vector acting on them, i.e.

$$\boldsymbol{\tau} = \boldsymbol{T}\boldsymbol{e}_3, \tag{46}$$

where $\boldsymbol{T}$ is the Cauchy stress tensor. Hence, the force and moment resultants on a cross section

$$\boldsymbol{n} = \hat{\boldsymbol{n}}(\zeta, t) \quad \text{and} \quad \boldsymbol{m} = \hat{\boldsymbol{m}}(\zeta, t) \tag{47}$$

can be defined by

$$\begin{aligned} \boldsymbol{n} &= \int_A \boldsymbol{\tau}\, dA \quad \text{and} \\ \boldsymbol{m} &= \int_A \boldsymbol{a} \times \boldsymbol{\tau}\, dA. \end{aligned} \tag{48}$$

The resultants $\boldsymbol{n}$ and $\boldsymbol{m}$ are affected by superposed rigid body motions and are, for this sake, not convenient for constitutive description. On the other hand, the rotated vectors

$$\boldsymbol{n}^r = \hat{\boldsymbol{n}}^r(\zeta, t) \quad \text{and} \quad \boldsymbol{m}^r = \hat{\boldsymbol{m}}^r(\zeta, t) \tag{49}$$

defined by

$$\boldsymbol{n}^r = \boldsymbol{Q}^T\boldsymbol{n} \quad \text{and} \quad \boldsymbol{m}^r = \boldsymbol{Q}^T\boldsymbol{m} \tag{50}$$

remain invariant under superposed rigid body motions. If one introduces the rotated stress vector $\boldsymbol{\tau}^r$ given by

$$\boldsymbol{\tau}^r = \boldsymbol{Q}^T\boldsymbol{\tau}, \tag{51}$$

the rotated cross section resultants can also be defined by

$$\begin{aligned} \boldsymbol{n}^r &= \int_A \boldsymbol{\tau}^r\, dA \quad \text{and} \\ \boldsymbol{m}^r &= \int_A \boldsymbol{a}^r \times \boldsymbol{\tau}^r\, dA. \end{aligned} \tag{52}$$

At this point we recall that $\boldsymbol{a}^r$, $\boldsymbol{\eta}^r$, $\boldsymbol{\kappa}^r$, $\boldsymbol{n}^r$, $\boldsymbol{m}^r$ and $\boldsymbol{\tau}^r$ have the same components on $\{\boldsymbol{e}_1^r, \boldsymbol{e}_2^r, \boldsymbol{e}_3^r\}$ as $\boldsymbol{a}$, $\boldsymbol{\eta}$, $\boldsymbol{\kappa}$, $\boldsymbol{n}$, $\boldsymbol{m}$ and $\boldsymbol{\tau}$ on $\{\boldsymbol{e}_1, \boldsymbol{e}_2, \boldsymbol{e}_3\}$.

Introducing (30) and (45) in $\boldsymbol{P} : \dot{\boldsymbol{F}}$ and considering that $\boldsymbol{P}\boldsymbol{F}^T = \det(\boldsymbol{F})\boldsymbol{T}$ is symmetric and for this reason $\boldsymbol{P}\boldsymbol{F}^T : \boldsymbol{\Omega} = \boldsymbol{O}$, from (43) one arrives at

$$P_{int} = \int_0^\ell (\boldsymbol{n}^r \cdot \dot{\boldsymbol{\eta}}^r + \boldsymbol{m}^r \cdot \dot{\boldsymbol{\kappa}}^r)\, d\zeta. \tag{53}$$

Defining the cross section vector of stress resultants by

$$\boldsymbol{\sigma} = \begin{bmatrix} \boldsymbol{n}^r \\ \boldsymbol{m}^r \end{bmatrix}, \tag{54}$$

(53) can be written as

$$P_{int} = \int_0^\ell \boldsymbol{\sigma} \cdot \dot{\boldsymbol{\epsilon}}\, d\zeta = \int_0^\ell \boldsymbol{\sigma} \cdot \boldsymbol{B}\boldsymbol{\Delta}\dot{\boldsymbol{d}}\, d\zeta, \tag{55}$$

where use of (39) was made.

Suppose that surface and body loadings are applied along the rod. The surface loading per unit reference area is mapped from S_L and denoted by $\bar{\boldsymbol{t}}$ while the body loading per unit reference volume is mapp[illegible] B and identified by $\bar{\boldsymbol{b}}$. The external power along the rod is then given by

$$P_{ext} = \int_0^{\ell} \Big[\int_C \bar{\boldsymbol{t}} \cdot \dot{\boldsymbol{x}} dC + \int_A \bar{\boldsymbol{b}} \cdot \dot{\boldsymbol{x}} dA \Big] d\zeta . \tag{56}$$

Introducing (27) in (56), one obtains

$$P_{ext} = \int_0^{\ell} (\bar{\boldsymbol{n}} \cdot \dot{\boldsymbol{u}} + \bar{\boldsymbol{m}} \cdot \boldsymbol{\omega})\, d\zeta , \tag{57}$$

where

$$\bar{\boldsymbol{n}} = \hat{\bar{\boldsymbol{n}}}(\zeta, t) \quad \text{and} \quad \bar{\boldsymbol{m}} = \hat{\bar{\boldsymbol{m}}}(\zeta, t) \tag{58}$$

are the external force and moment resultants per unit reference length given by

$$\begin{aligned} \bar{\boldsymbol{n}} &= \int_C \bar{\boldsymbol{t}} dC + \int_A \bar{\boldsymbol{b}} dA \quad \text{and} \\ \bar{\boldsymbol{m}} &= \int_C \boldsymbol{a} \times \bar{\boldsymbol{t}} dC + \int_A \boldsymbol{a} \times \bar{\boldsymbol{b}} dA . \end{aligned} \tag{59}$$

Introducing (29) in (57), one has

$$P_{ext} = \int_0^{\ell} (\bar{\boldsymbol{n}} \cdot \dot{\boldsymbol{u}} + \bar{\boldsymbol{\mu}} \cdot \dot{\boldsymbol{\theta}})\, d\zeta , \tag{60}$$

where

$$\bar{\boldsymbol{\mu}} = \hat{\bar{\boldsymbol{\mu}}}(\zeta, t) , \tag{61}$$

given by

$$\bar{\boldsymbol{\mu}} = \boldsymbol{\Gamma}^T \bar{\boldsymbol{m}} , \tag{62}$$

is the external loading energetically conjugate with $\boldsymbol{\theta}$. We emphasize that $\bar{\boldsymbol{m}}$ is not conjugate with $\boldsymbol{\theta}$.

At this point, the following rotated external force and moment per unit reference length can be introduced

$$\bar{\boldsymbol{n}}^r = \boldsymbol{Q}^T \bar{\boldsymbol{n}} \quad \text{and} \quad \bar{\boldsymbol{m}}^r = \boldsymbol{Q}^T \bar{\boldsymbol{m}} . \tag{63}$$

Taking account of (25), one has

$$\bar{\boldsymbol{\mu}} = \boldsymbol{\Gamma}^T \bar{\boldsymbol{m}} = \boldsymbol{\Gamma} \bar{\boldsymbol{m}}^r . \tag{64}$$

Introducing now the vector of external loading per unit reference length defined by

$$\bar{\boldsymbol{q}} = \begin{bmatrix} \bar{\boldsymbol{n}} \\ \bar{\boldsymbol{\mu}} \end{bmatrix} , \tag{65}$$

the external power can be written as

$$P_{ext} = \int_0^{\ell} \bar{\boldsymbol{q}} \cdot \dot{\boldsymbol{d}}\, d\zeta . \tag{66}$$

STATICS

The virtual strains

$$\delta\boldsymbol{\eta}^r = \delta\hat{\boldsymbol{\eta}}^r \qquad \delta\hat{\boldsymbol{\kappa}}^r(\zeta) \tag{67}$$

are obtained by consistent linearization of (24). Their expressions, similar to (32), are displayed below

$$\begin{aligned} \delta\boldsymbol{\eta}^r &= \boldsymbol{Q}^T [\delta\boldsymbol{u}' + \boldsymbol{z}' \times (\boldsymbol{\Gamma}\delta\boldsymbol{\theta})] \quad \text{and} \\ \delta\boldsymbol{\kappa}^r &= \boldsymbol{Q}^T (\boldsymbol{\Gamma}'\delta\boldsymbol{\theta} + \boldsymbol{\Gamma}\delta\boldsymbol{\theta}') , \end{aligned} \tag{68}$$

where

$$\delta\boldsymbol{u} = \delta\hat{\boldsymbol{u}}(\zeta) \quad \text{and} \quad \delta\boldsymbol{\theta} = \delta\hat{\boldsymbol{\theta}}(\zeta) \tag{69}$$

are virtual displacements. Hence, with help from

$$\delta\boldsymbol{\varepsilon} = \delta\hat{\boldsymbol{\varepsilon}}(\zeta) \quad \text{and} \quad \delta\boldsymbol{d} = \delta\hat{\boldsymbol{d}}(\zeta) , \tag{70}$$

which are defined similarly to (36) and (38), one has

$$\delta\boldsymbol{\varepsilon} = \boldsymbol{B}\boldsymbol{\Delta}\delta\boldsymbol{d} . \tag{71}$$

(71) is analogous to (39). The internal virtual work can then be expressed by

$$\begin{aligned} \delta W_{int} &= \int_0^{\ell} (\boldsymbol{n}^r \cdot \delta\boldsymbol{\eta}^r + \boldsymbol{m}^r \cdot \delta\boldsymbol{\kappa}^r) d\zeta \\ &= \int_0^{\ell} \boldsymbol{\sigma} \cdot \delta\boldsymbol{\varepsilon}\, d\zeta \\ &= \int_0^{\ell} \boldsymbol{\sigma} \cdot \boldsymbol{B}\boldsymbol{\Delta}\delta\boldsymbol{d}\, d\zeta , \end{aligned} \tag{72}$$

which are similar to (53) and (55). δW_{int} is a functional of the fields $\boldsymbol{\sigma}$ and $\delta\boldsymbol{d}$ as indicated below

$$\delta W_{int} = \delta\hat{W}_{int}[\boldsymbol{\sigma}, \delta\boldsymbol{d}] . \tag{73}$$

The external virtual work is defined by

$$\begin{aligned} \delta W_{ext} &= \int_0^{\ell} (\bar{\boldsymbol{n}} \cdot \delta\boldsymbol{u} + \bar{\boldsymbol{\mu}} \cdot \delta\boldsymbol{\theta})\, d\zeta \\ &= \int_0^{\ell} \bar{\boldsymbol{q}} \cdot \delta\boldsymbol{d}\, d\zeta , \end{aligned} \tag{74}$$

which are similar to (60) and (66). δW_{ext} is a functional of the fields $\bar{\boldsymbol{q}}$ and $\delta\boldsymbol{d}$ as indicated below

$$\delta W_{ext} = \delta\hat{W}_{int}[\bar{\boldsymbol{q}}, \delta\boldsymbol{d}] . \tag{75}$$

The weak form of the equilibrium equations is given by the virtual work theorem, viz.

$$\delta W_{int} - \delta W_{ext} = 0 , \quad \forall \delta\boldsymbol{d} \mid \delta\hat{\boldsymbol{d}}(0) = \delta\hat{\boldsymbol{d}}(\ell) = 0 . \tag{76}$$

Inserting (72) and (74) in (76) and performing partial integration on terms with $\delta\boldsymbol{u}'$ and $(\boldsymbol{\Gamma}\delta\boldsymbol{\theta})'$, one obtains, after some manipulation,

$$\int_0^{\ell} \big[(\boldsymbol{n}' + \bar{\boldsymbol{n}}) \cdot \delta\boldsymbol{u} + \boldsymbol{\Gamma}^T (\boldsymbol{m}' + \boldsymbol{z}' \times \boldsymbol{n} + \bar{\boldsymbol{m}}) \cdot \delta\boldsymbol{\theta} \big]\, d\zeta = 0 .$$

Hence, by the standard argument of variational calculus, the following local equilibrium equations in $(0,\ell)$ are obtained

$$\begin{gathered} n' + \bar{n} = o \quad \text{and} \\ m' + z' \times n + \bar{m} = o , \end{gathered} \tag{77}$$

where o is the null vector. With the aid of (50) and (63), the equilibrium equations can be replaced by

$$\begin{gathered} n^{r\prime} + \kappa^r \times n^r + \bar{n}^r = o \text{ and} \\ m^{r\prime} + \kappa^r \times m^r + (e_3^r + \eta^r) \times n^r + \bar{m}^r = o . \end{gathered} \tag{78}$$

The vector

$$q = \begin{bmatrix} n \\ \mu \end{bmatrix} , \tag{79}$$

which is similar to (65), is now introduced. μ in (79) is analogous to (64), i.e.

$$\mu = \Gamma^T m = \Gamma m^r . \tag{80}$$

(76) is now extended in order to incorporate the virtual work of the external forces on the rod ends, as follows

$$\delta W_{int} - \delta W_{ext} = q^\star \cdot \delta d \Big|_{\zeta=0}^{\zeta=\ell} , \quad \forall \delta d , \tag{81}$$

where $q^\star$ are prescribed values at $\zeta = 0$ and $\zeta = \ell$. Inserting (72) and (74) in (81), performing the partial integrations done in (76) and considering (77), one obtains

$$(q - q^\star) \cdot \delta d \Big|_{\zeta=0}^{\zeta=\ell} = 0 .$$

Thus the natural boundary conditions of this model are

$$q = q^\star \qquad \text{at} \quad \zeta = 0 \quad \text{and} \quad \zeta = \ell . \tag{82}$$

We remark that the natural boundary condition involves μ at the rod ends and not m.

POTENTIALS

A rod is called elastic if there is a scalar valued function

$$\psi_{int} = \hat{\psi}_{int}(\epsilon) \tag{83}$$

such that

$$\sigma = \frac{\partial \psi_{int}}{\partial \epsilon} . \tag{84}$$

ψ_{int} is called strain energy per unit reference length.

The gradient of σ defines an operator D, given by

$$D = \frac{\partial \sigma}{\partial \epsilon} = \begin{bmatrix} \partial n^r / \partial \eta^r & \partial n^r / \partial \kappa^r \\ \partial m^r / \partial \eta^r & \partial m^r / \partial \kappa^r \end{bmatrix} . \tag{85}$$

D contains the cross section elastic tangent moduli. Regarding (84), D is also given by

$$D = \frac{\partial^2 \psi_{int}}{\partial \epsilon^2} . \tag{86}$$

Thus, D is symmetric.

For linear elastic rods D is constant. Hence, for such rods, one has

$$\psi_{int} = \frac{1}{2} \epsilon \cdot D \epsilon \quad \text{and} \quad \sigma = D \epsilon . \tag{87}$$

The functional

$$\Psi_{int} = \hat{\Psi}_{int}[d] \tag{88}$$

defined by

$$\Psi_{int} = \int_0^\ell \psi_{int} \circ \hat{\epsilon}(d) \, d\zeta \tag{89}$$

is called internal potential energy or strain energy of the rod. In (89) the notation $\circ$ stands for the composition of two functions, as usual.

The Fréchet derivative of (88) with respect to d yields

$$\delta \Psi_{int} = \int_0^\ell \sigma \cdot B \Delta \delta d \, d\zeta . \tag{90}$$

$\delta \Psi_{int}$ is a functional of two fields indicated by

$$\delta \Psi_{int} = \delta \hat{\Psi}_{int}[d, \delta d] . \tag{91}$$

Note that $\delta \Psi_{int}$ can also be expressed by

$$\delta \Psi_{int} = \delta \hat{W}_{int} \left[\frac{\partial \psi_{int}}{\partial \epsilon} \circ \hat{\epsilon}(d), \delta d \right] . \tag{92}$$

The second Fréchet derivative of (88) with respect to d can be computed through the Gateaux derivative of (91) with respect to d. The outcome is a functional of two fields indicated by

$$\delta^2 \Psi_{int} = \delta^2 \hat{\Psi}_{int}[d, \delta d] \tag{93}$$

and given by the following symmetric bilinear form

$$\begin{aligned} \delta^2 \Psi_{int} = \int_0^\ell \big[& (D B \Delta \delta d) \cdot (B \Delta \delta d) + \\ & + (G \Delta \delta d) \cdot (\Delta \delta d) \big] \, d\zeta , \end{aligned} \tag{94}$$

where D is defined in (86) and G is a symmetric operator which characterizes the geometrical effects from the internal forces. G can be expressed by

$$G = \begin{bmatrix} O & G_{u'\theta} & O \\ G_{u'\theta}^T & G_{\theta\theta} & G_{\theta\theta'} \\ O & G_{\theta\theta'}^T & O \end{bmatrix} . \tag{95}$$

With the aid of the skew-symmetric tensors N and M, whose axial vectors are n and m, and introducing the following continuous functions of θ

$$f = \frac{c - b - 4d}{\theta^2} \quad \text{and} \quad g = \frac{d - }{} \tag{96}$$

the elements of G are

$$
\begin{aligned}
\boldsymbol{G}_{u'\theta} =& -\boldsymbol{N\Gamma}\,,\\
\boldsymbol{G}_{\theta\theta'} =& \frac{1}{2}\boldsymbol{\Gamma}^T\boldsymbol{M\Gamma}\\
&-\frac{1}{2}c(\boldsymbol{M\Theta}+\boldsymbol{\Theta M})\\
&-\frac{1}{2}d(\boldsymbol{\Theta m}\otimes\boldsymbol{\theta}+\boldsymbol{\theta}\otimes\boldsymbol{\Theta m})\\
&+\frac{1}{2}e(\boldsymbol{\Theta}^2\boldsymbol{m}\otimes\boldsymbol{\theta}+\boldsymbol{\theta}\otimes\boldsymbol{\Theta}^2\boldsymbol{m})\,,\\
\boldsymbol{G}_{\theta\theta} =& \frac{1}{2}\boldsymbol{\Gamma}^T(\boldsymbol{Z}'\boldsymbol{N}+\boldsymbol{N}\boldsymbol{Z}')\boldsymbol{\Gamma}\\
&+\frac{1}{2}(\boldsymbol{\Gamma}^T\boldsymbol{M}\boldsymbol{\Gamma}'-\boldsymbol{\Gamma}'^T\boldsymbol{M}\boldsymbol{\Gamma})\\
&-\frac{1}{2}c\big[(\boldsymbol{N}\boldsymbol{Z}'-\boldsymbol{Z}'\boldsymbol{N})\boldsymbol{\Theta}\\
&\qquad+\boldsymbol{\Theta}(\boldsymbol{N}\boldsymbol{Z}'-\boldsymbol{Z}'\boldsymbol{N})\\
&\qquad+\boldsymbol{M}\boldsymbol{\Theta}'+\boldsymbol{\Theta}'\boldsymbol{M}\big]\\
&-\frac{1}{2}d\big[\boldsymbol{\Theta}(\boldsymbol{n}\times\boldsymbol{z}')\otimes\boldsymbol{\theta}+\boldsymbol{\theta}\otimes\boldsymbol{\Theta}(\boldsymbol{n}\times\boldsymbol{z}')\\
&\qquad+\boldsymbol{\Theta}'\boldsymbol{m}\otimes\boldsymbol{\theta}+\boldsymbol{\theta}\otimes\boldsymbol{\Theta}'\boldsymbol{m}\\
&\qquad+\boldsymbol{\Theta m}\otimes\boldsymbol{\theta}'+\boldsymbol{\theta}'\otimes\boldsymbol{\Theta m}\big]\\
&+\frac{1}{2}e(\boldsymbol{\Theta\Theta}'\boldsymbol{m}\otimes\boldsymbol{\theta}+\boldsymbol{\theta}\otimes\boldsymbol{\Theta\Theta}'\boldsymbol{m}\\
&\qquad+\boldsymbol{\Theta}'\boldsymbol{\Theta m}\otimes\boldsymbol{\theta}+\boldsymbol{\theta}\otimes\boldsymbol{\Theta}'\boldsymbol{\Theta m}\\
&\qquad+\boldsymbol{\Theta}^2\boldsymbol{m}\otimes\boldsymbol{\theta}'+\boldsymbol{\theta}'\otimes\boldsymbol{\Theta}^2\boldsymbol{m})\\
&-\frac{1}{2}e(\boldsymbol{\theta}\cdot\boldsymbol{\theta}')(\boldsymbol{\Theta M}+\boldsymbol{M\Theta})\\
&-\frac{1}{2}f(\boldsymbol{\theta}\cdot\boldsymbol{\theta}')(\boldsymbol{\Theta m}\otimes\boldsymbol{\theta}+\boldsymbol{\theta}\otimes\boldsymbol{\Theta m})\\
&+\frac{1}{2}g(\boldsymbol{\theta}\cdot\boldsymbol{\theta}')(\boldsymbol{\Theta}^2\boldsymbol{m}\otimes\boldsymbol{\theta}+\boldsymbol{\theta}\otimes\boldsymbol{\Theta}^2\boldsymbol{m})\,.
\end{aligned}
\tag{97}
$$

The external loading $\bar{\boldsymbol{q}}$ is called conservative if there is a scalar valued function

$$\psi_{ext}=\hat{\psi}_{ext}(\boldsymbol{d}) \tag{98}$$

such that

$$\bar{\boldsymbol{q}}=-\frac{\partial\psi_{ext}}{\partial\boldsymbol{d}}\,. \tag{99}$$

Hence, for such loadings, the gradient

$$\boldsymbol{L}=\frac{\partial\bar{\boldsymbol{q}}}{\partial\boldsymbol{d}} \tag{100}$$

is a symmetric operator given by

$$\boldsymbol{L}=-\frac{\partial^2\psi_{ext}}{\partial\boldsymbol{d}^2}\,. \tag{101}$$

$\boldsymbol{L}$ characterizes the geometrical effects from the external loading distributed along the rod.

For example, if $\bar{\boldsymbol{t}}$ and $\bar{\boldsymbol{b}}$ do r n the displacements, one has

$$\boldsymbol{L}=\frac{\partial\bar{\boldsymbol{q}}}{\partial\boldsymbol{d}}=\Big[\ (\tag{102}$$

where, with the aid of the skew-symmetric tensors $\boldsymbol{A}$, $\bar{\boldsymbol{M}}$, $\bar{\boldsymbol{T}}$ and $\bar{\boldsymbol{B}}$, whose axial vectors are $\boldsymbol{a}$, $\bar{\boldsymbol{m}}$, $\bar{\boldsymbol{t}}$ and $\bar{\boldsymbol{b}}$, respectively, $\boldsymbol{L}_{\theta\theta}$ is given by

$$
\begin{aligned}
\boldsymbol{L}_{\theta\theta} =& \frac{1}{2}\boldsymbol{\Gamma}^T\Big[\int_C(\bar{\boldsymbol{T}}\boldsymbol{A}+\boldsymbol{A}\bar{\boldsymbol{T}})dC\Big]\boldsymbol{\Gamma}\\
&+\frac{1}{2}\boldsymbol{\Gamma}^T\Big[\int_A(\bar{\boldsymbol{B}}\boldsymbol{A}+\boldsymbol{A}\bar{\boldsymbol{B}})dA\Big]\boldsymbol{\Gamma}\\
&-\frac{1}{2}c(\bar{\boldsymbol{M}}\boldsymbol{\Theta}+\boldsymbol{\Theta}\bar{\boldsymbol{M}})\\
&-\frac{1}{2}d(\boldsymbol{\Theta}\bar{\boldsymbol{m}}\otimes\boldsymbol{\theta}+\boldsymbol{\theta}\otimes\boldsymbol{\Theta}\bar{\boldsymbol{m}})\\
&+\frac{1}{2}e(\boldsymbol{\Theta}^2\bar{\boldsymbol{m}}\otimes\boldsymbol{\theta}+\boldsymbol{\theta}\otimes\boldsymbol{\Theta}^2\bar{\boldsymbol{m}})\,.
\end{aligned}
\tag{103}
$$

If $\bar{\boldsymbol{t}}$ and $\bar{\boldsymbol{b}}$ do not depend on the displacements and comply with

$$\int_C(\bar{\boldsymbol{T}}\boldsymbol{A}+\boldsymbol{A}\bar{\boldsymbol{T}})dC+\int_A(\bar{\boldsymbol{B}}\boldsymbol{A}+\boldsymbol{A}\bar{\boldsymbol{B}})dA=\boldsymbol{O}\,, \tag{104}$$

then the external moment $\bar{\boldsymbol{m}}$ is called semi-tangential. Thus, for semi-tangential external moments, one has

$$
\begin{aligned}
\boldsymbol{L}_{\theta\theta} =& -\frac{1}{2}c(\bar{\boldsymbol{M}}\boldsymbol{\Theta}+\boldsymbol{\Theta}\bar{\boldsymbol{M}})\\
&-\frac{1}{2}d(\boldsymbol{\Theta}\bar{\boldsymbol{m}}\otimes\boldsymbol{\theta}+\boldsymbol{\theta}\otimes\boldsymbol{\Theta}\bar{\boldsymbol{m}})\\
&+\frac{1}{2}e(\boldsymbol{\Theta}^2\bar{\boldsymbol{m}}\otimes\boldsymbol{\theta}+\boldsymbol{\theta}\otimes\boldsymbol{\Theta}^2\bar{\boldsymbol{m}})\,.
\end{aligned}
\tag{105}
$$

Notice that, for semi-tangential moments, $\boldsymbol{L}_{\theta\theta}$ does not depend on the application points of the external forces. Semi-tangential moments are conservative and comply with

$$\dot{\bar{\boldsymbol{m}}}=\frac{1}{2}\boldsymbol{\omega}\times\bar{\boldsymbol{m}}\,. \tag{106}$$

(106) justifies the nomenclature.

An external moment such that

$$\bar{\boldsymbol{\mu}}=\boldsymbol{\Gamma}^T\bar{\boldsymbol{m}}=\text{constant} \tag{107}$$

is also conservative and leads to

$$\boldsymbol{L}_{\theta\theta}=\boldsymbol{O}\,. \tag{108}$$

However, in practice such a moment is unlikely to occur.

The functional

$$\Psi_{ext}=\hat{\Psi}_{ext}[\boldsymbol{d}] \tag{109}$$

defined by

$$\Psi_{ext}=\int_0^{\ell}\psi_{ext}\,d\zeta \tag{110}$$

is called external potential energy of the rod.

The Fréchet derivative of (109) with respect to $\boldsymbol{d}$ yields

$$\delta\Psi_{ext}=\int_0^{\ell}\frac{\partial\psi_{ext}}{\partial\boldsymbol{d}}\cdot\delta\boldsymbol{d}\,d\zeta\,. \tag{111}$$

$\delta\Psi_{ext}$ is a functional of two fields indicated by

$$\delta\Psi_{ext} = \delta\hat{\Psi}_{ext}[\boldsymbol{d}, \delta\boldsymbol{d}]. \tag{112}$$

Note that $\delta\Psi_{ext}$ can also be expressed by

$$\delta\Psi_{ext} = -\delta\hat{W}_{ext}\left[\frac{\partial\psi_{ext}}{\partial\boldsymbol{d}}, \delta\boldsymbol{d}\right]. \tag{113}$$

The second Fréchet derivative of (109) with respect to $\boldsymbol{d}$ can be computed through the Gateaux derivative of (113) with respect to $\boldsymbol{d}$. The result is the following symmetric bilinear form

$$\delta^2\Psi_{ext} = -\int_0^\ell (\boldsymbol{L}\delta\boldsymbol{d})\cdot\delta\boldsymbol{d}\, d\zeta. \tag{114}$$

The functional

$$\Psi = \hat{\Psi}[\boldsymbol{d}] \tag{115}$$

defined by

$$\Psi = \Psi_{int} + \Psi_{ext} \tag{116}$$

is the potential energy of the rod. In view of (76), (92) and (113), one concludes that

$$\delta\Psi = 0. \tag{117}$$

Thus, Ψ is stationary at an equilibrium configuration. On the other hand, regarding (94) and (114), the second Fréchet derivative of (115) with respect to $\boldsymbol{d}$ is the following bilinear form

$$\begin{aligned}\delta^2\Psi = \int_0^\ell \big[&(\boldsymbol{DB\Delta}\delta\boldsymbol{d})\cdot(\boldsymbol{B\Delta}\delta\boldsymbol{d}) + \\ &+(\boldsymbol{G\Delta}\delta\boldsymbol{d})\cdot(\boldsymbol{\Delta}\delta\boldsymbol{d}) - (\boldsymbol{L}\delta\boldsymbol{d})\cdot\delta\boldsymbol{d}\big]\, d\zeta.\end{aligned} \tag{118}$$

We remark that the bilinear form (118) is always symmetric, even far from an equilibrium state. (118) is important in numerical procedures like the Newton method as well as in the stability and bifurcation analysis of structures.

FINITE ELEMENTS

The application of the finite element method is standard. In a pure displacement model the displacement field $\boldsymbol{d}$ is interpolated within an element through

$$\boldsymbol{d} = \boldsymbol{Np}, \tag{119}$$

where $\boldsymbol{p}$ is the vector of the element nodal displacements, which collects the vectors $\boldsymbol{d}$ from the element nodes, and $\boldsymbol{N}$ is an interpolation matrix. For linear elements with two nodes $\boldsymbol{N}$ contains linear functions of ζ, while for quadratic elements with three nodes $\boldsymbol{N}$ contains quadratic functions of ζ. In the standard Galerkin projection the virtual displacements are likewise interpolated through

$$\delta\boldsymbol{d} = \boldsymbol{N}\delta\boldsymbol{p}. \tag{120}$$

The vector of the element nodal forces $\boldsymbol{\pi}$, that collects the vectors $\boldsymbol{q}^\star$ from the element nodes, is defined, in agreement with (81), by

$$\boldsymbol{\pi}\cdot\delta\boldsymbol{p} = \int_0^\ell [\boldsymbol{\sigma}\cdot\boldsymbol{B\Delta}\delta\boldsymbol{d} - \bar{\boldsymbol{q}}\cdot\delta\boldsymbol{d}]\, d\zeta. \tag{121}$$

Introducing (119) and (120) in (121), the resulting projection is

$$\boldsymbol{\pi} = \int_0^\ell [(\boldsymbol{\Delta N})^T\boldsymbol{B}^T\boldsymbol{\sigma} - \boldsymbol{N}^T\bar{\boldsymbol{q}}]\, d\zeta. \tag{122}$$

The element tangent stiffness matrix $\boldsymbol{K}$ is defined, in harmony with (121) and (118), by

$$\begin{aligned}(\boldsymbol{K}\delta\boldsymbol{d})\cdot\delta\boldsymbol{d} = \int_0^\ell \big[&(\boldsymbol{B}^T\boldsymbol{DB} + \boldsymbol{G})(\boldsymbol{\Delta}\delta\boldsymbol{d})\cdot(\boldsymbol{\Delta}\delta\boldsymbol{d}) \\ &- (\boldsymbol{L}\delta\boldsymbol{d})\cdot\delta\boldsymbol{d}\big]\, d\zeta.\end{aligned} \tag{123}$$

Introducing (119) and (120) in (123), the resulting projection is

$$\begin{aligned}\boldsymbol{K} = \int_0^\ell \big[&(\boldsymbol{\Delta N})^T(\boldsymbol{B}^T\boldsymbol{DB} + \boldsymbol{G})(\boldsymbol{\Delta N}) \\ &- \boldsymbol{N}^T\boldsymbol{LN}\big]\, d\zeta.\end{aligned} \tag{124}$$

An advantage of the developed formulation is that all interpolations and operations can be performed in the global system of the structure. This saves numerous transformations from element local systems to the global system or vice-versa. As a matter of fact, the transformation of $\boldsymbol{D}$ from the local reference system to the global system is the only one required in the code.

It is known that exactly integrated displacement finite element models, like the one derived above, present the phenomenon of shear locking. In the one-dimensional case this can be circumvented by reduced numerical integration. For example, in the case of linear elements a one-point Gauss scheme can be adopted while for quadratic elements a two-point Gauss scheme is sufficient. At first sight this seems a rather numerical trick. However it can be justified by mixed models, which interpolate simultaneously displacements, strains and stresses. The variational basis of such models is an extended functional that includes the fields $\boldsymbol{d}$, $\boldsymbol{\varepsilon}$ and $\boldsymbol{\sigma}$. This three-field functional

$$H = \hat{H}[\boldsymbol{d}, \boldsymbol{\varepsilon}, \boldsymbol{\sigma}] \tag{125}$$

can be given by

$$H = \int_0^\ell \left\{\hat{\psi}_{int}(\boldsymbol{\varepsilon}) + \boldsymbol{\sigma}\cdot\left[\hat{\boldsymbol{\varepsilon}}(\boldsymbol{d}) - \boldsymbol{\varepsilon}\right] + \hat{\psi}_{ext}(\boldsymbol{d})\right\} d\zeta. \tag{126}$$

The Fréchet derivative of (126) with respect to $\boldsymbol{d}$, $\boldsymbol{\varepsilon}$ and $\boldsymbol{\sigma}$ conducts to

$$\begin{aligned}\delta H = &\int_0^\ell (\boldsymbol{\sigma}\cdot\boldsymbol{B\Delta}\delta\boldsymbol{d} - \bar{\boldsymbol{q}}\cdot\delta\boldsymbol{d})\, d\zeta \\ &+ \int_0^\ell \left(\frac{\partial\psi_{int}}{\partial\boldsymbol{\varepsilon}} - \boldsymbol{\sigma}\right)\cdot\delta\boldsymbol{\varepsilon}\, d\zeta \\ &+ \int_0^\ell (\hat{\boldsymbol{\varepsilon}}(\boldsymbol{d}) - \boldsymbol{\varepsilon})\cdot\delta\boldsymbol{\sigma}\, d\zeta\end{aligned} \tag{127}$$

(127) is suitable for mixed Galerkin projection or for any other generalized projection like, for example, the collocation method.

NUMERICAL EXAMPLES

Some simple numerical examples are presented in this section as an illustration for the developed formulation. A linear elastic rod was assumed. The operator $\boldsymbol{D}$ in (87) was taken from the geometrically linear theory and its matrix in the rod local system at reference configuration is

$$\boldsymbol{D} = \begin{bmatrix} GA & 0 & 0 & 0 & 0 & GS_1^* \\ \cdot & GA & 0 & 0 & 0 & GS_2^* \\ \cdot & \cdot & EA & ES_1 & ES_2 & 0 \\ \cdot & \cdot & \cdot & EJ_{11} & EJ_{12} & 0 \\ \cdot & sym. & \cdot & \cdot & EJ_{22} & 0 \\ \cdot & \cdot & \cdot & \cdot & \cdot & GJ_t^* \end{bmatrix} . \quad (128)$$

In (128), E is the Young modulus, G is the shear modulus, A is the cross section area, S_α are the cross section static moments defined by

$$S_1 = \int_A x_2 dA \quad \text{and} \quad S_2 = -\int_A x_1 dA , \qquad (129)$$

$J_{\alpha\beta}$ are the cross section inertia constants defined by

$$\begin{aligned} J_{11} &= \int_A x_2^2 dA , \\ J_{22} &= \int_A x_1^2 dA \quad \text{and} \qquad (130) \\ J_{12} &= -\int_A x_1 x_2 dA , \end{aligned}$$

J_t^* is the torsion constant given by

$$J_t^* = J_t + A s_\alpha s_\alpha , \qquad (131)$$

where J_t is the Saint-Venant torsion constant and s_α are the coordinates of the cross section shear center. Finally, S_α^* are the following constants

$$S_1^* = -A s_2 \quad \text{and} \quad S_2 = A s_1 , \qquad (131)$$

The assumed cross sections are described in figure 2 and are represented by the letters R, T, I, C, L and V. All cross sections have the same area. The assumed material Young modulus was E=210,000 M[illegible] [illegible]he assumed shear modulus was G=800,000 M[illegible] [illegible]ples were computed with linear and qua[illegible] [illegible] with at least five elements. The result[illegible] [illegible] with respect to element type and nu[illegible]

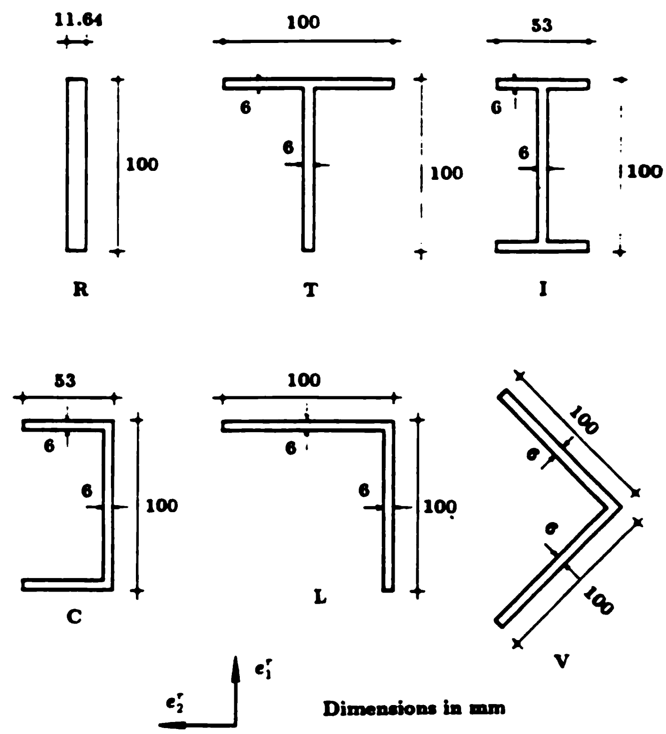

FIG 2. Cross sections

Example 1

The first example shows the lateral buckling of a cantilever beam with a concentrated load at the tip. Six cross sections were considered as displayed in the figure 2. The axis is placed along the cross section centroids and the load is applied on the axis in the direction of e_1^r, as displayed in the figure 2. Figure 3 shows the computed lateral displacements of the point of load application. Only three cases presented a symmetric stable bifurcation. Notice the large displacements and rotations. Rotation angles over 0.30 rd were observed. The Newton method for solving the nonlinear problem at each load level could be applied in exact form, showing always its characteristic quadratic asymptotic rate of convergence. The load increments were controlled by an automatic algorithm. To circumvent bifurcation points a very small geometric perturbation was introduced, when necessary. The examples were computed varying the position of the rod axis but retaining the position of the load. The results remained invariant.

Example 2

The second example, shown in figure 4, is similar to the first one, but the axis is placed along the cross section shear centers. The load at the tip is applied on the shear center of the end cross section. Notice that, this time, five cross sections have presented a symmetric stable bifurcation. Even the asymmetric C and V sections presented this time a bifurcation. Note that the T section has exhibited the highest critical load.

Example 3

This example shows the lateral buckling of a L-shaped frame with a concentrated load at the tip. Axis and load were placed on the shear centers of the cross sections. Only the frames with double-symmetric sections like the R and I section presented a stable symmetric bifurcation, as one can see in figure 5. In the other four cases a continuous nonlinear behavior was observed.

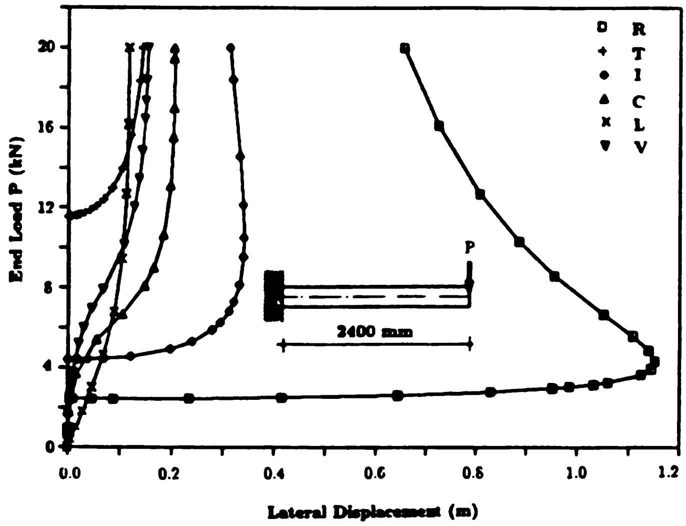

FIG 3. Example 1

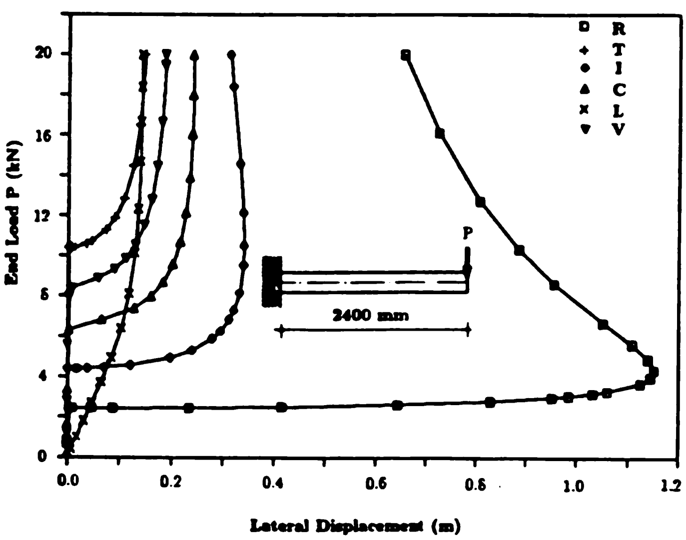

FIG 4. Example 2

Example 4

This example shows the lateral buckling of a I-beam under concentrated and uniformly distributed loading. The loadings were placed on the top and at the bottom of beam, as displayed in figure 6.

Example 5

This example, displayed in figure 7, shows the lateral buckling of a I-beam under different end moments. The first two cases correspond to quasi-tangential moments and the third case corresponds to a semi-tangential moment. The critical loads for the quasi-tangential moments coincide and are one half of the critical load for the semi-tangential moment.

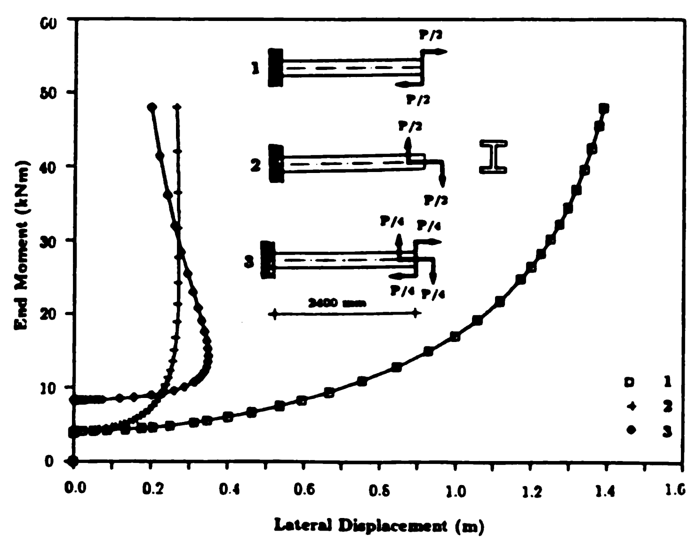

FIG 7. Example 5

CONCLUSIONS

A geometrically exact fully nonlinear rod model, which can be readily applied to finite element analysis of spatial frames, was formulated. The advantages of the model, that were pointed out by the authors in the introduction, could be corroborated along the text. Some simple numerical examples have shown the effectiveness of the developed formulation.

Determination of stress concentration factors for shallow and sharp v-notches using a hybrid method

José LF Freire, Eduardo A Carvalho, and Marco AM Cavaco

Departamento de Engenharia Mecânica, Pontifícia Universidade Católica do Rio de Janeiro PUC/Rio, 22453, Rio de Janeiro, Brazil

Stress distributions near the root of shallow and sharp V-notches are determined through a hybrid method which associates the isochromatic photoelastic response with the analytical description of the stress state for the points studied.

INTRODUCTION

Improvements in model preparation and loading cycle procedures, together with the well-known advantages of high resolution and whole-field technique, have maintained photoelasticity as a cost-effective method for stress analysis purposes. In the design stage, reasonably accurate stress concentration factors (SCF) may be quickly measured. More accurate SCF evaluation and analysis of photoelastic data, such as stress separation, are more time consuming and so considerable amount of research has been directed to speed and to augment photoelasticity capabilities by its coupling to image analysis techniques, to micro-computers and to appropriate numerical methods.

Several computer-based algorithms have been proposed to determine accurately fringe orders and stresses at interior and surface points of photoelastic models. Berghaus fitted photoelastic data to field differential equations of elasticity in finite difference [1] and finite element [2] forms. Thompson and co-workers [3,4] determined SCF and performed stress separation in plane problems by using asymptotic analysis and least-squares.

Sanford has shown that the photoelasticity [5] and other optical method [6] responses can be associated to the least-squares technique to determine key parameters of elasticity problems if their mathematical governing equations are known. Freire and co-workers proposed that suitable approximate stress functions could be used to fit photoelasticity isochromatic data [7] and other optical technique responses [8] to solve plane elasticity problems for isotropic and orthotropic materials. A similar procedure was also presented by Huang et alii [9]. These last two approaches [7,8,9] allowed the automatic stress separation of the photoelastic response without the need for collection of isoclinic data.

The present paper associates the isochromatic optical response of plane photoelastic models to approximate polynomial stress functions in order to generate analytical expressions for stress distributions near the root of shallow notches. The paper also uses the Creager-Paris [10] equations developed for blunt cracks in order to determine SCF for sharp V-notches where the opening angle is less than 60°.

BASIC EQUATIONS FOR PLANE ELASTICITY AND SHALLOW NOTCHES

Stress distributions near the root of shallow notches can be determined through the coupling of photoelasticity data collected inside the desired region and the analytic description of the stress state for each point studied. Using the Goursat-Kolosov complex representation of the plane problem and the potential functions φ and ψ, it is possible to describe the stress state as

$$\begin{aligned}\sigma_r &= 2Re\varphi' - Re[e^{2i\theta}(\overline{z}\varphi'' + \psi')]\\ \sigma_\theta &= 2Re\varphi' + Re[e^{2i\theta}(\overline{z}\varphi'' + \psi')]\\ \tau_{r\theta} &= Im[e^{2i\theta}(\overline{z}\varphi'' + \psi')]\end{aligned} \qquad (1)$$

The functions φ and ψ can be chosen to satisfy certain boundary or special loading conditions of the photoelastic models. For example,

$$\varphi(z) = \sum^{m}(a_m + ib_m)z^m + w\ell_n z \qquad (2)$$

$$\psi(z) = \sum^{n}(p_n + iq_n)z^n + h\ell_n z \tag{3}$$

can be used to fit isochromatic data for important problems such as stress concentration near holes, V - notches, and also the brazilian disc problem.

For example, polynomial functions work well for stress concentration problems such as bars with holes and U-notches. For a hole in a infinite plane subjected to tension load, $\varphi = a_{-1}z^{-1} + a_1 z$ and $\psi = p_{-3}z^{-3} + p_1 z$ give the exact solution. For other problems envolving holes and U-notches, polynomial functions such as

$$\varphi = \sum a_m z^m \qquad \text{and} \qquad \psi = \sum p_n z^n \tag{4}$$

give good results. In general, m and n vary from -3 to +5 to fit data which can be taken relatively far from the maximum stress location and may be affected by the far field stress distributions, including the influence of free boundaries.

The constants a_m, b_m, p_n, q_n, w and h are determined through a Newton-Raphson least-squares fitting technique as proposed by Sanford [5,6] using the basic photoelasticity equation,

$$\sigma_1 - \sigma_2 = \frac{N}{t} f_\sigma \tag{5}$$

where N is the isochromatic fringe order, f_σ is the fringe calibration value and t is the specimen thickness. For stress separation purpose, boundary conditions must be given. Free boundary conditions near the stress concentration location are given by

$$\sigma_n = 0 \qquad \text{and} \qquad \tau_{nt} = 0 \tag{6}$$

where n and t are the normal and tangential directions for points at the free boundary.

Additional conditions for points located along symmetry lines can be established as

$$\tau_{j\ell} = 0 \tag{7}$$

where j and ℓ are directions parallel and perpendicular to the symmetry axes. If the isochromatic fringe orders N for points along the free boundary can be reliably measured, equations (8) below can be applied

$$\sigma_t = \frac{N}{t} f_\sigma \tag{8}$$

Coupling equations (2) and (3) or (4) with (1) and substituting into (5) gives the non-linear equation

$$(\sigma_1 - \sigma_2)^2 = \left(\frac{N}{t} f_\sigma\right)^2 = (\sigma_r - \sigma_\theta)^2 + 4\tau_{r\theta}^2 = F_1(a_m, b_m \ldots, w, r, \theta) \tag{9}$$

Linear equations are generated from the substitutions of (2), (3) or (4) into (1) and later into (6) to (8), giving

$$\sigma_n = F_2(a_m, b_m, \ldots, w, r, \theta) = 0 \tag{10}$$

$$\tau_{nt} = F_3(a_m, b_m, \ldots, w, r, \theta) = 0 \tag{11}$$

$$\sigma_t = F_4(a_m, b_m, \ldots, w, r, \theta) = \frac{N}{t} f_\sigma \tag{12}$$

$$\tau_{j\ell} = F_5(a_m, b_m, \ldots, w, r, \theta) = 0 \tag{13}$$

It is interesting to note that the solution of the problem for $a_m, b_m, \ldots, w$ will need only data collection (isochromatic fringe orders) at interior points of the models. Use of equations (12) and (13) is optional and will depend on the quality of data N that can be collected along the boundary. Data need to be collected only inside the particular region of the model that is being studied. Depending on the model geometry, loading conditions, and complexity of the aproximated stress function selected to use in the problem, the chosen region may be the entire model or just a small part of it. A total of $i + s + c$ data points is collected, where i, s and c are, respectively, the number of data taken from the interior points, from the symmetry lines and from the free boundary.

In general, $i + s + 3c$ equations (9) to (13) are solved simultaneously through a Newton-Raphson least-squares fitting technique. For this, g functions are generated such that

$$g_{1i} = F_{1i}(a_m, b_m, \ldots, w, r_i, \theta_i) - \left(\frac{N_i}{t} f_\sigma\right) \tag{14}$$

$$g_{2c} = F_{2i} \tag{15}$$

$$g_{3c} = F_{3i} \tag{16}$$

$$g_{4c} = F_{4c} - \left(\frac{N_c}{t} f_\sigma\right)^2 \tag{17}$$

$$g_{5s} = F_{5s} \tag{18}$$

The unknowns $a_m, b_m, ..., w$ are iteractively determined using initial estimations such as a_{mo}, b_{mo}, ..., w_o and the recurrence expressions such as (19) where the Δ increments are determined from the matricial equation (20) - (23).

$$a_{m_{k+1}} = a_{m_k} + \Delta a_{m_k} \tag{19}$$

$$\Delta = (A^T A)^{-1} AG \tag{20}$$

$$\Delta^T = (\Delta a_m, \Delta b_m, ..., \Delta w) \tag{21}$$

$$G^T = (-g_{1i} W_1, ..., -g_{5s} W_5) \tag{22}$$

$$A = \begin{bmatrix} W_1 \frac{\partial_{g11}}{\partial_{a_m}} & W_1 \frac{\partial_{g11}}{\partial_{b_m}} & \cdots & W_1 \frac{\partial_{g11}}{\partial_w} \\ \vdots & & & \\ W_5 \frac{\partial_{g5s}}{\partial_{a_m}} & W_5 \frac{\partial_{5s}}{\partial_{b_m}} & \cdots & W_5 \frac{\partial_{g5s}}{\partial_w} \end{bmatrix} \tag{23}$$

It was shown in [11] that about $k = 10$ iteractions are needed to reach final convergence. The weight functions W_1 to W_5 were used to equilibrate numerically the system of equations and have the following shape [11],

$$W_1 = i / \sum_{p=1}^{i} (g_{1p})^2 . S \tag{24}$$

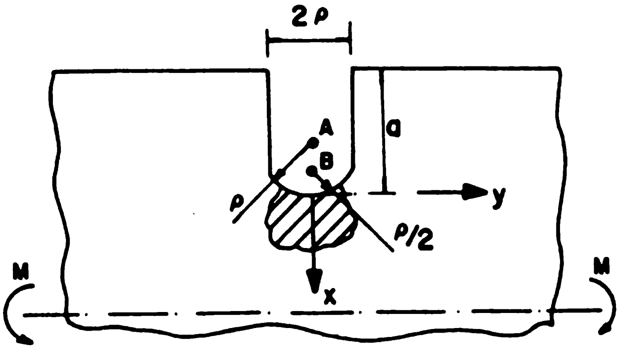
$$W_5 = s / \sum_{p=1}^{s} (g_{5p})^2 . S \tag{25}$$

$$S = \frac{(1 + s + 3c)}{\left(\sum^i g_1^2 + \sum^c g_2^2 + \sum^c g_3^2 + \sum^c g_4^2 + \sum^s g_5^2\right)} \tag{26}$$

Problems of the plane elasticity have already been tested with success. Among them are classical problems such as bars under uniaxial tension, three, and four point bending; finite and infinite bars with holes; U-notches under bending; and the brazilian disc problem. It can be noticed that stress separations were succesfully accomplished in both cases. In one case (brazilian disc) the whole specimen was analysed [7]. In the other case (U-notch) only a small region of interest, near the stress concentration, was focused. Results for this example are shown below.

Bar with Symmetrical U-Notches Under Bending

Data for this example was collected directly from a photograph presented by Frocht in [12], page 234. Results [12] for stress separation applying the shear difference and the slope equilibrium method were also used for comparison purposes.



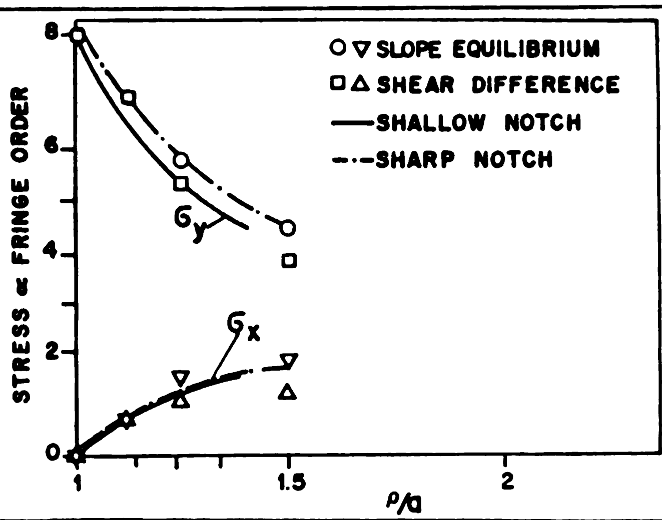


FIG. 1 - Bar with symmetrically located U-notches under bending. Comparison between stress separation results obtained from Frocht [12] and the present method. Region of data collection is shown in the Figure. A = origin for shallow notch approach. B - origin for sharp notch approach.

The region of data collection was small and is hown in Fig. 1. The coordinate system was coinided with the curvature center of the notch. Sixty ive data points were used, 45 of which were inteior points, 10 were along the symmetry line and .0 were along the notch boundary. The stress funcions φ and ψ used the terms $a(-2)$ to $a(5)$ and $p(-3)$ to $p(5)$. It should be noted that the terms $a(-1), a(1), p(-3)$, $p(-1)$ and $p(1)$ interpolate exactly the case of an infinite plane with a circular hole under tension.

Principal separated stress values obtained from equations (1) to (3) after determination of the terms a and p by the minimization scheme are presented n Fig. 1 and compared with Frocht's results. It can be seen that the agreement is very good. Results for he isochromatic fringe order fitting was also very good. Maximum fringe order determined by this nethod was 8.0, while Frocht's was 8.2.

Equations for Singular and Sharp V-Notches

After William's [1], Mahinfalah and Zachary [2] developed the following equations (27) for the stress components at points in the neighborhood of the vertex of reentrant singular corners for mixed mode I and II (Fig. 2). They used a stress function such as $\phi(z) = r^{\lambda+1} f(\theta)$. The stress equations are

$$\begin{aligned}
\sigma_r &= K_I r^{\lambda^+ -1} Q^+[f_1(\theta)] - K_{II} r^{\lambda^- -1} Q^-[f_2(\theta)] \\
\sigma_\theta &= K_I r^{\lambda^+ -1}(1+\lambda^+) Q^+[f_3(\theta)] - K_{II} r^{\lambda^- -1} \\
&\quad (1+\lambda^-) Q^-[f_4(\theta)] \\
\tau_{r\theta} &= K_I r^{\lambda^+ -1} Q^+[f_5(\theta)] + K_{II} r^{\lambda^- -1} Q^-[f_6(\theta)]
\end{aligned} \tag{27}$$

where K_I an K_{II} are defined as in expression (28) and the other terms are given in the Appendix.

$$K_{I,II} = \lim_{r\to 0} (2\pi)^{1/2} r^{\lambda - 1_{I,II}} \sigma_{I,II} \tag{28}$$

The values of λ^+ and λ^- are solutions of the eigenvalue equations

$$\lambda sin 2\alpha = \pm sin 2\lambda\alpha \tag{29}$$

and their first determinations (smaller values of $\lambda \neq 0$) are show in Fig. 2. The degree of singularity of the stress, $1-\lambda$, is maximum when the angle α of the V-notch is zero. For this case, $\lambda = 1/2$, and the notch assumes a crack shape. Freire and Carvalho [13] showed that stress intensity factors for 45° V-notches and crack-like notches ($\alpha = 0$) and their stress distributions near the notch tip are very simitar. For example, Fig. 3

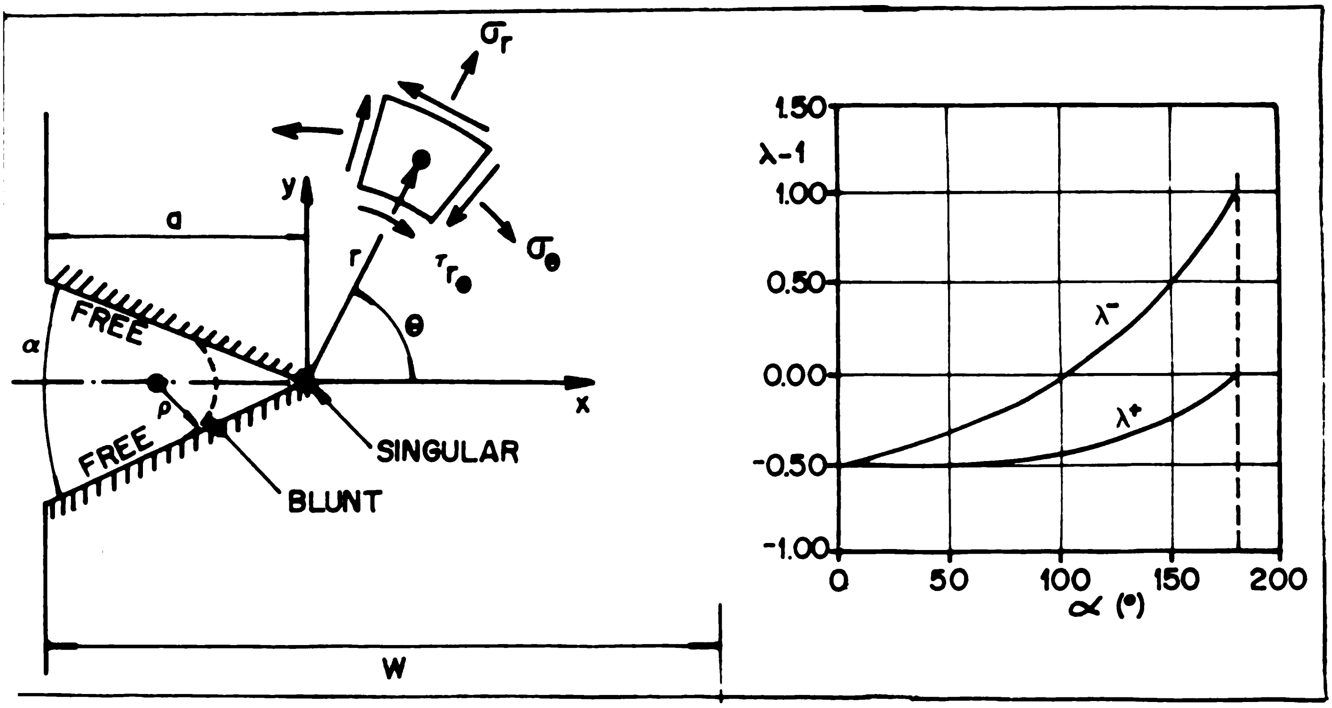

FIG. 2 - Geometry notation for singular and blunt V-notches. Degreee of singularity $(1-\lambda)$ with the angle (α) of the reentrant corner.

shows computer-plotted isochromatic fringe distributions for a crack and for a 45° V-notch specimens under tension [13]. Considering that $\lambda \simeq 1/2$ in mode I for V-notches with opening angle $0 < \alpha < 60°$, K_I for these notches and for cracks can be used indistinctly. Based on this conclusion it is possible to determine the stress field for the region near the root of blunt V-notches by coupling the isochromatic photoelastic response to the Creager-Paris equations [10] and to the Sanford's overdeterministic approach [5,6].

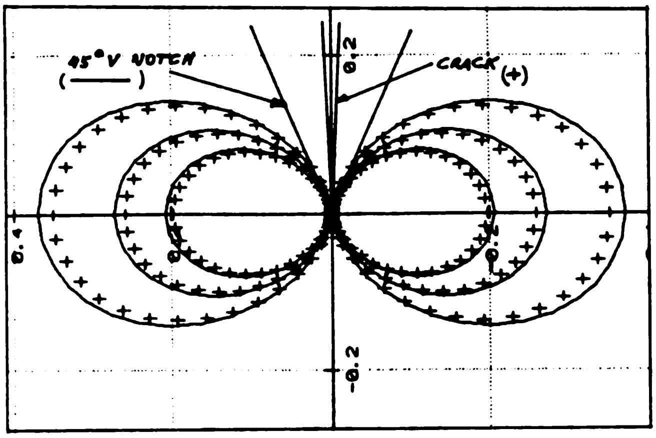

FIG. 3 - Computer-plotted isochromatic fringe distributions for a crack and for a 45° V-notch specimen under tension $a/w = 0.05$, near field.

The Creager and Paris [10] elastic stress equations for points near the root of sharp notches are presented below for mode I for blunt cracks (small ρ/a) in a form equivalent to the usual sharp crack-tip stress fields. They showed that their difference was a simple function of the curvature radius at the crack-tip. For these equations, the origin of the coordinate system (r, θ) is located $\rho/2$ away from the notch-root.

$$\begin{aligned}
\sigma_x &= \frac{K_I}{(2\pi r)^{1/2}} \cos\frac{\theta}{2}\left[1 - \sin\frac{\theta}{2}\sin\frac{3}{2}\theta\right] - \frac{K_I}{(2\pi r)^{1/2}}\frac{\rho}{2r}\cos\frac{3}{2}\theta \\
\sigma_y &= \frac{K_I}{(2\pi r)^{1/2}} \cos\frac{\theta}{2}\left[1 + \sin\frac{\theta}{2}\sin\frac{3}{2}\theta\right] + \frac{K_I}{(2\pi r)^{1/2}}\frac{\rho}{2r}\cos\frac{3}{2}\theta \\
\tau_{xy} &= \frac{K_I}{(2\pi r)^{1/2}} \sin\frac{\theta}{2}\cos\frac{\theta}{2}\cos\frac{3}{2}\theta - \frac{K_I}{(2\pi r)^{1/2}}\frac{\rho}{2r}\sin\frac{3}{2}\theta
\end{aligned} \tag{30}$$

Substitution of equations (30) into the photoelasticity equation (2) and generation of a functional G_i fort each collected i data point will give

$$G_i = (\sigma_1 - \sigma_2)_i^2 - \left(\frac{N_i}{t} f_\sigma\right)^2 = F_i(K_I, \rho, r_i, \theta_i) - \left(\frac{N_i}{t} f_\sigma\right)^2 \tag{31}$$

The application of the minimization scheme presented in the preceding section for G will lead to the determination of the K_I constant which best fit the data points in the least-squares sense. The determined K_I will be the stress intensity factor for a equivalent crack (or V-notch with $0 < \alpha < 60°$) which has its tip located at the origin of the (r, θ) coordinate system.

Two examples were chosen to demonstrate the method. The first example was a bar with symmetrical U-notches under bending. The second example envolved a bar with a sharp V-notch under tension. This U-notch geometry is equivalent to a Charpy notch used for impact tests.

Bar with Symmetrical U-Notches Under Bending

Due to its geometrical relations, this example can be considered as a limiting case, where both procedures for SCF determination for shallow and sharp notches can be applied.

Results for the sharp-notch SCF determination are also plotted in Fig. 1 for comparison purposes. It can be seen that these results agreed very well with the shallow notch procedure and also with Frocht's results. Only 25 data points were used in this case. K_I determination through the fitting procedure gave satisfactory results (10% difference from the analytical value), reminding that the effective crack length $a*$ should be determined from the origin of the system of coordinates, $a* = a - \rho/2$, for the sharp notch approach. In this case, it is not expected that the procedure furnish an accurate value for K_I since this geometry is considerably different from a crack. In this case, K_I plays the whole of an adjusting parameter for the experimental data.

Bar with Charpy V-Notch Under Tension

The second example applied the sharp notch procedure to the Charpy V-notch bar geometry under tension load (Fig. 4). The K_I determined value agreed with K_I for a crack with the same effective geometry (less than 1% difference).

The value of the maximum stress ($\sigma_y = \sigma_{max}$) at the notch-root ($\rho/2$, 0) can be determined using equations (30). In terms of the isochromatic fringe response, this value was calculated to be $N_{max} =$ 8.6 which is very close to the photoelastic direct observation ($N_{max} = 8.8$).

Using σ_{max} or N_{max} and a nominal stress or fringe order, the stress concentration factor for the Charpy V-notch can be calculated as $K_t = N_{max}/N_{nom}$. In the present case, the presence of bending in the net section was considered in the calculation of N_{nom} as suggested by Noda and Nisitani [14].

The values of K_t determined in this analysis were 3.4 and 3.5, respectively by the overdeterministic approach and by the photoelastic direct observation. Theoretical results from Noda and Nisitani [14] for $\alpha = 60°$ give $K_t = 3.7$. Recent results from Demelio et al. [15], approximated to the Charpy geometry and considering the N_{nom} calculated as in [14], give $K_t \simeq 3.6$.

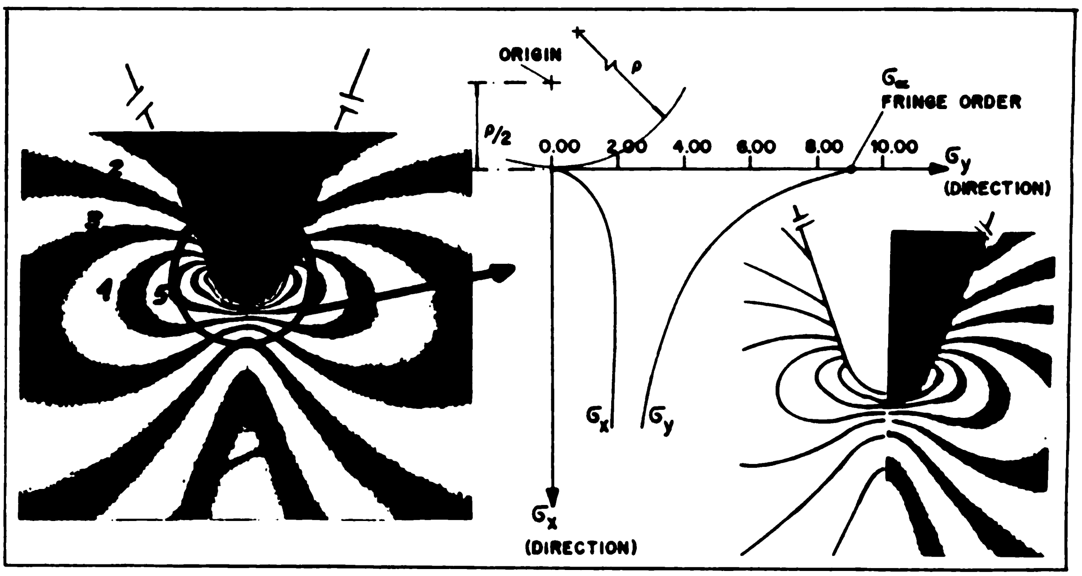

FIG. 4. Bar with a Charpy V-notch under tension. Distribution od stresses along the x axis in a region near the notch-root. Regenerated and original isochromatic distributions. Standard deviation between calculated and measured (25) data points is equal to 2.5%.

Fig. 4 gives the stress distributions for the photoelastic analysis in locations very near to the notch-root. This separation is possible if equations (30) are calculated independently for each point (r, θ) using ρ and the determined K_I value.

This Figure, also presents isochromatic fringe orders regenerated by the procedure using the calculated K_I value, equation (30) and equation (2). The calculated isochromatic fringe values and their distributions are commonly used to give a measure of how good the fitting procedure is working. This can be done visually or by comparing collected with calculated data point by point and determining their standard deviation. Good fittings generate standard deviations which are generally under 3%.

Micromechanics as a basis of stochastic finite elements and differences: An overview

M Ostoja-Starzewski

Department of Materials Science and Mechanics
Michigan State University, East Lansing, MI 48824-1226

A generalization of conventional deterministic finite element and difference methods to deal with spatial material fluctuations hinges on the problem of determination of stochastic constitutive laws. This problem is analyzed here through a paradigm of micromechanics of elastic polycrystals and matrix-inclusion composites. Passage to a sought-for random meso-continuum is based on a scale dependent window playing the role of a Representative Volume Element (RVE). It turns out that the microstructure cannot be uniquely approximated by a random field of stiffness with continuous realizations, but, rather, two random continuum fields may be introduced to bound the material response from above and from below. Since the RVE corresponds to a single finite element, or finite difference cell, not infinitely larger than the crystal size, these two random fields are to be used to bound the solution of a given boundary value problem at a given scale of resolution. The window-based random continuum formulation is also employed in analysis of rigid perfectly-plastic materials, whereby the classical method of slip-lines is generalized to a stochastic finite difference scheme. The present paper is complemented by a comparison of this methodology to other existing stochastic solution methods.

1. INTRODUCTION

The necessity to account for random effects in determining the response of a mechanical system is due, in general, to three different sources: random external forcing, random boundary conditions, and random material parameters. In the last fifteen years the powerful finite element method has undergone various new developments to incorporate these random effects, and is now termed Stochastic Finite Elements (SFE), see e.g. (Contreras, 1980; Benaroya and Rehak, 1988). In this paper we focus only on the type of SFE problems which deal with randomness stemming from fluctuations in material properties. Most of the past research in that area concerned linear elastic structural responses and relied on a straightforward generalization of Hooke's law, that is

$$\underset{\sim}{\sigma} = \underset{\sim}{C}(\underset{\sim}{x}, \omega)\,\underset{\sim}{\varepsilon} \tag{1.1}$$

In equation (1.1) $\underset{\sim}{x}$ stands for a location within the body domain, ω is an index from the sample space Ω, and $\underset{\sim}{C}(\underset{\sim}{x}, \omega)$ is a continuous realization of a random tensor field of stiffnesses. Part of the assumption (1.1) is the invertibility of such a constitutive law, that is

$$\underset{\sim}{\varepsilon} = \underset{\sim}{S}(\underset{\sim}{x}, \omega)\,\underset{\sim}{\sigma} \qquad \underset{\sim}{S}(\underset{\sim}{x}, \omega) = \underset{\sim}{C}^{-1}(\underset{\sim}{x}, \omega) \tag{1.2}$$

whereby $\underset{\sim}{\varepsilon}$ and $\underset{\sim}{\sigma}$ in (1.1) and $(1.2)_1$ are uniform fields applied to a hypothetical and unspecified Representative Volume Element (RVE) of a random medium. In fact, typically, a locally isotropic form

$$\sigma_{ij} = \lambda(\underset{\sim}{x}, \omega)\,\delta_{ij}\varepsilon_{kk} + 2\mu(\underset{\sim}{x}, \omega)\,\varepsilon_{ij} \tag{1.3}$$

is adopted by simply postulating one or both elastic constants, such as the Young's modulus, to be a random field.

While the effort in SFE has been on the development of efficient numerical methods for solution of boundary value problems, the above model - equations (1.1-3) - lacks a connection to the material microstructure. It is the determination of that missing micromechanics link, which forms the main objective of this paper. Additionally, our methodolgy may also be applied to other than elastic microstructures, and used in solution of random media problems by finite differences. A very closely related issue of specification of continuum random fields approximating elastic microstructures is studied by Ostoja-Starzewski (1993b).

The paper's outline is as follows. In Section 2 we describe the passage from the level of a linear elastic microstructure to that of two random meso-continuum models $\underset{\sim}{C}_{\delta}(\underset{\sim}{x}, \omega)$, where δ indicates the scale dependence. Next follows a stochastic variational formulation of finite elements - in both dispalcement and force approaches - which illustrates the role of these meso-continuum models in bounding the actual response. The micromechanics approach is employed in Section 3, which focuses on rigid--perfectly plastic materials with random fluctuations in the yield functions. It follows here that the method of slip-lines - well known from the deterministic homogenous media problems - is now to be generalized to stochastic finite differences. Section 4 is devoted to comparisons with other existing approaches. Thus, we briefly review the classical SFE methods for elastic structures and discuss their applicability in micromechanics-based analyses. In the area of plasticity, we discuss the relation of our formulation of Section 3 to a recent study of Nordgren (1992).

2. ELASTIC MEDIA PROBLEMS

2.1 Random medium model

Fundamental role in our formulation is played by the concept of a *random medium* (or *random microstructure*), which, as is commonly done in mechanics of random media (Willis, 1981), is taken as a family $\boldsymbol{B} = \{\mathbf{B}(\omega);\ \omega \in \Omega\}$ of deterministic media $\mathbf{B}(\omega)$, where ω indicates one specimen (realization), and Ω is an underlying sample (probability) space. Formally, Ω is equipped with a σ-algebra F and a probability distribution P. In an experimental setting P may be specified by a set of stereological measurements, while in a theoretical setting P is usually specified by a chosen model of a microstructure. All specimens $\mathbf{B}(\omega)$ occupy the same domain in x_1, x_2-plane; we employ a two-dimensional setting (2-D) for the clarity of presentation.

In the following we consider two types of the random medium $\boldsymbol{B}$. In the first one, we take every specimen $\mathbf{B}(\omega)$ to be modeled by a realization of a *Voronoi tessellation* (Fig. 1.a), while in the second by a realization of a matrix-inclusion composite (Fig. 1 b). Fundamental in both cases is a planar space-homogeneous Poisson process of some given density. In case of a Voronoi tessellation each cell, centered at a Poisson point $\underline{x}$, is assumed to be occupied by a homogeneous continuum governed by a stiffness tensor $\underline{C}(x, \omega)$ following a space-homogeneous probability distribution $P(\underline{C})$. In case of the matrix-inclusion composite, we use an inhibition Poisson process to ensure that there is no overlap of inclusions shaped as round disks. We assume the disks to be occupied by a homogeneous isotropic continuum of one kind, while the matrix by a continuum of another.

In case of both models we assume all the phases to satisfy the so-called *ellipticity conditions*: $\exists\alpha, \beta > 0$ such that for any $\underline{\varepsilon}$ the following inequalities hold for all the phases

$$\alpha\underline{\varepsilon}\underline{\varepsilon} \le \underline{\varepsilon}\underline{C}\underline{\varepsilon} \le \beta\underline{\varepsilon}\underline{\varepsilon} \tag{2.1}$$

Thus, we have two realistic ergodic media models without holes and rigid inclusions described by random fields $\underline{C} = \{\underline{C}(\underline{x}, \omega);\ \underline{x} \in B; \omega \in \Omega\}$ with piecewise-constant realizations. This piecewise-constant nature of stiffness fields is an obstacle to employing the governing equations of continuum elasticity, which require that the stiffness fields be differentiable. Thus, there is a need for another continuum model - one that possibly loses some information due to a "smearing-out" procedure, but is sufficiently differentiable and grasps the meso-level behavior.

2.2 Two scale-dependent random continuum fields

First, with the help of Fig. 1, we introduce a square-shaped *window* of scale

$$\delta = \frac{L}{d} \tag{2.2}$$

Equation (2.2) defines a nondimensional parameter δ, typically greater than 1, specifying the scale L of observation (and/or measurement) relative to a typical microscale d (i.e. grain size) of the material structure. $\delta = 1$ is the smallest scale we consider: scale of a crystal or inclusion. In view of the fact that the Voronoi tessellation is a random medium, the window bounds a random microstructure $B_\delta = \{B_\delta(\omega);\ \omega \in \Omega\}$, where $B_\delta(\omega)$ is a single realization from a given specimen $\mathbf{B}(\omega)$.

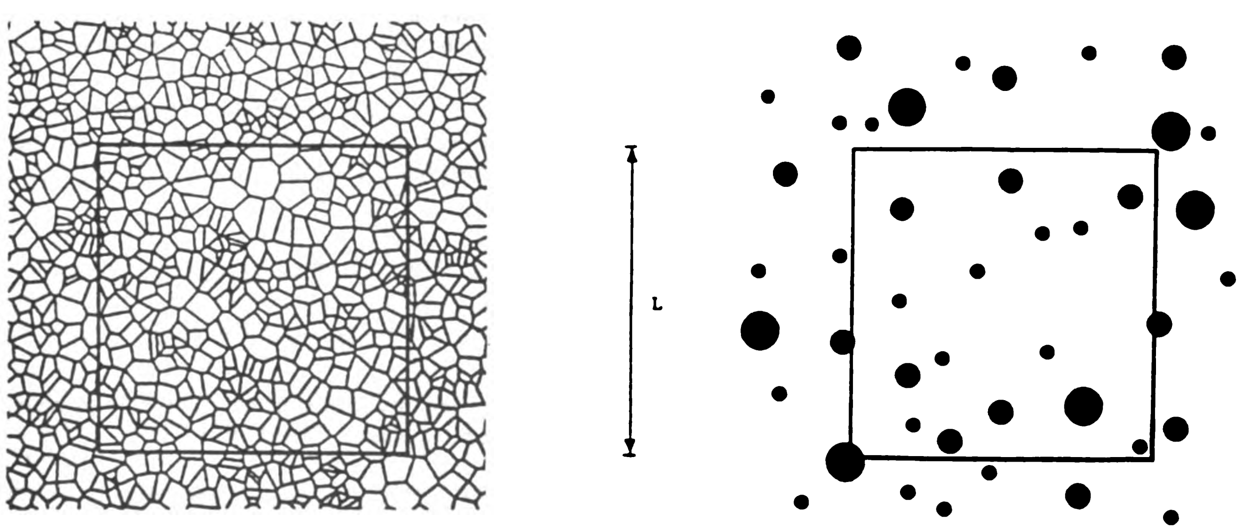

FIG 1.a) A Voronoi tessellation with an average cell size d; b) a matrix-inclusion composite with inclusions of average diameter d; in both cases a window of size L is indicated.

A continuum-type constitutive law is obtained by postulating the existence of an effective homogeneous continuum $B_\delta^{cont}(\omega)$ of the same volume V_δ (i.e. area in 2-D), whose potential energy U, or complementary energy U*, under given uniform boundary conditions equals that of a microstructure $B_\delta(\omega)$ under the same boundary conditions. These are of two basic types:

i) displacement-controlled (*essential*)

$$u(\underset{\sim}{x}) = \varepsilon_{ij}^0 x_j \qquad \text{on} \qquad \partial B_\delta \tag{2.3}$$

where $\underset{\sim}{\varepsilon}^0$ is a given constant tensor and ∂B_δ is the boundary of B_δ,

ii) stress-controlled (*natural*)

$$\underset{\sim}{t} = \sigma_{ij}^0 n_j \qquad \text{on} \qquad \partial B_\delta \tag{2.4}$$

where $\underset{\sim}{\sigma}^0$ is a given constant tensor.

Boundary condition (2.3) results in an effective random stiffness tensor $\underset{\sim}{C}_\delta^e(\omega)$, with the Hooke's law being

$$\bar{\underset{\sim}{\sigma}}(\omega) = \underset{\sim}{C}_\delta^e(\omega)\,\underset{\sim}{\varepsilon}^0 \tag{2.5}$$

which points to a random nature of the resulting stress field; overbar indicates a volume average (i.e. area average in 2-D). It has to be pointed out that the surface traction is random inhomogenous on $\partial B_\delta(\omega)$, with the fluctuations disappearing in the limit $\delta \to \infty$.

On the other hand, (2.4) results in a following random form of Hooke's law, involving a compliance tensor,

$$\bar{\underset{\sim}{\varepsilon}}(\omega) = \underset{\sim}{S}_\delta^n(\omega)\,\underset{\sim}{\sigma}^0 \tag{2.6}$$

which points to a random nature of the resulting strain field, and the presence of random fluctuations in the dispalcement u_i on the window boundary. Hereafter, superscripts ^{e} and ^{n} stand for essential and natural conditions, respectively. Also, we shall use the same type of notation for conductivity and out-of-plane elasticity, whereby $\underset{\sim}{\varepsilon}$ and $\underset{\sim}{\sigma}$ are vectors, C_{ij} is conductivity, and S_{ij} is resistivity.

Following (Ostoja-Starzewski, 1992a, 1993a, b) we list here these principal observations:

1. Due to the heterogeneity of the microstructure $B_\delta(\omega)$, the inverse

$$\underset{\sim}{C}_\delta^n(\omega) = \left[\underset{\sim}{S}_\delta^n(\omega)\right]^{-1} \tag{2.7}$$

is for any finite δ, in general, different from $\underset{\sim}{C}_\delta^e$ obtained under essential conditions.

2. $\underset{\sim}{C}_\delta^e(\omega)$ and $\underset{\sim}{C}_\delta^n(\omega)$ satisfy an inequality

$$\underset{\sim}{C}_\delta^n(\omega) \le \underset{\sim}{C}_\delta^e(\omega) \tag{2.8}$$

Hereinafter, for two fourth-rank tensors $\underset{\sim}{A}$ and $\underset{\sim}{B}$, an order relation $\underset{\sim}{B} \le \underset{\sim}{A}$ means

$$t_{ij} B_{ijkl} t_{kl} \le t_{ij} A \quad [illegible] \quad \neq 0 \tag{2.9}$$

3. In view of the spa[illegible] f microstructure's statistics, $\underset{\sim}{C}_\delta^n(\omega)$ and [illegible] as δ tends to infinity; this defines a deterministic continuum $\mathbf{B}_{det}$ for a single specimen $\mathbf{B}(\omega)$

$$\underset{\sim}{C}^{det}(\omega) = \underset{\sim}{C}_\infty^n(\omega) = \underset{\sim}{C}_\infty^e(\omega) \tag{2.10}$$

whereby the window of infinite extent plays the role of an RVE of deterministic elasticity theory; in other words, it is at $\delta \to \infty$ that the invertibility of the constitutive law is obtained.

4. Ergodicity of the microstructure implies that

$$\underset{\sim}{C}^{det}(\omega) = \underset{\sim}{C}^{eff} \qquad \forall \omega \in \Omega \tag{2.11}$$

where $\underset{\sim}{C}^{eff}$ is the effective response tensor (independent of ω) of a homogeneous medium.

5. At any finite δ both response tensors are, in general, anisotropic, with the nature of anisotropy dependent on any specific $B_\delta(\omega)$. This indicates that the model (1.3) is invalid. On the other hand, (2.8) is isotropic due to the spatial homogeneity and isotropy of the underlying Poisson point process and the spatial homogeneity of $P(\underset{\sim}{C})$.

6. Since the window may be placed arbitrarily in the domain of $\mathbf{B}(\omega)$, the essential and natural boundary conditions define two different inhomogeneous tensor fields at the scale δ with continuous realizations, which lead to two *random meso-continuum approximations*: $\boldsymbol{B}_\delta^e = \{\mathbf{B}_\delta^e(\omega)\,;\ \omega \in \Omega\}$ and $\boldsymbol{B}_\delta^n = \{\mathbf{B}_\delta^n(\omega)\,;\ \omega \in \Omega\}$, respectively. Accordingly, a window of size δ may be considered as an RVE of these two random continuum models; this calls into question the unique response law (1.1-2).

7. Our definition of two inhomogeneous tensor fields is conceptually similar - but not the same (!) - to the procedure of *local averaging* in the theory of random fields applied to a single realization $\underset{\sim}{C}(\omega)$; $\omega \in \Omega$ (Vanmarcke, 1983); it becomes the same in case of a 1-D model only when applied to compliance. In two and three dimensions computational mechanics methods have to be implemented - in a Monte Carlo sense - to find the energies and, hence, the effective moduli of finite windows and their probability distributions $P(\underset{\sim}{C}_\delta^e)$ and $P(\underset{\sim}{C}_\delta^n)$. Similarly, the autocorrelation (autocovariance) functions may be determined (see also Ostoja-Starzewski and Wang, 1989 and 1990).

8. Principles of minimum potential and complementary energies can be used to obtain a hierarchy of scale-dependent bounds on the effective stiffness tensor $\underset{\sim}{C}^{eff}$ (see also Huet, 1990)

$$\begin{gathered}(\underset{\sim}{S}^R)^{-1} \equiv \langle \underset{\sim}{S}_1^n \rangle^{-1} \le \langle \underset{\sim}{S}_{\delta'}^n \rangle^{-1} \le \langle \underset{\sim}{S}_\delta^n \rangle^{-1} \le \underset{\sim}{C}^{eff} \le \\ \langle \underset{\sim}{C}_\delta^e \rangle \le \langle \underset{\sim}{C}_{\delta'}^e \rangle \le \langle \underset{\sim}{C}_1^e \rangle \equiv \underset{\sim}{C}^V \qquad \forall \delta' < \delta\end{gathered} \tag{2.12}$$

This is equivalent, by inversion, to a hierarchy of bounds on the effective compliance $\underset{\sim}{S}^{eff} = (\underset{\sim}{C}^{eff})^{-1}$

$$\begin{gathered}\underset{\sim}{S}^R \equiv \langle \underset{\sim}{S}_1^n \rangle \ge \langle \underset{\sim}{S}_{\delta'}^n \rangle \ge \langle \underset{\sim}{S}_\delta^n \rangle \ge \underset{\sim}{S}^{eff} \ge \\ \langle \underset{\sim}{C}_\delta^e \rangle^{-1} \ge \langle \underset{\sim}{C}_{\delta'}^e \rangle^{-1} \ge \langle \underset{\sim}{C}_1^e \rangle^{-1} \equiv (\underset{\sim}{C}^V)^{-1} \qquad \forall \delta' < \delta\end{gathered} \tag{2.13}$$

9. Since two different random anisotropic continua result, a

given boundary value problem must then be solved to find the upper and lower bounds on response according as random fields $\underset{\sim}{C}_\delta^e$ and $\underset{\sim}{C}_\delta^n$ are employed, see Sections 2.3 and 2.4.

2.3 Variational approach to stochastic finite elements

2.3.1 The displacement method

We start from the principle of minimum potential energy for each $\mathbf{B}(\omega)$ of $\boldsymbol{B}$

$$\delta \Pi(\omega) = \delta (U(\omega) - W) = 0 \tag{2.14}$$

where $U(\omega)$ is the (random) strain energy and W is the work done by body forces $\underset{\sim}{f}$ and surface tractions $\underset{\sim}{t}$. More explicitly,

$$\delta \Pi(\omega) = \int_V \underset{\sim}{\sigma}(\omega)\,\delta\underset{\sim}{\varepsilon}\,dV - \int_V \underset{\sim}{f}\,\delta\underset{\sim}{u}\,dV - \int_{S_t} \underset{\sim}{t}\,\delta\underset{\sim}{u}\,dS = 0 \tag{2.15}$$

where S_t is the part of the body on which tractions are prescribed. Now, with respect to Fig. 2 showing a typical $\mathbf{B}(\omega)$, we introduce a triangulation of the body domain $\mathbf{B}$ of $\mathbf{B}(\omega)$, a closed set, into a finite number of (closed) triangles K_i (i = 1, 2, ... , N) such that

$$\mathbf{B} = \bigcup_{i=1}^{N} K_i \tag{2.16}$$

whereby (2.15) is replaced, approximately, by

$$\delta \Pi(\omega) =$$

$$= \sum_{i=1}^{N} \int_{V_i} \underset{\sim}{\sigma}(\omega)\,\delta\underset{\sim}{\varepsilon}\,dV - \sum_{i=1}^{N} \int_{V_i} \underset{\sim}{f}\,\delta\underset{\sim}{u}\,dV - \sum_{i=1}^{N} \int_{{}^iS_t} \underset{\sim}{t}\,\delta\underset{\sim}{u}\,dS = 0 \tag{2.17}$$

It is noted here, in this displacement method, that the kinematic constraints are imposed on each triangle so that the first term in (2.17) becomes

$$\sum_{i=1}^{N} \int_{V_i} \underset{\sim}{\varepsilon}\,{}^i\underset{\sim}{C}^e(\omega)\,\delta\underset{\sim}{\varepsilon}\,dV \tag{2.18}$$

where ${}^i\underset{\sim}{C}^e(\omega)$ should be the tensor $\underset{\sim}{C}_\delta^e$ determined according to Section 2.2 for the i-th particular triangular finite element. In other words, this finite element specifies a window over which the essential boundary conditions are prescribed, while δ may be chosen to be the base of an isosceles right triangle; of course some other definiton of δ may be adopted here, such as, for example, δ being an equivalent diameter of a circle of the same area as the given triangle.

An important issue concerns the choice of interpolation functions: linear ones

$$u_e(x_1, x_2) = a + bx_1 + cx_2 \tag{2.19}$$

are fully consistent with the uniform strain implied by (2.3). Observing that the uniform strain (as well as uniform stress) is *the* strain used in micromechanics to define a passage to effective constitutive law, we see an inconsistency in using micromechanical inputs for finite element methods using higher order interpolation functions. Thus, a 2-nd, and higher, order triangular elements as well as all quadrilateral elements would not be consistent with (2.3).

Returning to (2.17) and (2.18) we find

$$[K(\omega)]\{U\} = \{F\} \tag{2.20}$$

which provides the basis for a Monte Carlo solution of the finite element problem, as well as for solution in terms of moments; see Section 2.3.3 for a discussion of the ensemble average solution. The global stiffness matrix in (2.20) is synthesized from the stiffness matrices of all the elements

$$[K(\omega)] = \sum_{i=1}^{N} [{}^iK(\omega)] \tag{2.21}$$

where each $[{}^iK(\omega)]$ is obtained as follows

$$\begin{aligned}[{}^iK(\omega)] &= \int_{{}^iV} [{}^iB]^T [{}^iC(\omega)] [{}^iB]\,dV = \\ &= [{}^iB]^T [{}^iC] [{}^iB]\,{}^iV\end{aligned} \tag{2.22}$$

In the above $[{}^iC(\omega)]$ is the matrix of material moduli, given by ${}^i\underset{\sim}{C}^e(\omega)$, while $[{}^iB]$ is the gradient matrix.

2.3.2 The force method

We start from the principle of minimum complementary energy

$$\delta \Pi^*(\omega) = \int_V \delta\underset{\sim}{\sigma}\underset{\sim}{\varepsilon}(\omega)\,dV - \int_{S_u} \delta\underset{\sim}{t}\underset{\sim}{u}\,dS = 0 \tag{2.23}$$

for each $\mathbf{B}(\omega)$ of $\boldsymbol{B}$, and S_u is the part of the body on which displacements are prescribed. By employing the triangulation (2.16), we obtain (again approximately)

$$\delta \Pi^*(\omega) = \sum_{i=1}^{N} \int_{{}^iV} \delta\underset{\sim}{\sigma}\underset{\sim}{\varepsilon}(\omega)\,dV - \sum_{i=1}^{N} \int_{{}^iS_u} \delta\underset{\sim}{t}\underset{\sim}{u}\,dS = 0 \tag{2.24}$$

Since now force constraints are imposed on each triangle, the first term in (2.24) becomes

$$\sum_{i=1}^{N} \int_{{}^iV} \delta\underset{\sim}{\sigma}\,{}^i\underset{\sim}{S}^n(\omega)\,\underset{\sim}{\sigma}\,dV \tag{2.25}$$

where ${}^i\underset{\sim}{S}^n(\omega)$ should be the tensor $\underset{\sim}{S}_\delta^n(\omega)$ determined according to Section 2.2 for the i-th particular finite element. Also here the system (2.24) may now be expressed in a form.

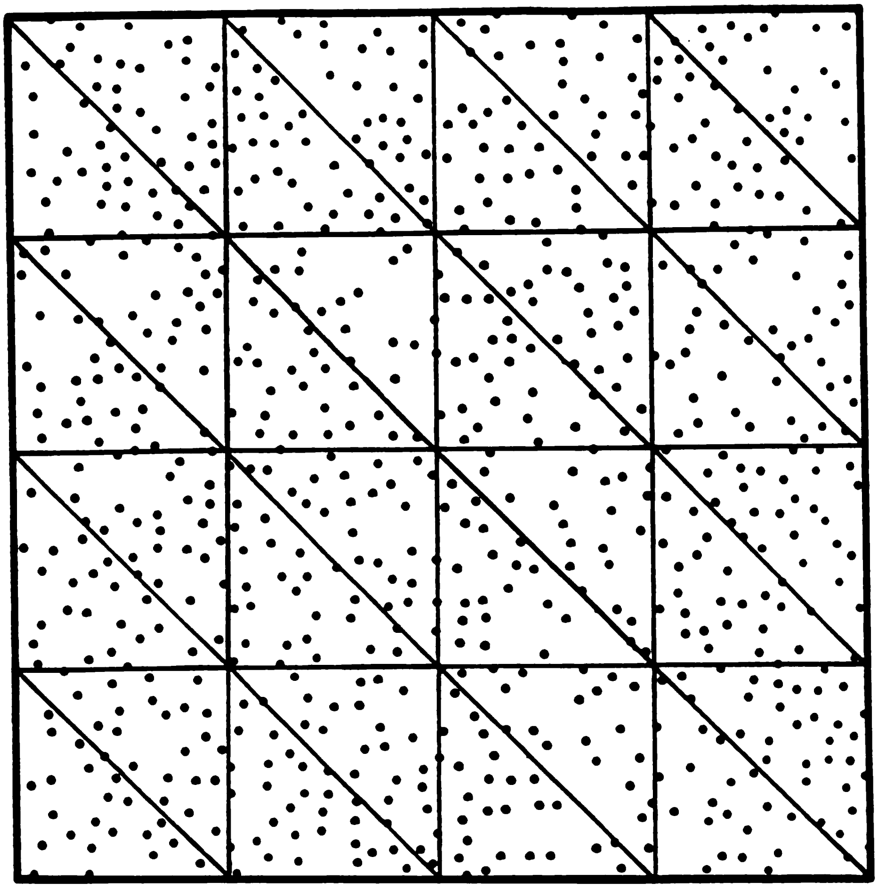

FIG 2. Showing a membrane of a matrix-inclusion composite with a finite element mesh of resolution δ.

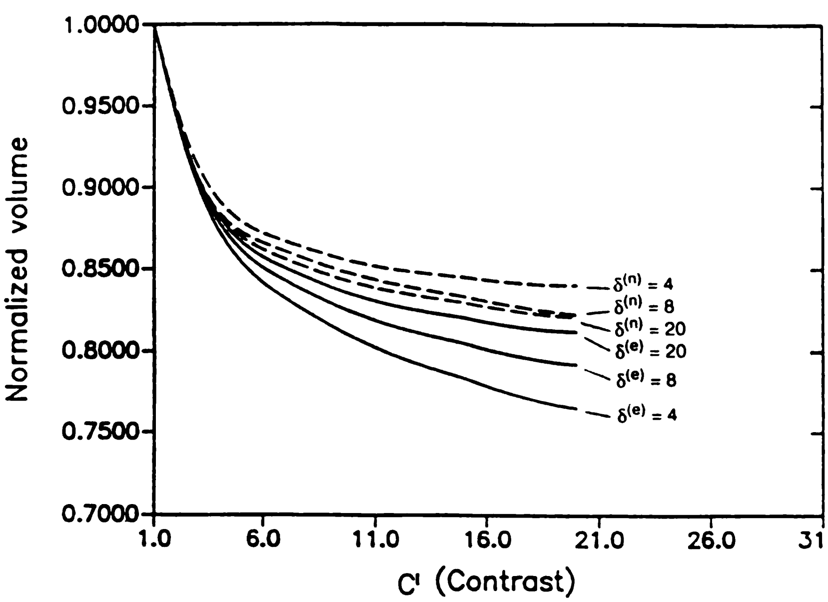

FIG 3. Graph of the ensemble average "upper" and "lower" responses, normalized over the deterministic case $C^i = C^m = 1$. $\delta^{(e)}$ and $\delta^{(n)}$ correspond to $\underline{C}^e_\delta$ and $\underline{C}^n_\delta$ in equation (2.29), respectively.

2.3.3 Ensemble average formulations

It follows from the Section 2.2 that (2.17) would provide a "stiffer" statistical solution $\{\underset{\sim}{u}^e(\omega);\omega\in\Omega\}$, while (2.24) a "softer" one $\{\underset{\sim}{u}^n(\omega);\omega\in\Omega\}$; ^{e} and ^{n} superscripts have the same meaning as defined earlier. The actual solution $\underset{\sim}{u}^{act}(\omega)$ lies between these two. However, the force method in finite element analyses has some well known drawbacks. Thus, a question arises whether a lower bound on $\underset{\sim}{u}^{act}(\omega)$ can be obtained by employing the displacement approach solely?

To this end, we carry out ensemble averaging of (2.6) to obtain

$$\langle\underset{\sim}{\varepsilon}\rangle = \langle\underset{\sim}{S}^n_\delta\rangle\underset{\sim}{\sigma}^0 \tag{2.26}$$

which results in a uniform strain field and linear displacements on the boundary of each i-th finite element. Since the surface tractions are now linear on the element boundary and there is no randomness present, this can now be used in a deterministic displacement formulation

$$\delta\langle\Pi\rangle = \sum_{i=1}^{N}\int_{V_e}\underset{\sim}{\sigma}\delta\underset{\sim}{\varepsilon}dV - \sum_{i=1}^{N}\int_{V_i}\underset{\sim}{f}\delta\underset{\sim}{u}dV - \sum_{i=1}^{N}\int_{S_t}\underset{\sim}{t}\delta\underset{\sim}{u}dS = 0 \tag{2.27}$$

providing we replace $\underset{\sim}{\sigma}$ by $\underset{\sim}{\sigma}^0 = \langle\underset{\sim}{S}^n_\delta\rangle^{-1}\langle\underset{\sim}{\varepsilon}\rangle$ and $\underset{\sim}{\varepsilon}$ by $\langle\underset{\sim}{\varepsilon}\rangle$. Of course the upper bound on $\underset{\sim}{u}^{act}(\omega)$ is obtained by either averaging $\{\underset{\sim}{u}^e(\omega);\omega\in\Omega\}$, or, more simply employing (2.22) above with an ensemble averaged form of (2.5)

$$\langle\underset{\sim}{\sigma}\rangle = \langle\underset{\sim}{C}^e_\delta\rangle\underset{\sim}{\varepsilon}^0 \tag{2.28}$$

Dually, one can set up a pair of lower/upper bound solutions by using the averaged version of the complementary energy principle of Section 2.3.2, but, in view of our observation at the top of this Section, this would seem to be of less interest.

2.4 Example results

An approximate solution method in an SFE problem has recently been implemented by Alzebdeh and Ostoja-Starzewski (1993). With respect to Fig. 2, which shows a typical realization B(ω) of $\boldsymbol{B}$, the problem was formulated and run as follows:

i) Out-of plane displacements $u(x_1, x_2)$ of a matrix-inclusion composite defined in Section 2.1 were studied. These were governed by a Poisson equation with Dirichlet boundary conditions

$$\frac{\partial}{\partial x_i}\left(C_{ij}(\underset{\sim}{x},\omega)\frac{\partial u}{\partial x_j}\right) = f \qquad u(\underset{\sim}{x}) = 0, \underset{\sim}{x}\in\partial\mathbf{B} \tag{2.29}$$

where f is constant throughout **B**, and C_{ij} are components and realizations of two conductivity random tensor fields (of second rank) of continuum approximations $\boldsymbol{B}^e_\delta$ or $\boldsymbol{B}^n_\delta$, where δ corresponds to the mesh size.

ii) Generation, in a Monte Carlo sense, of a realization **B**(ω) and calculation of the effective moduli $\underset{\sim}{C}^e_\delta$ and $\underset{\sim}{C}^n_\delta$ for each square-shaped window (recall Fig.1 b).

iii) Using of thus obtained ${}^i\underset{\sim}{C}^e(\omega)$ of any given square as ${}^i\underset{\sim}{C}^e(\omega)$ for the two (isosceles right) triangular-shaped windows making up the square-shaped one, and calculating the stiffer response using a triangular mesh.

iv) Using of ${}^i\underset{\sim}{C}^n(\omega)$ obtained in point ii) as ${}^i\underset{\sim}{C}^n(\omega)$ for the two triangular-shaped windows making up the square-shaped one, and calculating the softer response using a triangular mesh.

v) Repeating ii) - iv) a number of (say, twenty or fifty) times.

Fig. 3 gives results of the above solution method for three mesh sizes - δ = 4, 8, 20. Specifically, this figure shows the ensemble average volumes contained under the membrane - $V^{(e)}(\omega)$ and $V^{(n)}(\omega)$ versus increasing contrast, i.e. ratio of inclusion stiffness C^i to matrix stiffness C^m. In order to nondimensionalize the problem, we took $C^m = 1$. We see that, for a fixed δ, both curves are decreasing monotonically and diverging away from the homogenous medium case $C^i = C^m = 1$, with increasing C^i. In addition, for a fixed contrast, we see that the two responses (bounds) get closer with increasing δ, and have a tendency to converge to a unique value as $\delta\to\infty$, which corresponds to the deterministic case, recall (2.8). This limit, however, can only be thought of in an approximate sense (a finite element is *finite* !). In fact, in situations where a resolution of local stresses is desired, we would use rather small elements - i.e. small δ - and obtain two quite different bounds on the response, accompanied by significant fluctuations. Further discussion and results on the strength of fluctuations in $V^{(e)}(\omega)$ and $V^{(n)}(\omega)$ are given in (Alzebdeh and Ostoja-Starzewski, 1993).

3. PLASTIC MEDIA PROBLEMS

3.1 Random medium model

The basic concepts introduced in Section 2.1 - i.e. those of a random medium $\boldsymbol{B}$ of domain D defined on Ω and the x_1, x_2-plane, a window of scale δ, and a random continuum approximation $\boldsymbol{B}_\delta$ - may be applied to materials having a different constitutive response than the elastic one. Specifically, in view of the availability of an effective solution method for rigid-plastic materials - that is, the method of slip-lines - we focus on materials describable by the yield function

$$(\sigma_{11}-\sigma_{22})^2 + 4\sigma_{12}^2 = 4k_\delta^2 \tag{3.1}$$

in which k_δ is a random field, parametrized by x and y, that describes effective plastic limit of the microstructure according to the chosen resolution δ. A micromechanical basis for determination of k_δ is discussed in Section 3.2 below. At this stage we assume that the statistics of k_δ and, in particular, its average $\langle k_\delta\rangle$ and the autocorrelation distance r_c are known.

It is interesting to observe that (3.1) may be viewed as a special kind of a yield condition obtained from that of a partially cohesive granular-type medium (Sokolovskii, 1965)

$$(\sigma_{11}-\sigma_{22})^2+4\sigma_{12}^2 = (\sin\rho_\delta)^2(\sigma_{11}+\sigma_{22}+2H_\delta)^2 \tag{3.2}$$

where H_δ is the strength in uniform tension, while ρ_δ is the angle of internal friction; also here we have made the two constitutive coefficients scale-dependent. It is apparent that (3.1) may be obtained from (3.2) in the limit of H_δ going to infinity and ρ_δ going to zero. However, in the following we shall review our recent results for media governed by (3.1); plasticity of materials governed by (3.2) is studied elsewhere (Ostoja-Starzewski, 1993c).

In accordance with the foregoing developments, by $\boldsymbol{B}_\delta = \{\mathbf{B}_\delta(\omega);\ \omega \in \Omega\ \} = \{\mathbf{B}(k_\delta(\omega));\ \omega \in \Omega\ \}$ we denote a continuous random (plastic) medium specified by a scale δ with

$$k_\delta(\underline{x},\underline{\omega}) = \langle k_\delta\rangle + k_\delta'(\underline{x},\omega) \qquad \langle k'_\delta(\underline{x},\omega)\rangle = 0 \tag{3.3}$$

where k_δ' is the zero-mean noise in k_δ. In the following we assume:

- scale $\delta > r_c$, so that $k_\delta(\underline{x},\omega)$ may be treated as a white-noise random field on that scale;
- $k_\delta(\underline{x},\omega)$ is space-homogeneous, ergodic, and has a high signal-to-noise ratio

$$|k_\delta'| \ll \langle k_\delta\rangle \tag{3.4}$$

3.2 Slip-lines and stochastic finite differences

The field equations of any realization $\mathbf{B}_\delta(\omega)$ are

$$\frac{\partial\sigma_{11}}{\partial x_1}+\frac{\partial\sigma_{12}}{\partial x_2} = 0 \qquad \frac{\partial\sigma_{22}}{\partial x_2}+\frac{\partial\sigma_{12}}{\partial x_1} = 0$$
$$(\sigma_{11}-\sigma_{22})^2+4\sigma_{12}^2 = 4k_\delta^2 \tag{3.5}$$

In the above k_δ, and hence, σ_{11}, σ_{22}, σ_{12} are parametrized by ω, but for clarity of presentation we do not show this explicitly. As is usual in the theory of slip-lines (see e.g. Kachanov, 1971; Szczepinski, 1979), two functions p and φ are now introduced

$$\sigma_{11} = p+k_\delta\cos(2\varphi) \qquad \sigma_{22} = p-k_\delta\cos(2\varphi)$$
$$\sigma_{12} = k_\delta\sin(2\varphi) \tag{3.6}$$

Upon substitution of (3.6) into (3.5), and setting $\varphi = -\pi/4$ on differentiation, we get

$$\frac{\partial p}{\partial x_1}+2k_\delta\frac{\partial\varphi}{\partial x_1} = \frac{\partial k_\delta}{\partial x_2} \qquad \frac{\partial p}{\partial x_2}-2k_\delta\frac{\partial\varphi}{\partial x_2} = \frac{\partial k_\delta}{\partial x_1} \tag{3.7}$$

where the rectangular axes are now along the local slip-line directions. The above will be independent of the orientation of the axes if $\frac{\partial}{\partial x_1}$ and $\frac{\partial}{\partial x_2}$ are replaced by the tangential derivatives $\frac{\partial}{\partial s_\alpha}$ and $\frac{\partial}{\partial s_\beta}$ along the α and β characteristics, respectively. Hence,

$$dp+2k_\delta d\varphi = \frac{\partial k_\delta}{\partial s_\beta}ds_\alpha \qquad dp-2k_\delta d\varphi = \frac{\partial k_\delta}{\partial s_\alpha}ds_\beta \tag{3.8}$$

These relations represent a system of two quasi-linear hyperbolic equations driven by the random terms involving k_δ. The corresponding characteristic directions are specified by

$$\frac{dx_2}{dx_1} = \tan(\varphi+\pi/4) \qquad \frac{dx_2}{dx_1} = \tan(\varphi-\pi/4) \tag{3.9}$$

Equations (3.8) and (3.9) form the basis for a determination of the Hencky-Prandtl network of slip-lines in a given boundary value problem. In cases of Cauchy and characterisitc problems studied below this relies on the method of finite-differences for finding x, y, p, and φ at a new point N given the data $\{x_i, y_i, p_i, \varphi_i\}$ at the two preceding points i = 1, 2. As discussed by Ostoja-Starzewski (1992b), due to the randomness in k_1, k_2 and k_N, as well as the possible randomness in the initial data p_1, φ_1, p_2, and φ_2, two characteristics of the deterministic problem are replaced here by two wedges (cones) of forward dependence, which contain all the characteristics of the stochastic problem emanating from points 1 and 2. Additionally, there is randomness in p_N and φ_N at the new point N which definitely amplifies the uncertainty in the further evolution. The forward evolution from points 1 and 2 to N displays a Markov property ($x \equiv x_1$ and $y \equiv x_2$ here)

$$P\{[x,y,p,\varphi]_N | [x,y,p,\varphi]_{D^-}\} = P\{[x,y,p,\varphi]_N | [x,y,p,\varphi]_{(1,2)}\} \tag{3.10}$$

where D^- is the domain of backward dependence including points 1 and 2, see Fig. 4 a). In the finite difference discretization of the governing equations D^- consists of a system of points. The Markov property (3.10) may, in principle, be used to either solve the problem analytically by calculating the transition probability as the conditional probability specified by the right hand side above with the help of formulas (3.11-13) below. At the same time, the Markov property (3.10) also suggests two finite-difference methods of determination of the network of slip-lines: *an exact method* and a *mean field method.* The first one is based on an observation that any point of the intersection of two cones of forward dependence becomes the initial point of further evolution, and, hence, the probability distribution of $\{x_i, y_i, p_i, \varphi_i;\ i=1, 2\}$ leads to a probability distribution of $\{x_N, y_N, p_N, \varphi_N\}$, which, in turn, serves as input for calculation of the next point. On the other hand, the mean field method replaces the domain of intersection of both forward dependence cones by an average point $\langle N \rangle$, and uses it as input for further calculations. Henceforth we focus on the exact method.

Formulas of the exact method in the set-up of forward differencing follow from (3.9) as

$$
\begin{aligned}
x_N &= \frac{y_2 - y_1 + x_1 \tan\left(\varphi_1 + \frac{\pi}{4}\right) - x_2 \tan\left(\varphi_2 - \frac{\pi}{4}\right)}{\tan\left(\varphi_1 + \frac{\pi}{4}\right) - \tan\left(\varphi_2 - \frac{\pi}{4}\right)} \\
y_N &= \frac{x_2 - x_1 + y_1 \cot\left(\varphi_1 + \frac{\pi}{4}\right) - y_2 \cot\left(\varphi_2 + \frac{\pi}{4}\right)}{\cot\left(\varphi_1 + \frac{\pi}{4}\right) - \cot\left(\varphi_2 - \frac{\pi}{4}\right)}
\end{aligned}
\tag{3.11}
$$

and from (3.8) as

$$
\begin{aligned}
p_N &= p_1 - (k_N + k_1)(\varphi_N - \varphi_1) + \frac{\partial}{\partial s_\beta} ds_\alpha \\
\varphi_N &= [p_1 - p_2 + \varphi_1 (k_1 + k_N) + \varphi_2 (k_2 + k_N)] \\
&\quad \left. \frac{\partial k}{\partial s_\beta} ds_\alpha - \frac{\partial k}{\partial s_\alpha} ds_\beta \right] (k_1 + k_2 + 2k_N)^{-1}
\end{aligned}
\tag{3.12}
$$

where

$$
\begin{aligned}
ds_\alpha &= [(x_N - x_1)^2 + (y_N - y_1)^2]^{1/2} \\
ds_\beta &= [(x_N - x_2)^2 + (y_N - y_2)^2]^{1/2}
\end{aligned}
\tag{3.13}
$$

and the derivatives of k with respect to s_α and s_β are treated in the finite-difference sense.

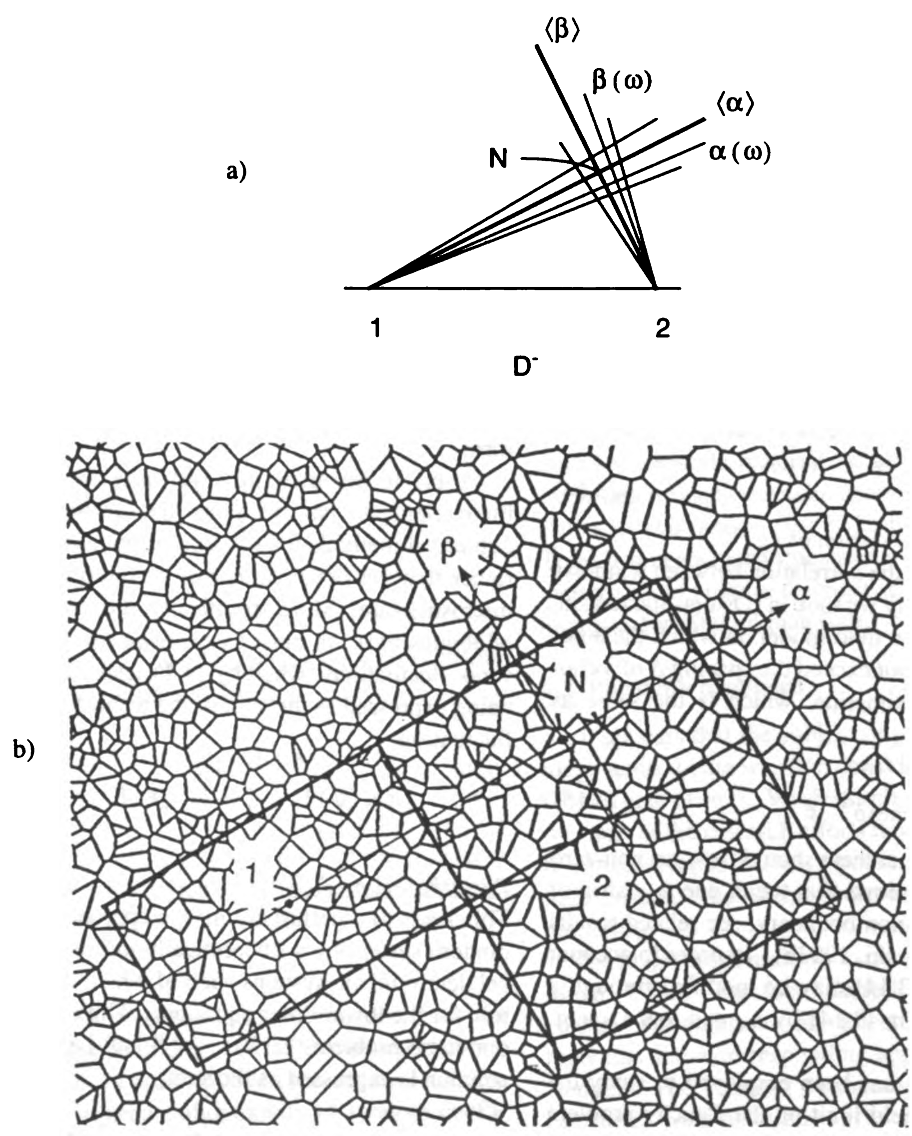

FIG 4. a) Scatter in the characteristics emanating from points 1 and 2; b) windows involved in finding the local average random field k_δ at 1, 2 and N from the microstructure.

Since the coefficients k_1, k_2 and k_N in the above are all random, the finite difference statement (3.11)-(3.12) of the field equations brings us back to the issue of choice of a random field k_δ. With reference to Fig. 4 b) we consider the random microstructure *B* to be represented by a Voronoi-type mosaic of grains, recall Fig. 1 a). Two characteristics α and β of the continuum approximation (at $\delta \cong 10$ here) are indicated as passing through points 1 and 2, respectively, and crossing at the new point N. Three rectangular shaped windows $B_1(\omega)$, $B_2(\omega)$ and $B_N(\omega)$ centered at these three particular points represent three domains of the microstructure $\mathbf{B}(\omega)$, whose effective plasticities are described by k_1, k_2 and k_N, respectively. Clearly, due to the finite crystal size, these three quantities cannot be taken as independent random variables, but should reflect the "local smearing out" in each window accounting for the correlation at their boundaries. Effective plasticity of a given window is a function of plasticities of all the crystals belonging to that window, and hence, in view of the results for elastic materials in Section 2.2, should generally be anisotropic. However, due to lack of such a model at present, we adopt here the very simple model of a moving average random field (Vanmarcke, 1983). Thus, at every location $\underset{\sim}{x}$ the value k_δ is an average of plasticities of all the crystals in the window centered at $\underset{\sim}{x}$. In other words, since all these crystals have random orientations and strengths, the average of their plasticities over a rectangular area with sides of length L_1 and L_2, respectively, is a new random field k_δ with a covariance function

$$C_{k_\delta}(\xi, \eta) = \begin{cases} \sigma_{k_\delta}^2 \left(1 - \frac{|\xi|}{L_1}\right)\left(1 - \frac{|\eta|}{L_2}\right) & |\xi| \le L_1 \\ & |\eta| \le L_2 \\ 0 & \text{elsewhere} \end{cases} \tag{3.14}$$

where σ_{k_δ} is the standard deviation of k_δ.

It is seen from (3.14) that the correlation between windows that touch is zero. This is why we took in (Ostoja-Starzewski, 1992b) a white-noise random field model, in which the autocorrelation distance r_c does not exceed the spacing Δ of a chosen finite difference approximation, which is the same as δ_{meso}

$$\Delta = \delta_{meso} \ge r_c \tag{3.15}$$

It can be argued, however, that there should be some non-zero correlation between the windows that touch due to a strip of crystals straddling the common boundary; see related results in elasticity (Ostoja-Starzewski, 1993b). In order to account for this effect, the model (3.14) may be modified through a replacement of L_1 and L_2 in (3.14) by $L_1 + d$ and $L_2 + d$, respectively.

The above formulation has been employed to study the effects of randomness in yield limit on the Cauchy problem and characteristic boundary value problems(Ostoja-Starzewski, 1992c), as well as on the load carrying capability of a pipe under internal pressure (Ostoja-Starzewski and Setyabudhy, 1992). It has been found that the averages of stochastic solutions tend to differ from the solution of a corresponding boundary value problem for a homogeneous deterministic medium when randomness in k_δ increases and is combined with the increasing inhomogeneity in boundary conditions.

4. COMPARISONS WITH OTHER THEORIES

4.1 Elasticity problems

4.1.1. A review of classical SFE methods

The need for development of finite element methods taking into account the uncertainty in structural material parameters has been recognized since the late seventies. As a result of the observation that many engineering structures are described by spatially random material properties, several theoretical methodologies were developed in the civil engineering literature. To the best of this author's knowledge all these studies in stochastic finite elements were and are being based on a simple generalization of the Hooke's law to an inhomogeneous locally isotropic continuum

$$\varepsilon_{ij} = \frac{1}{E(\underset{\sim}{x}, \omega)} [(1 + \nu(\underset{\sim}{x}, \omega))\sigma_{ij} - \nu(\underset{\sim}{x}, \omega)\delta_{ij}\sigma_{kk}] \tag{4.1}$$

where two elastic coeffiicients $E(\underset{\sim}{x}, \omega)$ and $\nu(\underset{\sim}{x}, \omega)$ are random fields. In fact, typically, the Young's modulus only has been adopted as random. In view of the micromechanical analysis of Section 2.2 it becomes evident that (4.1) is in error, since i) a unique random field of stiffness/compliance cannot be determined from the microstructure, ii) a random continuum approximation is, in general, of a locally anisotropic form.

It has to be noted, however, that the effort in stochastic finite elements has been on the development of efficient numerical methods for solution of boundary value problems, rather than on development of a connection to the material microstructure. More specifically, these classical SFE methodologies have, in most cases, been restricted to the case of weak fluctuations, whereby (4.1) leads to a stiffness matrix being expressed as the sum of the mean and the weak random fluctuation

$$[K(\omega)] = [\langle K\rangle] + \varepsilon[K'(\omega)] \tag{4.2}$$

Perturbation method

This leads to a perturbation-type approach: replacement of a random system by a (theoretically infinite) number of identical deterministic systems each of which depends on the solutoin for the lower order equations. Thus, to second order, for our static problem (2.120) - $[K(\omega)]\{U\} = \{F\}$ - the solution is expressed as the sum

$$\{U\} \cong \{U_0\} + \varepsilon\{U_1\} + \varepsilon^2\{U_2\} \tag{4.3}$$

where $\varepsilon << 1$

$$\{U_0\} = [\langle K\rangle]^{-1}\{F\}$$
$$\{U_1\} = -[\langle K\rangle]^{-1}[K'(\omega)]\{U_0\} \qquad (4.4)$$
$$\{U_2\} = -[\langle K\rangle]^{-1}[K'(\omega)]\{U_1\}$$

Neumann series method

This method, advanced by Shinozuka & Yamazaki (1988), is based on a Neumann series for the inverse of a random operator $[K(\omega)]$, which takes the following form

$$[K(\omega)] = (I - P(\omega) + P^2(\omega) - P^3(\omega) + \ldots)[\langle K\rangle]^{-1}$$
$$P(\omega) = [\langle K\rangle]^{-1}[K'(\omega)] \qquad (4.5)$$

The method was introduced as an avenue for a speedier way of solving the stochastic problem by a Monte Carlo simulation. To that end also a Cholesky decomposition of $[K(\omega)]$ is implemented.

Weigthed integral method

In contradistinction to the above two methods, this one focuses on the determination of the random stiffness matrix $[K(\omega)]$. The idea, in the setting of an elastic plate problem (Deodatis et al, 1991), is to start with a locally isotropic random field of, say, Young's modulus (recall eq (4.1) and the discussion following it) and assign it to all the finite elements according to

$${}^iE(\underline{x},\omega) = {}^i\langle E\rangle[1 + {}^if(\underline{x},\omega)] \qquad \langle {}^if(\underline{x},\omega)\rangle = 0 \qquad (4.6)$$

Next, all the elements of $[K(\omega)]$ are calculated as

$$[{}^iK(\omega)] = \int_{{}^iV} [{}^iB]^T[{}^iC(\omega)][{}^iB]\,dV = \left[{}^iK_0\right] + {}^iX_0(\omega)\left[\Delta^iK_0\right] \qquad (4.7)$$

where $\left[{}^iK_0\right]$ and $\left[\Delta^iK_0\right]$ are deterministic matrices, while ${}^iX_0(\omega)$ is a random variable given as

$${}^iX_0(\omega) = \int_{{}^iA} {}^if(\underline{x},\omega)\,d^iA \qquad (4.8)$$

From a micromechanics standpoint this approach gives a Voigt-type estimate for the effective stiffness of the i-th finite element; also, compare (4.7-8) with (2.20).

Spectral method

It is well known that in a representation of a random function by a Fourier series, the coefficients of the expansion become, in general, correlated. In order to retain the uncorrelatedness while obtaining the desired orthogonality of random coefficients, a Karhunen-Loéve expansion (see e.g. Yaglom, 1962) is introduced. This idea has been employed by Ghanem & Spanos (1991) to represent the spatial variability of random field of Young's modulus such as in (4.6). However, this method is not limited to weak fluctuations and avoids the inconsistencies between various other methods involved in the inversion of the random stiffness matrix $[K(\omega)]$. Also, it is designed to do away with the problem of dealing with a large number of random variates resulting from a pointwise representation of the random field $[E(\underline{x},\omega)]$.

While this method is elegant - recasting of the original problem in terms of a denumerable set of uncorrelated random variables - it has also suffered from a lack of good input from micromechanics. Additionally, its claim of being able to deal consistently with strong noise in material properties has to be qualified - this is discussed in Section 4.1.2 below.

4.1.2 Conclusions

The foregoing very brief review of the SFE methods leads to two principal conclusions:

i) a necessity of a correct link to micromechanics in setting up of the continuum random fields (Ostoja-Starzewski, 1993a) and of the random stiffness matrix $[K(\omega)]$,

ii) a need for a careful interpretation of the variational principles as a basis for SFE,

Thus, although an assumption such as (4.1) is generally incorrect, it follows that the classical SFE methodologies are amenable to possible modifications to incorporate the micromechanical input of the type described in Section 2.2. More precisely, once a continuum random field specification of a given material is found, an existing approach - such as perturbation, Neumann series, Karhunen-Loéve series - may be applied to determine the upper and lower bounds on response according to the stochastic variational formulation given in Section 2.3.

Presence of a strong noise in material properties requires particular attention. A valuable paradigm in the situation of strong microscale material variability is provided by studies in the deterministic *homogenization theory*, see e.g. (Sanchez-Palencia and Zaoui, 1987; Hollister and Kikuchi, 1992). Thus, it appears that a stochastic extension of homogenization theory should provide the most adequate formulation of finite elements for random materials.

4.2 Plasticity problems

It appears that the subject of plasticity of randomly inhomogeneous media was first considered in the seminal work of Olszak et al (1962). While, similar to the situation in elasticity, most of the research efforts have been on finding the effective macroscopic plastic response (see e.g. Zaoui, 1987), very little attention has been given to random meso-continuum modelling.

The major work we have to mention here is that due to Nordgren (1992). The focus there has been on an original stochastic formulation of lower-bound and upper-bound theorems and a corresponding application to the loading of a wedge. The random continuum model involves a three parameter yield function

$$f = aJ_2 + bI_1 + cI_1^2 - 1 \qquad (4.9)$$

where a, b, and c are strength parameters, and I_1 and J_2 are the (first and second) stress invariants of stress and deviatoric stress. a, b, and c are random fields obtained from an unconfined uniaxial compression test with yield stress q, for which (4.9) gives

$$\frac{1}{3}aq^2 - bq + cq^2 = 1 \tag{4.10}$$

Random nature of the field q is represented by the presence of fluctuations q' about the mean $\bar{q}$, that is

$$q(\underset{\sim}{x}, \omega) = \bar{q} + q'(\underset{\sim}{x}, \omega) \qquad \langle q'(\underset{\sim}{x}, \omega) \rangle = 0 \tag{4.11}$$

The correlation function of the random field q' is taken to be homogeneous and isotropic, and, in particular, of the following form

$$B(r) = B_0/(1 + r^2/h^2) \tag{4.12}$$

In (4.12) B_0 is the variance of fluctuations q', while h specifies their lengthscale.

We note here two differences of this model from ours assumed in Section 3:
i) no dependence on the scale δ versus such dependence implied in (3.3),
ii) the covariance in Nordgren's model goes to 0 only as the distance between two points goes to infinity - compare this with (3.14); this difference is due to taking the process of "local smearing out" as a point of departure in our approach to formulating random continuum models from micromechanics.

Solution of the boundary value problem of a wedge in (Nordgren, 1992) has been based on finding the mean of the minimum energy dissipation on the multiple branches of possible zig-zag velocity paths along the rigid-plastic boundary - an extensive computational procedure. By contrast, we propose solving a given stochastic boundary value problem directly by calculating a large number (one hundred, say) of responses in a Monte Carlo sense. Unless the mesh resolution is more than about fifty points, this is done in a matter of (at the most) a couple of minutes on a workstation or a personal computer and yields, practically, the whole range of possible behaviors - that is, the probability distributions of slip-line fields, stress fields, and velocity fields.

5. CLOSURE

In this paper we have discussed the formulation of finite element methods and differences for materials with random microstructures. The key role in this formulation is played by a window concept which, on one hand, leads to a specification of constitutive laws of a random meso-continuum, while on the other, corresponds to a single finite element or difference cell. It follows that by a relatively straightforward modification a finite element/difference program can be made to incorporate a meso-mechanical input. Such an input may, in principle by provided in three different ways:
i) a direct computational mechanics simulation of the microstructure in each window (cell), repeated n times in a Monte Carlo sense for various realizations;
ii) an assignment of medium's properties according to a random meso-continuum model (Ostoja-Starzewski, 1993b);
iii) an analytical derivation of the stochastic constitutive laws at the meso-scale.

Work is currently underway to include in our approach other constitutive responses - e.g. stochastic continuum damage mechanics (Ostoja-Starzewski, 1989) - and ideally, as mentioned at the end of Section 4.1, to integrate it with a stochastic version of the homogenization theory.

Dynamic post-buckling behavior of thin-walled structures with flexible knife-edge supports

MA Souza

Departamento de Engenharia Civil, Pontificia Universidade Católica do Rio de Janeiro
22453-900 Rio de Janeiro, Brazil

The paper discusses the influence that changes of the simply supported boundary condition during the loading process have on the dynamic post-buckling behavior of elastic thin-walled structures. Of special interest is the knife-edge type of support which is associated to the free-to-rotate boundary condition. The results presented show how changes of the free-to-rotate condition during the loading process can dramatically alter the response of thin-walled structures. This fact is highlighted by the equilibrium paths and the characteristic curves presented. The former relate the applied compressive load and the lateral displacement, whereas, the latter relate the compressive load and the square of the corresponding natural frequency of vibration. The importance of an adquate design of the supports is stressed in view of the observed dramatic changes. The work is done in the scope of the elastic stability and damping is not included in the analysis.

INTRODUCTION

The adequate design of the support is undoubtedly a major factor of success of any experimental program. The comparison between the results theoretically predicted and those obtained in the experiment is only valid and meaningful if the actual support conditions in the laboratory and those used in the theoretical analysis are exactly the same. Different support conditions lead to different response and, therefore, theory and experiment will disagree due to the sole factor that the theoretical and the experimental analysis were carried out for different support conditions, despite the fact that all the geometric and elastic parameters might be exactly the same.

An example of carefully designed support conditions can be found in the work of Albert et al. (1992) where several situations were analyzed and reported in detail. The experimental results presented in their paper highlight the importance of correctly considering the actual support conditions in the theoretical prediction of the results.

Theoretically the simply supported boundary condition is the simplest and for this reason frequently used in analytical solutions to illustrate how a particular theory works. In practice, though, it represents the most difficult support condition to be achieved in the laboratory, the main reason for this being the free-to-rotate requirement. For cylindrical shells, for instance, the free-to-rotate boundary condition means, in practice, a knife-edge type of support. For thin-walled cylindrical shells under axial compression it is not difficult to imagine that such a boundary condition cannot last long, since as the axial load is applied the knife-edge end will behave like a spring. The contact zone between the end of the shell and the supporting plate or disk, originally a circumferential line soon becomes a contact area due to the axial load and, therefore, the free-to-rotate condition is violated. The support condition is no longer the initially free-to-rotate one and, therefore, any comparison between theoretical and experimental results is meaningless, unless such changes of the support boundary conditions are previously incorporated in the theoretical analysis. The type of support condition described above is illustrated in Figs 1a-b where a schematic knife-edge condition corresponding to a cylindrical shell is shown, Fig. 1a, together with the detail of the end of the shell wall where the knife-edge is located. The detail presented refers to the loaded situation when the end of the shell behaves like a spring and this is schematically shown in Fig. 1b. The change from a a point contact, in the case of columns, or a line contact in the case of thin-walled cylindrical shells occurs during the loading process and is due to the axial compressive loading. The present work deals with such changes of the support conditions as described in the sequel.

b. The spring effect at the end of the shell

FIG 1. The knife-edge support

The influence of hardening and softening of the supports on the dynamic post-buckling behavior of thin-walled structures has previously been investigated by Souza (1987a, 1988, 1989). There, the goal was to understand how changes of the boundary conditions at the supports during the loading process affect the dynamic response. In this work the objective is to understand how the changes in the knife-edge supports during the loading process affect the post-buckling dynamic response. In order to do so a simplified model is introduced and discussed in detail.

THE SIMPLIFIED MODEL

The model used in the analysis is shown in Fig. 2 below. It consists of a rigid bar of length L free at one end where the vertical load P is applied and supported at the other end by a laterally fixed support able to displace vertically, and a flexible support which consists of a linear spring of stiffness K and a rotational spring of stiffness C. In the idealized situation corresponding to the simply supported condition we have $C = 0$ and $K \to \infty$.

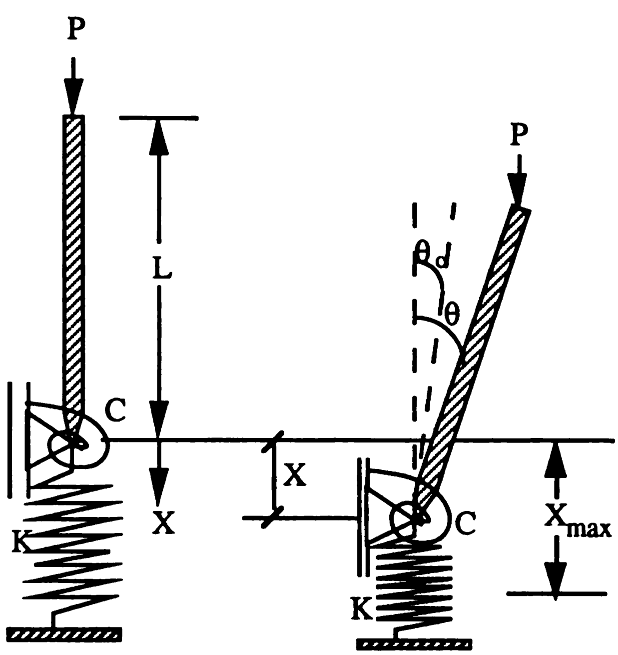

FIG 2. The simplified model

In order to model the loss of the knife-edge condition and, therefore, the loss of the free-to-rotate condition, the stiffness of the rotational spring, C, is considered as dependent on the vertical displacement X of the supported end, X_{max} being the maximum possible displacement, i.e., $0 \le X \le X_{max}$. In the unloaded situation corresponding to $P = 0$ and $X = 0$, the stiffness of the rotational spring has an initial value C_i. As the vertical load P is applied, the end support displaces of a value X and the stiffness of the rotational spring $C(X)$ increases, reaching a constant final value, C_f, when $X = X_{max}$. For the sake of simplicity a linear relationship between $C(X)$ and X is considered in the analysis. The use of the parameters ξ and γ, defined as

$$\xi = \frac{X}{X_{max}} \tag{1}$$

and

$$\gamma = \frac{C_f}{C_i} \tag{2}$$

together with the linear relationshipp between $C(X)$ and X, enables the expression of the rotational spring's stiffness as a function of ξ in the following form

$$\frac{1}{C_i} C(\xi) = \begin{cases} 1 + (\gamma - 1)\xi & \dots\ 0 \le \xi \le 1 \\ \gamma & \dots\ \xi \ge 1 \end{cases} \tag{3}$$

The free-to-rotate condition corresponds to the limiting situation $C_i \to 0$ for $P = 0$ and $X = 0$. Throughout the analysis C_i will be considered as nonzero due to the choice of the function $C(\xi)$ as defined in Eqn. (3), where the final constant value of the rotational spring's stiffness C_f, is considered to be proportional to its initial value, C_i. Therefore, $C_i \neq 0$ means that from the beginning the support is not completely free to rotate. The stiffness function of the rotational spring, $C(\xi)$, can be ilustrated as shown in Fig. 3.

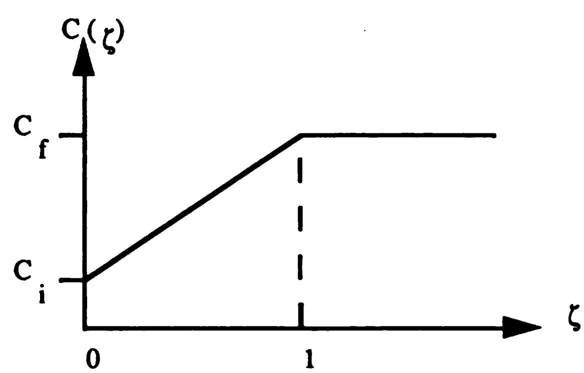

FIG 3. The stiffness function $C(\zeta)$

The model can be treated both as perfect or initially imperfect depending on the angular displacement θ_o, which corresponds to the value of θ for $P = 0$, Fig. 2. Therefore, $\theta_o = 0$ corresponds to the perfect situation, whereas, $\theta_o \neq 0$ corresponds to the initially imperfect one.

For the perfect model, $\theta_o = 0$, two situations can occur: i) the value of the critical load is greater than KX_{max}, in which case buckling occurs for $X = X_{max}$; ii) the value of the critical load is smaller than KX_{max} and, therefore, the model buckles for a value of X smaller than its maximum value X_{max}. The latter is the most interesting case since the model will buckle while still vertically displacing. This is the case chosen to be discussed in the paper.

The stability and the vibration characteristics of the model are investigated and summarized according to the procedure described by Souza (1987a). What follows is the study of such characteristics.

STABILITY CHARACTERISTICS

The stability characteristics are illustrated by the equilibrium paths which relate the applied load P and the angular displacement θ, Fig. 2. The equilibrium paths are obtained using the principle of the stationary potential energy (Souza, 1987b).

Equilibrium paths

The functional of total potential energy, V, for the most general case of initially imperfect model can be expressed in the following form

i) $0 \leq \xi \leq 1$

$$V = \frac{1}{2} KX_{max}\,\xi^2 + \frac{1}{2} C_i\left[1 + (\gamma - 1)\xi\right](\theta - \theta_o)^2 - P\left[X_{max}\,\xi + L\left(\cos\theta_o - \cos\theta\right)\right] \tag{4}$$

ii) $\xi \geq 1$

$$V = \frac{1}{2} C_i\,\gamma\,(\theta - \theta_o)^2 - PL\left(\cos\theta_o - \cos\theta\right) \tag{5}$$

where all the parameters have previously been defined.

For the first case, $0 \leq \xi \leq 1$ the equilibrium equations are

$$\frac{\partial V}{\partial \xi} = 0 \;;\; \frac{\partial V}{\partial \theta} = 0 \tag{6}$$

which lead to the following load displacement relationship:

$$p = \frac{\left[1 - \vartheta\dfrac{(\gamma - 1)}{2\beta}(\theta - \theta_o)\right]}{\left[1 - \vartheta\dfrac{(\theta - \theta_o)}{\sin\theta}\right]}\,\frac{(\theta - \theta_o)}{\sin\theta} \tag{7}$$

and

$$\xi = \frac{1}{\mu}p - \frac{\vartheta}{2\beta}(\theta - \theta_o)^2 \tag{8}$$

where p is the load parameter defined as

$$p = \frac{PL}{C_i} \tag{9}$$

and the parameters μ, ϑ and β are defined as follows:

$$\mu = \frac{KX_{max}}{C_i / L} \tag{10}$$

$$\vartheta = \frac{(\gamma - 1)}{\mu} \tag{11}$$

$$\beta = \frac{X_{max}}{L} \tag{12}$$

The value of the critical load parameter, p_{cr}, can be obtained by considering the perfect case, $\theta_o = 0$, and taking the limit of the load parameter p in Eq. (7) as $\theta \rightarrow 0$, i.e.

$$p_{cr} = \lim_{\substack{\theta \to 0 \\ (\theta_o = 0)}} p = \frac{1}{(1 - \vartheta)} \tag{13}$$

Therefore, the critical value of ξ, ξ_{cr}, can be obtained from Eqs. (8) and (13) as

$$\xi_{cr} = \frac{1}{\mu(1 - \vartheta)} = \frac{1}{\mu}p_{cr} \tag{14}$$

For the second case, $\xi \geq 1$, the equilibrium equation $\partial V / \partial\theta = 0$ leads to the following load displacement relationship

$$p = \gamma\,\frac{(\theta - \theta_o)}{\sin\theta} \tag{15}$$

It is worth noticing that in the case of a constant stiffness of the rotational spring, $C(\zeta) = C_f$, the value of the critical load parameter is $p_{cr} = \gamma$. Since we are interested in the situation in which the perfect model buckles while still vertically displacing, i.e. for $0 < \zeta < 1$ as previously mentioned, then $KX_{max} > C_f$, leading to the condition $\mu > \gamma$ according to the definition of μ and γ, Eqs. (10) and (2), respectively.

In order to illustrate the influence of the stiffness $C(\xi)$, which depends on the vertical displacement, on the equilibrium paths several situations with $\mu > \gamma$ will be considered. Initially, the influence of the various parameters will be illustrated, starting with the influence of μ on the relationship between p_{cr} and γ and shown in Fig. 4. It can be observed that μ is always greater then γ.

The linear relationship between p_{cr} and ξ_{cr}, Eq. (14), is shown in Fig. 5 for different values of γ.

Figure 6 illustrates the relationship between ξ_{cr} and μ for different values of the parameter γ, whereas, Fig. 7 shows how ξ_{cr} and γ are related.

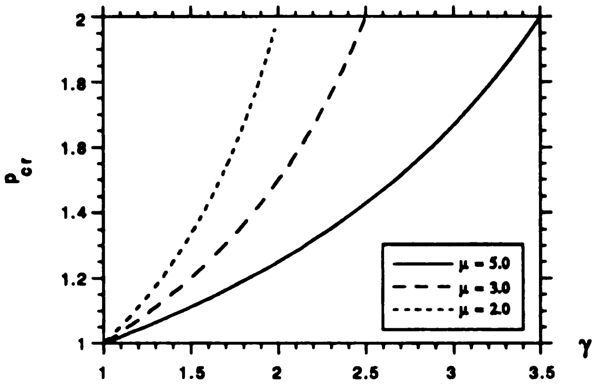

FIG 4. γ versus p_{cr}

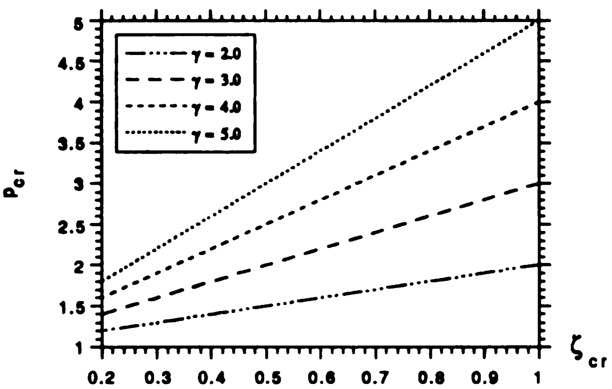

FIG. 5 ζ_{cr} versus p_{cr}

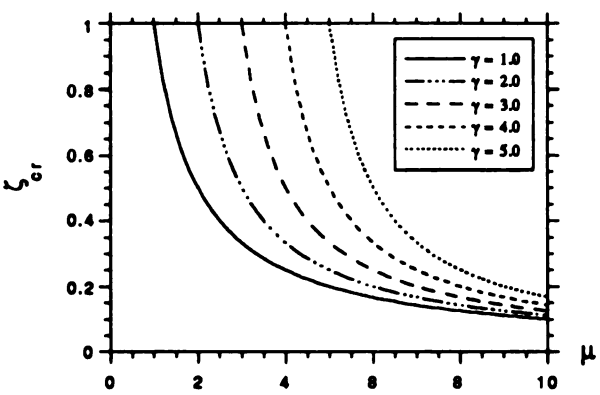

FIG. 6 ζ_{cr} versus μ

The relationship between ξ and p for $\gamma = 2$ and $\mu = 4$ and different values of the parameter β is illustrated by the curves presented in Fig. 8.

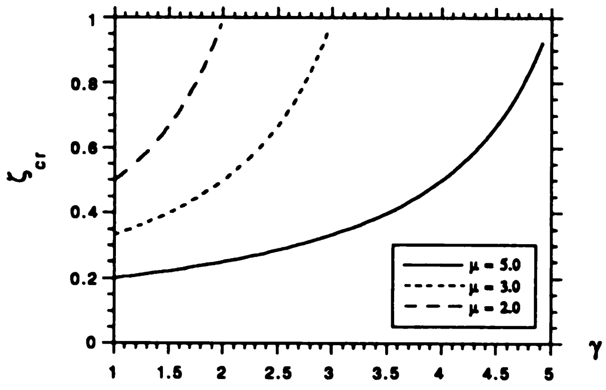

FIG. 7 ζ_{cr} versus γ

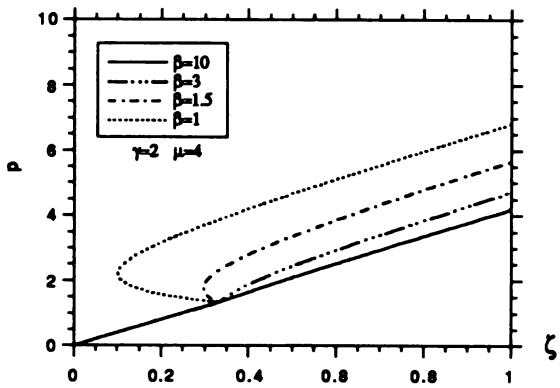

FIG. 8 ζ versus γ

Figure 9 shows how θ and ξ are related for $\gamma = 2$, $\mu = 4$ and different values of β.

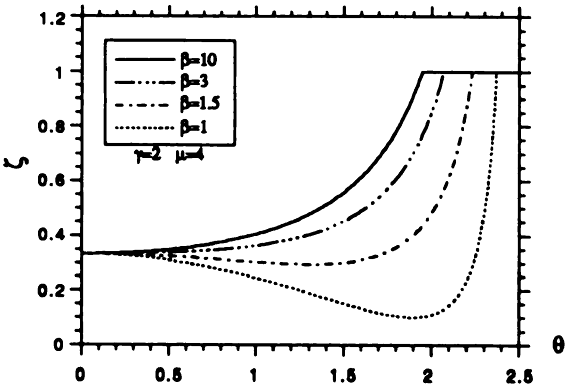

FIG. 9 θ versus ζ

The influence of β on the equilibrium paths is shown in Fig. 10 for $\gamma = 2$ and $\mu = 4$.

Figure 11 illustrates how the parameter γ affects the equiilibrium paths for $\mu = 4$ and $\beta = 10$.

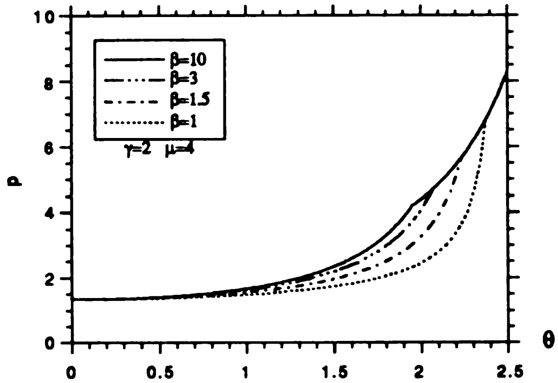

FIG. 10 Equilibrium paths - The influence of β

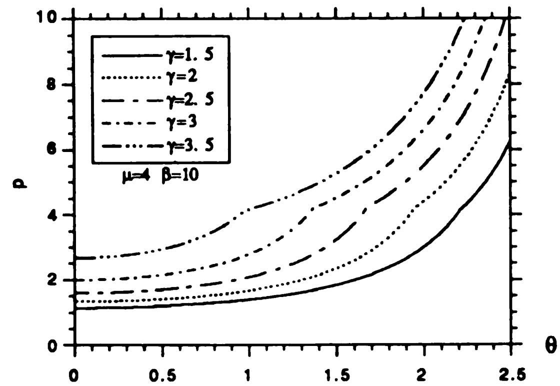

FIG. 11 Equilibrium paths - The influence of γ

The influence of γ on the relationship between θ and ζ can be observed in Fig. 12, corresponding to $\mu = 4$ and $\beta = 10$.

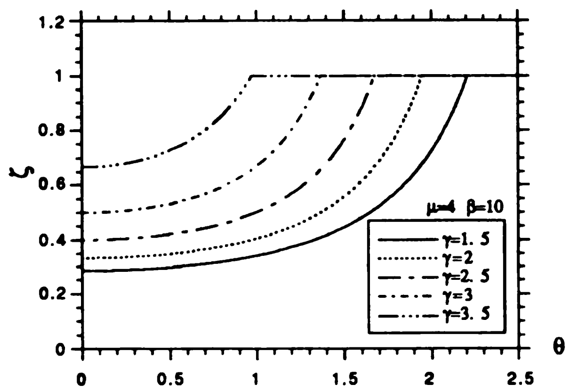

FIG. 12 θ versus ζ

Equilibrium paths for both the perfect and the imperfect model are shown in Fig. 13 for $\gamma = 4$, $\mu = 5$ and $\beta = 10$.

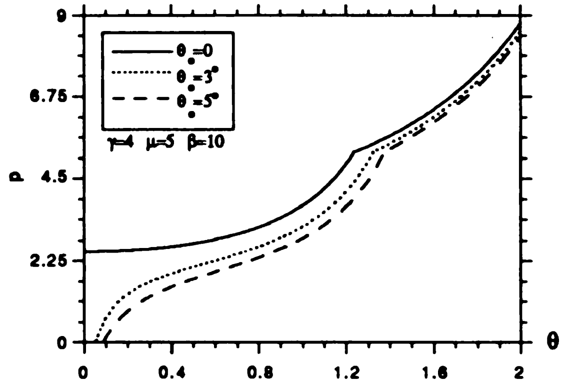

FIG. 13 Equilibrium paths

Figure 14 highlights the influence of the stiffness function $C(\zeta)$ on the equilibrium paths as compared to the case of constant stiffness C_f, for $\gamma = 4$, $\mu = 5$, $\beta = 10$ and $\theta_o = 0°$ and 3°. In brackets are indicated whether $C(\zeta)$ or C_f are considered, together with the value of θ_o, i.e. $[C(\zeta)$ or C_f, $\theta_o]$.

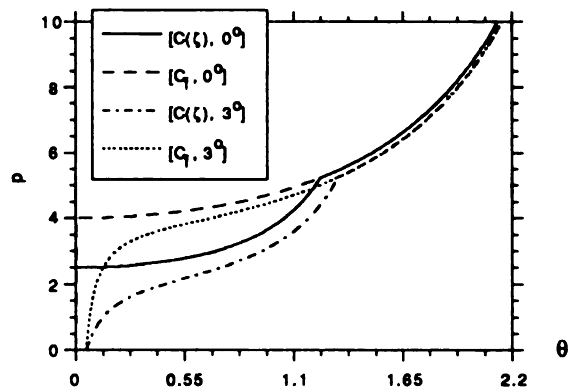

FIG. 14 Equilibrium paths (γ=4 μ=5 β=10)

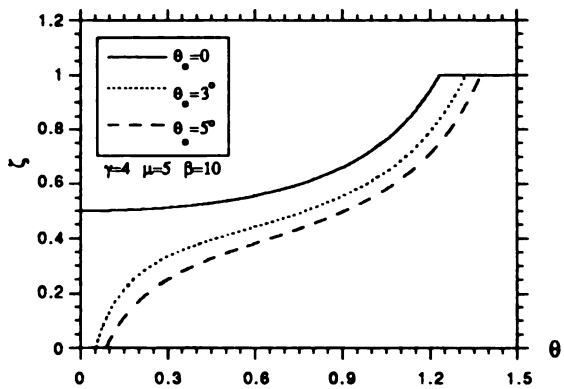

FIG. 15 θ versus ζ

Figure 15 shows the relationship between θ and ζ for $\gamma = 4$, $\mu = 5$, $\beta = 10$ and $\theta o = 0^o$, 3^o and 5^o. The relationship between ζ and p for the same parameters of Fig. 15 is shown in Fig. 16.

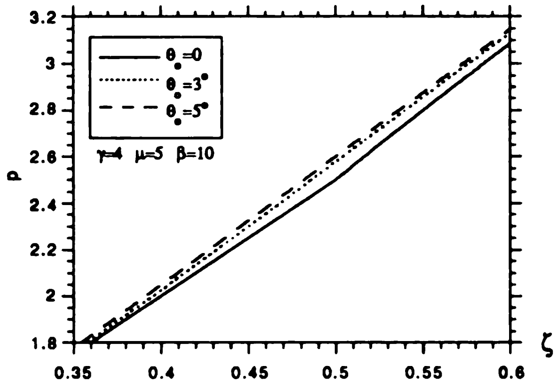

FIG. 16 ζ versus p

The results shown in Figs 4-16 illustrate how the changes of the support conditions in terms of a rotational spring's stiffness dependent on the linear displacement influence the equilibrium paths and also how the different parameters involved are related. Of special illustrative effect are the equilibrium paths of Fig. 13 where the effect of $C(\zeta)$ is clearly observed. Figure 13 should be interpretd as follows: had the system started with a constant stiffness $C(\zeta) = C_f$ then the equilibrium path would be the higher value one; since it started with $C(\zeta) = C_i$, it only reaches the same equilibrium path when $\zeta = 1$, which can be clearly observed.

The model presents equilibrium paths which are all stable: the primary path corresponding to $\theta = 0$ with $\theta_O = 0$, the scondary path corresponding to $\theta \neq 0$ with $\theta_O = 0$ and the imperfect path corresponding to $\theta_O \neq 0$. This can be proved from the second derivatives of the total potential energy functional, V.

Having discussed different aspects of the equilibrium paths of the model, what follows is the study of the characteristic curves which illustrate the vibration characteristics of the model.

VIBRATION CHARACTERISTICS

The vibration characteristics of the model are presented in terms of the characteristics curves which relate the applied load, P, and the square of the corresponding natural frequency of vibration ω.

Characteristics curves

The natural frequency of vibration corresponding to a given load level is determined by the procedure described in Souza (1987b). It consists of perturbing the equilibrium configuration and investingating the motion around such an equilibrium configuration. In order to investigate the lateral motion a small perturbation is introduced, represented by the angle ϕ shown in Fig. 17, keeping the load level constant. Therefore, the total potential energy functional V becomes a function of $(\theta + \phi)$. Such a procedure allows the determination of the natural frequency of vibration as a function of the applied compressive load.

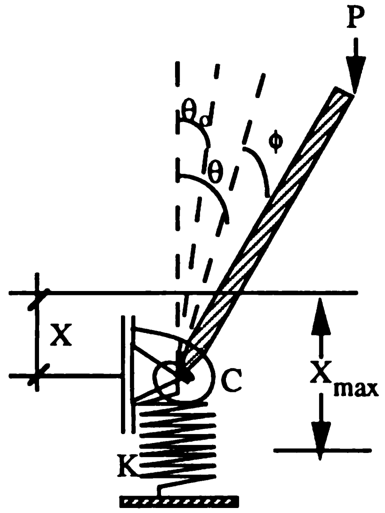

FIG. 17 The perturbed configuration

The equation of motion is obtained from the Euler-Lagrange equation (Souza, 1987b)

$$\frac{d}{dt}\frac{\partial T}{\partial \dot{\phi}} + \frac{\partial V}{\partial \phi} = 0 \tag{16}$$

where T is obtained the kinetic energy given by

$$T = \frac{1}{2} I^* \dot{\phi}^2 \tag{17}$$

I^* being the generalized moment of inertial and $\phi.dot$ is the angular velocity. It can be expressed as

$$\ddot{\phi} + \omega^2 \phi = 0 \tag{18}$$

where terms of of $O(\phi^2)$ and higher are neglected and ϕ is the natural frequency of vibration corresponding to the applied load level P. Before continuing, let us introduce the natural frequency of vibration function, f, defined as follows:

$$f^2 = \frac{C_i}{I^*} \omega^2 \tag{19}$$

The relationship between the applied load level, p, and the square of the corresponding natural frequency of vibration function, f, depends on the range of ζ and can be summarized as follows:

i) $0 \leq \zeta \leq 1$

$$f^2 = 1 - \frac{\vartheta(\gamma - 1)}{2\beta}(\theta - \theta_o)^2 + (\vartheta - cos\theta)\, p \tag{20}$$

ii) $\zeta \geq 1$

$$f^2 = \gamma - p \cos \theta \qquad (21)$$

All the parameters in Eqs (20) and (21) have previously been defined.

In order to illustrate the post-buckling dynamic response characteristic curves will be presented. Figure 18 shows characteristic curves for $\gamma = 2, \mu = 4$ and different values of β. Such characteristic curves correspond to the equilibrium paths shown in Fig. 10.

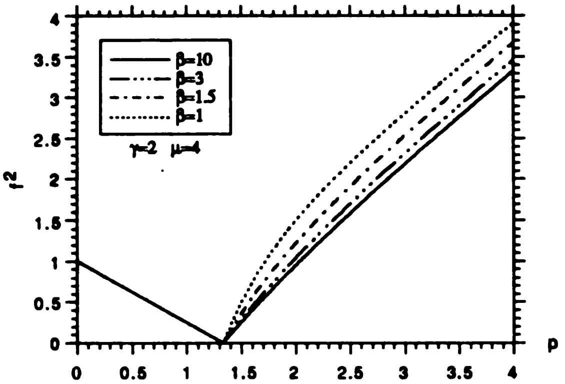

FIG. 18 Characteristic curves - The influence of β

The relationship between ζ and f^2 also for $\gamma = 2$, $\mu = 4$ and different values of β is illustrated by the curves of Fig. 19, corresponding to the ζ versus p curves of Fig. 8.

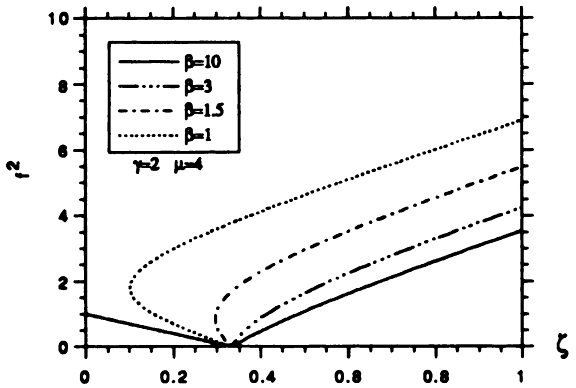

FIG. 19 ζ versus f^2

Characteristics curves corresponding to $\mu = 4, \beta = 10$ and different values of γ are shown in Fig. 20. The corresponding equilibrium paths are those shown in Fig. 11.

Figure 21 shows the characteristics curves corresponding to the equilibrium paths of Fig. 13 for $\gamma = 4$, $\mu = 5$, $\beta = 10$ and $\theta_0 = 0^o$, 3^o and 5^o.

The relationship between ζ and f^2 for the same parameters of Fig. 21 is shown in Fig. 22.

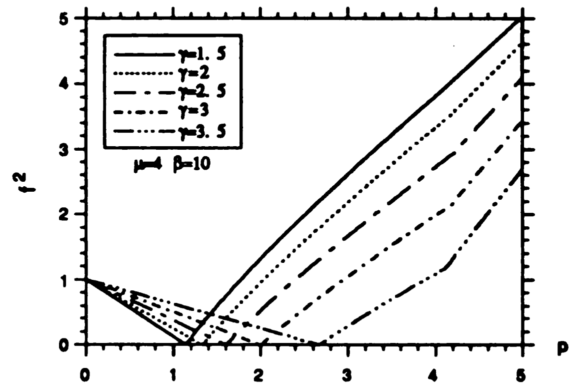

FIG. 20 Characteristic curves - The influence of γ

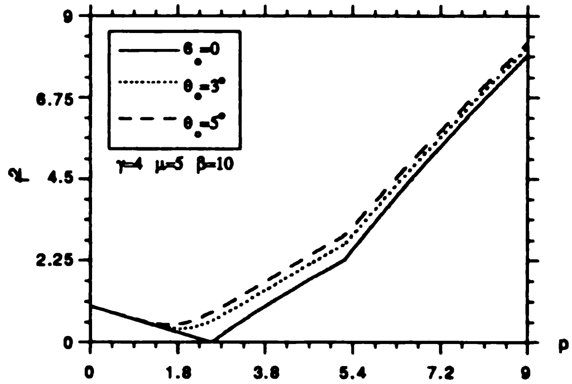

FIG. 21 Characteristic Curves

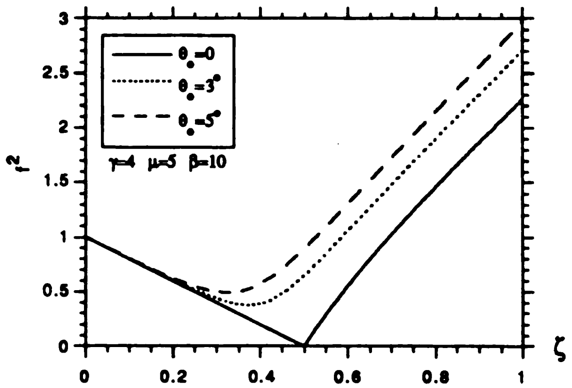

FIG. 22 Characteristic curves (ζ versus f^2)

The influence of the stiffness function $C(\zeta)$ can be observed in the characteristic curves shown in Fig. 23 for $\gamma = 4$, $\mu = 5$, $\beta = 10$ and $\theta_0 = 0^o, 3^o$ and 5^o. Figure 23 corresponds to the equilibrium paths of Fig. 14. In this case also the explanation is the same as that of Fig. 13: had the model started with a constant stiffness $C(\zeta) = C_f$, then the f^2 vs P curve would start at the value 4.0 $(= \gamma)$.

Since it starts with $C(\zeta) = C_i$, the characteristics curves only reach those corresponding to $C(\zeta) = C_f$ for $\zeta = 1$.

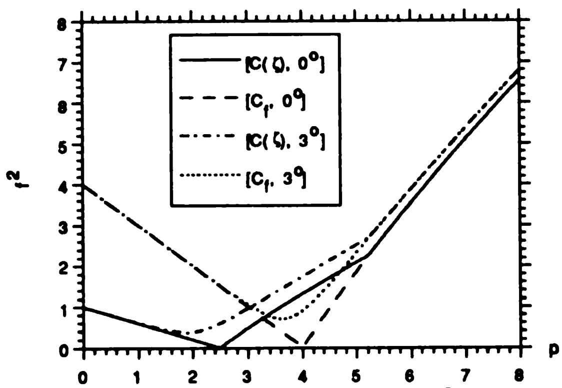

FIG. 23 Characteristic curves (γ=4 μ=5 β=10)

The results presented in Figs 18-23 illustrate how the dynamical response of the model is affected by the changes of the knife-edge support condition according to the $C(\zeta)$ function, described by Eq.(3) and illustrated in Fig. (3)..

DISCUSSION OF THE RESULTS

The results obtained illustrate how the changes in the boundary conditions of knife-edge type of supports due to the compressive loading affect the dynamic post-buckling response of thin-walled structures. As the loading process takes place the knife-edge support with the free-to-rotate capability is altered to that of a spring type of support in which the free-to-rotate condition no longer exists. Such behavior was modeled in a way that the coupling between the stiffening of the support resulting from the loss of the free-to-rotate boundary condition and the vertical displacement due to the load is incorporated.

Since the model exhibits a stable post-buckling behavior the results obtained are similar in nature to those previously obtained by the author (Souza, 1987a-b, 1988, 1989). In terms of the dynamic post-buckling behavior the main characteristic is related to the relationship between the applied load and the corresponding natural frequency of vibration: the level of the natural frequency of vibration of the initially imperfect model is always higher than the frequency level of the perfect counterpart for the same load level.

The results presented illustrate how changes of the knife-edge type of supports can alter the response of the of the structure both in terms of the equilibrium paths and the characteristic curves. It is also clear from the results obtained that unless the stiffness of the rotational spring is constant, a much more complex behavior is observed.

CONCLUSION

A careful investigation and design of the supports, in particular the knife-edge type, is a decise factor in the success of any experimental program dealing with thin-walled structures liable to buckling.

The influence of changes of the knife-edge support condition during the loading process on both the equilibrium paths and the characteristic curves was discussed. The loss of the free-to-rotate capability of the knife-edge support resulting from the increase of the load level leads to the stiffening of the support. The importance of incorporating such characteristics of the supports in the analysis is of major importance in order to allow a meaningful comparison between theoretical prediction and experimental results.

A simplified model with the capability of reproducing the behavior described above was introduced and a detailed analysis was carried out. The results obtained show how such stiffening of the support dramatically alter both the static and the dynamic post-buckling response. Knife-edge type of supports of thin-walled structures are bound to exhibit the behavior modeled in the paper. The results presented contribute for the understanding of the dynamic post-buckling behavior of thin-walled structures with flexible knife-edge supports.

Stability and bifurcations of nonlinear multibody systems

Edwin J Kreuzer

Ocean Engineering Section II, Technical University Hamburg-Harburg
D-21071 Hamburg, Germany

Many technical systems are adequately described only by means of nonlinear mathematical models. Multibody systems became the most important mechanical models for analyzing engineering dynamics problems. The long-term or steady-state behavior of such systems can have a periodic, quasi-periodic, or chaotic character. Changes of the qualitative behavior are characterized by local and global bifurcations. This paper deals with stability problems in multibody system dynamics and explains different bifurcation phenomena as well as methods for analyzing them. Results from a simple oscillator prove the applicability of the methods.

CONTENTS

INTRODUCTION

Growing demands on speed and precision make it necessary to operate closer to the dynamic limits. These increasing demands on dynamic systems such as vehicles, mechanisms, and all kinds of machinery have motivated progress in mechanical modeling. Multibody systems are among the most important models for mechanical engineering systems. Multibody system dynamics is, therefore, world wide a very active area of research for both: improving and extending modeling and simulation procedures as well as analyzing the stability with respect to variable design parameters.

Different types of nonlinearities in engineering mechanical systems cause problems in the stability analysis. Many mechanical systems consist of linear components with local nonlinearities introduced for example by nonlinear springs, nonlinear dampers, dry friction, and backlash. Such nonlinearities may be desirable to avoid excessively high responses or stresses but also undesirable because of extensive wear or noise problems. Global nonlinearities originate from geometrically or kinematically nonlinear behavior often observed in mechanism, robot, and vehicle dynamics.

The performance of a technical system depends on its dynamic behavior which can be predicted using mathematical models for the multibody system and the excitation. Local stability, in the neighborhood of a steady-state operating point, of mechanical systems has been the subject of many research projects. But, neither the system parameters nor the excitation are precisely known; both may even vary during operation. Moreover, if a structure is to require a control system, the dynamics must be well understood. While local stability studies may be used to determine whether a given operating point can be maintained, a complete stability study must involve global analysis. Furthermore, changes of systems parameters may cause smooth or drastic changes in the qualitative behavior of the nonlinear system: so-called local and global bifurcations. A common feature of nonlinear dynamic systems is that for a given set of inputs the systems possess multiple stable steady states. It is therefore concluded that local stability at an operating point does not gurantee that it can be maintained. A stable and robust engineering system must consequently account for the regions of attraction corresponding to the steady states and how they are affected by varying parameters.

The subject of this paper is to study the qualitative behavior of multibody systems with local nonlinearities, which are excited by periodic external load. The Lyapunov spectra computed from the mathematical model provides a quantitative diagnosis for the different types of behavior.

MATHEMATICAL MODEL

Equations of motion of multibody systems are given by

$$\dot{\boldsymbol{x}} = \boldsymbol{f}(\boldsymbol{x}, \boldsymbol{\mu}) \quad , \tag{1}$$

part of "MECHANICS PAN-AMERICA 1993" edited by MRM Crespo da Silva and CEN Mazzilli
ASME Reprint No AMR134
Appl Mech Rev vol 46, no 11, part 2, November 1993

where $\boldsymbol{x}, \boldsymbol{f} \in R^N$ and $\boldsymbol{\mu} \in R^P$ is a parameter vector. The formulation of analytical mathematical models (1) is nowadays convieniently performed by using computerized formalisms for the generation of symbolic equations of motion, see e.g. Daberkow et al (1993).

The governing equations of nonlinear dynamic systems show a rich and fascinating variety of qualitative behavior like periodic, quasiperiodic or chaotic solutions for various parameter sets or initial conditions. We want information about how the equilibrium or periodic orbit of a vector field described by (1) changes with perturbations. This aspect of studying how dynamics depends upon parameters is called bifurcation theory. The general approach in order to study bifurcations is based on ideas of multivariable calculus and differential topology. From an engineering point of view it is important to have some kind of toolbox which helps to locate bifurcations in parameter space. As a starting point we assume that $\boldsymbol{f}$ of (1) is periodic with a period T. Hence, instead of looking at trajectories in the time domain, we use the so-called Poincaré map

$$\boldsymbol{x}_{n+1} = \boldsymbol{g}(\boldsymbol{x}_n, \boldsymbol{\mu}) \tag{2}$$

for studying the stability of periodic solutions $\bar{\boldsymbol{x}}(t) = \bar{\boldsymbol{x}}(t+T)$. Again, $\boldsymbol{g}$ is a nonlinear vector valued function which is smooth if $\boldsymbol{f}$ is smooth; n is the discrete time. A periodic motion of the continuous system (1) corresponds to a fixed point of the discrete system (2).

LOCAL BIFURCATIONS

There is a highly developed theory that enables one to determine some types of local bifurcations of equilibria of (1) and fixed points of (2) with power series. This theory is called center manifold theory. The calculations begin with the determination of the linearized vector field at the equilibrium (fixed point) and its eigenvalues and eigenvectors. Based upon this information, we can produce a normal form for the bifurcation. The effect of such a coordinate transformation is that the computations are more easily carried out. The normal form is a parameterized power series expansion that provides simple analytic expressions of the vector field at the bifurcation point. Once the normal forms have been computed, one can investigate the dynamics of the normal forms and classify the situation under consideration.

For local codimension one bifurcations one is left with a few specific equations from which we can determine the qualitative features of each type of bifurcation, see e.g. Guckenheimer and Holmes (1986). The calculations are a combination of numeric and analytic ones. We are developing a program package based upon efficient numeric algorithms and symbol manipulation programs for analyzing local bifurcations, Kleczka and Kreuzer (1992). Symmetry properties of the vector fields are often observed in multibody system models and are therefore also considered.

GLOBAL BIFURCATIONS

Contrary to local bifurcations the situation is more difficult in the case of global bifurcations, where the global topological structure of the phase portrait changes qualitatively. Hence, the analysis of such a behavior cannot be reduced to the study of the neighborhood of an equilibrium or a fixed point of the discrete system. There may be global changes in a phase portrait associated with saddle-node bifurcations. But there are even more complex situations which result from intersections of homoclinic and heteroclinic orbits and the so-called crises phenomena.

Transverse homoclinic (heteroclinic) orbits of a Poincaré map which imply chaotic motions can be determined numerically and analytically by means of a global perturbation technique introduced by Melnikov. The analytical perturbation method invented by Melnikov can only be applied if the perturbations are small. The resulting Melnikov function is the lowest order approximation for the distance between the stable and unstable manifolds of a fixed point of (2). If the Melnikov function oscillates about zero and has simple zeros then the stable and unstable manifolds have transversal intersections. An interesting discussion of the theory can be found in Wiggens (1988).

The sudden disappearances and sudden blow-ups of chaotic attractors are called crises phenomena, e.g. Ueda (1980) or Grebogi, Ott, and Yorke (1983). An interior crisis is a sudden enlargement of a chaotic attractor (sometimes with symmetry properties) often resulting in a one piece strange attractor. An exterior crisis causes a chaotic attractor to disappear due to its collision with an unstable periodic solution.

Global bifurcations are not smooth. Consequently, the resulting changes of the dynamics are not smooth, and often the system jumps, collapses or explodes, in other words its behavior changes drastically.

The enormous value of computers for dynamical systems has been mainly as an experimental tool. With digital computers we have the ability to produce reproducible data and pictures, some of which are chaotic from simple explicit equations. A complex picture, however, does not necessarily elucidate an already complex phe-

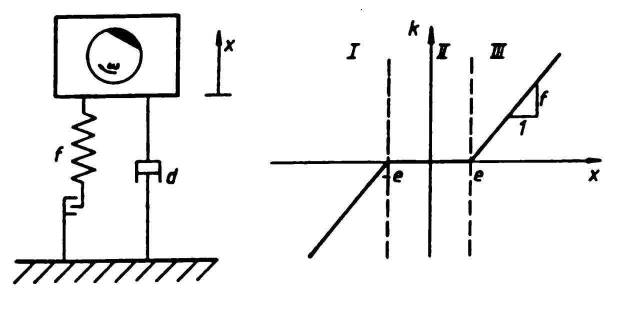

FIG 1. Model of the system and characteristic of the nonlinearity

nomenon unless we can organize the information the picture represents.

EXAMPLE

Vibrations of unloaded gears and synchronization parts within their functional backlash cause rattling noise. Increasing irregularities in shaft speed of modern engines and decreasing general sound level make this old comfort problem more important. Simultaneously, the hammering of the involved mechanical parts produces high dynamic overload. This is also a typical design problem.

A simple model of a mechanical system with backlash is a single degree-of-freedom oscillator with a piecewise linear, symmetric restoring force subjected to periodic excitations caused by an unbalanced rotor, see Fig 1 and Kleczka et al (1992). Because of its periodic time dependence, a common way to describe the dynamics is by means of an extended cylindrical state space

$$\begin{aligned} \boldsymbol{x} &= (x, y = \dot{x}\ , \quad \theta = t \bmod 2\pi) \in R^2 \times S^1, \\ & S^1 = [0, 2\pi) \quad , \end{aligned} \tag{3}$$

where x represents the position, y gives the velocity, and θ determines the circular coordinate and is to be interpreted as the phase angle of excitation. The resulting set of first order autonomous differential equations is given by

$$\begin{bmatrix} \dot{x} \\ \dot{y} \\ \dot{\theta} \end{bmatrix} = \begin{bmatrix} y \\ -2dy - k(x) + a\cos\theta \\ 1 \end{bmatrix} \tag{4}$$

with the nomalized parameters d of the damper, a of the amplitude of excitation, and the piecewise linear function $k(x)$ of the restoring force:

$$k(x) = \begin{cases} f(x-e) & , \quad x > e, \\ 0 & , \quad |x| \leq e, \\ f(x+e) & , \quad x < -e. \end{cases} \tag{5}$$

The following parameters have been kept fixed: amplitude of excitation a = 10.0, frequency of excitation $\omega = 1.0$.

This simple model shows the whole scenario of nonlinear behavior like periodic orbits, solutions of multiple period, chaotic solutions, various types of bifurcations and coexistence of even qualitatively different solutions. The global analysis of the nonlinear dynamics requires large-scale numerical investigations. Global stability analysis with respect to initial conditions leads to the problem of the determination of long-term behavior, i.e. attractors, and their domains of attraction.

A global analysis in parameter space can be carried out with a calculation of Lyapunov exponents and bifurcation diagrams. Lyapunov exponents are measures for the average exponential divergence or convergence of neighboring trajectories. Since they can be computed either from a mathematical model or from experimental data, they are widely used for the classification of attractors.

Lines in a bifurcation diagram represent periodic solutions changing under variation of the control parameter smooth or, in case of a local bifurcation, non-smooth. The corresponding Lyapunov exponent is negative, indicating stable, convergent long-term behaviour. Bifurcation points correspond to orbits of marginal stability and therefore have zero exponents. Chaotic dynamics produces non-periodic sequences of points in the bifurcation diagram leading to wide grey-patterned structures. The corresponding largest Lyapunov exponent is positive, in-

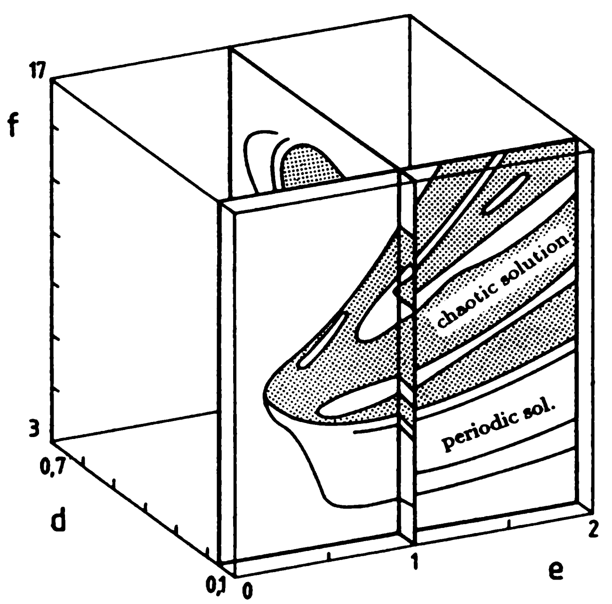

FIG 2. Stability diagram for parameters d, e, and f; solid lines indicate bifurcations.

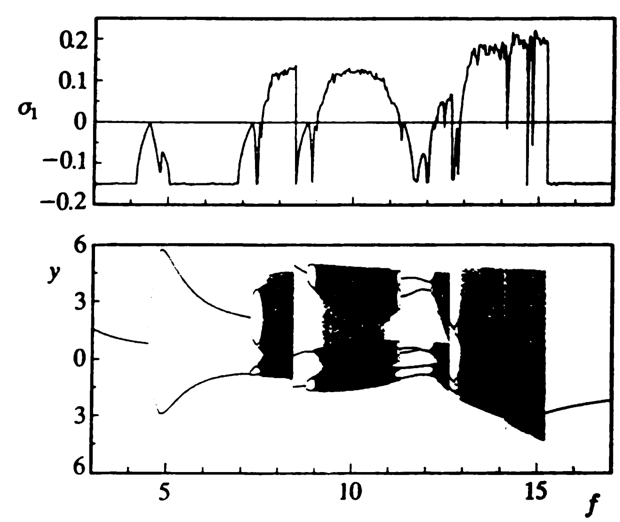

FIG 3. Bifurcation diagram and largest Lyapunov exponent σ_1 for variation of the stiffness ratio f.

dicating divergent, unpredictable dynamics. For a first overview on the dynamic behavior, the largest Lyapunov exponent was calculated for a broad range of parameter values in order to distinguish the parameter regions with regular and chaotic behavior reliable, Fig 2.

The analysis for variation of the stiffness ratio f only, all other values fixed ($d = 0.15$, $e = 1.0$, $a = 10.0$, $\omega = 1.0$), is shown in Fig 3. The stability and bifurcation analysis using center manifold theory is presented in Kleczka et al (1992).

For the backlash oscillator an unstable, saddle type, symmetric periodic orbit plays the decisive role in the global bifurcation scenario; its stable and unstable invariant manifolds intersect, leading to homoclinic structures with significant influence on the dynamics of the system, Fig 4 (a). In this case the emergence of the homoclinic intersection coincides with the emergence of a chaotic attractor. As the global topological structure of the system changes qualitatively, the system undergoes a global bifurcation.

Looking at the bifurcation diagram of Fig 3 one realizes that there are sudden disappearances and sudden blowups of the chaotic attractor: crisis phenomena.

(a)

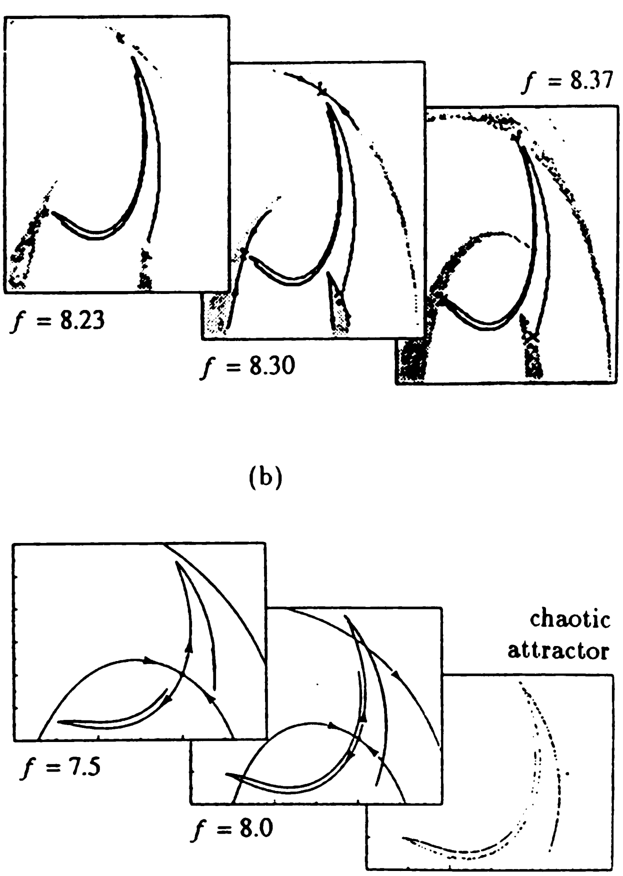

FIG 4. Poincaré maps of the backlash oscillator for demonstrating global bifurcations
(a) homoclinic bifurcation
(b) exterior crisis

An exterior crisis occurs at parameter value $f \approx 8.4$. The system abruptly terminates the chaotic behavior with a period three solution. How does the transition from chaotic to periodic occur as the parameter f is varied? The chaotic attractor vanishes, because it collides with an unstable periodic solution. Figure 4 (b) shows how basin boundary and unstable periodic orbits (fixed points) approach the chaotic attractor and finally destroy it by an exterior crisis. We observe that the chaotic attractor approaches the period three solution, the domain of attraction of the periodic solution grows towards the strange attractor in form of fingers, and the boundary crisis is triggered when the stable manifold of the saddle touches the unstable manifold.

An interior crisis can be observed at a parameter value of $f \approx 9.17$. More details may be found in Kleczka et al (1992).

CONCLUSIONS

The analysis of local and global bifurcations of mechanical systems replaced by multibody system models is discussed. The stability analysis of periodic motions is based upon Poincaré maps which have to be approximated analytically if local bifurcations are studied in a general form. Lyapunov exponents and bifurcation diagrams are helpful for the classification of the dynamic behavior of nonlinear systems. The global analysis requires normally large scale numerical simulations. By means of a combined computer aided numeric–symbolic approach a systematic analysis of bifurcation phenomena is visible.

Stability of linear mechanical systems with holonomic constraints

Peter C Müller

Safety Control Engineering, University of Wuppertal, D-42097 Wuppertal, Germany

Singular systems (descriptor systems, differential-algebraic equations) are a recent topic of research in numerical mathematics, mechanics and control theory as well. But compared with common methods available for investigating regular systems many problems still have to be solved making also available a complete set of tools to analyze, to design and to simulate singular systems. In this contribution the aspect of stability is considered. Some new results for linear singular systems are presented based on a generalized Lyapunov matrix equation. Particularly, for mechanical systems with holonomic constraints the well-known stability theorem of Thomson and Tait is generalized.

INTRODUCTION

In the last decade there was an essential progress dealing with dynamical systems described by differential-algebraic equations. In control theory descriptor systems (or singular control systems) have been investigated (Dai, 1989) and effective codes have been developed in numerical mathematics to simulate such systems, for example by Griepentrog and März (1986), Führer (1988), Hairer et al (1989), and Brenan et al (1989). But still there are many unsolved problems related to the analysis, design and simulation of descriptor systems. Here, we consider the stability behavior of differential-algebraic equations. Particularly, mechanical systems with explicit holonomic constraints are investigated. Mechanical systems with holonomic and/or nonholonomic constraints are a special class of descriptor systems which have been considered for long times in detail, for example by Neimark and Fufaev (1972), but even in this special case a lot of unsolved problems exist.

We are dealing with the stability problem of linear mechanical systems with holonomic constraints. Applying Lagrange's equation of the first kind systems with explicit constraints are governed by a set of differential equations of second order

$$\mathbf{M}\,\ddot{\mathbf{z}}(t) + (\mathbf{D}+\mathbf{G})\,\dot{\mathbf{z}}(t) + (\mathbf{K}+\mathbf{N})\,\mathbf{z}(t) = \mathbf{F}^T\,\boldsymbol{\lambda}(t) \tag{1}$$

and by algebraic equations representing the holonomic constraints

$$\mathbf{F}\,\mathbf{z}(t) = 0. \tag{2}$$

The square matrices **M**, **D**, **G**, **K** and **N** are related to inertia, damping, gyroscopic, stiffness, and circulatory forces, respectively (Müller 1977); $\mathbf{z}(t)$ denotes the f-dimensional vector of displacements and $\boldsymbol{\lambda}(t)$ is the p-dimensional vector of Lagrange's multipliers (or of the constraint forces). The $p \times f$-matrix **F** characterizes the constraints and is assumed to be row regular

$$\operatorname{rank}\mathbf{F} = p. \tag{3}$$

Usually Eq (2) is applied to eliminate redundant coordinates and to write down a set of regular equations of second order with respect to $f-p$ generalized coordinates without constraint forces. But here, the stability problem of the dynamical system (1, 2) is directly discussed without eliminating the constrained modes. Reasons for this may be the difficulties of handling large systems with some subsystems interconnected by Eq (2) or of manipulating kinematically closed-loop structures.

For a more general approach linear singular systems

$$\mathbf{E}\,\dot{\mathbf{x}}(t) = \mathbf{A}\,\mathbf{x}(t) \tag{4}$$

are considered where the matrix **E** is singular and $\mathbf{x}(t)$ denotes an n-dimensional vector of generalized state variables (or descriptor variables). The mechanical system of Eqs (1) and (2) is included into this notation by defining

$$\mathbf{x} = \begin{bmatrix} \mathbf{z} \\ \dot{\mathbf{z}} \\ \boldsymbol{\lambda} \end{bmatrix}, \quad \mathbf{E} = \begin{bmatrix} \mathbf{I} & & \\ & \mathbf{I} & \\ & & \mathbf{0} \end{bmatrix}, \tag{5}$$

part of "MECHANICS PAN-AMERICA 1993" edited by MRM Crespo da Silva and CEN Mazzilli ASME Reprint No AMR134
Appl Mech Rev vol 46, no 11, part 2, November 1993

$$\mathbf{A}=\begin{bmatrix} \mathbf{0} & \mathbf{I} & \mathbf{0} \\ -\mathbf{M}^{-1}(\mathbf{K}+\mathbf{N}) & -\mathbf{M}^{-1}(\mathbf{D}+\mathbf{G}) & \mathbf{M}^{-1}\mathbf{F}^T \\ \mathbf{F} & \mathbf{0} & \mathbf{0} \end{bmatrix}. \quad (6)$$

The dimensions are related by $n = 2f + p$.

In the following we are interested in the stability behavior of the equilibrium point $\mathbf{x} = \mathbf{0}$ and thus of the system of Eq (4). For this, first we have to define "stability" with respect to differential-algebraic systems and secondly to look for suitable criteria checking stability.

STABILITY

For regular dynamical systems the notation "stability" is well defined (even if there is not only one definition of stability but a great number of definitions related to different requirements of applications) and a related stability theory is well established (Hahn, 1967). For example, remember only the notion of stability in the sense of Lyapunov, asymptotic stability, absolute stability, and the well-known stability theory of Lyapunov.

Compared with the large amount of research related to stability problems of regular systems almost nothing has been investigated with respect to the stability behavior of singular systems. First general attempts have been presented by Bajić (1986, 1987, 1988a, 1988b), Bajić and Milić (1987), Bajić et al (1989), Griepentrog and März (1986), Dolezal (1987), Hill and Mareels (1990), März (1991). Additionally in case of linear time-invariant singular systems of Eq (4) stability has been defined by the eigenvalues of the matrix pencil $(\lambda\mathbf{E} - \mathbf{A})$.

One essential difficulty of a suitable stability definition is the problem in which (sub-) space stability has to be defined. Avoiding impulse solutions of Eq (4), initial conditions $\mathbf{x}(t_0) = \mathbf{x}_0$ must be consistent with the algebraic constraint equations. By the algebraic constraints nonimpulsive solutions belong to a consistent manifold $\mathcal{M}$ which is a subspace of the generalized state space. Restricting the stability problem to the consistent manifold $\mathcal{M}$, stability of an equilibrium point $\mathbf{x} = \mathbf{0}$ of Eq (4) can be defined in the sense of Lyapunov restricting the perturbed motion to the consistent manifold $\mathcal{M}$. Similarly asymptotic stability is defined with respect to $\mathcal{M}$.

This stability definition is useful no doubt and it corresponds exactly to the stability definition of the related regular system if the algebraic constraints are used to eliminate redundant coordinates ending in a regular set of ordinary differential equations. But this elimination procedure requires an exact description of the dynamical system and an exact elimination algorithm. If on the contrary there are some uncertain parameters in Eq (4) the above mentioned stability definition is unsatisfactory. The consistent manifold $\mathcal{M}$ is not certainly defined, and therefore the stability behavior of an uncertain system cannot be covered by this stability definition. Looking for robust stability a different definition is required.

Besides of the efforts of the group of Bajić (1986 etc.) actually there is no general stability theory available even confining ourselves to the definition of stability in the sense of Lyapunov restricted to $\mathcal{M}$. It may be expected that the method of Lyapunov functions for the stability problem of motions with respect to a part of the variables will be a helpful tool for further general stability investigations, see for example Oziraner and Rumiantsev (1972) or Müller (1982).

Contrary to the missing general theory in the special case of linear time-invariant singular systems of Eq (4) the stability behavior can be discussed in more detail as it is shown in the next sections.

LINEAR TIME-INVARIANT DESCRIPTOR SYSTEMS

Looking for the stability of the linear descriptor system (4) we use the stability definition of control theory (Dai, 1989):
Lemma: System (4) is called asymptotically stable *iff* all finite eigenvalues λ_i, $i = 1, \ldots, n_1$, of the matrix pencil $(\lambda\mathbf{E} - \mathbf{A})$ have negative real parts.

This definition assumes the existence of certain finite eigenvalues λ_i, $i = 1, \ldots, n_1$, of the matrix pencil $(\lambda\mathbf{E}-\mathbf{A})$, that is the vanishing of the characteristic polynomial

$$p(\lambda) \equiv det(\lambda\mathbf{E} - \mathbf{A}) \quad (7)$$

for some isolated values λ_i. That includes the requirements of quadratic matrices $\mathbf{E}$, $\mathbf{A}$ and additionally of

$$p(\lambda) \not\equiv 0\,. \quad (8)$$

These two requirements define a regular matrix pencil $(\lambda\mathbf{E} - \mathbf{A})$; otherwise the pencil is called singular. Therefore, the above stability definition is meaningful only for regular pencils; in case of singular pencils a stability definition does not exist. In the following regular matrix pencils are assumed in Eq (4). Mechanical systems described by Eqs (1) and (2) always define a regular matrix pencil via Eqs (5–6).

It is well-known in matrix theory that a regular matrix pencil $(\lambda\mathbf{E} - \mathbf{A})$ is strictly equivalent to the Kronecker canonical form (Dai, 1989), that is there exist two regular matrices

$$\mathbf{R} = \begin{bmatrix} \mathbf{R}_1 \\ \mathbf{R}_2 \end{bmatrix}, \qquad \mathbf{S} = \begin{bmatrix} \mathbf{S}_1 & \mathbf{S}_2 \end{bmatrix} \quad (9)$$

such that

$$\mathbf{RES} = \begin{bmatrix} \mathbf{I}_1 & \mathbf{0} \\ \mathbf{0} & \mathbf{N}_k \end{bmatrix}, \qquad \mathbf{RAS} = \begin{bmatrix} \mathbf{A}_1 & \mathbf{0} \\ \mathbf{0} & \mathbf{I}_2 \end{bmatrix}, \quad (10)$$

where the identity matrices $\mathbf{I}_1$, $\mathbf{I}_2$ are of dimen[illegible] n_2 with $n_1+n_2 = n$ and the $n_2 \times n_2$ matrix $\mathbf{N}_k$

index k ($\mathbf{N}_k^{k-1} \neq \mathbf{0}$, $\mathbf{N}_k^k = \mathbf{0}$) defining the index of the linear descriptor system (4). Introducing new coordinates

$$\begin{bmatrix} \mathbf{y}_1 \\ \mathbf{y}_2 \end{bmatrix} = \mathbf{S}^{-1}\mathbf{x}, \qquad \mathbf{x} = \mathbf{S}_1\mathbf{y}_1 + \mathbf{S}_2\mathbf{y}_2 \tag{11}$$

system (4) is decoupled in the "slow" subsystem

$$\dot{\mathbf{y}}_1 = \mathbf{A}_1\mathbf{y}_1 \tag{12}$$

and the "fast" subsystem

$$\mathbf{N}_k\dot{\mathbf{y}}_2 = \mathbf{y}_2\,. \tag{13}$$

Consistent solutions require $\mathbf{y}_2(t_0) = \mathbf{0}$ and therefore $\mathbf{y}_2(t) \equiv \mathbf{0}$. It is easily shown that the eigenvalues of the system (4) coincide exactly with the eigenvalues of the slow subsystem (12). Therefore, the asymptotic stability of Eq (4) is guaranteed *iff* the slow subsystem is asymptotically stable.

Besides the discussion of stability by eigenvalues the stability behaviour of linear regular systems can be handled by the Lyapunov matrix equation (Müller, 1977). Therefore, the stability of the slow subsystem can be investigated by definiteness properties of matrices $\mathbf{P}_1$, $\mathbf{Q}_1$ of the Lyapunov matrix equation

$$\mathbf{A}_1^T\mathbf{P}_1 + \mathbf{P}_1\mathbf{A}_1 = -\mathbf{Q}_1\,. \tag{14}$$

The question arises how to apply all the well-known results on Eq (14) to the original system matrices $\mathbf{E}$, $\mathbf{A}$. Performing the equivalence back-transformation of Eqs (10,11) the equation (14) results in a generalized Lyapunov matrix equation

$$\mathbf{A}^T\mathbf{P}\mathbf{E} + \mathbf{E}^T\mathbf{P}\mathbf{A} = -\mathbf{Q} \tag{15}$$

which includes besides of Eq (14) certain arbitrary terms with respect to the fast subsystem (13). This equation (15) may be also found by a Lyapunov function

$$v = \mathbf{x}^T\mathbf{E}^T\mathbf{P}\mathbf{E}\,\mathbf{x} \tag{16}$$

which leads in usual manner to

$$\dot{v} = \mathbf{x}^T(\mathbf{A}^T\mathbf{P}\mathbf{E} + \mathbf{E}^T\mathbf{P}\mathbf{A})\,\mathbf{x} \overset{!}{=} -\mathbf{x}^T\mathbf{Q}\,\mathbf{x}\,. \tag{17}$$

The stability requirement in Eq (17) results in Eq (15).

From Eqs (14–17) we have the first main result.

Theorem 1: If there are symmetric matrices $\mathbf{P}$, $\mathbf{Q}$ satisfying equation (15) and if

$$\mathbf{x}^T\mathbf{E}^T\mathbf{P}\mathbf{E}\,\mathbf{x} > 0 \qquad \forall \mathbf{x} = \mathbf{S}_1\,\mathbf{y}_1 \neq \mathbf{0}\,, \tag{18}$$

$$\mathbf{x}^T\mathbf{Q}\mathbf{x} \geq 0 \qquad \forall \mathbf{x} = \mathbf{S}_1\,\mathbf{y}_1 \tag{19}$$

then system (4) is asymptotically stable if

$$rank\begin{bmatrix} s\mathbf{E} - \mathbf{A} \\ \mathbf{S}_1^T\mathbf{Q} \end{bmatrix} = n \qquad \forall s \in \mathbb{C} \tag{20}$$

and marginally stable if condition (20) does not hold.

The term of marginal stability denotes stability in the sense of Lyapunov without asymptotic stability. It should be noted that Theorem 1 presents a generalization of a result by Owens and Debeljkovic (1985) where the observability condition (20) does not appear and the requirement (19) is replaced by its positive definite analogue. The weakening of inequality (20) to the positive semidefinite case requires the additional observability condition (20). In case of mechanical systems this generalization means that complete damping can be replaced by pervasive damping (Müller, 1977).

A special difficulty is the check whether the quadratic forms (18), (19) are positive (semi-) definite with respect to the states of the consistent manifold $\mathcal{M}$ only. Comparing the admissible states $\mathbf{x} = \mathbf{S}_1\mathbf{y}_1$ with the transformation (11) obviously the definiteness check is restricted to consistent states. The columns of $\mathbf{S}_1$ present a basis of $\mathcal{M}$. The condition (20) requires R-observability (Dai, 1989) of a fictitious measurement matrix $\mathbf{S}_1^T\mathbf{Q}$ with respect to the dynamic system (4). Compared with the usual observability condition in case of regular systems (Müller,1977), the projection on $\mathcal{M}$, that is ($\mathbf{S}_1^T\mathbf{Q}$), is needed instead of the full matrix $\mathbf{Q}$.

Applying Theorem 1 usually it is very difficult to find the matrix $\mathbf{S}_1$. Only if $\mathbf{S}_1$ can be calculated explicitly or if $\mathcal{M}$ can be imbedded in a subspace $\bar{\mathcal{M}} \supset \mathcal{M}$ and (18), (19) hold for all $\mathbf{x} \in \bar{\mathcal{M}}$, then Theorem 1 may lead to interesting stability results. In the following section the application of Theorem 1 to the mechanical system (1) with holonomic constraints (2) is shown.

LINEAR TIME-INVARIANT MECHANICAL SYSTEMS WITH HOLONOMIC CONSTRAINTS

Very often stability behavior of mechanical systems has been proved using the total energy, that is the Hamiltonian, as a Lyapunov function. In case of linear time-invariant mechanical systems this approach leads to the well-known theorem of Thomson and Tait which was strictly proved by Chetaev (Müller, 1977). Is it possible to generalize this theorem for mechanical systems (1) with holonomic constraints (2)?

As usual we have to restrict the problem to the non-circulatory case:

$$\mathbf{N} = \mathbf{0}\,. \tag{21}$$

Using the Hamiltonian

$$v = H = \frac{1}{2}\dot{\mathbf{z}}^T\mathbf{M}\,\dot{\mathbf{z}} + \frac{1}{2}\mathbf{z}^T\mathbf{K}\,\mathbf{z} \tag{22}$$

for the Lyapunov function (16) the Lyapunov matrix equation (15) holds for

$$\mathbf{P} = \frac{1}{2}\begin{bmatrix} \mathbf{K} & & \\ & \mathbf{M} & \\ & & \mathbf{0} \end{bmatrix}, \tag{23}$$

$$\mathbf{Q} = \begin{bmatrix} \mathbf{0} & & \\ & \mathbf{D} & -\frac{1}{2}\mathbf{F}^T \\ & -\frac{1}{2}\mathbf{F} & \mathbf{0} \end{bmatrix}. \tag{24}$$

It should be noted that neither the matrix $\mathbf{P}$ is positive definite (at best it is positive semidefinite only) nor the matrix $\mathbf{Q}$ is positive semidefinite (it is indefinite for $\mathbf{F} \neq \mathbf{0}$) but that the conditions (18), (19) are valid if the matrices $\mathbf{M}$, $\mathbf{K}$ are positive definite and $\mathbf{D}$ is positive semidefinite at least:

$$\mathbf{x}^T\mathbf{E}^T\mathbf{P}\mathbf{E}\,\mathbf{x} = H > 0, \tag{25}$$

$$\mathbf{x}^T\mathbf{Q}\,\mathbf{x} = \dot{\mathbf{z}}^T\mathbf{D}\,\dot{\mathbf{z}} \geq 0. \tag{26}$$

The main problem is the check of condition (20).

As mentioned above the essential step to check condition (20) is the calculation of the matrix $\mathbf{S}_1$ of the transformation (10,11). By Müller and Schüpphaus (1993) this transformation has been derived for mechanical systems (1) with holonomic constraints (2). The transformation matrices are given by

$$\mathbf{R} = \begin{bmatrix} \mathbf{L}(\mathbf{I}_f - \mathbf{V}^T\mathbf{F}) & \mathbf{0} & \mathbf{U}\bar{\mathbf{P}}\mathbf{V}^T \\ \mathbf{U}\bar{\mathbf{P}}\mathbf{V}^T\mathbf{F} & \mathbf{L}(\mathbf{I}_f - \mathbf{V}^T\mathbf{F}) & \mathbf{U}\mathbf{X}\mathbf{V}^T \\ \mathbf{0} & \mathbf{F} & \mathbf{0} \\ \mathbf{F} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{I}_p \end{bmatrix}, \tag{27}$$

$$\mathbf{S} = \Big[\underbrace{\begin{matrix} \mathbf{L}^+ & \mathbf{0} \\ \mathbf{0} & \mathbf{L}^+ \\ \mathbf{V}\bar{\mathbf{Q}}\mathbf{L}^+ & \mathbf{V}\bar{\mathbf{P}}\mathbf{L}^+ \end{matrix}}_{\mathbf{S}_1}\ \underbrace{\begin{matrix} \mathbf{0} & \mathbf{0} & \mathbf{V}^T \\ \mathbf{0} & \mathbf{V}^T & -\mathbf{L}^+\mathbf{U}\bar{\mathbf{P}}\mathbf{V}^T \\ \bar{\mathbf{F}} & \mathbf{V}\bar{\mathbf{P}}\mathbf{V}^T & \mathbf{V}\mathbf{X}\mathbf{V}^T \end{matrix}}_{\mathbf{S}_2}\Big], \tag{28}$$

with

$$\begin{aligned} \bar{\mathbf{P}} &= \mathbf{D} + \mathbf{G}, & \mathbf{L}^+ &= \mathbf{L}^T(\mathbf{L}\mathbf{L}^T)^{-1}, \\ \bar{\mathbf{Q}} &= \mathbf{K} + \mathbf{N}, & \mathbf{V} &= \bar{\mathbf{F}}\mathbf{F}\mathbf{M}^{-1}, \\ \bar{\mathbf{F}} &= (\mathbf{F}\mathbf{M}^{-1}\mathbf{F}^T)^{-1}, & \mathbf{U} &= \mathbf{L}\mathbf{M}^{-1}(\mathbf{I}_f - \mathbf{F}^T\mathbf{V}), \\ \mathbf{L} &= (kernel\ \mathbf{F})^T, & \mathbf{X} &= (\bar{\mathbf{Q}} - \bar{\mathbf{P}}\mathbf{L}^+\mathbf{U}\bar{\mathbf{P}}). \end{aligned}$$

The dimensions of the slow and fast subsystems Eqs (12, 13) are

$$n_1 = 2(f-p), \quad n_2 = 3p. \tag{29}$$

The matrix of the slow subsystem (12) results in

$$\mathbf{A}_1 = \begin{bmatrix} \mathbf{0} & \mathbf{I}_{f-p} \\ -\mathbf{U}\bar{\mathbf{Q}}\mathbf{L}^+ & -\mathbf{U}\bar{\mathbf{P}}\mathbf{L}^+ \end{bmatrix} \tag{30}$$

and the nilpotent matrix of Eq (13) is

$$\mathbf{N}_k = \mathbf{N}_3 = \begin{bmatrix} \mathbf{0} & \mathbf{I}_p & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{I}_p \\ \mathbf{0} & \mathbf{0} & \mathbf{0} \end{bmatrix} \tag{31}$$

From the transformation matrix $\mathbf{S}$, Eq (28), the submatrix $\mathbf{S}_1$ is available and condition (20) can be proved. From this, the second main result is obtained.

Theorem 2: If the system matrices of a non-circulatory mechanical system (1), (2), (21) satisfy

$$\mathbf{M} = \mathbf{M}^T > 0, \quad \mathbf{D} = \mathbf{D}^T \geq 0, \quad \mathbf{K} = \mathbf{K}^T > 0 \tag{32}$$

then the mechanical system is asymptotically stable if

$$rank \begin{bmatrix} \mathbf{M}s^2 + (\mathbf{D}+\mathbf{G})s + \mathbf{K} & -\mathbf{F}^T \\ \mathbf{F} & \mathbf{0} \\ (\mathbf{I} - \mathbf{F}^+\mathbf{F})\mathbf{D}s & \mathbf{0} \end{bmatrix} = f + p \tag{33}$$

for all $s \in \mathbb{C}$ holds and marginally stable if (33) does not hold.

Here, $\mathbf{F}^+$ represents the Moore-Penrose inverse matrix of $\mathbf{F}$.

Theorem 2 represents a very conservative result. It only states that if the unconstrained mechanical system is asymptotically stable and if the constraints do not block pervasive damping then the constrained mechanical system is asymptotically stable, too. But the effect of stabilization by the constraints is not included. But that can be shown very easily by a formal trick. If the holonomic constraints (2) are satisfied then the stability behavior of the mechanical system is not changed if the damping and stiffness matrices $\mathbf{D}$ and $\mathbf{K}$ are replaced by $\mathbf{D}+\alpha\mathbf{F}^T\mathbf{F}$ and $\mathbf{K}+\beta\mathbf{F}^T\mathbf{F}$. Then the third main result is immediately derived.

Theorem 3: If the system matrices of a non-circulatory mechanical system (1), (2), (21) satisfy

$$\mathbf{M} = \mathbf{M}^T > 0, \quad \mathbf{D} + \alpha\mathbf{F}^T\mathbf{F} \geq 0, \quad \mathbf{K} + \beta\mathbf{F}^T\mathbf{F} > 0 \tag{34}$$

for certain positive numbers $\alpha > 0$, $\beta > 0$ then the mechanical system is asymptotically stable if condition (33) holds and marginally stable if condition (33) does not hold.

Here, the stabilization effect of the holonomic constraints is explicitly shown. Theorem 3 represents the proper generalization of the stability theorem of Thomson, Tait, Chetaev including also the effect of pervasive damping.

CONCLUSION

This contribution deals with the stability problem of descriptor systems. It critically reviews the state of the art demonstrating problems in the kind of suitable definitions for stability of descriptor systems and indicating as well a lack of stability theory related to singular dynamical systems. It is hoped that a stability theory can be developed based on the results of partial stability. In case of linear descriptor systems some detailed stability results have been proved based on an extended Lyapunov matrix equation. But to improve the applicability of these results an effective algorithm has to be established characterizing the consistent solution subspace. This is possible in the case of constrained mechanical systems. There, the matrices of a transformation to the Kronecker canonical form can be calculated explicitly. Therefore, the general results on the stability of linear descriptor systems have been specialized to mechanical systems with holonomic constraints generalizing the famous theorem of Thomson, Tait, Chetaev.

Dynamic modelling and control strategies of space manipulators

A Ercoli-Finzi and P Mantegazza

Dipartimento di Ingegneria Aerospaziale
Politecnico di Milano, via Golgi 40, 20133 Milano, Italy

In this work the dynamics of a manipulator arm is analyzed by Maggi's formulation and by automatic development of the equations of motion. Two control strategies, that is an adaptive and a standard one, are taken into account in order to satisfactory perform pick and place maneuvers. Numerical simulations emphasize performance qualities and limits of the two choices and suggest a possible implementation of mixed control strategies.

CONTENTS

INTRODUCTION

Because of the difficulties and dangers connected with space exploration, robots and space manipulators have been heavily employed since the beginning of space activity. It is merit of Vikings and Luna probes (Gatland 1980) if a specific knowledge of some celestial bodies has been acquired. Future activities will be quite similar and robots and manipulators will be utilized more and more, as it now happens for manipulator arms designed for the Space Shuttle and HERMES.

Since their repairing and servicing cannot be easily and frequently scheduled and, on the other hand, requirements on their performances are very tight, the dynamic behavior of space manipulators must be deeply understood and accurately simulated and tested on ground, to avoid mistakes and, in some cases, disasters.

Numerical simulations imply the resolution of the equations of motion, whose number can be very high, because of the many degrees of freedom. On the other hand their structure is very complex, due to the complexity of the body chain, coming from their constraints and physical properties.

For that an accurate, realistic, easily implementable (and computationally effective) dynamic model is required. To this aim the method proposed by Maggi (1896) is adopted, because it allows to take into account both holonomic and non-holonomic constraints and at the same time is characterized by the simplest equations, obtained with the least mathematical complexity (Kane and Levinson 1980).

In order to guarantee real time simulations and the capability of facing dynamic systems with different physical and geometric characteristics, the symbolic equations manipulation can be adopted by making use of ad hoc developed or already existing software. As it will be shown, Maggi's equations are also well fitted to the adoption of different control strategies, to assure the end effector prescribed motion. In this case, if rapid highly non linear maneuvers are required, the inverse dynamics must be computed to anticipate control forces. By using symbolic manipulation, it is then possible to carry out real time simulations on realistic dynamic models.

Attention will be focused both on standard and adaptive control strategies, the latter being particularly suitable in case of badly known physical and geometric parameters.

KINEMATICS

The dynamic model here developed is referred to a tree like multibody chain, both open and closed, either connected to the ground or not. If an n-rigid link system is analyzed, its 3D configuration is described by $3n$ parameters x_{ki} (k = 1,2,3 i = 1,...n), related by m holonomic constraints equations

$$f_j(x_{ki}, t) = 0 \qquad (1)$$

A p-dimensional time function configuration vector $\{q\}$ can be defined, p=3n-m, constrained by m_a non-holonomic, i.e. differential equations

$$[A]\{\dot{q}\}+\{b\}=0 \qquad (2)$$

By partitioning the vector $\{q\}$ in a (p-m_a) component vector $\{q_i\}$ and a m_a component vector $\{q_d\}$, Eq (2) takes the form

$$[A_i, A_d]\{\dot{q}_i, \dot{q}_d\}+\{b\}=0 \qquad (3)$$

If $[A_d]$ is a non singular matrix, it is possible to solve Eq (3) with respect to $\{q_d\}$

$$\{\dot{q}_d\}=[C]\{\dot{q}_i\}+\{d\} \qquad (4)$$

and to introduce a p_a dimension parameter vector $\{u\}$, $p_a = p - m_a$, defined by

$$\{u\}=[U]\{\dot{q}_i\}+\{u_t\} \qquad (5)$$

which represents the independent parameter vector of the system, to be determined by integration of the equations of motion.

Linear and angular velocities of each link and body are functions of u according to

$$\{v\}=[V_r]\{u\}+\{v_t\} \qquad (6)$$

$$\{\omega\}=[\omega_r]\{u\}+\{\omega_t\} \qquad (7)$$

in which the columns of $[V_r]$ are the partial linear velocities.

In the case of open chains, with 1 degree of freedom rotatioual or translational joints, anchored to a main body, like the Shuttle or the Space Station, the total number of degrees of freedom is the joints number N, and the joint displacements can suitably be assumed as lagrangian coordinates. If the chain is not anchored, the configuration of one body must be defined with respect to a known reference frame; by introducing Euler angles and the coordinates of one point, that is 6 new degrees of freedom, the matrix $[U]$ takes the diagonal form

$$[U]=[[E_u];[E_d];1] \qquad (8)$$

$[E_u]$ being the coordinate transformation matrix and $[E_d]$ the Euler angles derivatives transformation matrix.

Internal constraints of closed loop chains can be taken into account by assuming the same linear and rotational velocities for the two parts of broken joints; their general compact form is of the type of Eq (2) that represents a generic non holonomic constrai[illegible]

In order to describe the k[illegible] [illegible]onships between a pair of adjacent links of [illegible] [illegible]cessary to know the position and orienta[illegible] [illegible]s and bodies as function of lagrangian coordinates. To this aim a reference frame must be assigned to each link: the coordinate transformation between two adjacent links is

$$\{x_{i-1}\}=[\Lambda_{i-1,i}]\{x_i\} \qquad (9)$$

where $[\Lambda_{i-1,i}]$ is the transformation matrix that can be computed through the Denavit-Hartenberg parameters. If $\{x_i\}$ is homogeneus and its fourth coordinate is taken always with unit value, we have

$$[\Lambda_{i-1,i}]=\begin{bmatrix} c\vartheta_i & -s\vartheta_i c\alpha_i & s\vartheta_i s\alpha_i & a_i c\vartheta_i \\ s\vartheta_i & c\vartheta_i c\alpha_i & -c\vartheta_i s\alpha_i & a_i s\vartheta_i \\ 0 & s\alpha_i & c\alpha_i & d_i \\ 0 & 0 & 0 & 1 \end{bmatrix} \qquad (10)$$

ϑ, α, a and d being the Denavit-Hartenberg parameters (Paul 1981).

The absolute position of the end effector is

$$\{x_0\}=[T]\{x_N\} \qquad (11)$$

where $\{x_N\}$ is its local position and

$$[T]=[\Lambda_{0,1}][\Lambda_{1,2}]\ldots[\Lambda_{N-1,N}] \qquad (12)$$

In the case of a floating arm

$$\{x_0\}=[T']\{x_N\}=[\Lambda][T]\{x_N\} \qquad (13)$$

$[\Lambda]$ being the transformation matrix between the first reference frame and the anchored one.

Linear and angular velocities depend only on the derivatives of $[\Lambda_{i-1,i}]$ and $[\Lambda]$ and the highly non linear kinematic equations allow to compute positions and velocities when q and $\dot{q}$ are known by

$$x_i = f_i(\{q\}) \qquad (14)$$

If the inverse kinematics is required, as it frequently happens for controlled dynamics, $\{q\}$ and $\{\dot{q}\}$ must be determined as a function of $\{x\}$. In this case

$$\{\dot{q}\}=[J]^{-1}\{\dot{x}\} \qquad (15)$$

where $[J]$ is the Jacobian of Eq (14).

Since it is generally almost impossible to obtain an analytical solution, in the following a numerical procedure, based on Newton-Raphson technique, is proposed (Teukolsky et al 1986), according to which Eq (14) becomes

$$\{x\} = [J]_0 \Delta\{q\} + F(\{q_0\}) \tag{16}$$

being $\{q_0\}$ supposed to be close to its actual value. If Jacobian matrix is not singular, $\Delta\{q\}$, and consequently $\{q\}$, can be evaluated and the procedure iterated till convergence.

DYNAMICS

As already said, the dynamic equations are derived by Maggi's method, with the advantage that only the internal forces driving the joints must be taken into account. No role is played by the reaction forces, related to the constraints, and by non-working forces. Besides, as stated by Kane, who is nowadays recognized as the developer of the equations themselves (Borri et al 1986), they are particularly suitable for implementation.

To this aim, the equations of motion of an N masses system, obtained from D'Alembert principle

$$\{F_j\} - m_j\{a_j\} = 0 \qquad j=1,\dots N \tag{17}$$

is projected on the partial linear velocities, giving

$$\{F_r\} + \{F_r^*\} = 0 \tag{18}$$

where

$$\{F_r\} = \sum_{j=1}^{N}\{V_r\}_j^T\{F_j\} \tag{19}$$

are the generalized active forces and

$$\{F_r^*\} = -\sum_{j=1}^{N}\{V_r\}_j^T m_r\{a_r\} \tag{20}$$

are the generalized inertia forces.

For a fixed constrained rigid body we have

$$\{\alpha\} = [\omega_r]\{\dot u\} + \{\dot q\}^T\left[\frac{\partial\omega_r}{\partial q_s}\right]\{u\} \tag{21}$$

$$\{a\} = [V_r]\{\dot u\} + \{\dot q\}^T\left[\frac{\partial V_r}{\partial q_s}\right]\{u\} \tag{22}$$

and

$$\{F_r^*\} = -\sum_{i=1}^{N}\Bigg\{\{V_r\}_i^T m_i\left(\sum_{s=1}^{Pa}\{V_s\}_i\dot u_s\right) + \{\omega_r\}_i^T[I]_i\left(\sum_{s=1}^{Pa}\{\omega_s\}_i\dot u_s\right) +$$
$$+\{V_r\}_i^T m_i\left(\sum_{s=1}^{Pa}\sum_{t=1}^{Pa}\frac{\partial\{V_s\}_i}{\partial q_t}u_s\dot q_t\right) +$$
$$+\{\omega_r\}_i^T\left[[I]_i\left(\sum_{s=1}^{Pa}\sum_{t=1}^{Pa}\frac{\partial\{\omega_s\}_i}{\partial q_t}u_s\dot q_t\right) + [\omega x]_i[I]_i\{\omega\}_i\right]\Bigg\} \tag{23}$$

It is remarked that $\{F_r^*\}$ linearly depends from $\{\dot u\}$ in Eq(23).

By a suitable rearrangement, the equations of motion can be given the compact form

$$[M]\{\dot u\} = \{f\} + \{\tau\} \tag{24}$$

$[M]$ being a positive definite matrix

$$M_{rs} = \sum_{i=1}^{N}\{V_r\}_i^T m_i\{V_s\}_i + \{\omega_r\}_i^T[I]_i\{\omega_s\} \tag{25}$$

and $\{f\}$ is the part of $\{F^*\}$ representing the forces due to the motion, like Coriolis, centrifugal, etc., and $\{\tau\}$ the generalized active force vector. A similar, even if much more complex system, can be obtained for flexible bodies (Galli 1991), but due to the large computer memory requirements only lumped deformable elements at the joints have been modelled.

IMPLEMENTATION AND RESULTS

The equations have been automatically derived by MACSYMA and subsequently solved numerically. As a first step a double tether system was tested, proving a very good agreement with theoretical results.

As a second step, an implementation has been carried out for the 3 d.o.f. Stanford and Puma manipulators, whose equations are known (Levi and Hemati 1986, Passera 1990), by Lagrangian derivation. Numerical solutions, compared with the results obtained by DADS, a general purpose computer program for the dynamic analysis of multybodies, evidenced an excellent agreement and a significant time saving, due to the appropriate formulation and to the symbolic manipulation of the equations of motion.

The most important conclusion from the operational point of view is that translational joints highly reduce the equation complexity with respect to rotation joints, due to the simpler Denavit-Hartenberg matrices. Anyway, even in the case of rigid link manipulators, the memory requirement is dramatically large, as proved by the f_1 element of Puma equations that covers more than 190 program rows.

CONTROL STRATEGIES

In the specific case of a space manipulator, the control system is devoted to solve tracking problems, that means to assure that the end effector describes a prescribed trajectory typical of a pick and place maneuver in presence of known obstacles.

The choice has been a multybody system without redundancies, so that only a finite number of configurations turns out to be compatible with each end effector position.

In this case the joints space control is the simplest one in that it is possible to find, by inverse kinematics, the joint displacements corresponding to the desired end effector positions. To this aim the trajectories are suitably checked as time functions and the corresponding joint positions are acquired by the procedure previously recalled. The inverse dynamic problem strongly asks for a symbolic manipulation, allowing at the same time accurate modelling and real time simulations.

The control problem finds its main difficulty in the not completely known physical characteristics of manipulators, as it frequently happens when they are devoted to transportation and manipulation of target objects. To avoid design errors coming from this insufficient knowledge, adaptive control strategies are suitable (Galli 1991).

ADAPTIVE CONTROL

In order to find the control law of model reference adaptive P.D. control system, utilizing a feed-forward and a feed-back loop (Craig 1988), the error vector

$$\{e\} = \{q_d\} - \{q\} \tag{26}$$

and a suitable evolution of the generalized velocities

$$\{\dot{u}^*\} = \{\ddot{u}_d\} + [K_p]\{e\} + [K_d]\{\dot{e}\} \tag{27}$$

are introduced. In the above equations d refers to the desired values and $[K_p]$, $[K_d]$ are positive definite matrices.

By inverse dynamics control $\{\tau\}$, responsible of the desired motion, can be evaluated when physical parameters are known, by the equation of motion

$$\{\tau\} = \sum_{i=1}^{rj} m_{ij} f_{ij}(\{q\},\{u\}) + \sum_{i=1}^{sj} n_{ij} g_{ij}(\{q\},\{u\}) \tag{28}$$

in which m_{ij} and n_{ij} are physical parameters, while f and g depend on geometric parameters.

The correlation between the coordinate error vector $\{x\}$

$$\{x\}_i = \tag{29}$$

and the parameter vector $\{\varphi\}$ is

$$\{\dot{x}\} = [A]\{x\} + [B][M']^{-1}[W]\{\varphi\} \tag{30}$$

where $[M']$ is the estimated mass matrix. If $[K_p]$ and $[K_d]$ are diagonal, $[A]$ and $[B]$ are also diagonal, with

$$A_{ii} = \begin{bmatrix} 0 & 1 \\ -k_{pi} & -k_{di} \end{bmatrix} \tag{31}$$

$$[B] = [0,1]^T \tag{32}$$

Lyapunov stability criterion assure that the system is stable if parameter estimation satisfies the condition

$$\{\dot{p}\} = [\Gamma][W]^T [M']^{-1}\{e\}_1 \tag{33}$$

being

$$\{e\}_1 = \{\dot{e}\} + [\psi]\{e\} \tag{34}$$

the filtered vector.

The implementation of the proposed control strategy requires the evaluation of $[W]$, in the case of symbolic manipulation. That is feasible when the equations of motion are first order equations with respect to the parameters. That implies a suitable choice of the parameters themselves that not always is an obvious one. In this case Eq (28) can be written in the form

$$[W]\{PAR\} = \{\tau\} \tag{35}$$

$\{PAR\}$ being the vector of the physical parameters, from which $[W]$ can be obtained.

STANDARD CONTROL

Due to the complex implementation of adaptive control, also a standard control strategy has been adopted.

The adopted control system is a double PID stage with a faster internal loop on the joint speed and an outer slower loop on positions. Passing band bounds must assure that no excitation of structural frequencies of elements connected to velocity and position sensors can occur (Paul 1981).

Attention must be paid also to possible instabilities due to the coupling of the velocity and position loop, caused by different changes in physical characteristics of the manipulator.

NUMERICAL SIMULATIONS

The designed adaptive control has been first tested on the double tether system, by asking the end effector to perform a circular trajectory with a mass estimation error of 80 per cent.

Numerical results prove that controls are well behaving: the parameter identification occurs in a few seconds and the actual trajectory is the desired one, Figs 1-2.

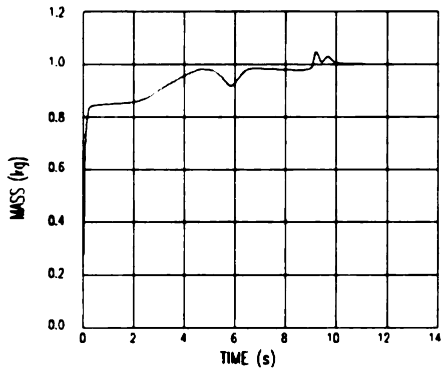

Fig 1. Double tether system: mass identification.

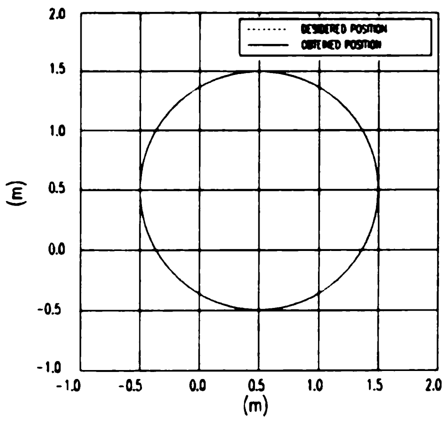

Fig 2. Adaptive double tether system: end effector trajectory.

Comparison with non adaptive control implementation making use of the same PD controller, Fig 3, enphasizes the efficiency of the adaptive law.

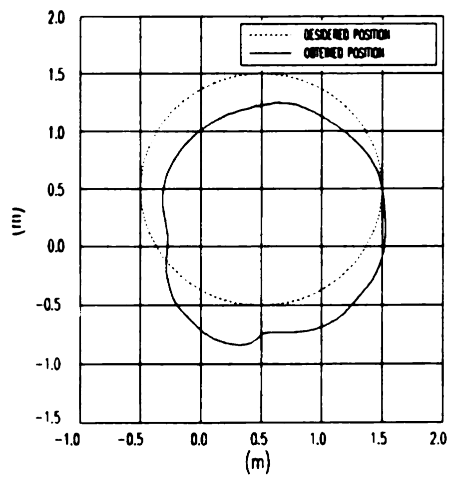

Fig 3. Non adaptive trajectory tracking.

Further simulations have been performed with the Stanford Manipulator, the physical and geometrical parameters of which are well known (Paul 1981). Identification of the inertial parameters of the third body has been carried out for a pick and place maneuver (Fig 4) of a 3 kg mass (Fig 5).

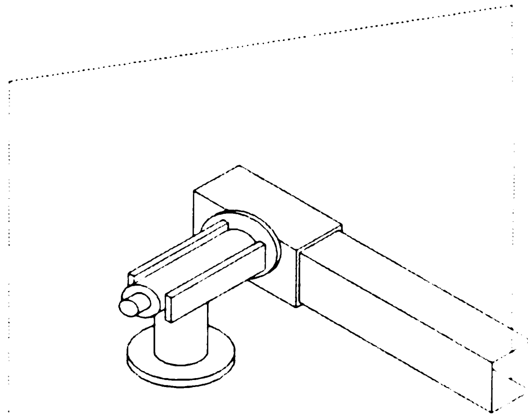

Fig 4. Pick and place trajectory.

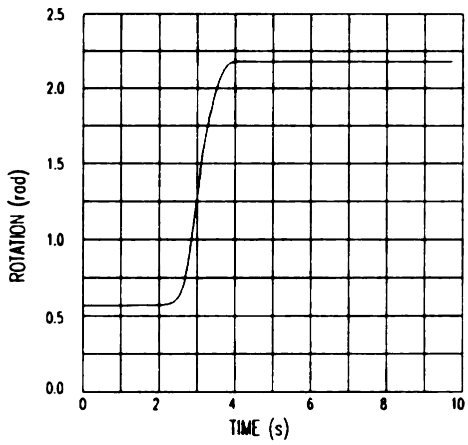

Fig 5. First coordinate behavior.

Figure 6 shows that the tracking error is quite small and anyway largely reduced with respect to non adaptive control.

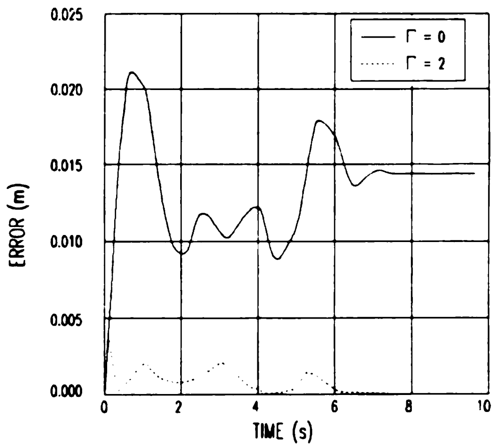

Fig 6. Tracking error with and without adaptivity.

The effect of Γ weight on the tracking is shown in Fig 7, according to which errors decrease for higher, even if bounded, Γ values.

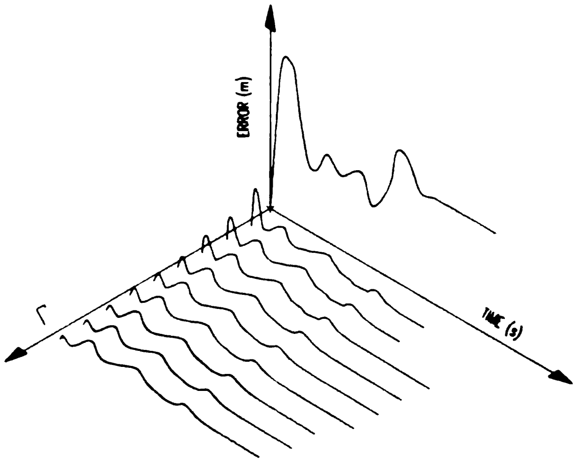

Fig 7. Tracking error for different adaptive weights.

Parameters convergence to the actual values occurs only if they can be univocally identified, otherwise their identification, even if inaccurate, corresponds to the exact values of the significant parameters in the equations of motion.

For the Stanford manipulator, the identification of the mass only brings to the fine value, Fig 8, while the mass and first order moment identification leads to incorrect values, Fig 9-10, that nevertheless imply the right weight moment on the second joint.

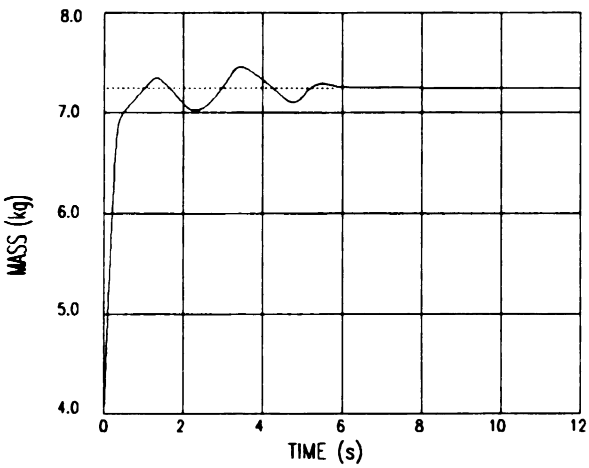

Fig 8. Mass identification.

In order to evaluate the performance of different control systems, a standard control based on the nominal characteristics of Stanford Manipulator has been implemented.

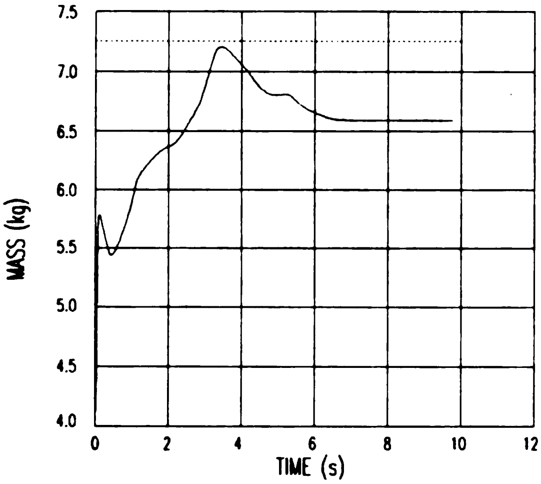

Fig 9. Mass identification.

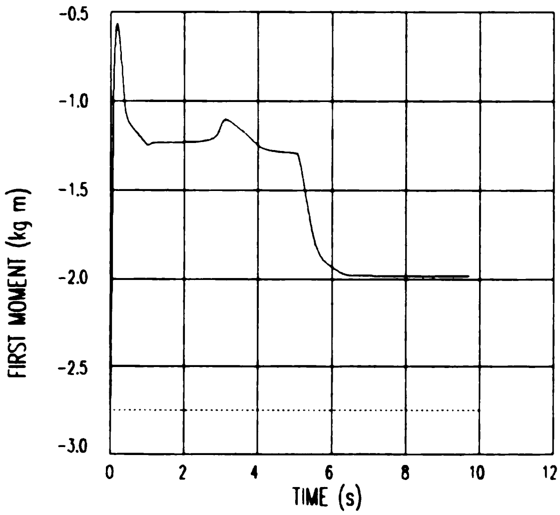

Fig 10. First moment identification.

Also in this case the errors are sufficiently small, Fig 11, and the tracking performance can be increased by feeding forward the system with the desired joint spin, Fig 12, reaching values comparable to those of the adaptive control.

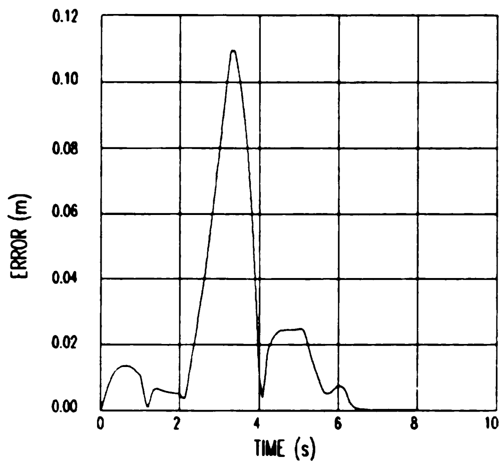

Fig 11. Tracking error with torque feed-forward.

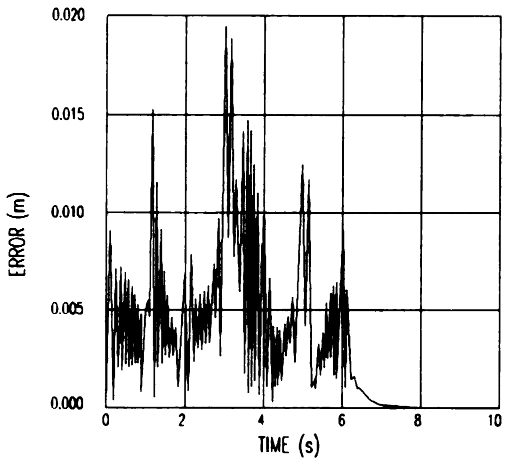

Fig 12. Tracking error with torque and velocity feed-forward.

Robustness of the control system has been tested by modelling external disturbances and actuator dynamics. In the first case viscous and Coulomb friction forces have been introduced. In this case, for the same pick and place maneuver, the adaptive controls presents errors similar to the previous ones, even if the final position is reached with major difficulty, Fig 13, due to the fact that the integration block is substituted by the adaptive block.

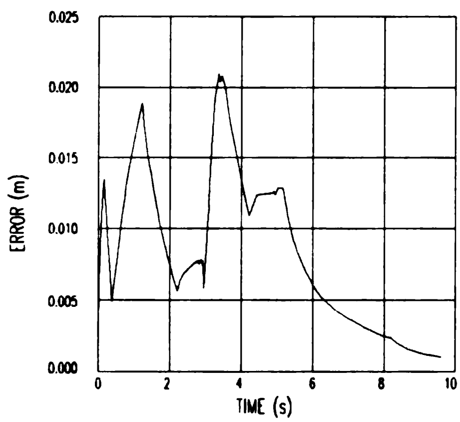

Fig 13. Adaptive control with friction: tracking error.

On the contrary standard control errors are not affected by the modelled disturb, Fig 14, on the basis of the design structure.

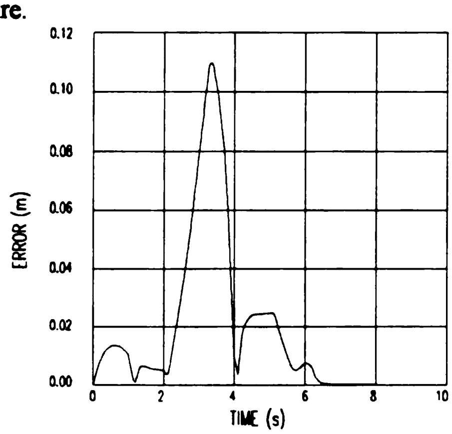

Fig 14. Standard control with friction: tracking error.

A similar behavior is noticed in the second case, when a limit torque is imposed on the DC actuator. The adaptive control becomes unstable and the end effector doesn't succeed in performing the maneuver, due to the fact that the Lyapunov function adopted is insensible to actuator dynamics.

Standard control errors instead increase, Fig 15, but only when a torque larger than the allowed is requested, otherwise the system shows a sufficiently high precision.

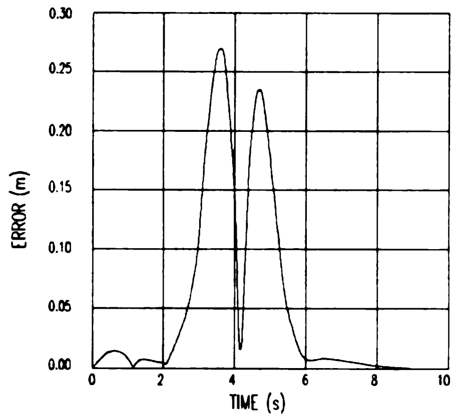

Fig 15. Standard control with torque saturation: tracking error.

CONCLUSION

The paper has shown that Maggi's method, particularly if coupled with symbolic manipulation, is suitable for the dynamic modelling of multibody systems.

Control systems, can obtain very good performances, even in case of badly known physical characteristics, if adaptive blocks are adopted.

In any case standard control systems, when accurately designed, can give excellent performances and in case of some unmodelled disturbances, e.g. saturation of the actuators, can behave even better than the adaptive ones.

The suggestion is here given that the adoption of a mixed control system, with two parallel stages, an adaptive and a standard PID, could lead to better overall results for widely varying operative conditions.

In this paper, some experimental results of modal tests performed on a large three-link flexible system are reported. These modal tests were conducted at the NASA's LSS GTF (Large Space Structures Ground Test Facility) located at MSFC (Marshall Space Flight Center). The experimental results were obtained for various configurations and compared with those obtained using the Component Mode Synthesis technique. The mode functions were selected to keep the computation as simple as possible without compromising the accuracy. The results obtained from the dynamic software simulation package called TREETOPS have also been included for completeness. It is found that the experimental results are in excellent agreement with those obtained by the use of component mode techniques for the aforementioned structures. The average percent change in the frequencies is observed to be 6.09%, while the average mode shape correspondence is noted as 94.5%.

INTRODUCTION

In recent years, the aerospace industry has been involved in the extensive use of multibodied structures. This is evidenced by many examples, such as, the space station, the space shuttle, space robots, and the list goes on. With the incorporation of composite materials, the ability to achieve a high payload to weight ratio has been facilitated. Also, scientists and engineers have been asking large lightweight robotic manipulators to perform precise, high speed maneuvers. In consequence, these lightweight structures exhibit high flexibilities, and due to the stringent requirements demanded of them, the study of their vibration characteristics has become of paramount importance.

The complexity of the LSS (Large space structures) is such that it has become increasingly difficult to accurately model their dynamic behavior. Therefore, high speed computers have been heavily relied upon for simulation and analysis. The modeling techniques utilized in the software packages are predominantly based on the finite element method. As the size of the system increases, the model becomes too complicated and simulation time is undesirably high. Therefore, the component mode techniques are being turned to as an alternate approach in simplifying the system model.

As industry is turning to the component mode techniques, the need to verify this procedure is becoming increasingly important. Despite the generous amounts of analytical research being conducted, there is a lack of experimental data available for verification. Therefore, NASA's MSFC has embarked on creating a national testbed for such structures. This testbed will be used to explore new issues associated with large flexible structures and also provide research data for which one use is the experimental verification of component mode techniques.

The component mode technique is based on simplifying the system model by reducing the system into separate components or substructures. This reduces the system of partial differential equations of motion, which sometimes can not be solved, down to a group of component equations that have known solutions. The knowledge of the component behavior, along with how they are constrained by the system configuration, can then be used to assemble a feasible mathematical model for the entire system. This is significant when one considers that many times the major components of large systems are being built by separate contractors and analysis of the entire assembled system is often times not feasible. Therefore, the component mode techniques allow for much of the analysis to be done on the component level.

Many methods have been developed on the basis of the component mode approach. Hurty, who is considered the pioneer in this field, developed the Component Mode Synthesis technique (Hurty, 1960; Thomson, 1988). The Craig-Bampton method differs only slightly from Hurty's and the two give the same numerical results (Craig, Jr and Bampton, 1968). Gladwell also developed a variant of Hurty's method which has come to be called the Branch Mode Analysis (Gladwell, 1964). Furthermore, Benfield and Hruda developed the Component Mode Substitution technique (Benfield and Hruda, 1971). Dowell has also developed a technique where he incorporates the use of Lagrange multipliers, in a systematic approach, to permit for various system constraints (Dowell, 1972, 1979, 1980a and b, 1983, 1984; Dowell and Klein, 1974). In general, these methods tend to differ only in the selection of the various component modes. In this paper Hurty's Method is utilized. For complete reference of this method see (Hurty, 1960; Thomson, 1988; Meirovitch, 1980; Meirovitch and Hale, 1980).

THEORETICAL ANALYSIS USING COMPONENT MODE SYNTHESIS

The various component mode techniques tend to differ, in general, only in the selection of the component mode functions, all of which can be determined by solving some type of component eigenvalue problem. For further reference one may look into Benfield and Hruda (1971), Rubin (1975), and Craig and Bampton (1968). In this investigation, we will be considering a slightly new approach. The component mode techniques, as stated earlier, were introduced to simplify the computation problems associated with other methods, and still produce a reliable approximation. With this premise in mind, we suggest the use of simple polynomials as alternative mode functions. Hurty has previously suggested this (Hurty, 1960), along with Meirovitch and Hale (1980).

The first criterion placed on these polynomials, is that they qualify as admissible functions. In general, the admissible functions must be selected such that displacements and forces exist at the internal boundaries of the system. The other criteria are that the admissible functions selected form a complete set, and they should be linearly independent. A reasonable check to see if the frequencies converge will provide assurance that a given set of mode functions forms a complete set. In considering the problem associated with early truncation of the mode function set, Macneal (1971) and Rubin (1975) proposed a technique to include the effect of residual modes not retained (Meirovitch, 1980; Meirovitch and Hale, 1980).

We will now consider a three link flexible system as shown in Fig 1, and examine the undamped, free vibration problem. We will denote Fig 1 as Configuration 1.

The equation of motion for an arbitrary substructure, is given as

$$[M_s]\{\ddot{\zeta}_s(t)\} + [K_s]\{\zeta_s(t)\} = \{0\} \tag{1}$$

where $[M_s]$ and $[K_s]$ are the substructure mass and stiffness matrices respectively, $\{\zeta_s(t)\}$ is the time dependent generalized coordinate, and the ¨ represents the second derivative with respect to time, [... 'es a matrix and { } represents a column vector). ... 'ict our analysis

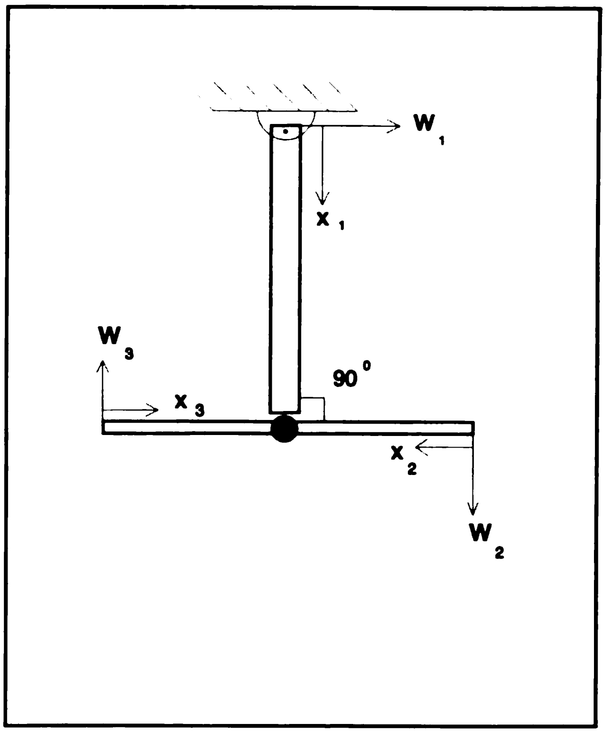

Figure 1. Configuration 1

to motions of small amplitude so that the free vibrations in longitudinal, transverse, and twisting motion are decoupled. Also, we shall assume infinite axial rigidity of all three members, which is later supported by experimentation. That is, the system considered in Fig 1 has two adjustable joints (top revolute joint at $x_1 = 0$ and bottom revolute joint between link 1 and the composite body formed by links 2 and 3). It should be noted that links 2 and 3 are rigidly clamped together at $x_2 = L_2$, $x_3 = L_3$. The other joints are locked in various configurations; hence a quasi-dynamic analysis is presented here. In addition, we are only concerned with vibration in the plane of the paper as shown by Fig 1.

Next, we will choose the transverse displacement vector for component 1 to be

$$w_1(x_1,t) = \left[\frac{x_1}{L_1}\right]^2 \zeta_1 + \left[\frac{x_1}{L_1}\right]^3 \zeta_2 + \dots + \left[\frac{x_1}{L_1}\right]^n \zeta_{n-1} \tag{2}$$

where ζ is taken to be a function of time although not explicitly shown, and n is equal to the highest power of the last spatial function. The displacement vector chosen for component 1 satisfies all geometric and force conditions at the external and internal boundaries of component 1, whereby the interface of the components is designated the internal boundary. These conditions are

$$\begin{aligned} &w_1(0) = 0,\ w_1'(0) = 0, \\ &w_1''(0) \neq 0,\ w_1'''(0) \neq 0, \\ &w_1(L_1) \neq 0,\ w_1'(L_1) \neq 0, \\ &w_1''(L_1) \neq 0,\ w_1'''(L_1) \neq 0 \end{aligned} \tag{3}$$

where the $'$ represents the derivative with respect to the spatial coordinate. Note that shear forces and moments are allowed at the interface.

We choose the displacement vectors for component 2

$$\begin{aligned} w_2(x_2,t) = 1(x_2)\zeta_n + \left[\frac{x_2}{L_2}\right]\zeta_{n+1} + \\ \left[\frac{x_2}{L_2}\right]^4 \zeta_{n+2} + \dots + \left[\frac{x_2}{L_2}\right]^m \zeta_{m+1} \end{aligned} \tag{4}$$

$$u_2(x_2,t) = 1(x_2)\zeta_{m+2} \tag{5}$$

where $u_2(x_2,t)$ is the axial displacement of component 2, and m is the highest power of the last spatial function. Here again, these displacement vectors were chosen so that they satisfy all geometric and force conditions at the boundaries of component 2. These conditions are as follows:

$$\begin{aligned} &w_2(0) \neq 0,\ w_2'(0) \neq 0, \\ &w_2''(0) = 0,\ w_2'''(0) = 0, \\ &w_2(L_2) \neq 0,\ w_2'(L_2) \neq 0, \\ &w_2''(L_2) \neq 0,\ w_2'''(L_2) \neq 0\ . \end{aligned} \tag{6}$$

In Eqs (2), (4), and (5), rigid body translation and rigid body rotation modes are represented by $1(x)$ and (x/L) respectively, whereas the remaining functions represent deformation modes. And similarly for component 3,

$$\begin{aligned} w_3(x_3,t) = 1(x_3)\zeta_{m+3} + \left[\frac{x_3}{L_3}\right]\zeta_{m+4} \\ + \left[\frac{x_3}{L_3}\right]^4 \zeta_{m+5} + \dots + \left[\frac{x_3}{L_3}\right]^m \zeta_{2m+1} \end{aligned} \tag{7}$$

$$u_3(x_3,t) = 1(x_3)\zeta_{2m+2} \tag{8}$$

where these displacement vectors satisfy similar boundary conditions as in Eq (6).

Now we compute the generalized mass matrix for each component which is derived as follows. Consider the displacement vector for a given beam

$$w_s(x_s,t) = \sum_{i=1}^{N} \phi_i(x_s)\zeta_i(t) \tag{9}$$

where ϕ is the spatial function and N is the desired number of mode functions. The velocity is

$$v_s(x_s) = \sum_{i=1}^{N} \phi_i(x_s)\dot{\zeta}_i(t) \tag{10}$$

and therefore the kinetic energy becomes

$$T_s = \frac{1}{2} \sum_{i=1}^{N}\sum_{j=1}^{N} \dot{\zeta}_i\dot{\zeta}_j \int \phi_i(x_s)\phi_j(x_s)dm \tag{11}$$

or

$$T_s = \frac{1}{2} \sum_{i=1}^{N}\sum_{j=1}^{N} m_{ij}\dot{\zeta}_i\dot{\zeta}_j \tag{12}$$

where the generalized mass is defined to be

$$m_{ij} = \int \phi_i(x_s)\phi_j(x_s)dm \tag{13}$$

and the integration is carried out over the entire system. Therefore applying Eq (13) to component 1 we obtain

$$m_{ij} = \int_0^{L_1} \rho_1(x_1)\phi_i(x_1)\phi_j(x_1)dx_1 \tag{14}$$

where ρ_1 is the mass density per unit length of component 1. For example, when n=3 in Eq (2), we obtain

$$m_{11} = \int_0^{L_1} \rho_1\phi_1\phi_1 dx_1$$

$$= \int_0^{L_1} \rho_1 \left[\frac{x_1}{L_1}\right]^4 dx_1 = \left[\frac{1}{5}\right]\rho_1 L_1 \tag{15}$$

$$m_{12} = m_{21} = \int_0^{L_1} \rho_1\phi_1\phi_2 dx_1$$

$$= \int_0^{L_1} \rho_1 \left[\frac{x_1}{L_1}\right] dx_1 = \left[\frac{1}{6}\right]\rho_1 L_1 \tag{16}$$

$$m_{22} = \int_0^{L_1} \rho_1\phi_2\phi_2 dx_1$$

$$= \int_0^{L_1} \rho_1 \left[\frac{x_1}{L_1}\right]^6 dx_1 = \left[\frac{1}{7}\right]\rho_1 L_1 \tag{17}$$

substituting in the appropriate values (Table 1)

$$[M_1] = \rho_1 L_1 \begin{bmatrix} \frac{1}{5} & \frac{1}{6} \\ \frac{1}{6} & \frac{1}{7} \end{bmatrix} . \tag{18}$$

TABLE 1. BASIC DATA *

In like manner, the generalized mass matrices for component 2 and 3 are computed for m=6. Noting that there is no coupling between the lateral and longitudinal displacements we obtain,

$$[M_2] = \rho_2 L_2 \begin{bmatrix} 1 & \frac{1}{2} & \frac{1}{5} & \frac{1}{6} & \frac{1}{7} & 0 \\ \frac{1}{2} & \frac{1}{3} & \frac{1}{6} & \frac{1}{7} & \frac{1}{8} & 0 \\ \frac{1}{5} & \frac{1}{6} & \frac{1}{9} & \frac{1}{10} & \frac{1}{11} & 0 \\ \frac{1}{6} & \frac{1}{7} & \frac{1}{10} & \frac{1}{11} & \frac{1}{12} & 0 \\ \frac{1}{7} & \frac{1}{8} & \frac{1}{11} & \frac{1}{12} & \frac{1}{13} & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \end{bmatrix} . \tag{19}$$

Changing subscripts 2 to 3, one obtains the definition for $[M_3]$. We arrange matrices, $[M_1]$, $[M_2]$, and $[M_3]$, into the system block diagonal matrix as

$$[M^d] = \begin{bmatrix} [M_1] & & \\ & [M_2] & \\ & & [M_3] \end{bmatrix} . \tag{20}$$

We form the generalized stiffness matrix by expressing the flexural potential energy for a- 'er-Bernoulli beam in bending.

$$U_s = \frac{1}{2} \int E_s I_s \left[\frac{dw_s}{dx_s} \right]^2 dx_s \, . \tag{21}$$

Substituting for w_s, as in Eq (9), we get

$$U_s = \frac{1}{2} \sum_i \sum_j \zeta_i \zeta_j \int E_s I_s \phi_i'' \phi_j'' \, dx_s \tag{22}$$

$$= \frac{1}{2} \sum_i \sum_j k_{ij} \zeta_i \zeta_j \tag{23}$$

where the generalized stiffness is defined to be

$$k_{ij} = \int_0^{L_s} E_s I_s \phi_i'' \phi_j'' \, dx_s \, . \tag{24}$$

Therefore, applying this Eq to component 1

$$k_{11} = E_1 I_1 \int_0^{L_1} \phi_1'' \phi_1'' \, dx_1$$

$$= E_1 I_1 \int_0^{L_1} \left[\frac{2}{L_1^2} \right] dx_1 = 4 \frac{E_1 I_1}{L_1^3} \tag{25}$$

$$k_{12} = k_{21} = E_1 I_1 \int_0^{L_1} \left[\frac{2}{L_1^2} \right] \times \left[\frac{6x_1}{L_1^3} \right] dx_1 = 6 \frac{E_1 I_1}{L_1^3} \tag{26}$$

$$k_{22} = 12 \frac{E_1 I_1}{L_1^3} \tag{27}$$

which results in

$$[K_1] = \frac{E_1 I_1}{L_1^3} \begin{bmatrix} 4 & 6 \\ 6 & 12 \end{bmatrix} . \tag{28}$$

Similarly, for component 2 we arrive at

$$[K_2] = \frac{E_2 I_2}{L_2^3} \begin{bmatrix} 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 28.8 & 40 & 51.43 & 0 \\ 0 & 0 & 40 & 57.143 & 75 & 0 \\ 0 & 0 & 51.43 & 75 & 100 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix} . \tag{29}$$

Again, changing subscripts 2 to 3, $[K_3]$ is similarly defined for component 3. Furthermore, assembling these matrices into the block diagonal stiffness matrix we obtain Eq (30).

Since we have formed the mass and stiffness matrix for the decoupled system, the equations must be coupled by a simple coordinate transformation. The transformation matrix

$$[K^d] = \begin{bmatrix} [K_1] & & \\ & [K_2] & \\ & & [K_3] \end{bmatrix} . \tag{30}$$

[β] is a transformation from the dependent generalized coordinate $\{\zeta(t)\}$, into a set of independent generalized coordinates $\{q(t)\}$

$$\{\zeta(t)\} = [\beta]\{q(t)\} . \tag{31}$$

This matrix, [β], is formed directly from the equations of constraint for the system, which arise due to the force and displacement compatibility requirements at the component interfaces. These constraint equations may be written in local generalized coordinates $\{\zeta(t)\}$. Upon forming all the constraint equations for each interface, we obtain a set of linear constraint equations which can be written as

$$[A]\{\zeta(t)\} = \{0\} \tag{32}$$

where $[A]$ is a (c x M) matrix of constant coefficients. Note that c is the total number of constraint equations, and M is the dimension of $\{\zeta(t)\}$. Next, the matrix may be partitioned as such

$$[A] = [A_1 \vdots A_2] \tag{33}$$

where $[A_1]$ is a square matrix of order (c x c). Furthermore, Eq (33) may now be written in the following form

$$[A_1]\{\zeta(t)\}_d + [A_2]\{q(t)\} = \{0\} \tag{34}$$

where $\{q(t)\}$ is a subset of $\{\zeta(t)\}$ which is chosen to include the independent variables, and $\{\zeta(t)\}_d$ is chosen to include the dependent variables. This is achieved by choosing $[A_1]$ to be nonsingular. Next, Eq (34) can be rewritten into the following form

$$\{\zeta(t)\}_d = -[A_1]^{-1}[A_2]\{q(t)\} . \tag{35}$$

Finally, the complete vector $\{\zeta(t)\}$ can be expressed in terms of the independent subset $\{q(t)\}$, by supplying the identity matrix where needed,

$$\{\zeta(t)\} = \begin{bmatrix} [I] \\ \hline -[A_1]^{-1}[A_2] \end{bmatrix} \{q(t)\} . \tag{36}$$

Therefore,

$$[\beta] = \begin{bmatrix} [I] \\ \hline -[A_1]^{-1}[A_2] \end{bmatrix} \tag{37}$$

which forms the coordinate transformation matrix [β] (Hurty, 1965).

Consider the case where the three link structure is in the configuration shown in Fig 1. In general, the displacement equations at the junction are

$$\begin{aligned} w_1(L_1) + u_2(L_2) &= 0 \\ w_1(L_1) - u_3(L_3) &= 0 \end{aligned} \tag{38}$$

$$\begin{aligned} w_2(L_2) &= 0 \\ w_3(L_3) &= 0 \end{aligned} \tag{39}$$

$$\begin{aligned} w_1'(L_1) - w_2'(L_2) &= 0 \\ w_1'(L_1) - w_3'(L_3) &= 0 . \end{aligned} \tag{40}$$

Equations (39) arise due to the assumption of infinite axial rigidity. Equations (40) enforce that the component rotations due to bending at the junction are equal. However, the links are modeled as Euler-Bernoulli beams and therefore, in the absence of shear deflection this rotation angle reduces to the slope. The force equilibrium equation is

$$M_1(L_1) + M_2(L_2) + M_3(L_3) = 0 \tag{41}$$

where M's are the moments. This equation is further simplified to

$$E_1I_1w_1''(L_1) + E_2I_2w_2''(L_2) + E_3I_3w_3''(L_3) = 0 . \tag{42}$$

In general, there would also be equations that would enforce the shear and axial force at the junction, but again for our assumptions these are neglected. These equations are now evaluated and expressed in terms of $\{\zeta(t)\}$ as in Eq (32), where $[A]$ is equal to the following constant matrix.

$$\begin{bmatrix} 0 & 0 & 1 & 1 & 1 & 1 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 1 & 1 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ \frac{2}{L_1} & \frac{3}{L_1} & 0 & \frac{-1}{L_2} & \frac{-4}{L_2} & \frac{-5}{L_2} & \frac{-6}{L_2} & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ \left(\frac{2I_1}{I_2L_1^2}\right) & \left(\frac{6I_1}{I_2L_1^2}\right) & 0 & 0 & \frac{12}{L_2^2} & \frac{20}{L_2^2} & \frac{30}{L_2^2} & 0 & 0 & 0 & \frac{12}{L_3^2} & \frac{20}{L_3^2} & \frac{30}{L_3^2} & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 1 & 1 & 1 & 1 & 0 \\ 1 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & -1 \\ \frac{2}{L_1} & \frac{3}{L_1} & 0 & 0 & 0 & 0 & 0 & 0 & 0 & \frac{-1}{L_3} & \frac{-4}{L_3} & \frac{-5}{L_3} & \frac{-6}{L_3} & 0 \end{bmatrix} \tag{43}$$

Because there are 14 generalized coordinates and 7 constraints this means that there are 14-7=7 redundant coordinates. The $[A]$ matrix is now partitioned as indicated Eq (33). Let

$$\begin{aligned} &\zeta_1 = q_1, \ \zeta_{12} = q_{12}, \ \zeta_2 = q_2, \ \zeta_{13} = q_{13}, \\ &\quad \zeta_3 = q_3, \ \zeta_{14} = q_{14}, \ \zeta_4 = q_4 \end{aligned} \tag{44}$$

where these are chosen to ensure that $[A_1]$ is nonsingular. Therefore, $[A_1]$ is formed by taking the first four and last three columns of $[A]$, and $[A_2]$ is formed by taking columns five through eleven of $[A]$. The transformation matrix [β] can now be formed from Eq (37), and is shown in the APPENDIX.

$$[M] = [\beta]^T [M^d] [\beta] \quad and \quad [K] = [\beta]^T [K^d] [\beta] \tag{45}$$

Finally, the system matrices are formed by the transformation defined below and are listed in the APPENDIX. Once the system matrices have been constructed, the natural frequencies can be obtained from the resulting eigenvalue problem, where the first four natural frequencies are

$$\omega_{n1} = 2.5390\ Hz \quad , \quad \omega_{n2} = 3.3339\ Hz$$
$$\omega_{n3} = 3.9432\ Hz \quad , \quad \omega_{n4} = 19.6606\ Hz \qquad (46)$$

To examine the possibility of premature truncation of the mode functions in the component displacement vectors, we will consider adding more terms in Eqs (2), (4) and (7) to test for convergence of the natural frequencies. Table 2 summarizes the results. At this stage, the mode shapes can be determined as described in the following. The eigenvalue problem can be solved for the independent coordinate vector $\{q(t)\}$ with respect to an arbitrary reference. Subsequently, $\{q(t)\}$ can be transformed into the dependent coordinate vector $\{\zeta(t)\}$, which can be used to find the respective component displacement vectors defined by Eqs (2), (4), (5), (7), and (8). Therefore, these component modes can be assembled to obtain the system natural modes.

TABLE 2. CONVERGENCE OF FREQUENCIES FOR CONFIGURATION 1

Frequency (Hertz) n=3 m=6	Frequency (Hertz) n=4 m=7	Frequency (Hertz) n=5 m=8	Frequency (Hertz) n=6 m=9	Frequency (Hertz) n=7 m=10
ω_{n1}=2.5390	2.5385	2.5385	2.5385	2.5385
ω_{n2}=3.3339	3.3338	3.3338	3.3338	3.3338
ω_{n3}=3.9432	3.9399	3.9398	3.9398	3.9398
ω_{n4}=19.6606	19.5271	19.5220	19.5340	19.5246

In a similar manner, the structure is analyzed in two more configurations shown in Figs 6 and 11. The convergence of the natural frequencies was found to be similar to configuration 1 and the mode shapes are shown in Figs 2-5, 7-10 and 12-15.

EXPERIMENTAL PROCEDURE

As was stated earlier, the experimental procedure was conducted at NASA Marshall Space Flight Center and signified the advent for the Multibody Modeling Verification and Control (MMVC) project.

The test article was designed to simulate a large flexible multibody system. One of the design criteria was that the structure should exhibit dense mode concentration at low frequencies. The closely packed modes were desirable because this typifies the dynamic behavior of multibodied, flexible structures in space environments. It was also designed so that the maximum deflections would fall within the linear deflection range and that the vibration was restricted to be in the plane shown by Fig 1.

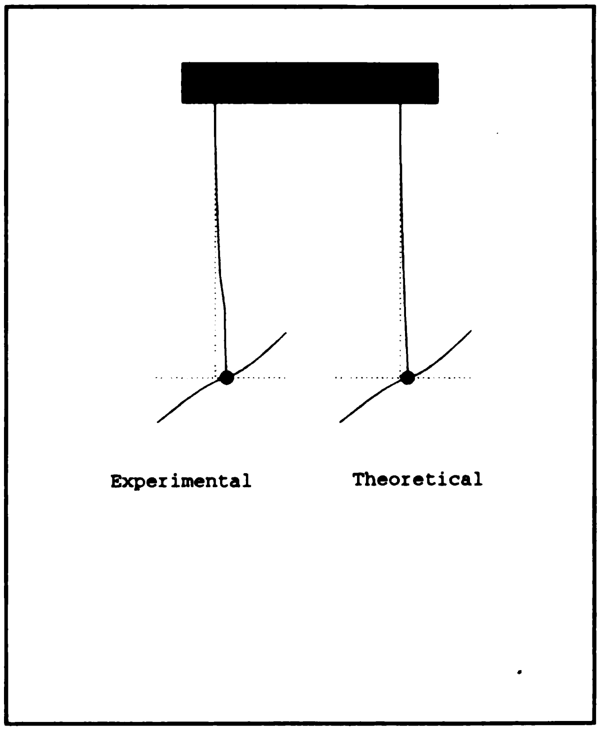

Figure 2. System Modes 1 for Configuration 1

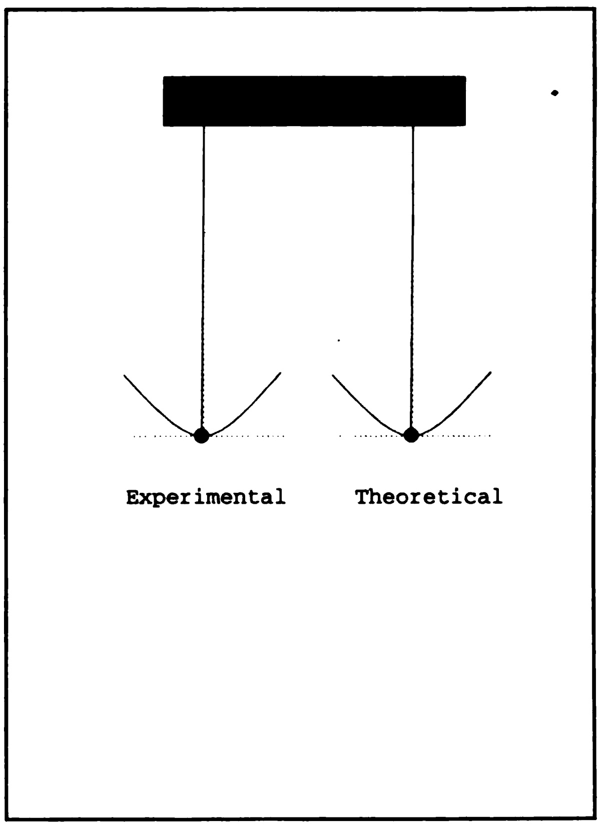

Figure 3. System Modes 2 for Configuration 1

The resulting dimensions for each component can be found in, Table 1. Essentially, the design process yielded a linear, time invariant, observable system, so that the modal analysis technique could be applied for the study.

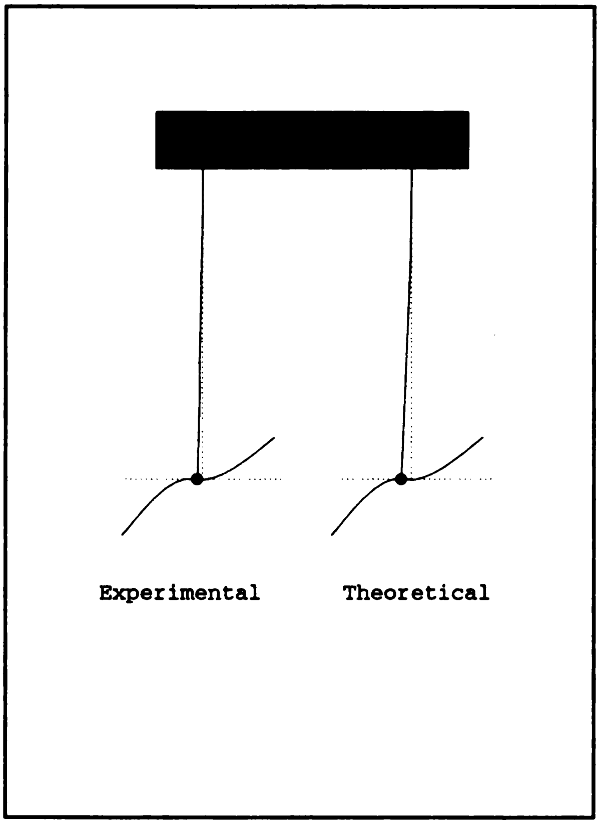

Figure 4. System Modes 3 for Configuration 1

After the system was assembled, the external boundary conditions were examined. The external joint that supported the structure was designed to facilitate the interchanging of the system components. Therefore, this fixed boundary condition was validated by testing the dynamic response of an isolated cantilever beam, which indeed closely resembled an actual cantilever beam response. Therefore, this joint closely approximated a fixed boundary. Also, each component was tested to show that the axial vibration for each respective component was negligible, and thus, the assumption of infinite axial rigidity was justified.

Each component was discretized into nine measurement response and force input points. These points were chosen to accurately excite and observe all modes of interest within the desired frequency range. The excitation was achieved by the direct impact hammer technique. This technique utilized the use of a load cell at the tip of the hammer to measure the force input. The tip of the hammer was selected to exhibit good frequency content throughout the frequency range of interest.

The piezoelectric accelerometer, or the response transducer, was located at the end of component 3. It was

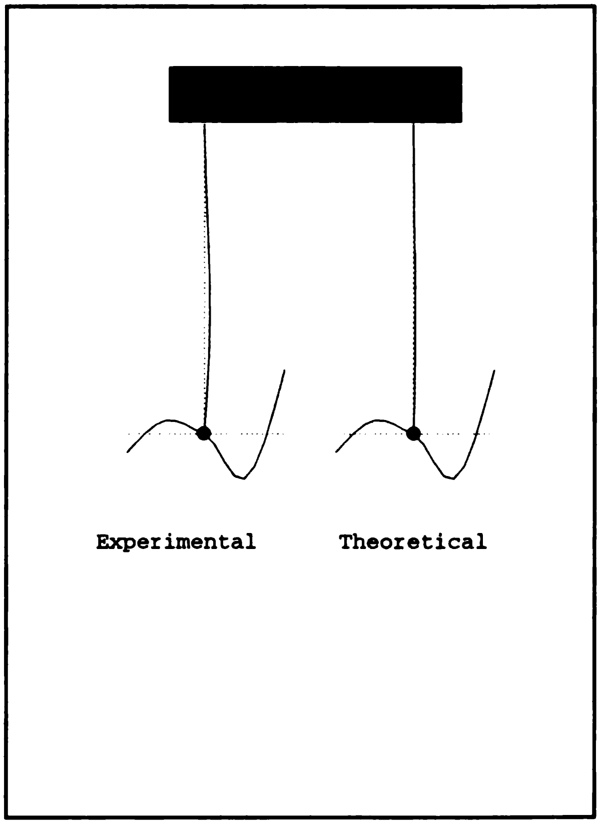

Figure 5. System Modes 4 for Configuration 1

mounted on the structure with a type of strong adhesive, and therefore, accurately described the response of the system. The structure was impacted by the hammer at all the points on each component, while frequency response data was collected. The accelerometer did not mass load the system, as was evidenced by doubling the weight of the accelerometer and noticing that there were no shifts in the frequency response function.

The system was tested in nine different configurations. It was speculated that gravity might have an effect on highly flexible, possibly nonlinear, structures. It was discovered that gravity had negligible effect on the frequencies and mode shapes of this system, and therefore, the original nine configurations reduced to three unique configurations. These configurations are depicted in Figs 1, 6, and 11. The experimental natural frequencies of the structure for all three configurations are summarized in Table 3. The experimental system mode shapes corresponding to these configurations are shown in Figs 2-5, 7-10 and 12-15.

A comparison of analytical and experimental values of frequencies are summarized in Table 4. In addition to the results from Secs 2 and 3, the results as computed by TREETOPS are also presented. As stated before, TREETOPS is a dynamic simulation software package that is based on component mode technique. The TREETOPS

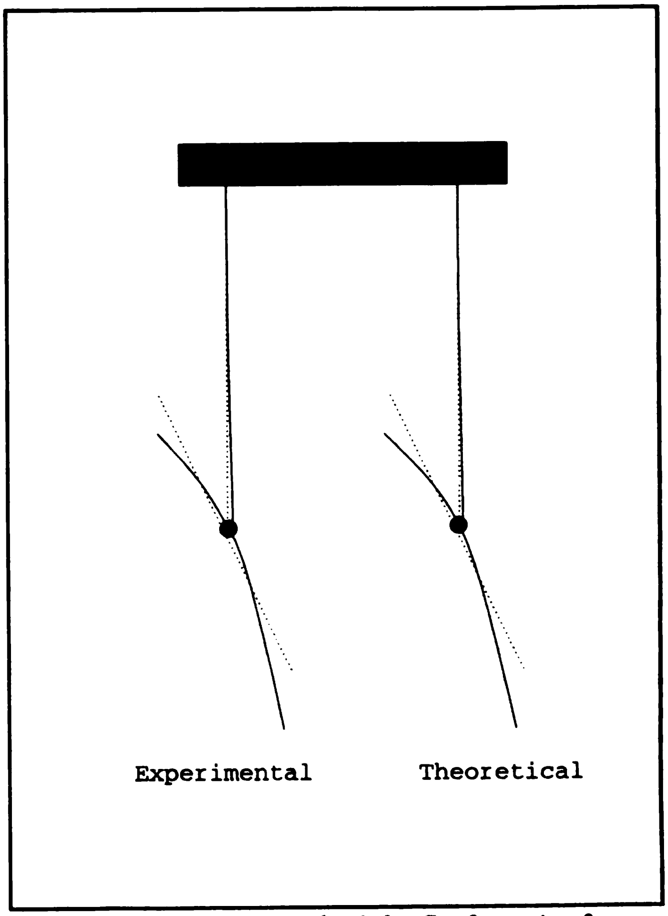

Figure 9. System Modes 3 for Configuration 2

results are based on the first five contilever beam modes selected as component modes. This flexible data was generated by another software package called TREEBEAMS.

An excellent agreement between the TREETOPS results and the experimental values was found. The detailed comparison is not included for brevity.

CORRELATION OF THEORETICAL AND EXPERIMENTAL RESULTS

The theoretical and experimental mode shapes are compared by the Modal Assurance Criterion (MAC). This condition number ranges from 0 to 1 where a 1 signifies perfect correspondence of the two modes. The MAC is defined as

$$0 \leq \frac{(v^T u)^2}{(v^T v)(u^T u)} \leq 1 \tag{47}$$

where v and u are the theoretical and experimental mode shapes, respectively. Table 5 summarizes the information for configurations.

TABLE 5. MAC FOR VARIOUS CONFIGURATIONS

Mode	Configuration 1	Configuration 2	Configuration 3
1	0.982	0.909	0.992
2	0.981	0.834	0.994

4	0.929	0.954	0.957

DISCUSSION AND CONCLUSIONS

For the first time, an experiment has been conducted to determine the natural frequencies and mode shapes of a large flexible three-link system and the results are compared with those obtained from a component mode synthesis technique. The theoretical results in this study show that the use of integral powers of (x/L) is an adequate approximation of the modes of vibration for Euler-Bernoulli beams in a chain-like structure. These polynomials proved to be suitable admissible functions for the system, as it is analyzed in three different configurations. The experimental evidence not only verified the use of these simple mode functions, but also validated the dynamic software simulation package, TREETOPS, which is based on the component mode technique. The influence of gravity turned out to be negligible because the cross sections of the links were relatively large. It was concluded that the gravitational forces could alter the frequencies and mode shapes only if the links are very flexible.

The results show that the average frequency difference between the experimental and the theoretical results was 6.09%. Yet this number can be misleading considering that seventy-five percent of the frequency results had an average percent difference of 2.22%. Also, the experimental and theoretical mode shapes, on the average, had 94.5% correspondence.

Although in this study the use of simple polynomials has produced good results, it is almost certain that this would not be the case for more complex systems. It would be an excellent idea to develop a library of suitable admissible functions for future use.

A major concern is how to accurately control large, flexible, multibody structures to perform precise maneuvers. In the future, as in the spirit of this research, decentralized control, or control on the component level should be investigated. Also, the nonlinear behavior of such structures undergoing large displacements and exhibiting large deflections will need to be addressed. Here again, the experimental evidence will prove to be a necessity in the exploration of these areas.

Coupled motion in the dynamic analysis of a three block structure

A Sinopoli

Dipartimento di Scienza e Tecnica del Restauro, Istituto Universitario di Architettura, Tolentini 197, 30135 Venezia, Italy

V Sepe

Dipartimento di Ingegneria Strutturale e Geotecnica, Universita "La Sapienza" Via Eudossiana 18, 00185 Roma, Italy

A mathematical model is presented for the in-plane dynamic analysis of a structure composed of three rigid blocks, simply supported on each other, in presence of dry friction. In order to investigate the dynamics excited by a given ground motion, a Lagrangian formulation is proposed, with displacements, velocities and reactive forces restricted in bounded fields, due to the incompenetrability of the elements. Special attention is devoted to the modelling of the impacts, and to the role of Coulomb friction during the smooth dynamics. Different failure modes are obtained, characterized by a different participation factor of the degrees of freedom. Regions of coupling between rocking and sliding-displacements can be identified, as a function of the features of the excitation and of the friction coefficients. Survival domains decreasing with time can be obtained. They seem to indicate that, in presence of an earthquake, excessive relative displacements in the contact surfaces between the elements would be the most probable cause of failure of such a structure.

INTRODUCTION

The dynamic analisys of structures made of rigid blocks has been the object of many researches since the latter part of the last century. The reason of such an interest was connected in the past, to the possibility to estimate the peak acceleration of an earthquake by observing the overturning of monumental columns or tombstones; more recently, to the necessity to evaluate the seismic stability and safety of structures, ranging from nuclear plants, to elevated tanks, to monumental buildings, like the Roman and Greek temples. Particularly in Europe, the problem of mainteinance and safety of the monumental patrimony has generated a renewed interest, both theoretical and experimental, on this argument.

In spite of the fact that monumental structures are made of many blocks, very few papers tackled with the dynamic analysis of multiblock systems. Certainly, this is due to the complexity of the dynamic behaviour of such systems. In fact, many efforts have been devoted exclusively to identify a general stability criterion for the rocking response, induced by a horizontal harmonic excitation on a single block on a rigid ground (Housner 1963, Yim 1980, Spanos 1984, Hogan 1989, Sinopoli 1991). Therefore, not enough attention has been devoted to the mechanical modelling of multiblock structures.

The dynamic behaviour of a structure made of three rigid blocks, simply supported on each other (i. e. a trilith: the simplest scheme of a columnade belonging to a temple) and excited by a sine wave ground motion, has been investigated only by means of a single degree of freedom model (Allen, Oppenheim et al, 1986).

However, the main purpose of a consistent mechanical model is to identify the most relevant aspects of the response, with minimum a-priori restrictions and to recognize a "safe domain" for the given structure, i. e. a domain in the in the load space, within which the structure survives (tipically, in case of seismic excitations, the load

part of "MECHANICS PAN-AMERICA 1993" edited by MRM Crespo da Silva and CEN Mazzilli ASME Reprint No AMR134

space is the one of the parameters of the external action, and the parameters are an "intensity" and a significative "frequency")

This must be done by taking into account all the possible dynamical modes. In case of multiblock structures, the absence of connections between the elements and the consequent unilateral constraints can give rise to several possible mechanisms, so that relevant aspects of the motion can be rocking, relative rotations with consequent impacts, slidings with friction, loss of equilibrium due to excessive rotations or relative displacements; the slidings, if bounded, determine permanent changes of the geometry.

The importance of these aspects on the dynamical behaviour has been outlined since some years, so that studies have been started concerning the simulation of the impact, the role of dry friction, the coupling between the degrees of freedom, the experimental investigation and numerical simulation of the dynamics. Further, an extensive review has been presented on the mechanical models relevant in the study of the free and forced dynamics of structures made by large blocks without mortar (Augusti and Sinopoli 1992).

In spite of the active interest aroused on these themes and many studies in the last decade, some aspects still remain to be investigated, above all the interplay between dynamics and friction, particularly at the time of impact (Shenton and Jones 1991, Sinopoli 1993). Anyhow, the first results obtained by investigations on the impact between rigid bodies (Sinopoli 1989, Ageno and Sinopoli 1991) showed that the coupling between the degrees of freedom cannot be ignored after an impact, even in the case of a single block on a rigid ground.

Further, a previous work on the dynamic analysis of a trilith (Sepe and Sinopoli, 1991) showed that the assumption of a system with one degree of freedom, for standard values of the mechanical and geometrical features, is correct only in the first part of the motion, until the system either overturns or comes back to the static equilibrium configuration; in the second case, the occurring impacts can be responsible of relative slidings between the blocks, so that a general model must be defined, where all the possible degrees of freedom of the system are taken into account.

The structure dealt with in this paper is made of three blocks, rigid by assumption and simply supported by each other. The aim of the research is to verify if relative sliding displacements can induce a failure mode due to the loss of geometrical configuration (that is increasing distance between the contact points at the top of the columns) and to quantify its probability with respect to overturning; this feature of the motion has never been analyzed or taken into account in the scientific literature.

The dynamic model presented here does not take into account the sliding of the structure with respect to the plane support; this assumption reduces the complexity of the investigation.

Special attention is devoted to the modelling of the contact law. With respect to the impact, a theoretical preliminary approach proposed by one of the authors is used, formulated here as a quadratic programming problem; it neglects the role of dry friction during the impact.

THE PROBLEM

The assumptions

Let us consider the plane structure shown in Fig.1, made of three rigid blocks, simply supported with each other, in presence of dry friction. Further, assume also that the possibility of sliding displacements of the two columns with respect to the plane support is not taken into account in the evaluation of the degrees of freedom of the system; such an assumption, which reduces quantitatively the complexity of the problem, is acceptable from a pratical point of view because relative sliding motions at the top of the columns are more probable and therefore more important than the corresponding ones at the bottom, in the failure mode due to the loss of the geometrical configuration.

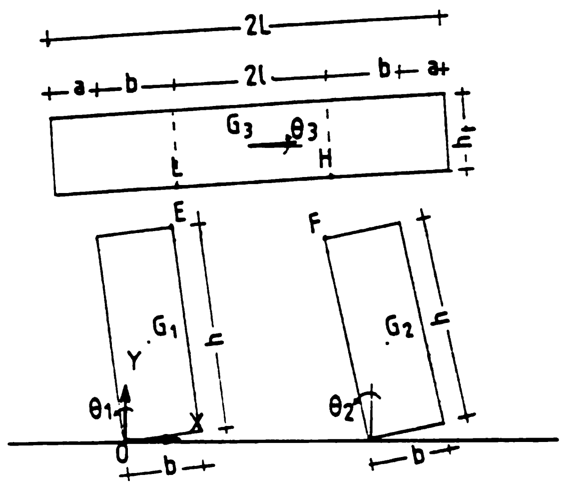

FIG 1. Geometrical features and degrees of freedom of the analyzed system.

The lagrangian coordinates q_k (with $k=1,2,..5$) describing the instantaneous configuration are: $q_1 = \theta_1$ and $q_2 = \theta_2$, that is the rotations of the left and right columns, and: $q_3 = x_3$, $q_4 = y_3$ and $q_5 = \theta_3$, respectively, the horizontal and vertical displacements, and the rotation of the architrave.

The absence of connections between the blocks and the rigidity assumption implies bounded variations for the lagrangian coordinates q_k; the boundaries of these domains depend on the instantaneous configuration and on its persistence with the time. For example, the boundaries for the rotations of the columns coincide always with the restraint of impenetrability with the ground; on the contrary, the bounded values for the coordinates of the architrave depend on the efficiency of the contacts with the columns.

During the motion, either free induced by given initial conditions or forced due to any excitation, many and different mechanisms are possible; they correspond to the many kinds of efficient contacts (see for example Fig. 2) and to the loss of any contact.

There are two kinds of loss of contact. The first one, due to excessive relative displacements along either tangent line to the blocks boundaries on the contact point, always induces the collapse of the structure, due to the gravitational field. The second one is the uplift of the lintel with respect to the columns; but, the possibility of a renewed possible contact must be checked with the time.

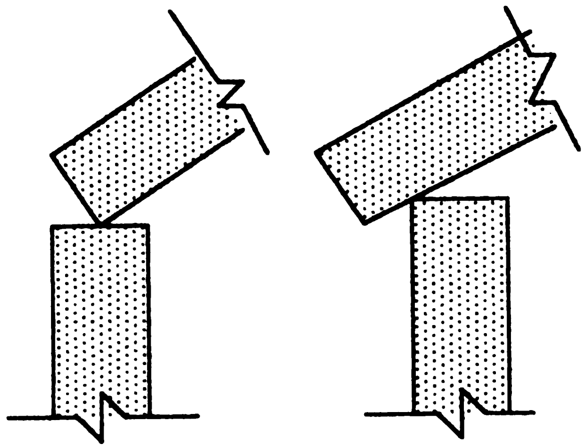

FIG 2. Different kinds of possible contacts.

During the motion the starting of each mechanism, which is governed by given differential equations, and the efficiency and the persistency of any contact depend on the geometrical and mechanical fetures of the system, and instantaneously on the values of the reactive forces in the contact points.

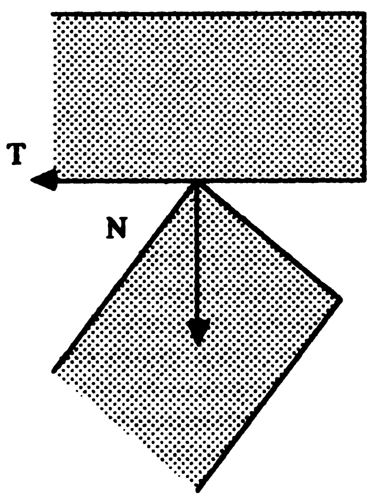

FIG 3. System of unit vectors on the contact point.

Therefore, the dynamic evolution requires a step by step control in order to check if the lagrangian coordinates, their derivatives and the contact reactions satisfy both the incompenetrability and the rigidity assumptions. That can be made by defining a contact law.

SMOOTH DYNAMICS

Let us consider any contact between the lintel and either column, involving only the point P_i belonging to both the boundaries of the blocks. Then, it is possible to define a normal system of unit vectors (T, N) such that T is parallel to the boundary of either element (Fig. 3). Let us define like u^{T}_{i}, u^{N}_{i} the tangen and normal relative position of the point P_i referred to the system (N, T) .

Normal contact law

The efficiency of the i-th contact is characterized by:

$$u^{N}_{i} = 0 \tag{1}$$

with:

$$u^{N}_{i} \geq 0 \tag{2}$$

The persistency of the same contact, on the contrary, depends on the value of the normal relative velocity $\dot{u}^{N}_{i}$; the contact is mantained if:

$$\dot{u}^{N}_{i} = 0 \tag{3a}$$

or lost, if:

$$\dot{u}^{N}_{i} > 0 \tag{3b}$$

with:

$$u^{N}_{i} \geq 0 \tag{4}$$

Then, it is expected that a reactive force:

$$F^{N}_{i} \geq 0 \tag{5}$$

acts in the contact point, in order that eq.(4) is satisfied. The loss of contact, that is eq. (3b), implies a zero value for the reactive force, the normal contact law can be expressed as:

$$\dot{u}^{N}_{i}\ F^{N}_{i} = 0 \tag{6}$$

with:

$$\left.\begin{aligned} \dot{u}^{N}_{i} &\geq 0 \\ F^{N}_{i} &\geq 0 \end{aligned}\right. \tag{6a}$$

for:

$$u^{N}_{i} = 0 \tag{6b}$$

And:

$$F^{N}_{i} = 0 \tag{7a}$$

for:

$$\dot{u}^{N}_{i} > 0 \tag{7b}$$

Equations (6) and (7) define the normal contact law like a linear complementarity problem (Jean and Moreau 1991).

Tangent contact law

In presence of dry friction, an interplay between dynamics and friction is expected, only when the contact is efficient.

Then, if eqs. (1) and (3a) are satisfied, the tangential Coulomb contact law assumes the form:

$$F^{T}_{i} \leq \mu_s \; |F^{N}_{i}| \tag{8a}$$

if and until:

$$\dot{u}^{T}_{i} = 0 \tag{8b}$$

whith μ_s static friction coefficient. On the contrary, if the tangential relative velocity is different from zero:

$$\dot{u}^{T}_{i} \neq 0 \tag{9a}$$

then:

$$F^{T}_{i} = -\,sgn(u^{T}_{i})\,\mu_k \,|F^{N}_{i}| \tag{9b}$$

where μ_k is the kinetic friction coefficient.

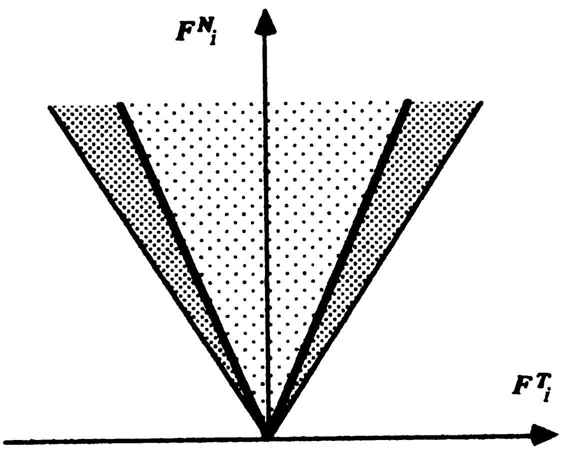

FIG 4. Coulomb cone.

Once more the reactive force disappears in correspondence to zero value of the normal relative velocity; then:

$$F^{T}_{i} = 0 \tag{10a}$$

for:

$$u^{N}_{i} > 0 \tag{10b}$$

NON - SMOOTH DYNAMICS

The impact

During the dynamic evolution, it may happen that one or more points P_i, starting from positions interior to the domain of the admissible values ($u^{N}_{i} > 0$), come suddendly in contact with the boundary of another element, but chracterized by negative values of the normal relative velocity $\dot{u}^{N}_{i}$. This situation violates the normal contact law expressed by eqs. (6); then, it is expected that at this instant an impulsive force acts on the contact, inducing a discontinuity on both the normal and tangential relative velocities.

The general analysis of the impact between rigid bodies, in presence of dry friction, when the area of the surfaces involved in the phenomenon is different from zero, is in our opinion a still open problem.

Different are the solutions proposed in the scientific literature (Housner 1963, Ishiyama 1982, Jean and Moreau 1991, Shenton and Jones 1991). A common feature of is the elimination of the apparent indetermination by means of some "a priori" assumptions.

For example, one of them concerns the "a priori" choice of the point candidate to mantain the contact after the shock; consequently, the Newton experimental law can be utilized with zero value for the restitution coefficient, typical of the inelastic shocks between rigid bodies.

One of the Authors (Sinopoli 1989) proposed, on the contrary, an approach where the inelastic impact, in absence of friction, is formulated as a problem of dynamical evolution governed by a variational principle, without reference to the restitution coefficient. The solutions is then determined the minimum value of a quadratic form R, subject to the constrains imposed to the system. After an impact, among all the admissible motions, the actual one is the closest (in the space the metric of which is the kinetic energy) to the one characterizing the system if it could become completely free.

In presence of friction, the most critical point is the evaluation of its role during the impact. Following a weak formulation, the friction performance must be expressed in terms of restraints on the velocities, which remain constant during the impact (persistent constraints); but, the character of a frictional contact is that it generally varies and depends on the instantaneous redistribution of the velocities (Augusti and Sinopoli 1992).

In this respect, two formulations have been proposed, where the friction has been either taken into account roughly (Sinopoli 1987) or neglected (Sinopoli 1989); the validity of either model depends mainly on the assumptions concerning the starting instant of the friction performance and, then, on the impact unelasticity, on the rigidity of the material and on the duration of the impact. The main point whose treatment is still unsatisfactory, is the coupling between rocking and sliding. This point is particularly relevant for actual structures, made of many blocks: slides, in fact, make loss of equilibrium possible, but at the same time dissipate energy; the prevalence of either aspect decides the safety of a structure. Another question regards the validity of the "Coulomb friction" hypothesis, or the values of static and kinetic friction coefficients: the first one can be particularly high when ancient costructions are concerned, in which the surfaces may have remained in standing contact for centuries.

For this reason, an experimental investigation has been performed (Ageno and Sinopoli 1991) on marble blocks of several sizes, impacting a marble ground. As a consequence a new theoretical model has been formulated recently (Sinopoli 1993b).

In this paper, the friction performance starts to act only after the impact; so that during the shock no restrictions must be imposed to the tangential velocities of points P_i.

If $\dot{q}^-$ is the velocity vector of the system before the impact, the velocity $\dot{q}^+$ after the shock is determined among all the admissible ones q as:

$$min \left\{ R = (\dot{q} - \dot{q}^-)^* M \ (\dot{q} - \dot{q}^-) \right\} \tag{11}$$

where $*$ means transposition and M is the mass matrix, subject to the constraint of inpenetrability:

$$\dot{u}^N{}_i \geq 0 \tag{12}$$

which must be satisfied by all the points P_i of the elements coming into contact.

DYNAMICS EQUATIONS

Let us consider the dynamics induced by a given horizontal ground motion: $x(t) = x_o \sin(\omega t + \phi)$ and represent the corresponding acceleration, in g units (where g is the garvity acceleration) as: $x(t) = K_s \, g \sin(\omega t + \phi)$.

The periodicity and then the stationarity character of such an excitation makes it very different from an earthquake. Nevertheless, it can be considered as a preliminary step toward the knowledge of the forced dynamics of the system.

During the time, the dynamics are governed by a set of differential equations, the number and the form of which change depending on the started or mantained mechanisms.

For example, if all the contacts are efficient and persistent without sliding displacements, referring to the Lagrangian formalism, the system of dynamics equations is:

$$d/dt \ (\partial L/\partial \dot{q}_k) - (\partial L/\partial q_k) = Q_k \qquad k=1,2,..5 \tag{13}$$

together to the differential kinematic relationships, expressing the constraints imposed to the normal relative velocities $\dot{u}^N{}_i$ of the contact points P_i:

$$\dot{u}^N{}_i = \sum_{k=1}^{5} a^N{}_{ik} \, \dot{q}_k = 0 \qquad i = 1, 2 \tag{14a}$$

and to the tangential relative velocities $u^T{}_i$:

$$\dot{u}^T{}_i = \sum_{k=1}^{5} a^T{}_{ik} \dot{q}_k = 0 \qquad i = 1, 2 \tag{14b}$$

In eq. (13) L is the Lagrangian of the system, which takes into account the effects of the ground motion and of the gravity, and Q_k is the generalized force, representing the effects on the k-th degree of freedom of the interactions $F^N{}_i$ and $F^T{}_i$ between the parts of the system. $F^N{}_i$ and $F^T{}_i$ are present in the expression of Q_k as a given combination of the Lagrangian multipliers corresponding to the constraints equations satisfied by the $\dot{q}_k$

The particular expression of Q_k depends on the kind of the contact (absence or presence of relative sliding motions, or uplift), in accord to the stated contact laws.

If any *i-th* contact is absent, the corresponding *i-th* constraint equation and the *i-th* term in the expression of Q_k disappear.

NUMERICAL INVESTIGATION AND RESULTS

A numerical investigation has been performed as a function of the amplitude K_S, the frequency ω of the horizontal sine wave excitation, and of the static and kinetic dry friction coefficients. The sizes of the elements of the analyzed system are shown in Fig. 5; they correspond to a columnade of the E3 Greek temple at Selinus (Sicily).

A temptative value equal to *3* has been selected for the mass ratio between the lintel and a column. Such a value is probably too large in comparison with the actual one, so that the inertial effects on the dynamics response are emphasized; but, as it will be clear in the following, the features of the dynamics and the aim of this paper allow such a choice as a preliminary investigation.

Following the dynamic evolution, it has been very difficult to give a systematic interpretation of the results obtained.

As an example, in Fig. 6 the time history of the relative displacement between the contact points at the top of the left column is shown, for different values of the frequency ω, for a given amplitude $K_S = 0.4$ and for values of friction coefficients f_s and f_k, respectively equal to 0.6 and to 0.3.

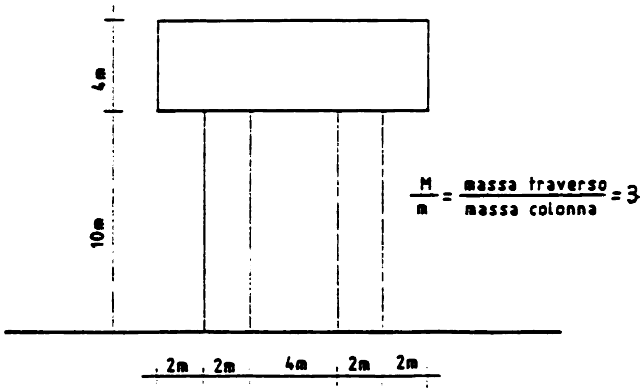

FIG 5. Sizes of the analyzed system.

An adimensionalized time has been used: $t/T = \omega t/2\pi$, in order to compare the motions in one period of the excitation.

It is evident that small variations in the features of the ground motion can induce completely different responses.

Nevertheless, something can be said by comparison with the dynamic response obtained in the previous one degree of freedom model (Sepe and Sinopoli 1991).

In fact, by analyzing the response of the same trilith in the simple rocking model, three regions were identified, if K_S was increased for a given ω in the (ω, K_S) plane, where respectively: a) there was no motion; b) the motion was orbitally stable; c) the motion was orbitally unstable (overturning).

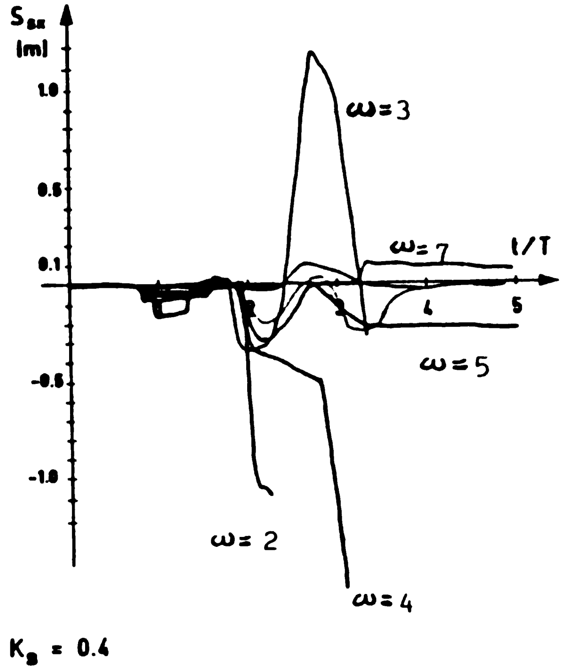

FIG 6. Time history of the relative displacement for different values of the angular frequency ω.

Only the first and the third regions remain almost unvaried in the coupled slide-rocking model.

The most important difference is in the second region, where now the motion is generally unbounded and two different failure modes can be identified: the overturning and the failure due to the loss of the geometrical configuration for either eccessive slidings or coupled effects between excessive slidings and rotation.

Therefore, as a first step, let us evaluate the sensitivity of the system to cumulate slidings in a given

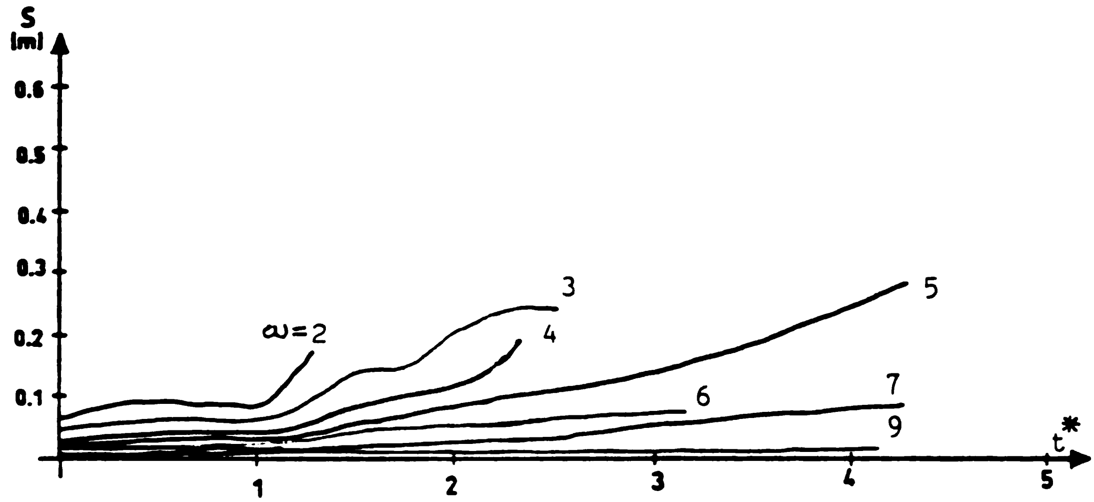

FIG 7. Mean absolute relative displacement for different values of the angular frequency ω.

time interval. To this aim let the absolute value of the mean relative displacement S, in a given time interval $(0 - t^*)$, be defined as:

$$S = \frac{1}{t^*}\int_0^{t^*} (\,|S_l| + |S_r|\,)\, dt \qquad (15)$$

where S_l and S_r are, respectively, the mean relative displacement cumulated in the time t^* at the top of the left and right column; t^* is the time measured from the first impact and adimensionalized with respect to the period T of the excitation. A better interpretation of the dynamic response is then obtained. In Fig.7, the dependence of S on the time t^* is shown for a given value of K_s ($K_s = 0.4$) and of the static and kinetic friction coefficients ($\mu_s = 0.6$ and $\mu_k = 0.3$) and for different values of ω.

Generally, S decreases with ω for a given K_s, and increases with K_s, but in a different way depending on ω; this circumstance can be observed in Figs.8, where the rate of S, as a function of the angular frequency ω, .has been measured in meters per periods T (Fig.8a) and in meters per seconds (Fig.8b).

Both S and its velocity are absolute values; therefore, they are correlated with the energy dissipated by the system due to the slidings. By observing Figs. 8 and 9, it seems that for small values of the angular frequency such an energy is large, but it tends quickly to zero with ω.

This fact alone cannot give us any information about the safety of the structutre; in the sense that a little amount of dissipated energy, either per period or per second, does not imply necessarily failure for increasing dynamic response, due to the strong non linearity of the system.

It is necessary to examine closely the features of the motion and, particularly, to investigate the effects of the coupling between the degrees of freedom.

Our parametric investigation considered a domain in the load space of the ground motion, defined by values of the angular frequency ω ranging from 1 to 12 rad/sec,

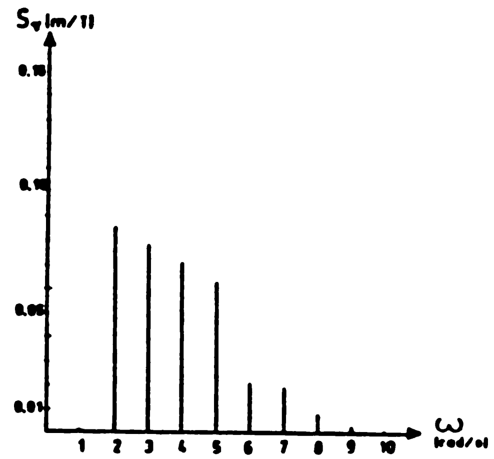

FIG 8a. Mean velocity of S (meters/ period) as a function of the angular frequency ω for $k_s = 0.4$.

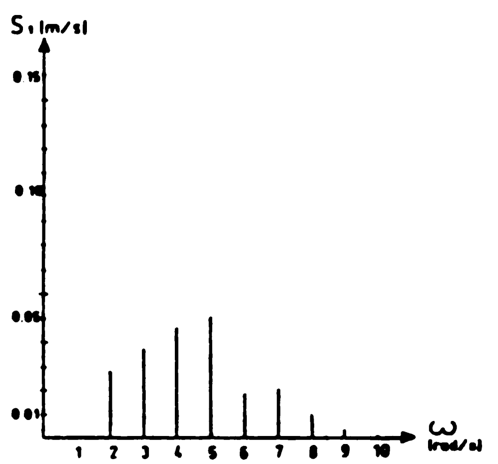

FIG 8b. Mean velocity of S (meters/ seconds) as a function of the angular frequency ω for $k_s = 0.4$.

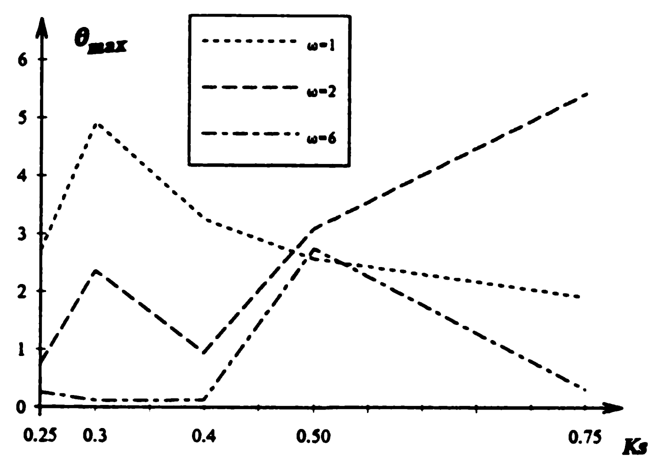

FIG 9a. Maximum rotation of either column as a function of K_s.

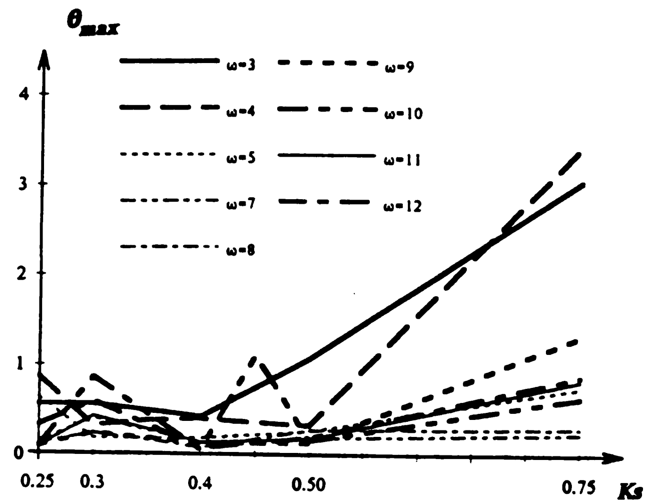

FIG 9b. Maximum rotation of either column as a function of K_s.

and of the acceleration amplitude K_S ranging from *0.2* to *0.75*, in gravity acceleration units; smaller values of K_S cannot induce motion due to the character of the equilibrium configuration (Sinopoli 1990).

Unfortunately, the dynamic responses obtained don't exhibit any periodic feature, except some isolated case which will be discussed later. Anyhow, let us show the maximum rotation of either column (adimensionalized with respect to the angle corresponding to the unstable static equilibrium configuration; i. e. center of the mass of the column along the vertical line), as a function of K_S for different values of ω (Figs. 9a and 9b), until five seconds.

The rotations shown in Fig. 9b increase on the average with K_S and reach dangerous values of the angle only for very large values of the acceleration. On the contrary, anomalous behaviours can be observed in Fig. 9a, possibly due to the coupling with the slidings.

Then, let us analyze and compare the responses of the different degrees of freedom, in order to verify the role of the coupling in the loss of the geometrical configuration responsible of the failure.

The loss of the geometrical configuration means not only the variation of the configuration due to the dynamics, but especially the increased distance between the support points of the lintel.

The variation of the geometric features of the system persists even if the dynamics stop at a given instant and the trilith comes back to the initial equilibrium configuration; then the cumulate sliding can be considered as a measure of the permanent damage induced by the excitation on the structure. Further, such loss of the geometric configuration is always present in the second region of the load plane, where the simple rocking model was characterized by periodic and bounded responses.

The maximum values of the adimensionalized rotation and of the relative displacement (adimensionalized with respect to the width of the column), are shown respectively in Fig. 10a and 10b.

The rotation for the case $K_S = 0.4$ is strictly exponentially decreasing with ω, a typical behaviour of the simple rocking model. The same occurs only on the average for the other cases (Fig. 10a), but with the exception of some evident

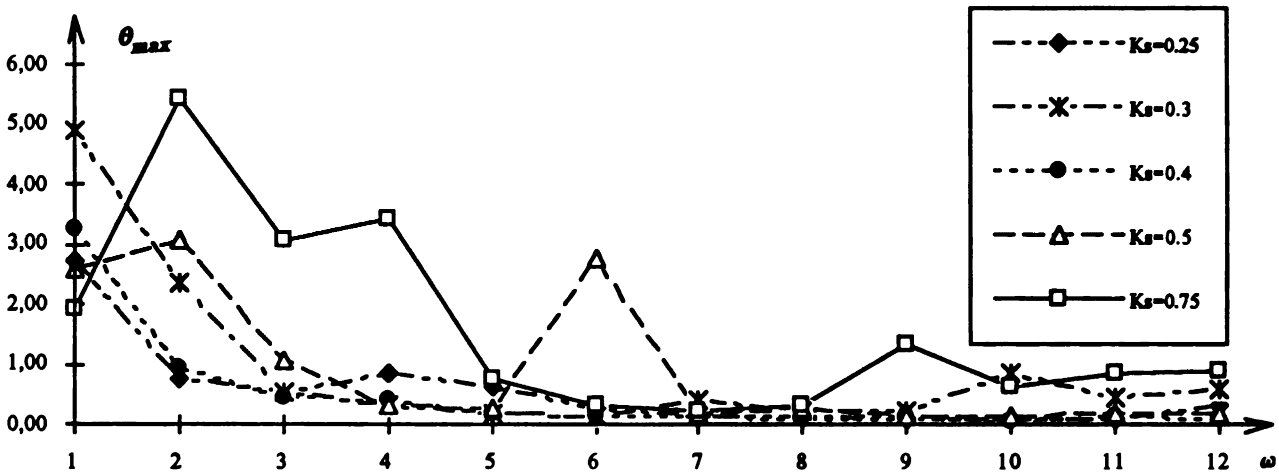

FIG 10a. Maximum adimensionalized rotation of either column until 5 sec.

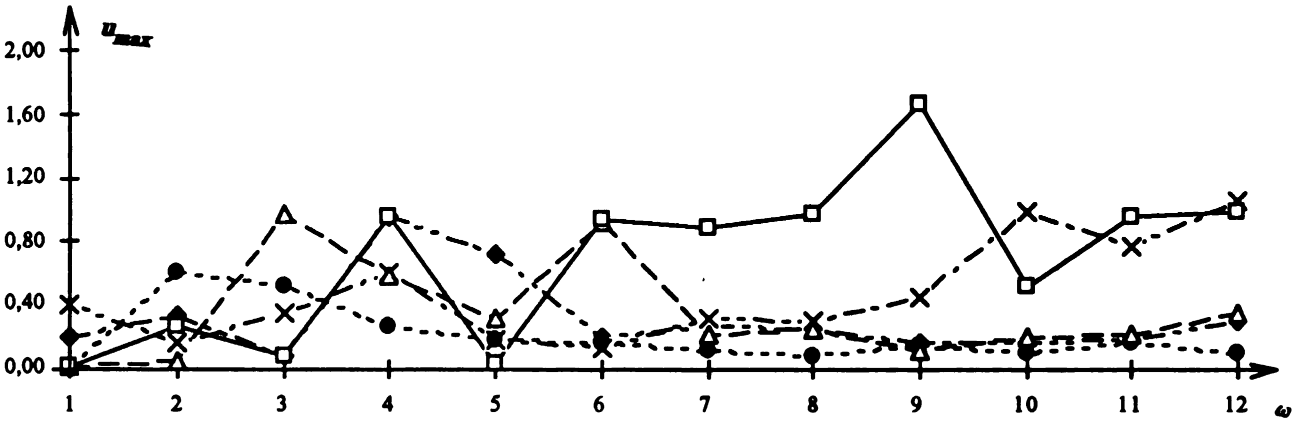

FIG 10b. Maximum adimensionalized relative displacement on either contact point until 5 sec.

peak; for example the one for $\omega = 6$ *rad/sec* and $K_s = 0.5$.

The same peaks can be observed in Fig. 10b for the relative displacement; they suggest a strong coupling influence on the dynamics response.

Furthermore, by comparison from the two figures, it can be said that for small values of ω and of K_s, on the average , the rotations and the slidings have a dual behaviour as a function of the angular frquency. Particularly, the rocking is dominant for small values of the frequency, while the sliding prevails in the remaining range.

Anyway, under a deterministic point of view, no systematic trend for the rocking can be identified by increasing the amplitude of the excitation, as can be verified by checking the corresponding values for $\omega = 1$.

Once more the rotation increases with K_s, only on the average, inducing increasing values of the slidings especially for large ω.

By following the dynamics evolution for a long time interval, the mean behaviour outlined above becomes more and more evident. In fact, the same variables of the motion of Figs. 10a and 10b are shown in Figs. 11a and 11b, after a time span equal to *1000 sec*.

For small values of the frequency, the rocking response is almost unvaried; on the contrary, the sliding is increased. Both slidings and rotations become important in the range of large frequencies, with well evident coupled peaks.

With respect to the cumulative slidings, even if in a given time interval they are not quantitatively large, it is sufficient to wait for a time long enough, in order that the failure occurs in any case.

With respect to the maximum value of the angle, the results suggest that, in correspondence to a given value of the amplitude acceleration, a value for the frequency can be determined below which a failure due to overturning is expected for the structure; such a value of the frequency is very small in comparison with the one characterizing the peak acceleration of an earthquake, so that this failure mode seems quite improbable.

On the contrary, for increasing values of the frequencies, both the dynamic responses increase with the time so that

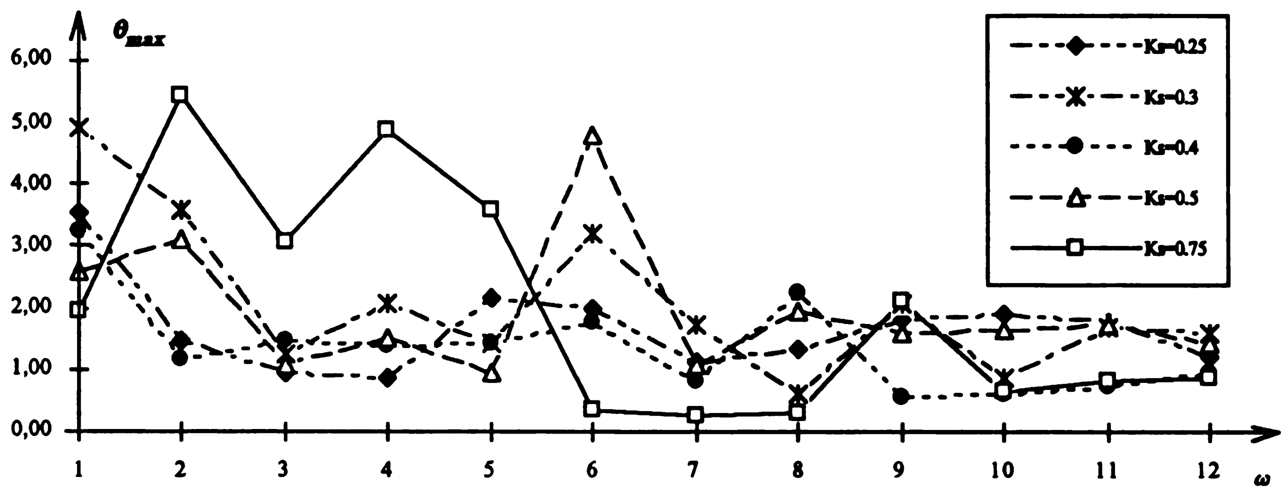

FIG 11a. Maximum adimensionalized rotation of either column until the collapse or 1000 sec.

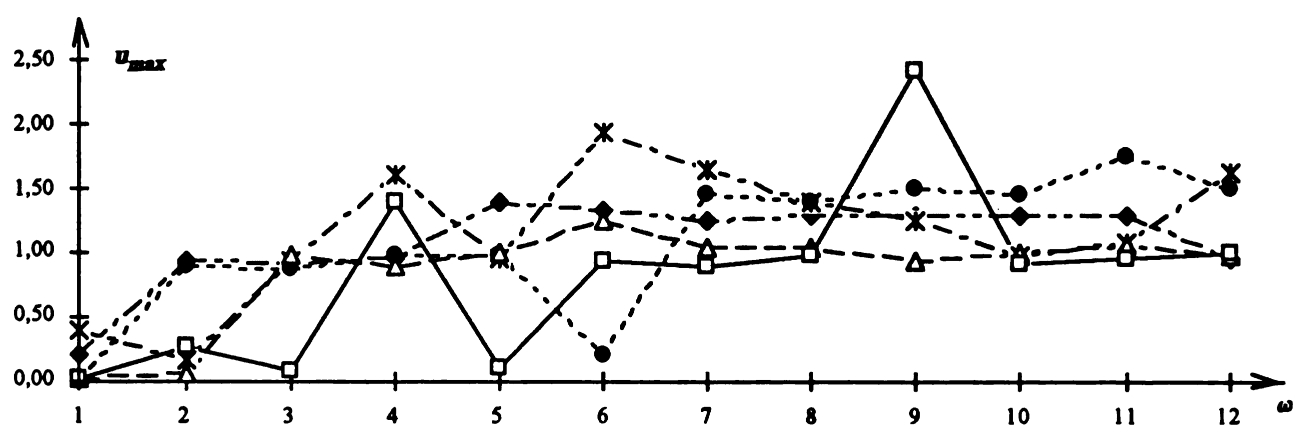

FIG 11b. Maximum adimensionalized relative displacement on either contact point until the collapse or 1000 sec.

both the failure modes, due to overturning and excessive slidings, are expected for the coupling between the degrees of freedom.

In effects, the slidings seem to be more important than the rocking; but, the coupling unpredictable in terms of dependence on the angular frequency, generates the coupled peaks mentioned above so that relative displacements and rotations must be considered as equally determinant in the coupled motion for the collapse.

Such peaks recall the parametric resonance identified as a feature of the response of a single degree of freedom model, investigated by means of an analytical approach.

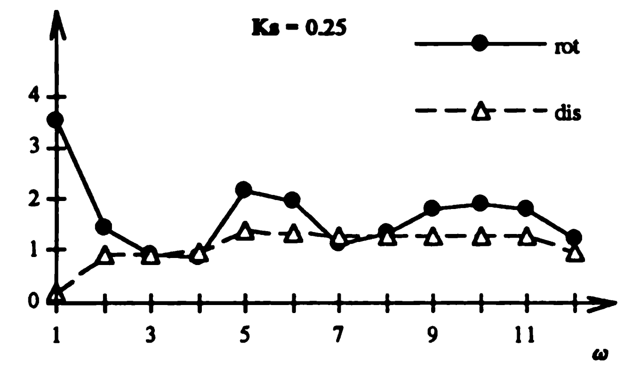

FIG 12a. Maximum rotation and sliding for *Ks=0.25.*

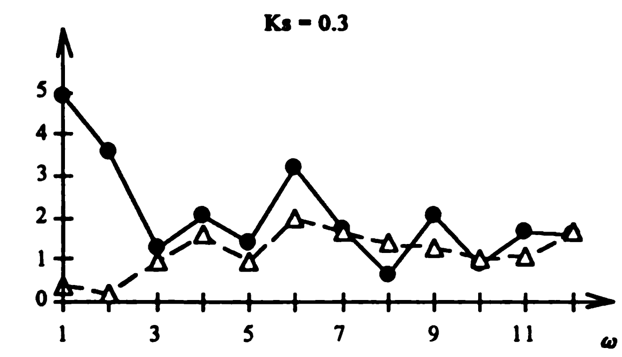

FIG 12b. Maximum rotation and sliding for *Ks=0.3.*

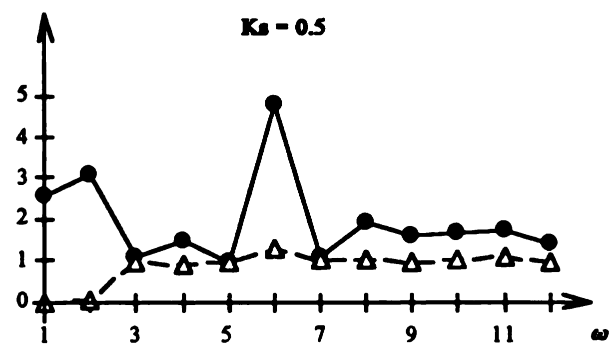

FIG 12c. Maximum rotation and sliding for *Ks=0.5.*

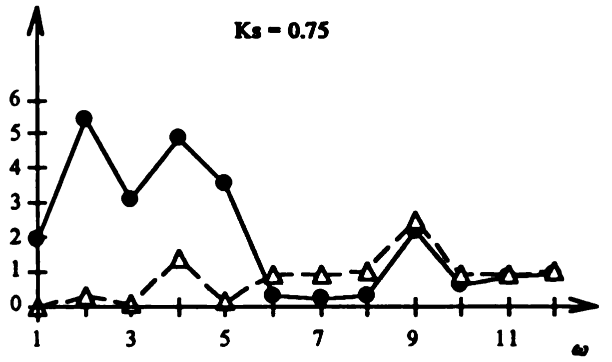

FIG 12d. Maximum rotation and sliding for *Ks=0.75.*

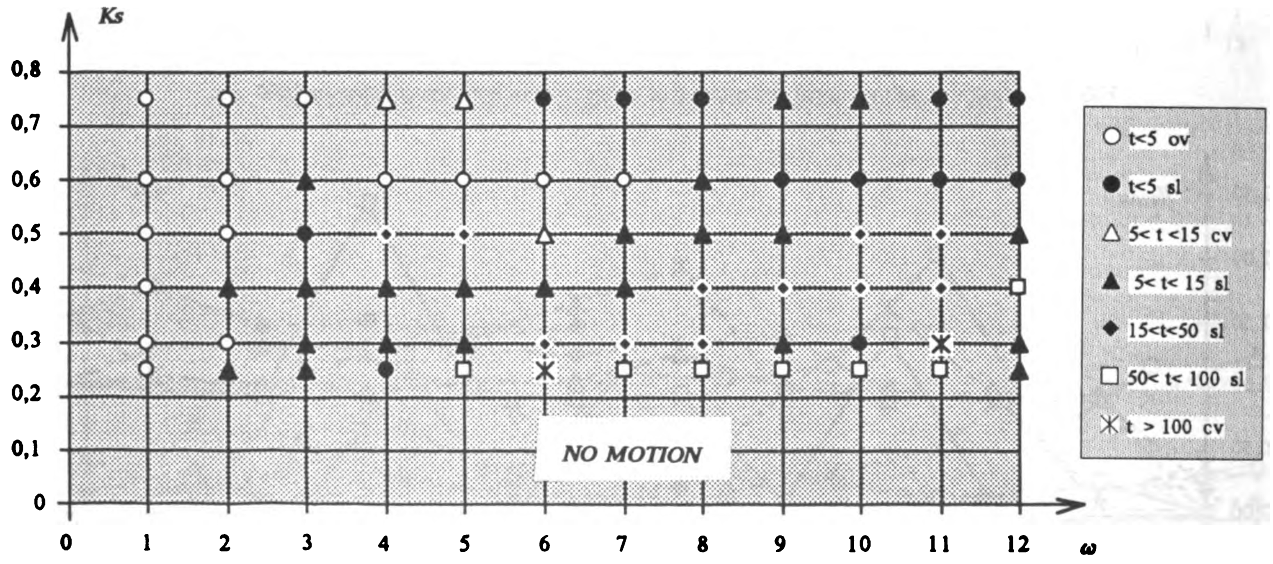

FIG 13. Survival domains for $f_s = 0.6$ and $f_k = 0.3$.

There, the character of the differential equations governing the motion were determined by matching the equation governing the motion of different mechanisms into a unique equation, able to take into account the discontinuity character of the dynamics (Sinopoli 1991)..

But, in the present model, any analytical investigation is not allowed. due to the large number of degrees of freedom and the complexity of the differential equations

In Figs. 12a-d, the strong coupling between the rocking and the sliding, for ω larger than *3 rad/sec*, can be observed in detail, after a time span of *1000 sec.*

From the considerations made until now, it follows that it is difficult to give some criterion about the safety of the structure, by analyzing the features of the motion. In fact, the response of any degree of freedom is generally increasing with the time.

Only one case has been found, for $\omega = 6$ *rad/sec* and $K_s = 0.25$, where the rotation of the right column seemed to librate around the unstable static equilibrium configuration; while, the other degrees of freedoms were oscillating with amplitude slowly increasing with time. Therefore, the global motion was unbounded in any case.

Probably, the most interesting result of this investigation is the definition of a survival domain in the load plane (ω,K_s), where many and different regions can be identified, characterized by different failure modes and by different instant into when such a collapse occurs.

Then, it is possible to follow the evolution of the boundaries of the safe region for the trilith with time; further, it is evident that, for such a kind of structure, the probability of failure is an increasing function of time, which reaches the value one with the time increasing to infinity.

The role of dry friction coefficients

Given a time interval, the position and the global area of the survival domain in the load plane depend on the geometry and on the mass ratio of the system, and moreover, on the contact law and on the performance of friction.

In fact, the main difference between the results of the present study and the ones obtained with the simple rocking model, is the loss of systematic trends of the dynamic response with respect to the parameters of the excitation, due to the presence of the slidings; therefore, it is expected that the variations of the friction coefficient can modify the features of the motion sensibly.

A further parametric investigation has then been performed for different values of the friction coefficients and of their ratio. Three cases will be presented here. The first, case a) for for values of friction coefficients f_s and f_k, respectively equal to *0.6* and to *0.3*; the second one: case b), for values equal to *0.6* and *0.6*, and the third one: case c), for values equal to *0.75* and *0.25*.

The variation of the survival domains for case c) can be observed in Fig. 14 and compared with the similar one of Fig. 13, for case a).

The areas corresponding to a long survival time have disappeared, while the area of the regions where an early collapse occrs are increased.

In order to understand the results obtained, let us observe that the values of the friction coefficients for case c) implie a decreased possibility to start the sliding during the smooth dynamics. Therefore, it is expected that the value of the maximum rotation increases with time until the first impact occurs; at this instant, relative displacements between the

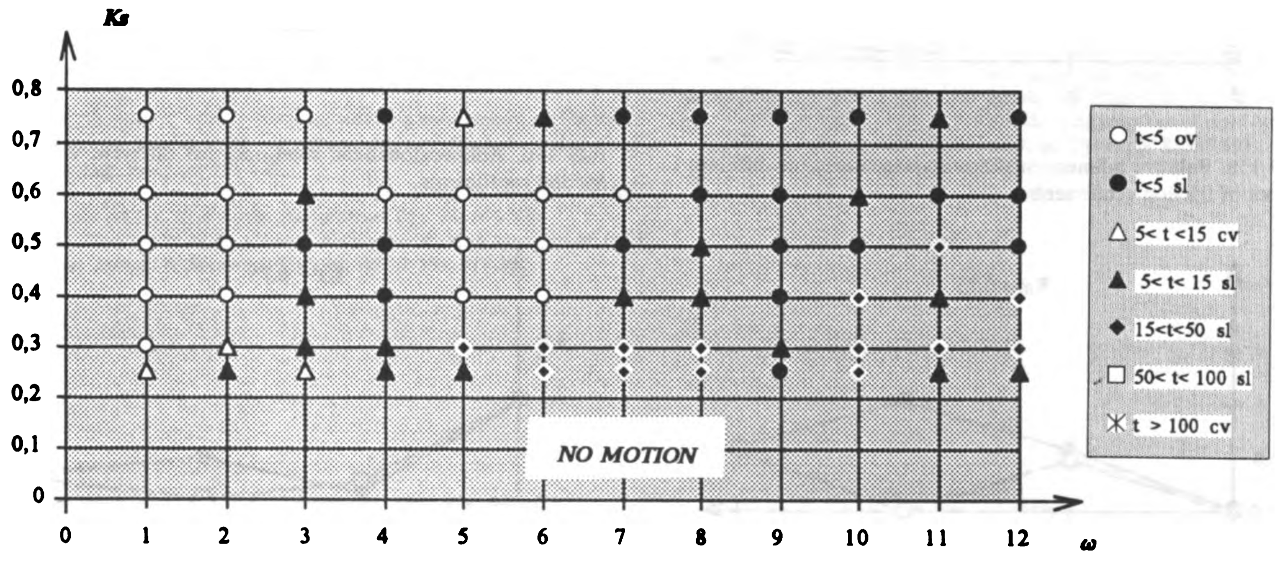

FIG 14. Survival domains for $f_s = 0.75$ and $f_k = 0.25$.

lintel and the columns can start as a consequence of the shock.

However, the small value of the kinetic friction coefficient does not allow the system to dissipate energy enough, so that it is expected that the trilith collapses earlier than in case a).

The comparison between the coupled responses, for the three cases analyzed, is shown in Fig. 15 and 16, for a time duration of five secondsGenerally, an increased value of the static friction coefficient determines larger values for both the maximum rotation and the relative displacement, except for large values of K_s $(K_s = 0.75)$.

On the contrary, the increase of the kinetic coefficient determines reduced or equal values for both rotation and sliding.

CONCLUSIONS

The dynamical behaviour of blocks structures, in particular under an earthquake-type load, is a well developed field of research, which has already given some significative results. Much less developed appear the applications of these studies to actual problems, by means of correct models able

to simulate the actual behaviour.

Even in the few cases in which the importance of the problem forced a systematic study parallel to the actual works, like the restoration of the Parthenon, the dynamic aspects have been somewhat undervalued, and the structural analysis followed the quasi-static approach.

The present paper is an attempt towards filling this gap.

A model to investigate the coupled motion of a trilith with the same geometric features of the columnade of the E3 Temple at Selinus (Sicily) has been proposed.

Special attention has been devoted to the modelling the contact law and the impact problem. Some assumptions, due both to the necessity to reduce the complexity of the study and to still open problem, have been made.

A parametric investigation has been performed as a function of the excitation parameters and of the mechanical features of the system.

Collapse by overall excessive rotation is a rather improbable failure mode under seismic loads; on the contrary, both overturning and collapse due to excessive sliding as a consequence of the coupled dynamics, seem to be a mode of collapse, which requires only a time long enough.

The effects of the variations for the values of the friction coefficients have been analyzed.

Further, survival domains in the load plane have been identified, the position and the area of which depend on the duration of the time interval analyzed.

Knowledge-based shock-wave modeling by GENESIS

Barry Hunt and Arthur P Adamson (retired)

GE Aircraft Engines, Cincinnati OH 45215

GENESIS—GEneralized Nonlinear Extension of Surface Integral Schemes—offers the prospect of extending existing 3-D panel codes, originally developed for *linear* flows over complex configurations, to the general régime of flows governed by the unsteady Euler equation—without significant increases in computational time or resources. The boundary representation of a shock discontinuity exploits its causal link with conditions at the sonic point to suppress, non-dissipatively, the physically-impossible formation of an expansion shock. Three approaches are described, two approximate and one nominally exact, for solving the transonic Euler equation on conventional computers; some 2-D transonic results are presented, obtained on a PC in about one second.

INTRODUCTION. Panel codes for the numerical solution of aerodynamic problems expressed in the form of *integral equations* had attained a stage of relatively complete maturity, for *linear* applications, more than a decade ago (Hunt, 1982). Integral methodologies were then generally considered to have reached their limit of useful development, and attention was switched to tools offering a more complete understanding of *nonlinear* phenomena. The prime focus became the numerical solution of problems expressed in the form of *differential equations*; in particular, finite-difference and finite-element schemes became predominant. Today, almost the entire budget of both industry and government for computational tools for aerodynamic prediction is vested in differential methods, both in terms of the number of researchers addressing their refinement and the amount of computational resources attached to their solution.

Computational solutions of the *Navier-Stokes* equation (or more usually its non-dissipative approximation expressed by the Euler equation) are now starting to become commonplace even for complete airframe geometries, and for major portions of their propulsion units. Significant design improvements can be attributed in large part to the availability of such tools. However, these successes are, unquestionably, neither cost-free nor problem-free. Differential methods are making heavy and increasing demands on human and computational resources. Their application and interpretation requires specialists who are often far removed from the engineering design process. Their fidelity in the representation of certain important flow features (*e.g.* shock-waves) is sometimes dubious, as is their performance near the "linear" end of the flow spectrum. Their integration with computational schemes simulating other, *interacting* physical processes (*e.g.* heat transfer, mechanical distortion and vibration) may never be achievable for realistic configurations.

There is now a growing recognition that *integral* methodologies may remove or significantly reduce all these differential difficulties. Integral methods are *not* intrinsically linear, as was once believed — even *boundary* integral methods. It is likely, in fact, that the old generation of panel codes can be updated, relatively easily, to address most, if not all, of the same set of flow problems that differential methods are now addressing. Work is currently in hand to develop a general boundary-integral framework—**GENESIS**—for nonlinear, unsteady aerodynamic and aero-acoustic problems involving arbitrary motions of flexible 3-D bodies—*without any field integrations*. The present paper focuses on *steady-state*, transonic flows.

1 CONCEPTUAL OVERVIEW OF LINEAR AERODYNAMIC PANEL CODES

Boundary integral methods (BIM's), generally known as *panel codes*, have been a mainstream tool in the aerodynamic design of military and civil aircraft for more than a quarter of a century [Hunt, 1978, 1980a,b, 1982] Most major airframers have developed their own in-house codes, with varying degrees of sophistication. For the *linear, incompressible* flow régimes to which they apply, these codes generally offer arbitrarily high accuracy at affordable cost, in terms of both data-preparation and computation time on conventional computers. The primary reason for this economy is the fact that, for such types of flow régime, the problem reduces to the computation of certain quantities *only* on the configuration surface.

For an *irrotational* flow, the velocity vector $\vec{V}$ is the gradient of a scalar potential: $\vec{V} = \nabla\Phi$. If the flow is also *incompressible*, we have $\nabla \cdot \vec{V} = 0$, so that the potential Φ now satisfies *Laplace's Equation* : $\nabla^2\Phi = 0$. We here designate any BIM which solves the equations of incompressible, irrotational flow, subject to some prescribed set of boundary conditions, as a *Laplace BIM*.

Some Laplace BIM implementations are couched in terms of the velocity potential Φ, and some in terms of the velocity vector, $\vec{V}$ (Hunt, 1978, 1980a). We shall consider here only **velocity-based formulations**. One particular velocity-based formulation known by the acronym SAVER will be outlined in Sec 2 .

1 .1 Surface singularity types

Panel codes discretize the configuration surface into some number N of surface *panels*, each patched with one or more types of "***surface singularity***" distribution. These distributions (prescribed or unknown) relate to either the *potential-jump* $\Delta\Phi$ or the *vector velocity-jump* $\Delta\vec{V}$ across that panel, between a (fictitious) *interior* domain Ω_{int} and the (physical) *exterior* domain Ω (see Fig 1). Different implementations imply different fictitious interior fields and therefore different surface singularity distributions. The most common implementations use some combination, or just one, of the following types of singularity distribution:

- *Sources* : A locally continuous surface-source patch on each panel; the local source density σ is *defined as* the normal component of the vector velocity jump across the panel: $\sigma = \hat{n} \cdot \Delta\vec{V}$, with $\Delta\vec{V} = \vec{V}_{ext} - \vec{V}_{int}$ and where the local surface unit normal $\hat{n}$ points into the physical domain Ω;

- *Vorticity* : A locally continuous surface-vorticity patch on each panel; the (vector) vorticity $\vec{\omega}$ is *defined* to lie in the local tangent plane and be equal in magnitude and orthogonal to the in-plane component of the vector velocity jump: $\vec{\omega} = \hat{n} \times \Delta \vec{V}$;
- *Dipoles* : A locally continuous surface-dipole (doublet) patch on each panel; the axis of each elemental dipole vector is parallel to the local surface unit normal $\hat{n}$, and the local dipole density μ is *defined* as the potential jump across the panel: $\vec{\mu} = \Delta\Phi\,\hat{n}$, with $\Delta\Phi = \Phi_{ext} - \Phi_{int}$.

Note 1: A normal-dipole distribution and a vorticity distribution are in fact **equivalent.** [see Hunt (1978, 1980a), where a complete discussion of the above singularity types and their association with a variety of boundary conditions is given].

1.2 Influence matrices

The dominant part of a panel-code computation is the formation of an *influence matrix*. We here use the symbolic notation $[\vec{U}]$ to represent the vector **velocity-influence matrix**, and $\{\lambda\}$ the **singularity array** defining the values of the singularity distribution(s) at a set of *N control points*. Some of the values in $\{\lambda\}$ may be prescribed, while the remainder, generally of a different *type*, will be unknown and must be computed such that a prescribed set of boundary conditions $\{V_{nBC}\}$ is satisfied—usually at the same N control points.

In a 3-D velocity-based formulation, the *vector* element $\vec{U}(i,j)$ of the vector influence matrix $[\vec{U}]$ represents the normal component $U_n(i,j)$ and two orthogonal tangential components $U_{s1}(i,j)$, $U_{s2}(i,j)$ of the *perturbation velocity* "induced" at a specific control point on panel i by unit value of the jth singularity patch, λ_j. The vector influence matrix $[\vec{U}]$ is generally stored as its three scalar component matrices: the **normal influence matrix** $[U_n]$, and the two **tangential influence matrices** $[U_{s1}]$ and $[U_{s2}]$. If the formulation employs vorticity as a singularity type, the vorticity $\vec{\omega}$ on each patch will also be a vector, orthogonal to $\hat{n}$, and may be defined in terms of its components ω_1, ω_2 along two directions $\hat{s}_1$, $\hat{s}_2$ associated with that patch. These local (unit) tangent vectors $\hat{s}_1(i)$, $\hat{s}_2(i)$ associated with $U_{s1}(i,j)$, $U_{s2}(i,j)$, $\omega_1(i)$ and $\omega_2(i)$ are defined at control point i, relative to a coordinate system fixed in the body. [Generally, only $\hat{s}_1(i)$ needs to be stored, since usually $\hat{s}_2(i) = \hat{s}_1 \times \hat{n}$.]

In 2-D, there is again the normal influence matrix $[U_n]$, but only *one* tangential influence matrix, $[U_s]$; if the formulation employs vorticity, that vorticity $\vec{\omega}$ is then a vector oriented into the paper.

In both the 2-D *and* the 3-D case, the evaluation of each vector element $\vec{U}(i,j)$ is usually performed analytically, but sometimes numerically [Hunt, 1978, 1980a,b].

Note 2: For velocity-based implementations employing both source and vorticity distributions (such as the SAVER formulation discussed in Sec 2), the vector influence matrix $[\vec{U}]$ for only *one* of these singularity types is needed: the other matrix is obtained by simple vector rotation of each vector matrix element $\vec{U}(i,j)$.

Note 3: Some more sophisticated implementations also take account of the gradient of the boundary distribution(s) λ, and employ curved instead of planar panels—still with analytic coefficicients.

2 SAVER: SOURCE AND VORTICITY EVALUATION BY RELAXATION

2.1 Conceptual overview of SAVER

A particularly effective Laplace-BIM formulation known as SAVER (Source And Vorticity Evaluation by Relaxation) has been developed at GE Aircraft Engines. First introduced in Hunt (1991a) and inspired by a novel work by Raj and Gray (1979), SAVER has been applied successfully to a wide range of cases. The underlying model is outlined here for the 2-D case; its extension to 3-D is described in Sec 4.1 . In 2-D, the local (unit) tangent vector at the body surface is uniquely defined by $\hat{s} = \hat{j} \times \hat{n}$, with $\hat{j}$ oriented into the paper. The normal component of $\vec{V}$ is $V_n = \hat{n} \cdot \vec{V}$ and the remaining tangential part, defined in 3-D by $\vec{V}_s = \vec{V} - V_n\,\hat{n} = (\hat{n} \times \vec{V}) \times \hat{n}$, reduces in 2-D to $\vec{V}_s = \hat{s} \cdot \vec{V}\,\hat{s}$, or $V_s = \hat{s} \cdot \vec{V}$.

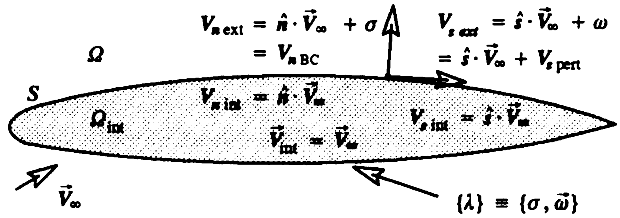

Fig 1. SAVER implies an internal field $\vec{V}_{int} = \vec{V}_\infty$ by fixing the boundary source as : $\sigma = -\hat{n} \cdot \vec{V}_\infty + V_{nBC}$ and relaxing the vorticity : $\{\omega\} = [U_s]\{\sigma, \vec{\omega}\} \equiv \{\vec{V}_{s\,pert}\}$

With SAVER (see Fig 1), the velocity field in the (fictitious) interior domain Ω_{int} inside a closed body is *implied* to be equal to the unperturbed (uniform) onset flow vector $\vec{V}_\infty$. This simple condition, equivalent to requiring that the *perturbation velocity* be zero throughout the interior of the body, is then used by SAVER to imply the required normal-velocity boundary condition, as follows:

a) The boundary singularity distribution $\{\lambda\}$ is defined to consist of *both* a source distribution σ and a vorticity distribution ω on the body boundary, S. Symbolically: $\{\lambda\} \equiv \{\sigma, \omega\}$.

b) The boundary source distribution σ [defined earlier as equal to the normal component of $\Delta\vec{V} = \vec{V}_{ext} - \vec{V}_{int}$, *i.e.* the vector velocity jump] is *fixed a priori* as being locally equal to the quantity $-\hat{n} \cdot \vec{V}_\infty + V_{nBC}$, where V_{nBC} is the prescribed normal-velocity boundary condition. If the implication is correct that the total velocity on the *inner* face of S is $\vec{V}_\infty$, then the total normal velocity on its *outer* face must therefore be equal to $\hat{n} \cdot \vec{V}_\infty + \sigma = V_{nBC}$.

c) The local boundary-vorticity vector $\vec{\omega} = \omega\hat{j}$, [defined earlier to be equal in magnitude and orthogonal to the in-plane component of the vector velocity jump, $\vec{\omega} = \hat{n} \times \Delta\vec{V} = \hat{n} \times \Delta\vec{V}_{pert}$] is then coerced to be equal in magnitude and orthogonal to the tangential component $\{V_{s\,pert}\}$ of the computed perturbation velocity $\{\vec{V}_{pert}\} = [\vec{U}]\{\lambda\}$ *induced* by the overall distribution $\{\lambda\}$ (*i.e.* by σ and ω) at the set of control points in Ω, *i.e.* on the *outer* face of S. That is, the boundary-vorticity part ω of the overall singularity distribution $\{\lambda\}$ is updated iteratively, starting from some assumed initial guess for $\{V_{s\,pert}\}$, by the ***relaxation cycle*** :

$$\{\omega\} = \{V_{s\,pert}\}$$
$$\{V_{s\,pert}\} = [U_s]\{\sigma, \omega\}$$

Note 4: This condition (coerced on the *outer* face of the boundary S) implies that the tangential component of the perturbation velocity on the *inner* face of S must be zero.

Note 5: SAVER has the option of computing the actual value V_n on the body surface S, and applying a secondary sequence to adjust σ to strictly enforce the required condition V_{nBC} (Hunt, 1991b).

Note 6: SAVER reinforces a *Kutta condition* at each cycle (Hunt, 1991b) by adding a multiple of a (pre-computed) circulatory vorticity *eigendistribution* ω_c to force equality of the trailing-edge velocities.

Once the relaxation cycle has converged (typically four or five iterations), SAVER gives the required total velocity at the boundary simply as $\vec{V} = \vec{V}_\infty + \vec{V}_{pert}$, which will be *tangential* if the solid boundary-condition $V_{nBC} = 0$ was used in step (b) above to fix σ.

SAVER in its present 2-D form employs piecewise-quadratic distributions σ and $\vec{\omega}$ on circular-arc or planar panels. All influence coefficients are evaluated analytically. For all (thick and thin) airfoils evaluated, this second-order accurate code produces results more accurately and more rapidly than any other known code. These virtues can be expected to carry across in large part to 3-D.

In a proposed variant **DESIGN SAVER**, the boundary *vorticity* ω is prescribed a priori, and the boundary *source* σ is coerced to equal the computed *normal* velocity perturbation: $\{\sigma\} = \{V_{n\,pert}\}$. In 2-D, the local vorticity ω is a unique function of the local pressure (thus allowing the pressure to be the prescribed quantity). Moreover, the resulting source σ can be interpreted directly as a local *surface transpiration function*, $V_{trn} = \sigma$, which is related (analogously to boundary-layer modeling) to an equivalent normal displacement of the body boundary. It seems likely that development of this concept could lead to a 3-D shape-design capability. It is worth noting that the numerical conditioning of this proposed "design" variant is exactly the same as that of the "analysis" form outlined above: the same matrices are used in both cases. **DESIGN SAVER** thus promises to share the computational efficiency of **SAVER**.

2.2 SAVER as the basis for generalized, nonlinear flows

Three specific features uniquely equip SAVER as the basis of a generalized solver for ***unsteady, compressible flows***: first, its foundation in the vector *velocity* field (rather than a scalar potential); second, its explicit coupling between the singularity distributions, the boundary conditions, the onset-flow vector and the perturbation velocity; and third, the remarkably low number of relaxation cycles it requires to obtain a converged tangential velocity solution, V_t.

A velocity-based approach to unsteady, *incompressible* flows was introduced in Hunt (1982). Work is underway to extend this to unsteady, compressible flows by coupling it with the GENESIS methodology first introduced in Hunt and Plybon (1990) for steady-state, compressible, rotational flows.

GENESIS converts *field* nonlinearities to equivalent *boundary* functions. These consist of:

i) a local correction to be added to the prescribed normal-velocity boundary condition V_{nBC}. The resulting sum V'_{nBC} is used by SAVER in its definition of the boundary source σ. This yields an *equivalent pseudo-Laplace problem*, with boundary condition V'_{nBC}, to be solved by SAVER for the *pseudo-Laplace tangential velocity* V'_t.

ii) a local correction to be added to the computed pseudo-Laplace tangential velocity V'_t. The resulting sum V_t is the required solution of the original nonlinear (compressible and/or rotational) problem.

These two corrections are computed from the current estimate of the local nonlinear velocity V_t on the boundary S.

The fundamental principles and current status of GENESIS for steady flows will be outlined in Section 4.1. First, we give in Sec 3 an "integral viewpoint" of the fundamentals of transonic flow.

3 COMPRESSIBLE, TRANSONIC FLOWS

We give here an overview of the steady-state modeling of real, compressible flows by the Euler equation and the so-called full-potential equation. The extension of incompressible, steady-state panel codes to such compressible flows will be discussed in Sec 4.

Real, *transonic* flows involve flow discontinuities across compression shocks. Mechanical dissipation and heat conduction in the internal structure of a physical shock (considered to be properly modeled by the Navier-Stokes equations, even in the shock interior) generally produce an overall increase in the entropy along any streamline traversing the shock. The local entropy increase depends on the interaction between these two dissipative effects. For flows of aerodynamic interest, this increase is quasi-discontinuous across the shock. The flow is usually considered to be non-conducting (adiabatic), so that (in a steady flow) the *stagnation-enthalpy* flux along any stream-tube is constant, even when the stream-tube traverses a shock. The dissipative processes, however, produce a quasi-discontinuous reduction in stagnation *pressure* across the shock. This irreversible loss is related to the entropy jump. The jumps in the various thermodynamic properties across a shock are expressed by the *Rankine-Hugoniot* (R-H) relations presented in Sec 3.1 below.

The "*full potential*" (FP) approximation of a transonic flow assumes that the entropy jump across a shock is small enough to be ignored; this is tantamount to assuming that the flow remains homentropic and irrotational in traversing a shock, so that the velocity vector can be still be expressed throughout the smooth part of the flow as the gradient of a scalar potential. This approximation implies that, even in the absence of numerical errors, the solution of the FP equation is generally incapable of giving an accurate simulation of the jump properties across a shock, and of the shock location. Numerous empirical devices have been developed in an attempt to produce numerical FP solutions which are reasonably close to physical reality. These devices are necessary not only to give a reasonable simulation of compression shocks, but also to prevent the formation of non-physical *expansion shocks* in the numerical solution.

The *Euler* equations go a step further than the potential approximation, in the sense that they do support the *presence* of field vorticity in their solution. However, the absence of mechanical and thermal dissipative effects in the equations implies that they do not support the *creation* of vorticity: this requires an extra set of dissipative terms which are modeled in the *Navier-Stokes* (N-S) equations through the presence of finite coefficients of viscosity and thermal conduction [Hunt and Plybon, 1990]. It is possible to argue that the Euler equations represent a limit of the N-S equations, in which these coefficients each go to zero while keeping the same *ratio* as that required to produce an R-H shock. Nonetheless, with *zero* coefficients in the numerical equations, it is still necessary to apply an extraneous condition (equivalent to the second law of thermodynamics) **to prevent the formation of *expansion* shocks**. If such a condition is enforced properly, *and* the compression shock is coerced to simulate an R-H shock, the solution of the Euler equations can be considered as an infinite-Re solution of the N-S equations. [Note, however, that an accurate *inviscid* solution, without numerical errors, can still deviate from physically observed flows, because of viscous effects which can be significant in traversing a shock wave at a solid boundary.]

The values of the thermodynamic variables (pressure, density, temperature, etc.) can be expressed *everywhere* purely in terms of the local velocity $\vec{V}$, both for the FP and Euler equations. This fact is one of the fundamental pillars enabling velocity-based integral methods to serve as the basis of generalized, nonlinear flow solvers.

3.1 Thermodynamic variables as functions of velocity

For a *steady, adiabatic* flow of an ideal fluid with local temperature T, the ***conservation of stagnation enthalpy*** is expressed by:

$$c_p T + \tfrac{1}{2}V^2 = c_p T_\infty + \tfrac{1}{2}V_\infty^2 = c_p T_{t\infty} = \tfrac{1}{2}V_{max}^2 \qquad (1)$$

where c_p is the specific heat at constant pressure, $T_{t\infty}$ is the freestream stagnation temperature, $c_p T_{t\infty}$ the stagnation enthalpy, and V_{max} the maximum speed thermodynamically possible :

$$V_{max} = \frac{V_\infty}{M_\infty}\sqrt{M_\infty^2 + \frac{2}{\gamma - 1}} \qquad (2)$$

We introduce a ***reference Mach number*** $M_{ref} = V_{ref}/a_\infty$ with a_∞ the freestream sonic speed defined either by $a_\infty = (\gamma \Re T_\infty)^{1/2}$ or by $a_\infty = V_\infty/M_\infty$ if $V_\infty \neq 0$. The quantity V_{ref} is any suitable ***reference speed***. The specific-heats ratio γ, gas constant $\Re$ and c_p

are related by $c_p = \gamma\Re/(\gamma-1)$. Introducing an *incompressible pressure coefficient*: $C_{pINC} = (V_\infty^2 - V^2)/V_{ref}^2$, eq (1) then gives a globally-valid expression for a ***relative temperature*** $T_r \equiv T/T_\infty$:

$$T_r = 1 + \frac{\gamma-1}{2}\frac{V_\infty^2 - V^2}{a_\infty^2} = 1 + \frac{\gamma-1}{2} M_{ref}^2 C_{pINC} . \quad (3)$$

This equation gives the local relative temperature (and hence T) in a compressible flow, once the local flowspeed V is known. The local sonic speed is then given by: $a = a_\infty T_r^{1/2}$. In order to obtain the local density and pressure, we first introduce the concept of a local ***relative stagnation pressure*** $p_{t\,r} \equiv p_t/p_{t\infty}$, where p_t is the local stagnation pressure and $p_{t\infty}$ the freestream stagnation pressure. The local ***relative pressure*** p_r and ***relative density*** ϱ_r are then :

$$p_r \equiv p/p_\infty = p_{t\,r} T_r^{\frac{\gamma}{\gamma-1}} \quad \text{and} \quad \varrho_r \equiv \varrho/\varrho_\infty = p_r/T_r . \quad (4)$$

For adiabatic, homentropic flows, p_t is constant, *i.e.* $p_{t\,r} = 1.0$. This applies everywhere if the FP approximation is used, but only upstream of shocks if the Euler equation is used.

For the Euler equation, the computation of pressure and density *downstream of a shock*, given the local flowspeed V, needs to take account of the jumps across the shock and of the reduced stagnation pressure p_t downstream of it. Let subscript 1 denote the local upstream face of a shock, and 2 its local downstream face. The stagnation temperature is constant: $r_{Tt} \equiv T_{t2}/T_{t1} = 1.0$. The jumps in the other flow properties are given by the so-called *Rankine-Hugoniot* (R-H) relations. These can be expressed purely in terms of the local *shock-normal velocity* $V_{\nu 1}$ entering the shock: $V_{\nu 1} = \hat{\nu}\cdot\vec{V}_1$, with $\hat{\nu}$ the unit normal to the shock surface, oriented downstream. It is useful to introduce the local *shock-entry normal Mach number:* $M_{\nu 1} = V_{\nu 1}/a_1$, with a_1 obtained from $V = V_1$ as above. The R-H *normal velocity ratio* $r_V \equiv V_{\nu 2}/V_{\nu 1}$ is given by:

$$r_V = [1 + \tfrac{\gamma-1}{2} M_{\nu 1}^2] / [(1 + \tfrac{\gamma-1}{2}) M_{\nu 1}^2] . \quad (5)$$

The other relevant steady-state R-H relations are then:

- *Normal-velocity jump* $\sigma_\nu \equiv V_{\nu 2} - V_{\nu 1} = (r_V - 1) V_{\nu 1}$.
- *Density ratio* $r_\varrho \equiv \varrho_2/\varrho_1 = 1/r_V$.
- *Pressure ratio* $r_p \equiv p_2/p_1 = [\gamma M_{\nu 1}^2 - \tfrac{\gamma-1}{2}] / [1 + \tfrac{\gamma-1}{2}]$
- *Stagnation pressure and density ratios* $r_{pt} \equiv p_{t2}/p_{t1}$ and $r_{\varrho t} \equiv \varrho_{t2}/\varrho_{t1}$ are both equal to $\left(r_p / r_\varrho^\gamma\right)^{-1/(\gamma-1)}$.

To compute p and ϱ at a point P further downstream of the shock, eq (4) again applies, but now with the relative stagnation pressure $p_{t\,r}$ defined by the R-H stagnation pressure ratio: $p_{t\,r} = r_{pt}$, this being computed at the shock on the same streamline on which P lies (on the boundary S, $V_{\nu 1}$ is thus the shock-entry velocity on S).

3.2 Field variables in an integral method

In addition to the local velocity vector $\vec{V}$, it is convenient with an integral method to define a flow in terms of the divergence and curl of $\vec{V}$, instead of using the thermodynamic variables. These functions are termed respectively the ***field source*** $\Sigma = \nabla\cdot\vec{V}$ and ***field vorticity*** $\vec{\Gamma} \equiv \nabla\times\vec{V}$. For the Euler equation, we denote these functions by Σ_E and $\vec{\Gamma}_E$; they can be expressed everywhere purely in terms of the flowspeed V and its derivatives, as we show below.

3.2.1 Field source in a steady, transonic "Euler" flow

For *steady, adiabatic* flows of an ideal fluid governed by the Euler equation, conservation of stagnation enthalpy is expressed by (1).

The *isentropic relation* written as $T/T_{up} = (\varrho/\varrho_{up})^{\gamma-1}$, where the subscript "up" relates to some point upstream, is valid everywhere for a shock-free flow, or everywhere upstream of shocks in a shocked flow; in these cases we can take the freestream T_∞, ϱ_∞ as the "upstream" values. For a transonic flow, this relation is also valid along any one streamline *downstream* of a shock, but the values T_2, ϱ_2 on the downstream face of the shock for that streamline (see below) then need to be taken as the "upstream" values for the downstream part of the streamline. Thus for *any* streamline in a shock-free or shocked flow of a perfect gas we can readily obtain from (1):

$$\gamma\Re T_{up}\left(\varrho/\varrho_{up}\right)^{\gamma-1} = \frac{\gamma-1}{2}(V_{max}^2 - V^2) . \quad (6)$$

Taking the streamwise derivative of (6) in any continuous region of the flow (*i.e.* applying the operator $\hat{s}\cdot\nabla$ where $\hat{s}$ is the local unit vector of the velocity), and removing a factor $\gamma - 1$, gives:

$$\gamma\Re T_{up}\left(\frac{\varrho}{\varrho_{up}}\right)^{\gamma-2}\frac{\hat{s}\cdot\nabla\varrho}{\varrho_{up}} \equiv \gamma\Re T\,\hat{s}\cdot\nabla\varrho/\varrho$$
$$\equiv \gamma\Re T\,\frac{1}{\varrho}\frac{\partial\varrho}{\partial s} = -\,\hat{s}\cdot\nabla\tfrac{1}{2}V^2 \quad (7)$$

so that, introducing the local sonic speed a defined by $a^2 = \gamma\Re T = \frac{\gamma-1}{2}(V_{max}^2 - V^2)$, we have :

$$\frac{1}{\varrho}\frac{\partial\varrho}{\partial s} = -\frac{\hat{s}\cdot\nabla\frac{1}{2}V^2}{a^2} . \quad (8)$$

The continuity equation for steady flow is $\nabla\cdot(\varrho\vec{V}) = 0$, giving $\nabla\cdot\vec{V} = -\vec{V}\cdot\nabla\varrho/\varrho = -(V/\varrho)\,\partial\varrho/\partial s$ which, using (8) and introducing the local Mach number $M = V/a$, becomes:

$$\Sigma_E \equiv \nabla\cdot\vec{V} = \frac{V}{a^2}\,\hat{s}\cdot\nabla\tfrac{1}{2}V^2 = \frac{V^2}{a^2}\frac{\partial V}{\partial s} = M^2\frac{\partial V}{\partial s} . \quad (9)$$

The field source relation $\Sigma_E = M^2\partial V/\partial s$ is valid in any ***non-dissipative*** part of a steady flow governed by the FP or Euler equation.

Note 7: The value of the steady-state Euler field source Σ_E can also be derived from the steady-state (inviscid, non-dissipative) momentum equation, which can be expressed in the form $-\nabla p/\varrho = \nabla\frac{1}{2}V^2 + \vec{V}\times(\nabla\times\vec{V})$. Taking the scalar product of this equation with the local velocity vector $\vec{V} = V\hat{s}$ gives $-(V/\varrho)\,\partial p/\partial s = \vec{V}\cdot\nabla\frac{1}{2}V^2$. Then, since p/ϱ^γ is constant along a streamline upstream of a shock and equal to a different constant downstream of the shock, we have $\partial p/\partial s = (\gamma p/\varrho)\partial\varrho/\partial s = a^2\,\partial\varrho/\partial s$, giving $\Sigma_E = -(V/\varrho)\,\partial\varrho/\partial s = \vec{V}\cdot\nabla\frac{1}{2}V^2/a^2 = M^2\partial V/\partial s$, i.e. the expression obtained in eq (9) from the (non-dissipative) equation expressing conservation of stagnation enthalpy.

Note 8: The adiabatic (non-dissipative) shock normal-velocity jump [σ_{ad}, say] can be considered to result from traversing an infinitely dense *volume*-source distribution Σ_E representing the shock discontinuity: $\sigma_{ad} = V_{\nu 2} - V_{\nu 1} = \int\Sigma_E\,ds$. Now, under the adiabatic assumption we have from eq (1): $a^2 = \frac{\gamma-1}{2}(V_{max}^2 - V^2)$; the function $M^2\partial V/\partial s$ in (9) defining the Euler source can thus be seen to be precisely the derivative w.r.t. s of a *transcendental function* F:

$$F = \frac{1}{\gamma-1}\left(V_{max}\,\ell n\,\frac{V_{max} + V}{V_{max} - V} - 2V\right) . \quad (10)$$

Note 9: It then readily follows that the non-dissipative velocity jump σ_{ad} consistent with the non-dissipative Euler (or FP) equation must be the solution, for a given entry value $V_{\nu 1}$, of the equation:

$$\sigma_{ad} = \frac{V_{max}}{\gamma+1}\,\ell n\left(\frac{V_{max} + V_{\nu 1} + \sigma_{ad}}{V_{max} - V_{\nu 1} - \sigma_{ad}}\,\frac{V_{max} - V_{\nu 1}}{V_{max} + V_{\nu 1}}\right) . \quad (11)$$

Note 10: Equation (11) can be solved numerically, for any entry speed $V_{\nu 1}$, by using a *calculus of variations* approach or by the method discussed in Sec 5.1 ; the resulting shock jump σ_{ad} is *not* equal to the R-H value $\sigma_\nu = (r_V - 1)V_{\nu 1}$, and diverges significantly from it as V_{max} decreases (i.e. as the Mach number M_∞ increases). [**Example:** For $M_\infty = 0.5$ corresponding to $V_{max} = \sqrt{21} \approx 4.58$, and a shock-entry normal velocity of $V_{\nu 1} = 2.5\,V_\infty$ corresponding to $M_{\nu 1} = 1.4555$, the solution of (11) is $\sigma_{ad} = -1.42\,V_\infty$ while the R-H jump is $\sigma_\nu = -1.10\,V_\infty$.] The reason for this discrepancy is that in the interior of a real shock, the flow process is ***dissipative***: the shock is σ_{ad} corresponding to the non-dissipative equation used in the region of the flow does *not* correspond to the R-H jump σ_v. If the computed flow solution is to exhibit a realistic jump, the R-H value $\sigma_v = (r_V - 1) V_{v1}$ corresponding to the computed local entry value V_{v1} *must be imposed extraneously*. This is analogous to coercing an inviscid flow to satisfy the physically observed Kutta condition by extraneously supplying that model with the correct amount of "vorticity" — the amount that would be produced by the (viscous) Navier-Stokes equation under the same pressure field (see Note 6).

3.2.2 *Field vorticity in a steady, transonic "Euler" flow*

For notational simplicity, we confine our attention here to the 2-D case. Upstream of shocks, the flow is irrotational, $\vec{\Gamma} = 0$, so the local vorticity jump across a shock is the value of $\nabla \times \vec{V} = \vec{\Gamma}_g = \Gamma_g \hat{j}$ on the downstream face of the shock. Using *Crocco's theorem* and the fact that the stagnation enthalpy is constant, it can be shown (Hunt and Plybon, 1990) that the ***field vorticity*** at a point on the downstream face of the shock is given by:

$$\Gamma_2 = (1 - M_{v1}^2)\mathcal{K}_1 \sigma_v \tag{12}$$

where $\mathcal{K}_1$ is the streamline curvature at shock entry. Downstream of such a shock, the flow generally remains rotational and, assuming that dissipative processes are negligible everywhere outside shocks (inviscid, adiabatic flow) the entropy remains constant along any one streamline. The vorticity Γ_g, however, varies along a streamline in proportion to the local static pressure, p. Thus $\Gamma_g / p =$ ***constant*** $= \Gamma_2 / p_2$, or, using the relative pressure defined in (4), $\Gamma_g = \Gamma_2(p_r / p_{r2}) = \Gamma_2(T_r / T_{r2})^{\gamma/(\gamma-1)}$, where the relative temperatures T_r and T_{r2} are evaluated from (3), purely in terms of the local flowspeed V and the shock-exit speed V_2 on the same streamline.

4 NEW-GENERATION PANEL CODES FOR STEADY, COMPRESSIBLE FLOWS

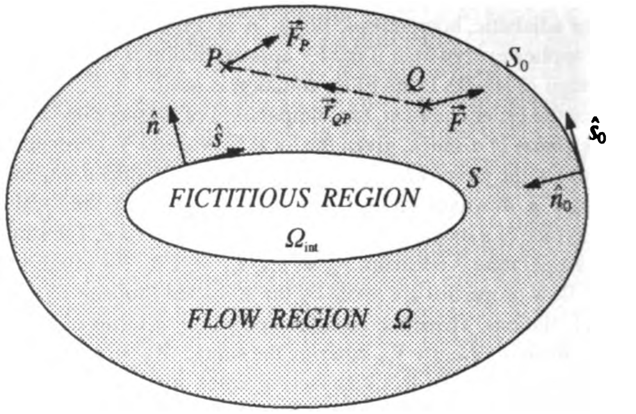
It was shown in Sec 3 that for an ideal gas flow governed by the steady-state *Euler* equation, the divergence of the velocity—interpreted as a local ***field source*** Σ_g—is given by (9). Expressions for the curl of the velocity vector—interpreted as local ***field vorticity***—for regions downstream of compression shocks, were given in Sec 3.2.2. In recent years, a number of *field-integral* methods (FIMs) have been developed for solving the *full potential* equation, both for steady flows and for unsteady flows [*e.g.* Hu and Chu (1990), Morino and Iemma (1993)]. In an FP approximation, the field vorticity is ignored, and the field source Σ_g in (9) is considered as a finite entity *inducing* a velocity perturbation. In all cases reported to date, the overall perturbation velocity has been evaluated by performing a ***field integration*** over the region of space where Σ_g has a finite value. This leads to a computational process with a large operation count, comparable to that of conventional (differential) CFD approaches. Like conventional CFD, FIMs have problems with non-physical, "non-dissipative" shock jumps [see Note 10 at the end of Sec 3.2.1]. They also suffer from the need to artificially modify the equation to be solved—rendering it *dissipative*—in order to suppress the formation of ***expansion shocks*** which would otherwise be just as likely to form as compression shocks in the absence of dissipation. Such expansion shocks, while mathematically valid, are not physically admissible in a dissipative (real) flow.

We now introduce a generalization of the full-potential FIM process to the complete steady-state *Euler* equation, and show how a mathematical framework known as GENESIS enables the *field* integrals for both source and vorticitv · ·ansformed first into *surface* integrals, and then into a si ' modification of the boundary conditions for an r) pseudo-Laplace problem. This sequence of li lved by the SAVER algorithm described in Sec

4.1 The GENESIS identity for a stationary body

4.1.1 *GENESIS for a field integral method (FIM)*

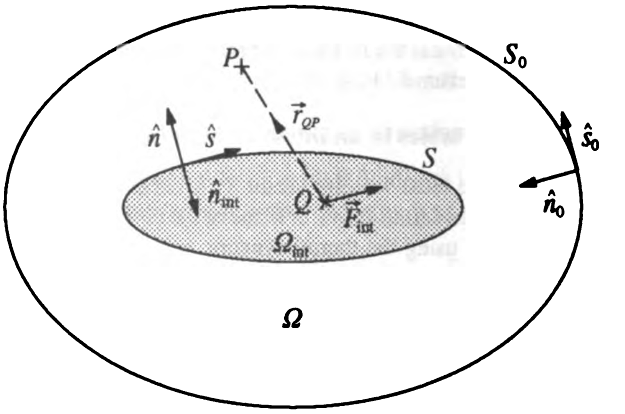
GENESIS—**GE**neralized **N**onlinear **E**xtension of **S**urface **I**ntegral **S**chemes—was first introduced in Hunt and Plybon (1990), and has continued to develop [Hunt (1991a,b), Hunt and Adamson (1992a,b,c)] towards a generalized methodology for the solution of unsteady, nonlinear, multidisciplinary problems. We here outline its basic principles for steady-state problems. First we introduce the vector *inverse-square operator* defined in 3-D by $\vec{K} = \vec{r}_{QP} / 4\pi r_{QP}^3$ (in 2-D the operator becomes $\vec{K} = \vec{r}_{QP} / 2\pi r_{QP}^2$), where $\vec{r}_{QP}$ is the line vector drawn from a running point Q to a fixed point P, with both points in a domain Ω external to a body with boundary S (see Fig 2). The outer boundary of Ω is denoted by S_0.



$$\vec{F}_P = \int_{S+S_0} (\hat{n}\cdot\vec{F})\,\vec{K}\,dS + \int_{S+S_0} (\hat{n}\times\vec{F})\times\vec{K}\,dS + \int_{\Omega} (\nabla\cdot\vec{F})\,\vec{K}\,d\Omega + \int_{\Omega} (\nabla\times\vec{F})\times\vec{K}\,d\Omega \tag{13}$$

Fig 2. Running point Q in Ω ; Fixed point P in Ω.

For any *arbitrary*, continuous vector field $\vec{F}$ in Ω, it can be shown [Hunt, 1977] that the ***identity*** (13) in Fig 2 holds for any point P in Ω, or lying on the face of its boundary S or S_0 belonging to Ω. In eq (13), the unit normal vector $\hat{n}$ at a running point Q on S or S_0 points into Ω, and the gradient operator ∇ is applied with respect to the coordinates of the running point Q.



$$0 = \int_S (-\hat{n}\cdot\vec{F}_{int})\,\vec{K}\,dS + \int_S (-\hat{n}\times\vec{F}_{int})\times\vec{K}\,dS + \int_{\Omega_{int}} (\nabla\cdot\vec{F}_{int})\,\vec{K}\,d\Omega_{int} + \int_{\Omega_{int}} (\nabla\times\vec{F}_{int})\times\vec{K}\,d\Omega_{int} \tag{14}$$

Fig 3. Running point Q in Ω_{int} ; Fixed point P in Ω.

We now consider the "fictitious" domain Ω_{int} in the interior of the body, and hypothesize an arbitrary, continuous vector field $\vec{F}_{int}$ in Ω_{int} (Fig 3). We let the running point Q now range over Ω_{int} and its boundary S, but keep the fixed point P the same as above, *i.e.* P is still in Ω, or on the face of its boundary S or S_∞ belonging to Ω. It can be shown the identity (14) in Fig 3 now holds for the interior field $\vec{F}_{int}$ in Ω_{int}, relative to the fixed point P (*external* to Ω_{int}). In eq (14), the unit normal $\hat{n}_{int}$ pointing into the *interior* domain Ω_{int} at a running point Q on S or S_∞ has been replaced by $-\hat{n}$, (see Fig 3).

Suppose we first choose *both* vectors $\vec{F}$ in Ω and $\vec{F}_{int}$ in Ω_{int} to be identical to the uniform, "unperturbed" velocity $\vec{V}_\infty$. Adding (13) and (14), with all field derivatives now zero, then gives:

$$\vec{V}_\infty = \int_{S_\infty}(\hat{n}\cdot\vec{V}_\infty)\,\vec{K}\,dS + \int_{S_\infty}(\hat{n}\times\vec{V}_\infty)\times\vec{K}\,dS . \quad (15)$$

Suppose we next keep $\vec{F}_{int} = \vec{V}_\infty$ in Ω_{int}, as above, but now let the field $\vec{F}$ in Ω be equal to the overall velocity field $\vec{V}$ comprising the sum of $\vec{V}_\infty$ and the perturbation velocity $\vec{V}_{pert}$ *induced* by the presence of the body boundary S. We assume here that the body is *stationary* and that the normal velocity of the air at the boundary S is given by $\hat{n}\cdot\vec{V} = V_{nBC}$. [For a solid body we will have $V_{nBC} = 0$, and, in the general case, the total velocity field $\vec{V}$ in Ω will be both compressible and rotational.] Adding (13) and (14) now gives:

$$\begin{aligned}\vec{V}_P = & \int_{S+S_\infty}(\hat{n}\cdot\vec{V})\,\vec{K}\,dS + \int_{S+S_\infty}(\hat{n}\times\vec{V})\times\vec{K}\,dS \\ & - \int_S(\hat{n}\cdot\vec{V}_\infty)\,\vec{K}\,dS - \int_S(\hat{n}\times\vec{V}_\infty)\times\vec{K}\,dS \\ & + \int_\Omega(\nabla\cdot\vec{V})\,\vec{K}\,d\Omega + \int_\Omega(\nabla\times\vec{V})\times\vec{K}\,d\Omega . \quad (16)\end{aligned}$$

Note that $\vec{V}\rightarrow\vec{V}_\infty$ at the outer boundary S_∞, if that boundary is sufficiently far removed from the body. Thus, using (15) and the definition $\vec{V} = \vec{V}_\infty + \vec{V}_{pert}$, we obtain from (16):

$$\begin{aligned}\vec{V}_P = \vec{V}_\infty & + \int_S(\hat{n}\cdot\vec{V}_{pert})\,\vec{K}\,dS + \int_S(\hat{n}\times\vec{V}_{pert})\times\vec{K}\,dS \\ & + \int_\Omega(\nabla\cdot\vec{V})\,\vec{K}\,d\Omega + \int_\Omega(\nabla\times\vec{V})\times\vec{K}\,d\Omega . \quad (17)\end{aligned}$$

Writing the (solid-body) boundary condition on S as $\hat{n}\cdot\vec{V}_{pert} = -\hat{n}\cdot\vec{V}_\infty + V_{nBC}$ and introducing a *fixed boundary source distribution* $\sigma = -\hat{n}\cdot\vec{V}_\infty + V_{nBC}$, we finally obtain the *GENESIS identity for compressible, rotational flow over a stationary body*:

$$\begin{aligned}\vec{V}_{P\,pert} = & \int_S\sigma\vec{K}\,dS + \int_S(\hat{n}\times\vec{V}_{pert})\times\vec{K}\,dS \\ & + \int_\Omega(\nabla\cdot\vec{V})\,\vec{K}\,d\Omega + \int_\Omega(\nabla\times\vec{V})\times\vec{K}\,d\Omega . \quad (18)\end{aligned}$$

If the total field $\vec{V}$ is *incompressible and irrotational*, (18) reduces to the identity underlying the SAVER algorithm of Sec 2:

$$\vec{V}_{P\,pert} = \int_S\sigma\vec{K}\,dS + \int_S(\hat{n}\times\vec{V}_{pert})\times\vec{K}\,dS . \quad (19)$$

- If the velocity field $\vec{V}$ is *compressible but irrotational*, (18) with $\nabla\times\vec{V} = 0$ forms the basis of a *field integral method* (FIM) for the FP equation. In a FIM, the field source Σ_s is computed *on each field-mesh cell*, using $\Sigma_s = M^2\partial V/\partial s$ (see Sec 3 .2 .1).
- For the transonic Euler equation, the field vorticity $\nabla\times\vec{V}$ in (18), (see Sec 3 .2 .2), is zero upstream of shocks but not downstream of shocks. This vorticity co-exists with the "full potential" field source Σ_s to give a FIM for the Euler equation.

Note 11: If compression shocks are allowed to form spontaneously during the iterations of the FIM, *i.e.* as a dense concentration of the *field* source Σ_s, the shock will be smeared across some number of cells of the field mesh, but even in the limit of zero cell size will *not* have the R-H jump value (see Note 10 in Sec 3 .2 .1).

Note 12: It is permissible within such a FIM to *fit* a compression shock *explicitly* as a *surface* source distribution on the shock face, with strength equal to the R-H velocity jump $\sigma_v = (r_V - 1)\,V_{v1}$ [see Sec 3 .1]. We justify this (see Note 11) by hypothesizing that the shock is contained in a "thin" but finite volume Δ, of thickness δh, say, and with a linear variation of $\vec{F}$ across that thickness, with slope equal to $\sigma_v/\delta h$. The evaluation of the volume integrals for this shock volume is performed separately from those for the smooth regions outside the shock. In the limit as $\delta h\rightarrow 0$, the volume integral $\int_\Delta(\nabla\cdot\vec{V})\,\vec{K}\,d\Delta$ relating to the "Rankine-Hugoniot" *volume* source distribution within the shock can be replaced exactly by the surface integral $\int_{S_{sh}}\sigma_v\vec{K}\,dS_{sh}$ over the shock surface S_{sh}. The contribution from the volume integral $\int_\Delta(\nabla\times\vec{V})\times\vec{K}\,d\Delta$ for the shock vorticity vanishes if we assume that the velocity component tangential to the shock is continuous across the shock. [The contribution from the shock footprint, of width δh on the body surface S, also vanishes.]

4 .1 .2 *Transformation of field integrals to boundary form*

With again $\sigma = V_{nBC} - \hat{n}\cdot\vec{V}_\infty$, we can express (18) in the form:

$$\vec{V}_{P\,pert} = \vec{V}_{FP} + \int_S\sigma\vec{K}\,dS + \int_S(\hat{n}\times\vec{V}_{pert})\times\vec{K}\,dS \quad (20)$$

where $\vec{V}_{FP}$ is the *nonlinear field-induced velocity perturbation*:

$$\vec{V}_{FP} = \int_\Omega(\nabla\cdot\vec{V})\,\vec{K}\,d\Omega + \int_\Omega(\nabla\times\vec{V})\times\vec{K}\,d\Omega . \quad (21)$$

Suppose we are able to *construct* a field $\vec{F}$ such that throughout Ω:

$$\nabla\cdot\vec{F} = \nabla\cdot\vec{V} \quad \text{and} \quad \nabla\times\vec{F} = \nabla\times\vec{V} . \quad (22)$$

Then we will have, using (13):

$$\begin{aligned}\vec{V}_{FP} & = \int_\Omega(\nabla\cdot\vec{F})\,\vec{K}\,d\Omega + \int_\Omega(\nabla\times\vec{F})\times\vec{K}\,d\Omega \\ & = \vec{F}_P - \int_{S+S_\infty}(\hat{n}\cdot\vec{F})\,\vec{K}\,dS - \int_{S+S_\infty}(\hat{n}\times\vec{F})\times\vec{K}\,dS . \quad (23)\end{aligned}$$

If we choose to construct the field $\vec{F}$ such that $\vec{F}\rightarrow 0$ sufficiently quickly as the outer boundary S_∞ is approached, the contribution from the boundary integrals over S_∞ will evaluate to zero at P. Suppose further that we introduce on the body boundary S the boundary functions σ_F and $\vec{\omega}_F$ defined by:

$$\sigma_F = -\hat{n}\cdot\vec{F} \quad \text{and} \quad \vec{\omega}_F = -\hat{n}\times\vec{F} . \quad (24)$$

We designate $\vec{F}$ an "*equivalent vector field*", and σ_F and $\vec{\omega}_F$ "*equivalent boundary source and vorticity distributions*": on the basis of (21) and (23) they are *equivalent* to the actual field functions $\nabla\cdot\vec{V}$ and $\nabla\times\vec{V}$. For points P lying on S we can now write $\vec{F}_P = -\sigma_{FP}\,\hat{n} - \vec{\omega}_{FP}\times\hat{n}$. Thus (23) becomes:

$$\begin{aligned}\vec{V}_{FP} & = \int_S\sigma_F\vec{K}\,dS + \int_S\vec{\omega}_F\times\vec{K}\,dS + \vec{F}_P \\ & = \int_S\sigma_F\vec{K}\,dS + \int_S\vec{\omega}_F\times\vec{K}\,dS - \sigma_{FP}\,\hat{n} - \vec{\omega}_{FP}\times\hat{n} \quad (25)\\ & \qquad \textit{when } P \textit{ lies on } S.\end{aligned}$$

Thus the *field* integrals defining the nonlinear field-induced perturbation in (21) can be replaced by the *surface* integrals [plus local contribution $\vec{F}_P$] in (25). Putting (25) in (20) and rearranging gives:

$$\vec{V}_{P\,pert} - \vec{F}_P = \int_S(\sigma + \sigma_F)\vec{K}\,dS + \int_S(\hat{n}\times\vec{V}_{pert} + \vec{\omega}_F)\times\vec{K} \quad (26)$$

or, finally, the ***equivalent pseudo-Laplace problem***:

$$\vec{V}'_{P\,\text{pert}} = \int_S \sigma' \vec{K}\, dS + \int_S (\hat{n}\times\vec{V}'_{\text{pert}})\times\vec{K}\, dS = \int_S \sigma' \vec{K}\, dS + \int_S \vec{\omega}'\times\vec{K}\, dS \tag{27}$$

where we have introduced the notation:

$$\vec{V}'_{\text{pert}} = \vec{V}_{\text{pert}} - \vec{F}$$
(pseudo-Laplace perturbation velocity)

$$\sigma' = \sigma + \sigma_F = -\hat{n}\cdot\vec{V}_\infty + V_{nBC} + \sigma_F \tag{28}$$
(fixed, given σ_F)

$$\vec{\omega}' = \hat{n}\times\vec{V}_{\text{pert}} + \vec{\omega}_F = \hat{n}\times\vec{V}'_{\text{pert}}$$
(to be determined by relaxation).

Equation (27), representing the compressible/rotational field problem, is formally identical to the SAVER identity (19) representing the linear "Laplace" (incompressible, irrotational) problem. Thus, to summarize, in order to solve the nonlinear Euler equation:

- We *construct* a vector field $\vec{F}$ in Ω, with $\vec{F}\to 0$ sufficiently quickly as the outer boundary S_∞ is approached, and such that $\nabla\cdot\vec{F} = \nabla\cdot\vec{V}$ and $\nabla\times\vec{F} = \nabla\times\vec{V}$ throughout Ω, these field functions being defined for the nonlinear Euler equation, purely from the computed $\vec{V}$, as in Secs 3 .2 .1 and 3 .2 .2 .
- The *pseudo-Laplace problem* (27), which is a transformation of the general nonlinear form (18), is solved by first fixing the surface source on S as $\sigma' = -\hat{n}\cdot\vec{V}_\infty + V_{nBC} + \sigma_F$ [*i.e.* the normal-velocity boundary condition for the pseudo-Laplace problem is that of the physical problem augmented by the ***boundary-condition increment*** $\sigma_F = -\hat{n}\cdot\vec{F}$]. The surface vorticity $\vec{\omega}'$ is then obtained by SAVER, coercing $\vec{\omega}'$ at each iteration to be equal to the currently computed value $\hat{n}\times\vec{V}'_{\text{pert}}$.
- At convergence, the *nonlinear* velocity field is given by $\vec{V} = \vec{V}_\infty + \vec{V}'_{\text{pert}} + \vec{F}$, with $\vec{V}'_{\text{pert}}$ the solution of the pseudo-Laplace problem (27); in particular, in the 2-D case the tangential velocity at a point P on the boundary is given by :
$$V_{sP} = V'_{sP} - \omega_{FP} \,. \tag{29}$$
- During the iteration, the unconverged values V_{sP} are used to update the Euler field source $\nabla\cdot\vec{F} = \nabla\cdot\vec{V}$ and vorticity $\nabla\times\vec{F} = \nabla\times\vec{V}$ defined by (9) and (12). These values are then used to construct the next estimate of the vector field $\vec{F}$ in Ω. The overall cycle defined above is repeated to convergence.
- Three different ways of constructing $\vec{F}$, either nominally exactly or approximately, are outlined in Sec 5 below. Note that a discontinuous $\vec{F}$ can be constructed such that no explicit source-sheet representation of a shock is required: even this can be represented fully by "equivalent" surface distributions on S.
- In the case of lifting configurations, the overall surface S carrying the "equivalent" boundary source and vorticity distributions also includes the vortical wake surface(s) emanating from the body. These wakes may either be assumed to be "rigid" (pre-defined location), or they may need to be "relaxed" to their rolled-up, force-free position (Hunt, 1978).

5 CONSTRUCTION OF THE EQUIVALENT FIELD $\vec{F}$

The construction of a vector field $\vec{F}$ whose divergence and curl match those of the physical field, either approximately or nominally exactly, is fundamental to GENESIS. In the case of an *unbounded domain* Ω with outer boundary S_∞ at infinity, it is convenient to construct $\vec{F}$ such that $\vec{F}\to 0$ sufficiently quickly as S_∞ is approached; this extra condition is no[illegible] a bounded domain (internal flows). Only unbounde[illegible] considered here.

Three distinct methods have been devised for the construction of the equivalent vector field $\vec{F}$.

The **Semi-Analytic Method** is outlined in Sec 5 .1 . This method is *approximate*: it introduces a new field, called the semi-analytic field, which is "close to" but different from the Euler field. The Semi-Analytic Method reduces the flowfield problem to a set of local, multi-valued, algebraic equations with a clear distinction between subsonic and supersonic *local candidate solutions*: this enables compression shocks to be modeled as exact discontinuities, and expansion shocks to be explicitly suppressed from the solution. This method involves no field evaluations: *all* computations are performed on the body boundary. The error field (the difference between the semi-analytic field and the Euler field), can be reduced or eliminated by one of the other two methods described below.

The **Uncurling Method** evaluates the *field functions* Σ_E and $\vec{\Gamma}_E$ of Secs 3 .2 .1 and 3 .2 .2 on a *field mesh* covering the region of Ω where those functions are non-zero. "Uncurling" then reduces these to an equivalent field vector $\vec{F}$, and then to boundary source σ_F and vorticity $\vec{\omega}_F$ — no field *integrals* are evaluated. The Uncurling Method, outlined in Sec 5 .2 , is *nominally exact*: the computed result approaches the exact Euler solution as the field mesh is refined.

The **Profile Method** computes the exact Euler field values Σ_E and $\vec{\Gamma}_E$ *on the boundary* S, but *approximates* their functional variation along lines drawn outwards from S, using shape functions with pre-defined profile shape. The equivalent field vector $\vec{F}$ is evaluated on S as the solution of an *ordinary* (vector) differential equation expressed on S. This solution is formed piecewise as the sum of a particular integral and a complementary function, and is effected through the use of combined *marching* and *shooting* techniques; this forces continuity of $\vec{F}$ between the beginning and end of the marching range, but allows a shock to be treated anywhere in the range as an exact discontinuity with the physical (R-H) jump condition. With this method, *all* computations are performed on the body boundary.

Both the Profile Method and the Uncurling Method can be applied either to solve the complete Euler field, or to eliminate the error field arising from application of the Semi-Analytic Method.

5 .1 The Semi-Analytic Method

The Semi-Analytic Method for the construction of the equivalent field $\vec{F}$ was developed specifically to deal with the difficult problems associated with shock waves and the mixed elliptic/hyperbolic equation types arising in transonic flows. It is an approximate method, generally requiring correction by the Uncurling Method of Sec 5 .2 or the Profile Method of Sec 5 .3 . Numerous variants of the Semi-Analytic Method are possible (Hunt and Adamson, 1992a), all based on identifying a suitable ***perfect (vector) differential function***. The variant described here is known as the **D-Field** approximation. We consider only the 2-D case in a cartesian x, z system with unit vectors $\hat{i}, \hat{k}$; the extension to 3-D is straightforward.

In the D-Field, the local flowspeed V is replaced by its x-component $U = \hat{i}\cdot\vec{V}$, and its streamwise derivative is replaced by an x-derivative. The Euler source $\Sigma_E = M^2\partial V/\partial s$ is thus approximated by the *D-Field source* $\Sigma_D = M_D^2\partial U/\partial x$, where M_D is the *D-Mach number* defined by $M_D = U/a_D$. Here, a_D is the *D-sonic speed* defined by $a_D^2 = \frac{\gamma-1}{2}(V_{\max}^2 - U^2)$, approximating the Euler sonic speed given earlier by $a^2 = \frac{\gamma-1}{2}(V_{\max}^2 - V^2)$. Moreover, the Euler field vorticity $\vec{\Gamma}_E$ is replaced in the D-Field by a ***spurious vorticity*** $\vec{\Gamma}_D = \Gamma_D\hat{j}$, defined by $\Gamma_D = M_D^2\partial U/\partial z$. The purpose of introducing this spurious vorticity is to allow an equivalent vector field $\vec{F}_D$ to be constructed *analytically* as a perfect differential function.

5.1.1 *The perfect differential defining the D-Field*

Consider the vector field function $\vec{F}_D$ defined by:

$$\vec{F}_D = F_D(U)\,\hat{i} \qquad \text{with} \qquad F_D(U) = \lambda(U) + \lambda_\infty \tag{30}$$

$$\text{where} \quad \lambda(U) = \frac{2}{\gamma - 1}\left[V_{max}\, \ell n \sqrt{\frac{V_{max} + U}{V_{max} - U}} - U \right]$$

$$\text{and} \quad \lambda_\infty = \frac{2}{\gamma - 1}\left[V_{max}\, \ell n \sqrt{\frac{V_{max} - U_\infty}{V_{max} + U_\infty}} + U_\infty \right].$$

It is easy to show that $\partial F_D/\partial U = \partial\lambda/\partial U = M_D^2$, from which it immediately follows that the divergence and curl of $\vec{F}_D$ are respectively the functions Σ_D and $\vec{\Gamma}_D$ defined above. It can also readily be seen that $F_D(U) \to 0$ as $U \to U_\infty$, *i.e.* on the outer boundary S_∞.

For a solid body with local unit normal $\hat{n} = n_x\hat{i} + n_z\hat{k}$ and tangent $\hat{s} = \hat{j}\times\hat{n} = n_z\hat{i} - n_x\hat{k}$, the vector velocity on S must satisfy $\vec{V} = V_s\,\hat{s}$, so that $U = n_z V_s$. From (24) and (30) we have $\omega_F = -n_z F_D$. Finally, from (24) and the relation $\vec{V}'_{pert} = \vec{V}_{pert} - \vec{F}$ in (28), we deduce in the 2-D case that $V_s = V'_s - \omega_F$. Combining these equations for U, V_s and ω_F gives the following nonlinear (*transcendental*) equation at a point on S:

$$U - n_z^2 F_D(U) = U' \tag{31}$$

where U' is defined by $U' = n_z V'_s$. [This is *not* the x-component of the pseudo-Laplace velocity $\vec{V}'_s$ since the normal component V'_n in the equivalent pseudo-Laplace problem is not in general zero.]

Equation (31), giving the value of the nonlinear velocity component U as an implicit function of the pseudo-Laplace quantity U' for given values of n_z and V_{max}, is termed the ***D-equation***. The generic graph of the D-Equation for some point P is shown in Fig 4. Only the physically relevant part of this graph is shown—there are other, non-physical branches corresponding to values of U greater than the maximum possible value V_{max}. We also consider here only positive values of U, thus limiting the present discussion to *attached* flows (this is *not* a necessary assumption). One of the key processes in the GENESIS algorithm is solving (31) for U at each point on S, given the current estimate of U'. A method of solution is outlined in Sec 5.1.4, but first we need to address the problem of the *existence* or "*feasibility*" of solutions of (31) at every point on the boundary.

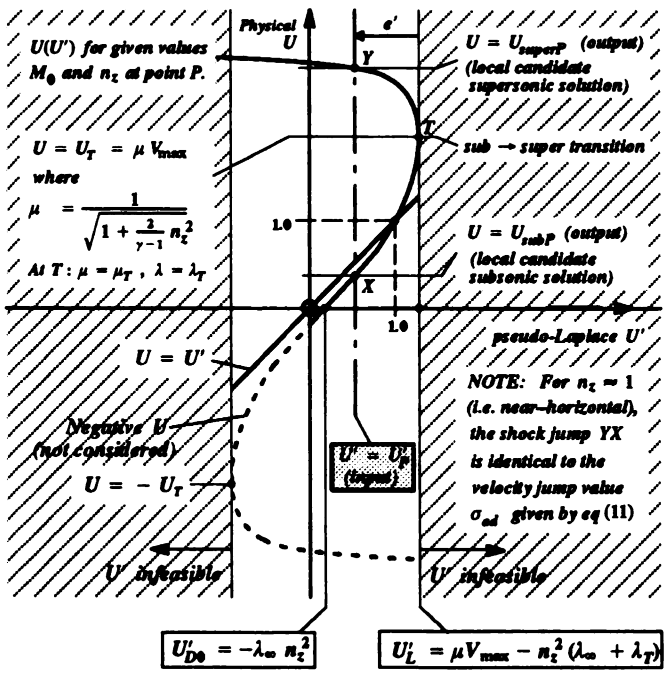


Fig 4. Generic graph of the D-Equation.

We see from Fig 4 that a solution U of the D-Equation can exist at a point P only for a pseudo-Laplace value U' which is less than a ***local limit value*** U'_L. For given values n_z and V_{max}, it can easily be shown that, at this limit value of U', the corresponding "D-critical" value U_T of U [indicated by T on Fig 4; see also Note 14 below] is given by $U_T = \mu V_{max}$, where μ is a local *geometric* constant: $\mu = \left(1 + \frac{2}{\gamma-1}n_z^2\right)^{-1/2}$. Inserting $U = U_T$ into (30) and (31) gives the *maximum feasible value* (limit value) of U' at P as:

$$U'_L = \mu V_{max} - n_z^2(\lambda_\infty + \lambda_T) \tag{32}$$

$$\text{where} \quad \lambda_T(V_{max}, n_z) = \frac{2}{\gamma - 1} V_{max}\left[\ell n \sqrt{\frac{1+\mu}{1-\mu}} - \mu \right].$$

It is convenient to consider the pseudo-Laplace tangential velocity V'_s as the sum of the "Laplace" tangential velocity and a *tangential velocity increment* associated with the nonlinearity of the D-Field, as represented by the equivalent distributions σ_F and $\vec{\omega}_F$ defined in (24). We denote by V'_{sA} the *unperturbed Laplace solution* [*i.e.* the local tangential velocity obtained by SAVER with $\sigma_F = 0$ in (24)], and by V'_{sF} the ***field-induced increment*** in the pseudo-Laplace tangential velocity when the finite ("compressible") value defined by (24) is used for σ_F:

$$V'_{sF} = V'_s - V'_{sA}. \tag{33}$$

Thus the x-component of the tangential velocity increment [*i.e.* multiplying (33) by n_z] is given by:

$$U'_F = U' - U'_A. \tag{34}$$

From the definition of the local limit value U'_L in (32), it follows that the *local maximum-feasible increment* in the pseudo-Laplace solution, *due to the boundary-condition increment* σ_F, is given by:

$$U'_{FL} = U'_L - U'_A. \tag{35}$$

Note 13: For a given "shape" of the distribution F_D evaluated on S, the local increment U'_F in (34) is *proportional* at any point P to the value of $\sigma_F = -n_x F_D$ at that point: if we scale the entire distribution F_D (and thus σ_F) by a constant factor, r_T say, the entire distribution U'_F will scale by that same factor. This follows from the linear nature of the pseudo-Laplace field. Thus, given the values F_D and U'_F at a particular point, we can write a **proportionality relation** at that point:

$$\partial U'_F/\partial F_D = K = U'_F/F_D. \tag{36}$$

Note 14: The "D-critical" value U_T defined earlier as $U_T = \mu V_{max}$, with $\mu = \left(1 + \frac{2}{\gamma-1}n_z^2\right)^{-1/2}$, reduces for a horizontal local boundary (i.e. $n_z^2 = 1$) to $U_T = \sqrt{\frac{\gamma-1}{\gamma+1}}\,V_{max}$; this is identical to the **critical speed** for the Euler equation, at which the local Mach number has unit value. This justifies the use of the term "D-critical."

5.1.2 *The exceedance parameter defining the flow state*

It is now convenient to introduce the concept of a local exceedance e', defined at a particular point by:

$$e' = U'_F - U'_{FL} \equiv U' - U'_L. \tag{37}$$

We denote by e'_T the *maximum* value of e' found on the body boundary during a particular iteration [*i.e.* the most positive value detected in the pseudo-Laplace computation: $e'_T = \mathbf{max}(e')$]. Suppose that this maximum is detected at a point P_T.

Except for P_T, there will be *two* relevant can[illegible] [illegible]lutions for U at each point P. These are a ***candidate*** [illegible] [illegible]n U_{sub}

(marked as X in Fig 4) and a ***candidate supersonic solution*** U_{sup} (marked as Y). At P_T, these two candidate solutions will coincide exactly, both being equal to the local D-sonic (D-critical) speed at that point: the point T on Fig 4 thus corresponds to a point of *continuous transition between D-subsonic and D-supersonic states.*

The value of the maximum exceedance e'_T ***defines the global state of the nonlinear flow***. Three possibilities exist for the value of the maximum exceedance: $e'_T = 0$ [*i.e.* $U' = U'_L$ at one or more points on S, implying the limit of global feasibility] ; $e'_T < 0$ [*i.e.* $U' < U'_L$ everywhere, implying global feasibility]; $e'_T > 0$ [*i.e.* $U' > U'_L$ at one or more points, implying global infeasibility].

- If $e'_T = 0$ when the subsonic candidate U_{sub} is taken at all points, the flow is ***subsonic D-critical, sonic at*** P_T. We call the unique freestream Mach number at which this condition occurs, the "*subsonic D-critical Mach number*", $M^*_{D_{sub}}$.
- If $e'_T = 0$ when the supersonic candidate U_{sup} is taken at all points, the flow is ***supersonic D-critical, sonic at*** P_T. We call the unique freestream Mach number at which this condition occurs, the "*supersonic D-critical Mach number*", $M^*_{D_{sup}}$.
- If $e'_T = 0$ when the solution has candidates of both types, arranged quasi-physically, it is a ***feasible D-transonic flow***.
- If $e'_T < 0$ when U takes its subsonic candidate value at every boundary point, the flow is ***fully D-subsonic***.
- If $e'_T < 0$ when U takes its supersonic candidate value at every boundary point, the flow is ***fully D-supersonic***.
- If $e'_T > 0$ (*i.e.* $U' > U'_L$ at one or more points), the overall flow is ***infeasible***, and some adjustment is needed to the underlying hypotheses: this is discussed in Sec 5 .1 .3 .

Note 15: The physics of a real flow requires that a transition from a subsonic state to a supersonic state be *smooth* (no expansion shock).

Note 16: A transition from a supersonic to a subsonic state will usually (but not always) occur through a discontinuity. (There is the possibility of a shock-free transonic flow.)

Note 17: The difference XY in Fig 4 between the D-subsonic and D-supersonic candidate solutions at a point with horizontal surface tangent ($n_z^2 = 1$) is equal to the "adiabatic shock jump" obtained by an alternative method in Note 10 in Sec 3 .2 .1 .

Note 18: As discussed earlier, the Euler equation lacks the dissipative mechanisms needed to suppress the formation of (non-physical) expansion shocks. The extraneous enforcement of smoothness through a D-sonic point P_T — only for a subsonic-to-supersonic transition, and the logic governing the choice of candidate (Sec 5 .1 .4), justify the use of the term "knowledge-based" for the semi-analytic GENESIS approach described here.

5 .1 .3 Scaling of infeasible flows

As indicated in Sec 5 .1 .2 , the *entire pseudo-Laplace solution* is considered to be *infeasible* if for *any* boundary point the computed field-induced increment $U'_F = n_z V'_{tF}$ exceeds its local maximum-feasible value U'_{FL} , *i.e.* if $e'_T > 0$. If this occurs, some adjustment needs to be made to the parameters defining the pseudo-Laplace problem; specifically, some adjustment to the boundary-condition increment $\sigma_F = -n_x F_D$, and thus to F_D , is needed. The required change in e'_T [*i.e.* the *reduction* required in U'_F at the maximum-exceedance (D-sonic) point P_T to make the pseudo-Laplace solution "feasible"] is clearly equal to $-e'_T$. The determination of the corresponding adjustment needed for F_D is based on the "proportionality" relation (36) presented above. At P_T, (37) and (36) become:

$$e'_T = U'_{FT} - U'_{FL} \equiv U'_T - U'_L \quad \text{and} \quad \frac{\partial U'_{FT}}{\partial F_{[illegible]}} \; [illegible] = \frac{U'_{FT}}{F_{DT}} . \tag{38}$$

For a D-transonic solution (defined in Se[illegible] [illegible]$_{max}$ fixed (*i.e.* prescribed M_∞), the only free parameters available are the unknown shock locations. We shall not consider *shock relaxation* here, except to note that a simple technique can be envisaged, determining the sensitivity of e'_T to the shock location.

If, on the other hand, we are attempting to determine a D-critical solution as defined in Sec 5 .1 .2 , or a D-transonic solution with a single, *prescribed* shock location, we can see from (30) that the only parameter available to modify F_D, given the body geometry, is V_{max} . This is related uniquely to the freestream Mach number M_∞ through (2). Differentiating the first equation in (38) w.r.t. V_{max}, then using the second equation, gives a *sensitivity relation* at P_T :

$$\frac{\partial e'_T}{\partial V_{max}} = K_T \frac{\partial F_{DT}}{\partial V_{max}} - \frac{\partial U'_L}{\partial V_{max}} . \tag{39}$$

Introducing the parameters (written here for $U_\infty = 1$) :

$$\chi_T = \frac{2}{\gamma - 1}\left(K_T + n_{zT}^2\right), \qquad Y_\infty = \frac{1}{V_{max}^2 - 1}$$
$$B_\infty = \ln\sqrt{\left(\frac{V_{max}-1}{V_{max}+1}\right)}, \qquad \mu_T = \left(1 + \frac{2}{\gamma-1} n_{zT}^2\right)^{-1/2} \tag{40}$$
$$B_{\mu T} = \ln\sqrt{\left(\frac{1+\mu_T}{1-\mu_T}\right)} , \qquad D_{\mu T} = B_{\mu T} - \mu_T ,$$

we can show from (30), (32) and (39) that the first and second derivatives of e'_T w.r.t. V_{max} are given by :

$$\partial e'_T / \partial V_{max} = \chi_T \left(B_\infty + D_{\mu T} + V_{max} Y_\infty\right) - \mu_T$$
$$\text{and} \quad \partial^2 e'_T / \partial V_{max}^2 = -2 \chi_T Y_\infty^2 . \tag{41}$$

This allows the required change in V_{max} to drive $e'_T \to 0$ to be obtained by a first- or second-order *Newton-Raphson* iteration cycle: $V_{max} = V_{max} + \delta V_{max}$, with δV_{max} at each iteration defined by:

$$\delta V_{max} = -\eta_{01}(1 + \underbrace{\eta_{01}\eta_{21}}_{\text{2nd order term}}) . \tag{42}$$

Here η_{01} and η_{21} indicate ratios of e'_T and the derivatives in (41):

$$\eta_{01} = \frac{e'_T}{\partial e'_T / \partial V_{max}} \quad \text{and} \quad \eta_{21} = \frac{\partial^2 e'_T / \partial V_{max}^2}{\partial e'_T / \partial V_{max}} . \tag{43}$$

This cycle is iterated until V_{max} converges. At convergence, the resulting *scaled* value of U'_F at the maximum-exceedance point P_T will be precisely equal to the *new*, local limit value U'_{FL} corresponding to the converged V_{max} value. The *entire* U'_F and V'_{tF} distributions, scaled in the same ratio, r_T say, will then be "feasible". The new, "feasible" freestream Mach number is obtained from (2) as:

$$M_\infty = \left(\frac{\gamma-1}{2}\left(V_{max}^2 - 1\right)\right)^{-1/2} . \tag{44}$$

To determine the scaling ratio r_T, we insert the new V_{max} into (30) to obtain the "scaled" value of F_D at the point P_T. The ratio r_T of the new F_D to its previous value is then applied to (linearly) scale the entire U'_F and V'_{tF} distributions. Added to the (Laplace) U'_A distribution, the scaled U'_F gives a *globally feasible* U' distribution.

The nonlinear D-equation (31) now needs to be re-solved for the (subsonic or supersonic) value of U at each point, given this (scaled) feasible distribution U' and the new V_{max} (*i.e.* the new M_∞).

5 .1 .4 Solution of the D-Equation at each boundary point

Given V_{max} and a *feasible* estimate of the pseudo-Laplace U' distribution (*i.e.* one which nowhere exceeds its local maximum feasible value U'_L), we need to evaluate the subsonic candidate solution U_{sub} or the supersonic candidate solution U_{sup} at every point on the body boundary. These are distinct roots of the nonlinear (transcendental) D-equation (31) at each point, with F_D defined by (30).

The choice of which root to select at each boundary point is a *knowledge-based* decision. If the flow is fully D-subsonic, as defined in Sec 5.1.2, the subsonic root should always be taken. If the flow is D-transonic, the supersonic root should be taken for points lying downstream of a D-sonic (maximum-exceedance) point P_T but upstream of a compression shock; all other points take the subsonic root. The choice of root at a particular point may vary as the iteration proceeds and the location identified for P_T varies.

GENESIS uses a 2nd-order *Newton-Raphson* scheme to solve (31) for U_{sub} or U_{sup} at each point, given the pseudo-Laplace distribution U'. The ***initial estimate*** of U to start the iteration depends on the local U' value, and is determined adaptively, as follows.

If U' is close to its local limit value U'_L [Fig 4], then U will be close to its D-sonic value $U_T = \mu V_{max}$; a function of the form $U = U_T(1+\Delta)$ is therefore used to give an initial estimate of U. Replacing U in (30) by this form and inserting in (31) allows a power-series expansion about point T in Fig 4 to be developed, relating Δ implicitly to a *proximity parameter* $\Delta' = e'/U_T$, where e' is the exceedance parameter defined by (37). The assumption that Δ is small allows the series to be inverted, giving Δ explicitly as a simple function of Δ'. We take $\Delta > 0$ to get U_{sup}, otherwise $\Delta < 0$.

If the proximity parameter Δ' is not small, the linear approximant $U = U' - U'_{D*}$ is instead used as initial estimate, with the origin shift U'_{D*} defined by $U'_{D*} = -\lambda_\infty n_\zeta^2$ as shown in Fig 4.

Starting from this initial estimate, the Newton-Raphson iteration is defined by $U = U + \delta U$, with δU defined at each iteration by:

$$\delta U = -\eta_{01}(1 + \underbrace{\eta_{01}\eta_{21}}_{\text{2nd order term}}) \tag{45}$$

with now:

$$\eta_{01} = \frac{n_\zeta^2 F_D - U + U'}{\eta_1} \quad \text{and} \quad \eta_{21} = \frac{\gamma - 1}{2}\,\frac{U}{\eta_1}\left(\frac{n_\zeta V_{max}}{a_D^2}\right)^2 \tag{46}$$

in which $\eta_1 = (n_\zeta U)^2/a_D^2 - 1$ and $a_D^2 = \frac{\gamma-1}{2}(V_{max}^2 - U^2)$, with F_D defined by (30) using the current estimate of U. The adaptive initialization described above ensures that U_{sub} or U_{sup} at each point is obtained to machine precision in two or three iterations, for a given U' distribution. At convergence, the nonlinear D-Field tangential velocity is obtained from the pseudo-Laplace solution, using (29).

5.1.5 *Example solution of the D-Field*

A transonic solution of the D-Field for a non-lifting NACA0012 airfoil, obtained numerically by the GENESIS Semi-Analytic Method, is shown in Fig 5 below. The figure also shows the subsonic D-critical solution and the linear (Laplace) solution $V'_{\zeta A}$.

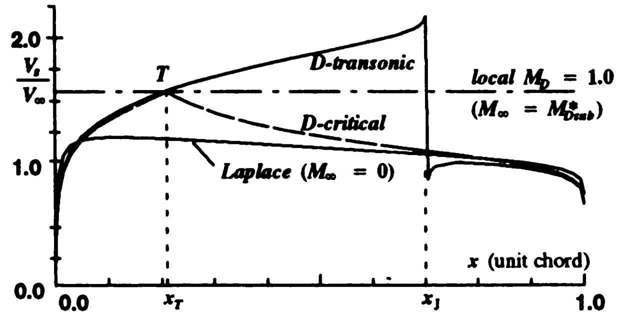

Fig 5. NACA0012, α = 0, D–Field. No correction for spurious vorticity

Note that *no correction* for the spurious vorticity $\Gamma_D = M_D^2 \partial U/\partial z$ implicitly present in the D-Field has been applied in Fig 5: without correction, this solution can therefore *not* be interpreted as an accurate Euler solution. Generally, a correction needs to be incorporated within the Semi-Analytic Method to annihilate the spurious vorticity. Two corrective methods are discussed in their own right in Secs 5.2 and 5.3, and then as part of a composite method in Sec 5.4.

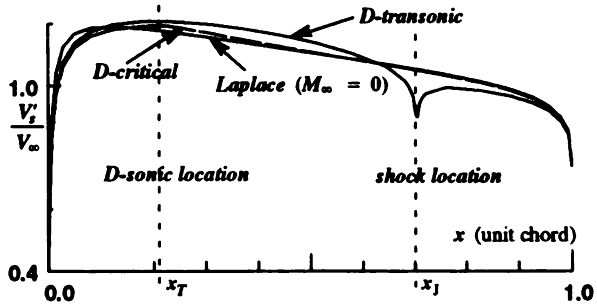

Fig 6. Pseudo–Laplace solution V'_ζ for D–Field, before application of the correction $-\omega_F$

The *pseudo-Laplace solution* corresponding to Fig 5 is shown in Fig 6. It can be seen from Fig 6 that the D-critical pseudo-Laplace solution lies close to the actual Laplace solution $V'_{\zeta A}$, and that even the transonic pseudo-Laplace solution itself is relatively close. Most of the difference between the nonlinear solutions in Fig 5 comes from (29), *i.e.* the final application of the tangential correction $-\omega_F$. The small departure of the pseudo-Laplace solution from the actual Laplace solution is responsible for the rapid convergence characteristics demonstrated by the GENESIS Semi-Analytic Method. In fact, a relatively good result is obtained for D-Field in the *first iteration* of the overall algorithm [*i.e.* starting with the *Laplace* value $U'_A = n_\zeta V'_{\zeta A}$ for U in (30)], with complete convergence generally in about three or four iterations. The results shown here were obtained in about one second of CPU time on a 486 personal computer, using a non-optimized pilot code written in ADA.

5.2 The Uncurling Method

"Uncurling" offers a ***nominally exact*** means of constructing an equivalent field $\vec{F}$, given the Euler values Σ_E and $\vec{\Gamma}_E$ of Secs 3.2.1 and 3.2.2 on a *field mesh* external to the body. The process is outlined here for the 2-D case. We suppose that Σ_E and $\vec{\Gamma}_E = \Gamma_E \hat{j}$ are known at each corner point × on the "active mesh" shown cross-shaded in Fig 7, and are numerically zero everywhere outside that mesh (*e.g.* on the "passive" and "polar" meshes shown in the figure).

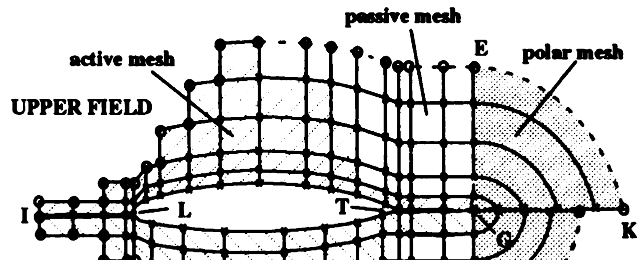

Fig 7. Active, passive and polar meshes used for the (nominally-exact) Uncurling Method.

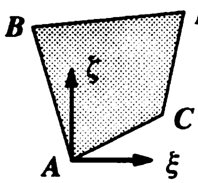
A generic cell of *arbitrary* shape is shown in Fig 8. The values of Σ_E and Γ_E are known at its four vertices. From these eight values, *bilinear approximations* $\Sigma(\xi,\zeta)$ and $\Gamma(\xi,\zeta)$ shown in (47) can be derived for this cell, using local cartesian coordinates ξ and ζ measured from corner A [*e.g.*, a least-squares fit could be used]. These bilinear functions will *not* generally match the 8 known corner values precisely, as only 6 coefficients are available. The functions Σ

and Γ will thus display slight discontinuities across cell boundaries, but the error will decrease continuously as the cell size is reduced.



$$\Sigma(\xi,\zeta) = \Sigma_A + \Sigma_X \xi + \Sigma_Z \zeta \approx \Sigma_B(\xi,\zeta)$$
$$\Gamma(\xi,\zeta) = \Gamma_A + \Gamma_X \xi + \Gamma_Z \zeta \approx \Gamma_B(\xi,\zeta) \qquad (47)$$

Fig 8 . Generic cell from mesh in Fig 7 .

From $\Sigma(\xi,\zeta)$ and $\Gamma(\xi,\zeta)$, the uncurling process constructs an equivalent vector field $\vec{F}$ cell-by-cell on the compound mesh shown in Fig 7 (active, passive and polar meshes), such that:

- $\nabla\cdot\vec{F} = \Sigma(\xi,\zeta)$ and $\nabla\times\vec{F} = \Gamma(\xi,\zeta)\,\hat{j}$ *exactly*, on every cell;
- $\vec{F}$ is *continuous* across cell boundaries (but see Note 20 below);
- $\vec{F}$ is *zero* on the outer edge of the mesh (circles in Fig 7).

We construct $\vec{F}$ as a piecewise *bi-quadratic* vector field. For the generic cell in Fig 8 , we use the bi-quadratic vector representation:

$$\vec{F}(\xi,\zeta) = \vec{F}_A + \vec{F}_{X1}\,\xi + \vec{F}_{X2}\,\xi^2 + \vec{F}_{Z1}\,\zeta + \vec{F}_{Z2}\,\zeta^2 + \vec{F}_{XZ}\,\xi\zeta \quad (48)$$

Six vector coefficients are needed in this equation (*i.e.* the 12 scalar values F_{Ax}, F_{Az}, F_{X1x}, F_{X1z}, F_{X2x}, F_{X2z}, F_{Z1x}, F_{Z1z}, F_{Z2x}, F_{Z2z}, F_{XZx}, F_{XZz} for this cell). Now *six* scalar values defining $\vec{F}$ at three of the cell corners (say, A, B and C) will be known, either from adjacent cells computed earlier, or from $\vec{F}=\mathbf{0}$ at the outer edge of the mesh; six further scalar equations are thus needed. These are obtained by matching the coefficients of $\nabla\cdot\vec{F}$ and $\nabla\times\vec{F}$ obtained from (48) with those in (47). For example, we have:

$$\nabla\cdot\vec{F}(\xi,\zeta) = (F_{X1x} + F_{Z1z}) + (2F_{X2x} + F_{XZz})\,\xi + (2F_{Z2z} + F_{XZx})\,\zeta$$
$$\text{and } \Sigma(\xi,\zeta) = \quad \Sigma_A \quad + \quad \Sigma_X\,\xi \quad + \quad \Sigma_Z\,\zeta \qquad (49)$$

giving three of the extra six equations needed :

$$F_{X1x} + F_{Z1z} = \Sigma_A\ ; \qquad 2F_{X2x} + F_{XZz} = \Sigma_X\ ;$$
$$\text{and} \quad 2F_{Z2z} + F_{XZx} = \Sigma_Z\ . \qquad (50)$$

The three final equations result from equating the coefficients of $\nabla\times\vec{F}$ and $\vec{\Gamma}$. Solving the resulting set of 12 independent, linear equations gives the desired coefficients for (48). The value of $\vec{F}$ at the fourth corner of the cell, D say, then follows immediately.

This "cartesian uncurling" process constructs $\vec{F}$ starting from the first cell in the active mesh to the last cell in the passive mesh [in which Σ_A, Σ_X, Σ_Z, Γ_A, Γ_X, Γ_Z in (47) are all zero]. The upper and lower fields are uncurled separately. The equivalent surface source σ_F and vorticity $\vec{\omega}_F$ [eq (24)] are located on the body surface ***LT*** (Fig 7), its extensions ***IL*** and ***TG***, and the vertical plane ***EGH***.

An analogous "polar uncurling" process constructs a vector field $\vec{F}$ on the cylindrical polar mesh (shown shaded in Fig 7), starting from the values obtained on the vertical plane ***EGH*** by the cartesian uncurling process described above. In this polar mesh region both $\nabla\cdot\vec{F}$ and $\nabla\times\vec{F}$ would here be taken as zero, though finite values could also be used. This process effectively transfers the equivalent distributions σ_F and $\vec{\omega}_F$ from ***EGH*** to the horizontal surface ***GK***.

Note 19: The *symbolic matrix* defining the 12 linear equations to be solved on each cell can be inverted *analytically*, though the algebra is somewhat tedious. If this symbolic inverse is available, the computational work involved in constructing the field over the entire mesh would be relatively small. If the symbolic inverse is not available, a numerical matrix for each set of 12 equations, i.e. for each cell, would in general need to be inverted separately. However, if the mesh used has all cells geometrically identical (for example, square cells), the numerical matrix needs to be inverted only once. This would offer an efficient means of solution for the entire mesh.

Note 20: The uncurling process can be applied to solve the complete Euler equations, nominally exactly. If shock waves are present (see Note 12), they can be considered to be contained within cells of infinitesimal width, coinciding with cell boundaries. Instead of $\vec{F}$ being transmitted *continuously* from one cell to its neighbor downstream, the R-H discontinuity can then be applied at the cell interface. By this means, the shock-wave discontinuity is transmitted entirely to the body boundary, and will appear as a discontinuity in the equivalent boundary distributions — primarily $\vec{\omega}_F$.

Note 21: The uncurling process can alternatively be applied to eliminate an error field associated with the use of a less accurate method. Two such methods are the Semi-Analytic Method of Sec 5 .1 , and the Profile Method discussed below. If used in this way, a coarser mesh may suffice for the uncurling process, and this may need to extend only a short distance away from the body.

5 .3 The Profile Method

The Profile Method for the construction of the equivalent vector field $\vec{F}$ is an adaptation of the classical *separation of variables* approach (Hunt and Plybon, 1990). It is an *approximate* method, and can be used as an economic alternative to the Uncurling Method. The equivalent field functions $\Sigma = \nabla\cdot\vec{F}$ and $\vec{\Gamma} = \nabla\times\vec{F}$ (and possibly some number of their normal derivatives) are given the exact Euler-field values Σ_E and Γ_E *on the boundary S*. However, their functional variation along lines drawn outwards from S is *approximated* using ***decay functions*** of pre-defined profile shape, analogously to classical boundary-layer theory. Two variants have been developed: one (cartesian) uses exponential decay functions; the other (cylindrical polar) has inverse-power radial-decay functions. Only the polar profile method will be outlined here (Fig 9).

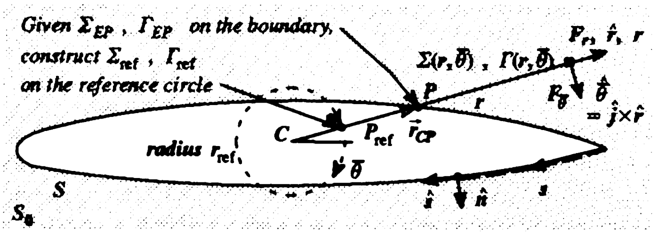


Fig 9 . Coordinate system for Polar Profile Method.

With origin C, reference radius r_{ref} and $\bar{\theta}$ measured *clockwise*, the approximating functions Σ, Γ have profiles matching Σ_E, Γ_E on S:

$$\nabla\cdot\vec{F} = \Sigma(r,\bar{\theta}) = \Sigma_{ref}(\bar{\theta})\,(r/r_{ref})^{-(p+1)}$$
$$\text{where} \quad \Sigma_{ref}(\bar{\theta}) = \Sigma_{EP}(\bar{\theta})\,(r_{CP}/r_{ref})^{(p+1)}$$
$$\text{and} \quad \nabla\times\vec{F} = \vec{\Gamma}(r,\bar{\theta}) = \vec{\Gamma}_{ref}(\bar{\theta})\,(r/r_{ref})^{-(p+1)} \qquad (51)$$
$$\text{where} \quad \Gamma_{ref}(\bar{\theta}) = \Gamma_{EP}(\bar{\theta})\,(r_{CP}/r_{ref})^{(p+1)} \quad \text{with } p = \text{constant.}$$

Suppose the equivalent field $\vec{F} \equiv F_r\,\hat{r} + F_{\bar{\theta}}\,\hat{\bar{\theta}}$ has the form :

$$F_r(r,\bar{\theta}) = F_{r\,ref}(\bar{\theta})\,(r/r_{ref})^{-p} \text{ so that } F_{rP} = F_{r\,ref}\,(r_{CP}/r_{ref})^{-p}$$
$$F_{\bar{\theta}}(r,\bar{\theta}) = F_{\bar{\theta}\,ref}(\bar{\theta})\,(r/r_{ref})^{-p} \text{ so that } F_{\bar{\theta}P} = F_{\bar{\theta}\,ref}\,(r_{CP}/r_{ref})^{-p}\ . \qquad (52)$$

The divergence and curl of $\vec{F}$ in this polar system are given by:

$$\nabla\cdot\vec{F} = \frac{1}{r}\left[\frac{\partial}{\partial r}(r\,F_r) + \frac{\partial F_{\bar{\theta}}}{\partial\bar{\theta}}\right]\ ;\ \nabla\times\vec{F} = \frac{1}{r}\left[\frac{\partial}{\partial r}(r\,F_{\bar{\theta}}) - \frac{\partial F_r}{\partial\bar{\theta}}\right]\hat{j} \quad (53)$$

Then it is easy to show that $F_{\bar{\theta}\,ref}$ and $F_{r\,ref}$ must satisfy a coupled pair of *ordinary differential equations* written on the reference circle as :

$$\frac{dF_{r\,ref}}{d\bar{\theta}} + a\,F_{\bar{\theta}\,ref} = -\,r_{ref}\,\Gamma_{ref}\ ; \quad \frac{dF_{\bar{\theta}\,ref}}{d\bar{\theta}} - a\,F_{r\,ref} = r_{ref}\Sigma_{ref} \quad (54)$$

in which we have written $a = p - 1$. It is also easy to show that the contribution from the boundary S_∞ at infinity will vanish if $p > 0$.

Equations (54) possess a *vector complementary-function* $\vec{F}_{CF}$ such that $\nabla\cdot\vec{F}_{CF} = 0$ and $\nabla\times\vec{F}_{CF} = 0$ for any constants A, B:

$$F_{CFr}(\bar{\theta}) = A\cos a\bar{\theta} + B\sin a\bar{\theta}$$
$$F_{CF\bar{\theta}}(\bar{\theta}) = A\sin a\bar{\theta} - B\cos a\bar{\theta}. \quad (55)$$

If a is non-integer (*i.e* p non-integer), $\vec{F}_{CF}$ will be *discontinuous* across $\bar{\theta} = 2\pi \to 0$; the components of the discontinuity are:

$$\Delta F_{CFr} \equiv F_{CFr}(2\pi) - F_{CFr}(0) = B\sin p2\pi - A(1-\cos p2\pi)$$
$$\Delta F_{CF\bar{\theta}} \equiv F_{CF\bar{\theta}}(2\pi) - F_{CF\bar{\theta}}(0) = A\sin p2\pi + B(1-\cos p2\pi). \quad (56)$$

Suppose we now approximate the (known) functions $r_{ref}\Sigma_{ref}(\bar{\theta})$ and $r_{ref}\Gamma_{ref}(\bar{\theta})$ on panel j by *quadratic* representations:

$$r_{ref}\Sigma_{ref} = \Sigma_0 + \Sigma_1\theta' + \Sigma_2\theta'^2; \quad r_{ref}\Gamma_{ref} = \Gamma_0 + \Gamma_1\theta' + \Gamma_2\theta'^2 \quad (57)$$

with each coefficient constant on panel j, and with θ' measured from its midpoint (positive clockwise). We next form a quadratic *vector particular integral* $\vec{F}_{PI} = F_{PIr}\hat{r} + F_{PI\bar{\theta}}\hat{\bar{\theta}}$, defined by:

$$F_{PI\bar{\theta}}(\bar{\theta}) = F_{\bar{\theta}0} + F_{\bar{\theta}1}\theta' + F_{\bar{\theta}2}\theta'^2; \quad F_{PIr}(\bar{\theta}) = F_{r0} + F_{r1}\theta' + F_{r2}\theta'^2 \quad (58)$$

We force $\vec{F}_{PI}$ to be an exact solution of (54) on panel j by inserting (58) in (53) and matching the coefficients of $r_{ref}\nabla\cdot\vec{F}_{PI}$ and $r_{ref}\nabla\times\vec{F}_{PI}$ on the reference circle with those in (57), to give:

$$\begin{aligned} F_{\bar{\theta}2} &= -\Gamma_2/a; & F_{r1} &= (2F_{\bar{\theta}2} - \Sigma_1)/a; \\ F_{\bar{\theta}0} &= -(F_{r1} + \Gamma_0)/a; & F_{r2} &= -\Sigma_2/a; \\ F_{\bar{\theta}1} &= -(2F_{r2} + \Gamma_1)/a; & F_{r0} &= (F_{\bar{\theta}1} - \Sigma_0)/a. \end{aligned} \quad (59)$$

We can now add to the particular-integral vector $\vec{F}_{PI}$, *locally* on panel j, the complementary function vector $\vec{F}_{CF}(\bar{\theta})$, with the local coefficients A, B in (55) chosen to make the resulting vector $\vec{F}_{ref} = \vec{F}_{PI} + \vec{F}_{CF}$ at entry to panel j equal to that at exit from panel $j-1$ (unless a shock is present: see Note 22 below). This process is repeated from the first to the last panel on the body, to form a vector $\vec{F}_{ref}$ which is C_0–continuous for $\bar{\theta} = 0 \to 2\pi$ but *discontinuous* across $\bar{\theta} = 2\pi \to 0$. Finally, we *globally* add the discontinuous vector $\vec{F}_{CF}(\bar{\theta})$ with global coefficients A, B in (55) now chosen to force $\Delta\vec{F}_{CF}$ in (56) to exactly cancel this remaining discontinuity in $\vec{F}_{ref}$.

Note 22: Only a slight modification is required when shocks are present. These are treated using an argument similar to that presented in Note 20 for the Uncurling Method. Suppose a shock exists at the junction of panels $j-1$ and j, with required velocity jump $\Delta\vec{V}$. Then, instead of selecting the local coefficients A, B in the additive complementary function $\vec{F}_{CF}(\bar{\theta})$ for panel j so as to make the vector $\vec{F}_{ref}$ entering panel j continuous with that exiting panel $j-1$, as above, we enforce a *vector discontinuity* $\Delta\vec{V}$ between $j-1$ and j.

Note 23: The Profile Method can be improved by constructing n vectors $\vec{F}_{ref}$, instead of only one. This enables $n-1$ normal derivatives of Σ_E and Γ_E to be matched on S, as well as their values.

5 .4 Composite GENESIS: Correction of semi-analytic fields

The Semi-Analytic Method of Sec 5 .1 provides rapid solution of an *approximation* of the Euler equation. The solution (*e.g.* the D-Field) has three errors: the *spurious vorticity* $\vec{\Gamma}_D$ differs significantly from $\vec{\Gamma}_E$, the Euler vorticity; the *field source* Σ_D differs somewhat from Σ_E; and the *shock jump* differs somewhat from the R-H value, σ_r. We can remove or significantly reduce these errors, by combining this method with the Uncurling Method or the Profile Method.

The required Euler source Σ_E and vorticity $\vec{\Gamma}_E$ can be expressed as the sum of a *semi-analytic field* and a *corrective field.* Rather than restrict ourselves to the particular case of the D-Field, we use here a more general semi-analytic field $\vec{F}_{SA} = F_{SA}(U)\hat{i}$ [Hunt and Plybon, 1990]. We use the symbol m to denote the pseudo-Mach number U/c for this field, with c a general pseudo-sonic speed [Hunt and Adamson (1992a) also define a *C-Field*, with $c = a_\infty$ = constant.] Thus we have in this more general semi-analytic case:

$$\Sigma_E = m^2\partial U/\partial x + \Sigma_{CORR} \text{ and } \quad \Gamma_E = m^2\partial U/\partial z + \Gamma_{CORR} \quad (60)$$

At a point P, where the velocity is $\vec{V} = V_s\hat{s}$ with $\hat{s} = s_x, s_z$ the local streamline unit vector, let the *streamline curvature* be $\mathcal{K}$, with $\mathcal{K} > 0$ when the local streamline is concave when viewed from the body. It can be shown that Σ_{CORR} and Γ_{CORR} at P are given by:

$$\Sigma_{CORR} = (1 - m^2 s_z^2)\Sigma_E - m^2[C_2 DV_s + S_2(\mathcal{K}V_s - \tfrac{1}{2}\Gamma_E)]$$
$$\Gamma_{CORR} = (1 - m^2 s_x^2)\Gamma_E + m^2[C_2\mathcal{K}V_s - S_2(DV_s - \tfrac{1}{2}\Sigma_E)] \quad (61)$$

where $C_2 = s_x^2 - s_z^2$, $S_2 = 2s_x s_z$, and $DV_s \equiv dV_s/ds$ is the local velocity gradient evaluated in the direction $\hat{s}$. The Euler values Σ_E, $\vec{\Gamma}_E$, and thus the corrective fields Σ_{CORR}, Γ_{CORR} in (61), can be evaluated everywhere, as before, from the current estimate of $\vec{V}$.

A corrective field vector $\vec{F}_{CORR}$ equivalent to Σ_{CORR}, Γ_{CORR} can now be constructed, either *nominally exactly* (by the Uncurling Method, Sec 5 .2), or *approximately* (by the Profile Method, Sec 5 .3). The *composite* equivalent vector $\vec{F}$ is then the sum of the semi-analytic and corrective fields: $\vec{F} = F_{SA}\hat{i} + \vec{F}_{CORR}$. The (composite) equivalent boundary distributions are thus given by:

$$\sigma_F = -n_x F_{SA} + \sigma_{CORR} \quad \text{and} \quad \omega_F = -n_z F_{SA} + \omega_{CORR} \quad (62)$$
$$\text{where} \quad \sigma_{CORR} = -\hat{n}\cdot\vec{F}_{CORR} \quad \text{and} \quad \omega_{CORR} = -\hat{s}\cdot\vec{F}_{CORR}.$$

When the Semi-Analytic Method is based on the D-Field, *i.e.* $F_{SA} \equiv F_D$ [eq (30)], the procedure is almost exactly as in Sec 5 .1 , with the exception that, given the current estimate of the pseudo-Laplace function U', the D-Equation (31) to be solved at each point for U_{sub} or U_{sup} is now replaced by the *composite D-Equation*:

$$U - n_z^2 F_D(U) + U'_{CORR} = U' \quad \text{with} \quad U'_{CORR} = n_z\omega_{CORR}. \quad (63)$$

Here we are still using the same definition of the pseudo-Laplace function $U' = n_z V_s'$, but with V_s' [*i.e.* the pseudo-Laplace tangential velocity] now computed by SAVER with the *composite* boundary condition (prescribed source) $V_n' = \sigma_F = -n_x F_{SA} + \sigma_{CORR}$. This composite D-Equation can more conveniently be written:

$$U - n_z^2 F_D(U) = U'' \quad \text{where} \quad U'' = U' - U'_{CORR}. \quad (64)$$

The generic graph of (64) is identical to that in Fig 4 , but with U' replaced by U''. Thus it is now the maximum feasible value of U'' which is defined by the function on the r.h.s. of (32). Hence the local *maximum-feasible value* (limit) of the pseudo-Laplace function U', again symbolized as U_L', is defined for the *composite* D-Field by:

$$U_L' = \mu V_{max} - n_z^2(\lambda_m + \lambda_T) + U'_{CORR}. \quad (65)$$

The *maximum feasible increment* in the pseudo-Laplace function U' due to the (composite) boundary-condition increment σ_F, again symbolized as U_{FL}', still has the same symbolic form as (35), but with U_L' now defined by (65). The local *exceedance parameter* for the *composite* field has the same form as (37).

The scaling process defined in Sec 5 .1 .3 for "infeasible" flows [*i.e.* the adjustment of M_∞ when, for at least one point on the boundary, U' exceeds its local maximum-feasible value U_L' — now defined by (65)] is still fully applicable for the *composite* field, if the function U'_{CORR} in (63) and (65) is obtained using values established at the previous iteration, and is regarded as *frozen* for the current iteration. Once a (transonic) problem has been rendered feasible, the point P_T where the maximum exceedance $e_T' = \max(e') = 0$ occurs is now the sonic point of the *composite* field, *i.e.* the Euler field.

Inserting the (scaled) pseudo-Laplace function U' and the current estimate of U'_{CORR} into the second equation in (64), gives a new estimate of the (feasible) distribution U'', which then allows the (Euler) velocity field $\vec{V}$ to be updated (Sec 5 .1 .4). The value of U for the composite field (*i.e.* for the Euler field) is obtained at every point on the body boundary as the local subsonic or supersonic candidate solution U_{sub} or U_{sup} of (64); this is done exactly as described in Sec 5 .1 .4 , but with U' in (43) now replaced by U''. At convergence, the tangential velocity in the composite (Euler) field is obtained from the pseudo-Laplace solution, using (29) with the tangential velocity correction $\vec{\omega}_F$ now defined by (62).

6 SUMMARY

We have described the current status of the evolving GENESIS methodology. The GENESIS semi-analytic method offers a totally rational, boundary-only, nominally exact solution of a field approximating the transonic Euler equation, with a precise treatment of compression shocks and explicit suppression of expansion shocks. Uncorrected 2-D transonic results have been presented for this method, demonstrating its high speed and fidelity. Two corrective methods were introduced for the annihilation of the error field resulting from this semi-analytic method: one of them is nominally exact, and involves simple computations on a field mesh; the other is itself approximate, but involves only boundary computations. A proposed composite method embeds either of these corrective methods within the iteration cycle of the semi-analytic method. This offers the prospect of accurate, 2-D transonic Euler solutions for lifting bodies, with physically correct shock treatment, in a few seconds CPU time on a personal computer.

The extension to three-dimensions appears straightforward, building upon the existing power, flexibility and ease of use of the various 3-D panel codes available to the aerospace community. GENESIS could merely modify the boundary conditions satisfied by these existing codes, but significant advantage would be gained if the SAVER methodology were used to replace their existing singularity representations and solution algorithms. The resulting code would offer transonic 3-D Euler solutions for little more CPU time than current *linear* computations, for the same configurations.

Extension to arbitrary, unsteady motions also appears achievable. The mathematical identity underlying GENESIS relates to an arbitrary vector field, and can be applied equally validly to an *instantaneous snapshot* of a time-varying vector velocity field. The field source and vorticity terms, described here for only the steady-state case, would then also involve the evaluation of instantaneous time derivatives of some of the thermodynamic variables.

It can very plausibly be conjectured that generalized boundary-integral schemes may in the relatively near future be addressing compressible, rotational flow problems for three-dimensional multi-body configurations, in the general fields of *unsteady aerodynamics* and *aero-acoustics*. The way will then be open to general *multi-disciplinary* simulations, either on conventional computer architectures, or on vector machines—for which integral methods are particularly well suited (Hunt and Adamson, 1992c).

ACKNOWLEDGMENT The first author has engaged a number of his colleagues in discussions relating to some of the innovative concepts introduced in this paper, and would like to express particular thanks to *George Converse*, *Ron Plybon* and *Jim Keith* at GE Aircraft Engines, and to *Carson Yates* (NASA LaRC).

Variational-asymptotical analysis of initially curved and twisted composite beams

Carlos ES Cesnik and Dewey H Hodges

School of Aerospace Engineering, Georgia Institute of Technology, Atlanta GA 30332-0150

An asymptotically exact methodology, based on geometrically nonlinear, three-dimensional elasticity, is presented for cross-sectional analysis of initially curved and twisted, nonhomogeneous, anisotropic beams. Through accounting for all possible deformation in the three-dimensional representation, the analysis correctly accounts for the complex elastic coupling phenomena in anisotripic beams associated with shear deformation. The analysis is subject only to the restrictions that the strain is small relative to unity and that the maximum dimension of the cross section is small relative to the wave length of the deformation and to the minimum radius of curvature and/or twist. The resulting cross-sectional elastic constants exhibit first-order dependence on the initial curvature and twist. As is well known, the associated geometrically-exact, one-dimensional equilibrium and kinematical equations also depend on initial twist and curvature. Present numerical results show that it is insufficient to account for initial twist and curvature in the beam equations only. The corrections to the stiffness model derived herein are also necessary in general for proper representation of anisotropic beams.

INTRODUCTION

When a flexible structure has one dimension that is larger than the other two, it can often be treated as a beam, a one-dimensional structure. Many engineering structures can be idealized as beams, leading to much simpler equations than would be obtained if complete three-dimensional elasticity were used to model the structure. Although dimensional reduction processes can be extremely simple for homogeneous, isotropic, prismatic beams, and especially for restricted cases of deformation, they are far less tractable for composite beams undergoing arbitrary deformation. It is known that, in general, all possible deformations of the three-dimensional structure must be included in the formulation, as decribed by Giavotto *et al.* (1983) and Atılgan and Hodges (1991).

In this paper, we refer to all three-dimensional cross-sectional deformation as "warping" – whether the displacement is in the cross-sectional plane or out of it. All the components of warping in composite beams may be coupled. Also, there may be elastic couplings among all the global deformation components. This means that instead of 6 fundamental stiffnesses (extension, bending in the 2 principal directions, torsion, and shear in the 2 principal directions), there could be as many as 21 (a fully populated, symmetric 6×6 matrix). Furthermore, simple integrals over the cross section will not suffice to determine these elastic constants for the most general case. These complexities make the determination of the elastic constants (what is termed herein as "modeling") a much more difficult task.

There have been many investigators approaching the problem of a naturally curved and twisted beams in the literature, although no one has carried this out in a general way as it is proposed in this paper. Among them, Washizu (1964) considers the problem of an initially curved and twisted rod, but restricts it only to the homogeneous and isotropic case. Note, however, that Washizu deals with restrained warping, which is beyond the scope of our present work. Whitman and Cohen (1978) present an elegant approach to the problem, including the effects of initial stress, but they do not include any kind of warping in the kinematics. Berdichevsky and Staroselsky (1983) introduce the variational-asymptotic method to this problem, but limit their analysis to isotropic materials only. More recently, there are the works of Bauchau and Hong (1988) and Kosmatka (1991). Even though both works deal with nonhomogeneous anisotropic beams, they are restricted to thin-walled cross sections. Furthermore, the first one does not take into account in-plane warping, and the second one only considers initial twist. A more complete work is presented by Borri *et al.* (1992). They deal with initial twist as well as initial curvature for anisotropic beams and the formulation correctly accounts for generalized warping. It is an extension of Giavotto *et al.* (1983) and, therefore, based on the linear Saint-Venant approach. Hodges and Atılgan (1991) offer an overview of other works in this field.

In this paper, to further explore these issues, we present an anisotropic beam theory from geometrically nonlinear, three-dimensional elasticity. The kinematics are derived for arbitrary warping based upon the general framework of Danielson and Hodges (1987). Next, the three-dimensional strain energy based on this strain field is dimensionally reduced via the variational-asymptotical method of Berdichevsky (1981), which involves taking advantage of some small parameters. We consider only geometrically nonlinear theory, so that the maximum strain, ε, is small compared to unity. For the other two small parameters, we consider three lengths: h, a cross-sectional dimension, ℓ, the wavelength of the beam (one-dimensional) deformation, and R, the maximum radius of initial curvature and/or twist. In light of the slenderness of beamlike structures, we take the other two small parameters as $\frac{h}{\ell}$ and $\frac{h}{R}$.

The resulting equations govern both sectional and global deformation, as well as provide the three-dimensional displacement and strain fields in terms of beam deformation quantities. The formulation also naturally leads to geometrically exact, one-dimensional kinematical and intrinsic equilibrium equations for the beam deformation developed in Hodges (1990).

CROSS-SECTIONAL ANALYSIS

The kinematics of the beam are based on the general formulation of Danielson and Hodges (1987). Local rotation, as defined therein, is taken to be of the order of the strain. Since only geometrically nonlinear behavior is considered, the strain can be treated as small relative to unity without imposing any explicit restrictions on the magnitudes of the displacement of the reference line or the section rotation. Subject only to these restrictions, all possible deformations of beams are taken into account in the analysis.

The objective is to derive a strain energy function in terms of one-dimensional quantities only. To proceed, we first define the geometry of the undeformed beam and the displacement field. A typical point in the undeformed beam can be located by its arclength x_1 along a reference line r and its cross-sectional Cartesian coordinates x_2 and x_3 so that the position vector to an arbitrary point in the beam can be written as

$$\hat{\mathbf{r}}(x_1,x_2,x_3) = \mathbf{r}(x_1) + x_\alpha \mathbf{b}_\alpha(x_1) \tag{1}$$

where $\mathbf{r}(x_1)$ is the position vector to an arbitrary point on r. (Roman indices vary from 1 to 3, while Greek indices vary from 2 to 3; repeated indices are summed over their range.) The unit vectors $\mathbf{b}_\alpha(x_1)$ are parallel to planar Cartesian coordinates x_α in the plane of the reference cross section at a typical value of x_1; vectors $\mathbf{b}_i(x_1)$ form an orthonormal triad with $\mathbf{b}_1$ being perpendicular to the reference cross-sectional plane and tangent to r (see Fig 1).

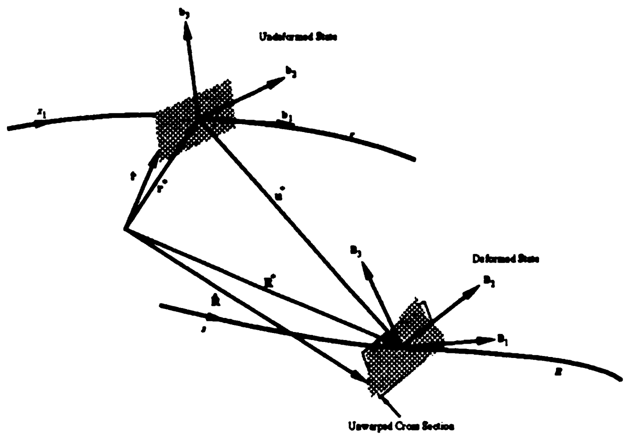

FIG 1. Schematic of beam deformation

Because of the arbitrary deformation, the material points that make up the reference cross section no longer stay exactly in a plane as the beam deforms. However, this set of points does lie very close to a plane, the orientation and displacement of which vary with the axial coordinate x_1. Since the characteristic length over which the deformation varies is assumed to be large relative to the largest cross section dimension, restrained warping (edge-zone) effects are not treated.

The position vector to an arbitrary point in the deformed beam can be then represented by

$$\begin{aligned}\hat{\mathbf{R}}(x_1,x_2,x_3) = \mathbf{R}(x_1) + x_\alpha \mathbf{B}_\alpha(x_1) \\ + w_i \mathbf{B}_i(x_1)\end{aligned} \tag{2}$$

where $\mathbf{R}(x_1) = \mathbf{r}(x_1)+\mathbf{u}(x_1)$, $\mathbf{u} = u_i\mathbf{b}_i$ is the displacement vector of points on the reference line r, and $w_i(x_1,x_2,x_3)$ is the general warping displacement of an arbitrary point in the cross section, consisting of both in- and out-of-plane components so that all possible deformations are considered. Eq (2) is six times redundant because of the manner in which warping is introduced; this redundancy is dealt with below. Note that $\mathbf{B}_1 = \mathbf{B}_2 \times \mathbf{B}_3$ is not in general tangent to the reference line of the deformed beam. The relationship between $\mathbf{B}_i$ and $\mathbf{b}_i$ is determined by

$$\mathbf{B}_i(x_1) = C_{ij}(x_1)\mathbf{b}_j(x_1) \tag{3}$$

where $C(x_1)$ is the matrix of direction cosines.

Further details of the kinematics are available in Danielson and Hodges (1987), where the three-dimensional strain field is developed in a particularly simple form when strain and local rotation are small

$$\Gamma^* = \frac{\chi + \chi^T}{2} - I \tag{4}$$

Here I is the 3×3 identity matrix, Γ^* is a 3×3 symmetric matrix with elements Γ^*_{ij}. The matrix χ is given by

$$\begin{aligned}\chi_{ij} &= \mathbf{B}_i \cdot \mathbf{G}_k \mathbf{g}^k \cdot \mathbf{b}_j \\ \mathbf{G}_i &= \frac{\partial \hat{\mathbf{R}}}{\partial x_i} \\ \mathbf{g}^i &= \frac{1}{2\sqrt{g}} e_{ijk} \frac{\partial \hat{\mathbf{r}}}{\partial x_j} \times \frac{\partial \hat{\mathbf{r}}}{\partial x_k}\end{aligned} \tag{5}$$

where $\sqrt{g} = 1 - x_2k_3 + x_3k_2 > 0$, e_{ijk} is the permutation symbol, and k_α are measure numbers in the $\mathbf{b}_i$ basis of the initial curvature of the undeformed beam. Introducing the initial twist k_1 and column matrices w, k, and ξ, containing, respectively, the components w_i, k_i, and $\lfloor 0 \ x_2 \ x_3 \rfloor^T$, one can express the strain field as a 6×1 column matrix $\Gamma = \lfloor \Gamma^*_{11} \ 2\Gamma^*_{12} \ 2\Gamma^*_{13} \ \Gamma^*_{22} \ 2\Gamma^*_{23} \ \Gamma^*_{33} \rfloor^T$ so that

$$\Gamma = \begin{bmatrix} \frac{1}{\sqrt{g}} I & -\frac{1}{\sqrt{g}}\tilde{\xi} \\ 0 & 0 \end{bmatrix} \begin{Bmatrix} \gamma \\ \kappa \end{Bmatrix} + \begin{bmatrix} \frac{1}{\sqrt{g}} I \\ 0 \end{bmatrix} w' + \begin{bmatrix} \partial_1 \\ \partial_2 \end{bmatrix} w$$

$$\partial_1 \triangleq \frac{1}{\sqrt{g}}\tilde{k} + \frac{k_1 I}{\sqrt{g}}\left(x_3\frac{\partial}{\partial x_2} - x_2\frac{\partial}{\partial x_3}\right) + \begin{bmatrix} 0 & 0 & 0 \\ \frac{\partial}{\partial x_2} & 0 & 0 \\ \frac{\partial}{\partial x_3} & 0 & 0 \end{bmatrix} \tag{6}$$

$$\partial_2 \triangleq \begin{bmatrix} 0 & \frac{\partial}{\partial x_2} & 0 \\ 0 & \frac{\partial}{\partial x_3} & \frac{\partial}{\partial x_2} \\ 0 & 0 & \frac{\partial}{\partial x_3} \end{bmatrix}$$

where $\widetilde{(\ )}_{ij} = -e_{ijk}(\ )_k$; $\gamma = \lfloor \gamma_{11} \ 2\gamma_{12} \ 2\gamma_{13} \rfloor^T$ and $\kappa = \lfloor \kappa_1 \ \kappa_2 \ \kappa_3 \rfloor^T$, the so-called force and moment strain measures. Note that γ_{11} is an extensional strain measure, $2\gamma_{1\alpha}$ are a shear strain measure, κ_1 is the elastic twist per unit length, and κ_α are the elastic components of the bending curvature. These strain measures can be expressed in matrix form as

$$\begin{aligned}\gamma &= C(e_1 + u' + \tilde{k}u) - e_1 \\ \tilde{\kappa} &= -C'C^T + C\tilde{k}C^T - \tilde{k}\end{aligned} \tag{7}$$

Here $u = \lfloor u_1\ u_2\ u_3 \rfloor^T$ and $e_1 = \lfloor 1\ 0\ 0 \rfloor^T$. The force and moment strain measures are so designated because they are conjugate to the actual section force and moment, respectively.

Since warping displacements are very small relative to the cross section dimensions, the few nonlinear terms in the strain field, which couple w and κ, are of higher order and have been neglected in Eq (6). The form of the strain field is of great importance because it is now linear in γ, κ, and w_i and its derivatives.

VARIATIONAL-ASYMPTOTICAL FORMULATION

In constructing a one-dimensional beam theory from three-dimensional elasticity, we attempt to represent the strain energy stored in a three-dimensional body by finding the strain energy which would be stored in an imaginary one-dimensional body.

This modeling process cannot be performed in an exact manner. However, due to the interest of working with a simple one-dimensional theory, researchers have turned to asymptotical methods in order to reduce the dimension of the model for bodies which contain one or more small parameters. Beams are such bodies, because the characteristic cross-sectional dimension of the beam is much smaller than its length.

Thus, in what follows we replace the three-dimensional beam problem by an *approximate* one-dimensional one in which the strain energy per unit length will be a function only of x_1. This will be done with the aid of the variational-asymptotical formulation of Berdichevsky (1981). (See Atılgan *et al.* 1991 for additional discussion of this methodology.)

The strain energy per unit length can then be written as

$$U = \frac{1}{2}\langle Z^T \Gamma \sqrt{g}\rangle \tag{8}$$

where the angle brackets signify the integral over the cross sectional area, Z is the three-dimensional Jaumann stress, which is conjugate to the Jaumann strain (Γ)

$$Z = D\Gamma \tag{9}$$

and D is the 6×6 symmetric material matrix. This functional is to be minimized with the following constraints

$$\begin{aligned}\langle w_i\rangle &= 0\\ \langle w_{2,3} - w_{3,2}\rangle &= 0\\ \langle \xi_\alpha w_1\rangle &= 0\end{aligned} \tag{10}$$

which are discussed in more detail in Hodges *et al.* (1992).

Assuming small to moderate curvatures, one can take

$$(\sqrt{g})^{-1} \approx 1 + x_2 k_3 - x_3 k_2$$

so that $O(\frac{h^2}{R^2})$ terms are neglected, where $R = (k^T k)^{-\frac{1}{2}}$.

Let us first consider the case where the strain energy is approximated so that all terms of higher order than $O(\frac{\mu \varepsilon^2 h^2}{R^2})$, as well as all $\frac{h}{l}$ contributions, are ignored. So, the strains must be developed to include all terms that are $O(\varepsilon)$ and $O(\frac{h\varepsilon}{R})$. With these considerations, the Jaumann strain can be approximated as

$$\Gamma = X\epsilon + \partial w + X_k\epsilon + \partial_k w \tag{11}$$

where

$$\begin{aligned}
X &\triangleq \begin{bmatrix} I & -\widetilde{\xi} \\ 0 & 0 \end{bmatrix} \qquad \epsilon \triangleq \lfloor \gamma\ \ \kappa \rfloor^T\\
X_k &\triangleq X(x_2k_3 - x_3k_2)\\
\partial &\triangleq \begin{bmatrix} 0 & 0 & 0\\ \frac{\partial}{\partial x_2} & 0 & 0\\ \frac{\partial}{\partial x_3} & 0 & 0\\ 0 & \frac{\partial}{\partial x_2} & 0\\ 0 & \frac{\partial}{\partial x_3} & \frac{\partial}{\partial x_2}\\ 0 & 0 & \frac{\partial}{\partial x_3} \end{bmatrix}\\
\partial_k &\triangleq \begin{bmatrix} \widetilde{k} + Ik_1\left(x_3\frac{\partial}{\partial x_2} - x_2\frac{\partial}{\partial x_3}\right)\\ 0 \end{bmatrix}
\end{aligned} \tag{12}$$

The presence of the warping in the above creates practical difficulties because it is a three-dimensional quantity. Thus, we must eliminate the warping, and we do so using a combination of the variational-asymptotical method, originally developed by Berdichevsky (1981), and the finite element method, following Hodges *et al.* (1992). First, the warping can be discretized by using the finite element technique. Let

$$w = SW \tag{13}$$

in which the matrix S contains the shape functions and W is the nodal displacement column matrix. Now the strain becomes

$$\Gamma = X\epsilon + BW + X_k\epsilon + B_kW \tag{14}$$

where

$$B \triangleq \partial S \qquad B_k \triangleq \partial_k S \tag{15}$$

In terms of energy density

$$\begin{aligned}\delta U =& \langle(\delta\epsilon^T X^T + \delta W^T B^T + \delta\epsilon^T {X_k}^T\\ &+ \delta W^T {B_k}^T)D(X\epsilon + BW + X_k\epsilon\\ &+ B_kW)\,(1 - x_2k_3 + x_3k_2)\rangle\end{aligned} \tag{16}$$

We can now rewrite the strain energy density in terms of the new matrices defined in the Appendix

$$\begin{aligned}\delta U =& \delta\epsilon^T(A\epsilon + R^TW + {C_k}^T\epsilon + {R_k}^TW\\
&+ C_k\epsilon + {L_k}^TW + G_k\epsilon + {M_k}^TW)\\
&+ \delta W^T(R\epsilon + EW + L_k\epsilon + F_kW\\
&+ R_k\epsilon + {F_k}^TW + M_k\epsilon + E_kW)\\
&+ \delta\epsilon^T(\bar{A}\epsilon + \bar{R}^TW + \bar{C}_k^T\epsilon + \bar{R}_k^TW\\
&+ \bar{C}_k^T\epsilon + \bar{L}_k^TW + \bar{G}_k^T\epsilon + \bar{M}_k^TW)\\
&+ \delta W^T(\bar{R}\epsilon + \bar{E}W + \bar{L}_k\epsilon + \bar{F}_kW\\
&+ \bar{R}_k\epsilon + \bar{F}_k^TW + \bar{M}_k\epsilon + \bar{E}_kW)\end{aligned} \tag{17}$$

Noticing that every $(\bar{\ })$ term is one order higher than the correspondent ( ), the above functional can be approximated asymptotically by

$$\begin{aligned}\delta U =& \delta\epsilon^T(A\epsilon + R^T W) \\ &+ \delta W^T(R\epsilon + EW)\end{aligned} \tag{18}$$

which is exactly the same expression obtained for the first approximation without initial twist or curvature by Hodges *et al.* (1992). Therefore,

$$W = -E^{-1}R\epsilon \tag{19}$$

which is $O(\varepsilon)$. Note here that in order to solve for the warping in this manner, the six constraints defined by Eq (10) were first applied to W in the energy.

Now, substitute Eq (19) into the original energy density functional (Eq (17))

$$\begin{aligned}\delta U =& \delta\epsilon^T[A - R^T E^{-1}R + \bar{A} + 2C_k \\ &- {R_k}^T E^{-1}R - (E^{-1}R)^T R_k \\ &- \bar{R}^T E^{-1}R - (E^{-1}R)^T\bar{R} \\ &- (E^{-1}R)^T L_k - {L_k}^T(E^{-1}R) \\ &+ (E^{-1}R)^T(F_k + {F_k}^T)(E^{-1}R) \\ &+ (E^{-1}R)^T(\bar{E})(E^{-1}R) + G_k \\ &- {M_k}^T(E^{-1}R) - (E^{-1}R)^T M_k \\ &+ (E^{-1}R)^T E_k(E^{-1}R) + 2{C_k}^T \\ &- {\bar{R}_k}{}^T E^{-1}R - (E^{-1}R)^T\bar{R}_k \\ &- (E^{-1}R)^T\bar{L}_k - {\bar{L}_k}{}^T(E^{-1}R) \\ &+ (E^{-1}R)^T(\bar{F}_k + {\bar{F}_k}{}^T)(E^{-1}R) \\ &+ \bar{G}_k - \bar{M}_k(E^{-1}R) \\ &- (E^{-1}R)^T\bar{M}_k \\ &+ (E^{-1}R)^T\bar{E}_k(E^{-1}R)]\epsilon\end{aligned} \tag{20}$$

which directly leads us to the candidate for the first approximation

$$\delta U_1 = \delta\epsilon^T(A - R^T E^{-1}R)\epsilon \tag{21}$$

The next step is to go to the second approximation with the substitution

$$W = -E^{-1}R\epsilon + V \tag{22}$$

where V is the perturbation of the previous solution. It can be shown that

$$\begin{aligned}V =& -E^{-1}[L_k + R_k - \bar{E}E^{-1}R \\ &- (F_k + {F_k}^T)E^{-1}R]\epsilon\end{aligned} \tag{23}$$

which is $O(\frac{h\epsilon}{R})$, *i.e.*, one order higher than W. This leads us to two important conclusions: (a) Eq (21) is *the* first approximation of Eq (16); and (b) all terms in the Eq (20) that include V are of order $(\frac{h}{R})^2$ or smaller relative to the leading terms. This means that they can be neglected for the level of approximation sought here. We note that W, Γ, and Z can now be calculated to first order in $\frac{h}{R}$.

Analogous to what was done above, the second approximation can be written as

$$\begin{aligned}\delta U_2 =& \delta\epsilon^T[(A - R^T E^{-1}R) + C_k \\ &+ (E^{-1}R)^T(F_k + {F_k}^T)(E^{-1}R) \\ &- (E^{-1}R)^T R_k - {R_k}^T(E^{-1}R) \\ &+ (E^{-1}R)^T\bar{E}(E^{-1}R)]\epsilon\end{aligned} \tag{24}$$

Therefore, for the second approximation, the strain energy density can be written as

$$2U = \epsilon^T\hat{S}\epsilon \tag{25}$$

where

$$\begin{aligned}\hat{S} =& A - R^T E^{-1}R + C_k \\ &+ (E^{-1}R)^T(F_k + {F_k}^T)(E^{-1}R) \\ &- (E^{-1}R)^T R_k - {R_k}^T(E^{-1}R) \\ &+ (E^{-1}R)^T\bar{E}(E^{-1}R)\end{aligned} \tag{26}$$

from where one can easily see that the initial curvature and twist do change the sectional stiffness matrix to first order in $\frac{h}{R}$.

Finally, we note that under certain circumstances $\hat{S}$ can be reduced, as noted by Hodges *et al.* (1992). This matrix is 6×6 because of the presence of shear deformation. There are also transverse shear related effects associated with slenderness, which are accounted for in higher asymptotical approximations. Thus, for slender beams one may not need to use the full 6×6 form of $\hat{S}$. Minimization of $\hat{S}$ with respect to the transverse shear measures $2\gamma_{1\alpha}$ produces a 4×4 stiffness matrix denoted by $\mathcal{S}$. This minimization is equivalent to undertaking the following operations on the stiffness matrix: (1) invert the 6×6 matrix; (2) ignore the rows and columns associated with transverse shear, leaving a 4×4 matrix; (3) invert this resulting 4×4 matrix yielding the "reduced" stiffness matrix associated with extension, torsion, and two bending measures. The result is an approximate strain energy per unit length of the form

$$2U^* = \begin{Bmatrix}\gamma_{11} \\ K\end{Bmatrix}^T [\mathcal{S}] \begin{Bmatrix}\gamma_{11} \\ K\end{Bmatrix} \tag{27}$$

Thus, the strain energy is in the same *form* as in classical theory (which has no transverse shear deformation in the one-dimensional energy). However, the appropriate coupling effects involving transverse shear, first noted by Rehfield *et al.* (1990), are present in Eq (27); and the numerical values of the resultant elastic constants can differ considerably from those of a "classical" theory, in which shear deformation is set equal to zero at the outset. This reduction is suitable for slender beams undergoing low-frequency (i.e., long wavelength) vibration.

APPLICATIONS

A cross-sectional analysis computer code called VABS (*V*ariational-*A*symptotical *B*eam *S*ectional Analysis) has been developed based upon the theoretical formulation presented herein. From it one gets a reduced, asymptotically correct stiffness matrix and warping displacements for a general, nonhomogeneous, anisotropic beam cross section. The discretization of the cross-sectional domain is made with the finite element technique. The element which has been developed is four-noded, planar, and rectangular, with three degrees of freedom per node. The algebraic operations at the element level, including element quadrature, were carried out via symbolic manipulation by using *Mathematica* (see Wolfram 1988).

VABS has been verified before for prismatic anisotropic beams and its results agree very well with experimental data as shown by Hodges *et al.* (1992). Here, the code is first verified for an isotropic square cross section with dimensions 2.0×10^{-2} m by 2.0×10^{-2} m. The material properties are assumed to be $E = 26$ MPa and $\nu = 0.3$.

To present results for initially curved and twisted beams, we examine the isotropic case for which closed-form solutions for the Saint-Venant stiffnesses are known. For small to moderate initial twist or curvature (small $\frac{h}{R}$ ratio), there is no change in the diagonal terms of the stiffness matrix (namely extension, twist and bending stiffnesses) when compared to the prismatic ones. However, there is extension-twist coupling due to initial twist and extension-bending coupling due to initial curvature. These are given in closed form by Berdichevsky and Staroselsky (1983)

$$\begin{aligned} \hat{S}_{14} &= E(I_{22} + I_{33} - J)\, k_1 \\ \hat{S}_{15} &= -\,(1+\nu)EI_{22}\, k_2 \\ \hat{S}_{16} &= -\,(1+\nu)EI_{33}\, k_3 \end{aligned} \tag{28}$$

and are used as baseline values for the present results.

Some sample results are shown here for the sake of evaluating the convergence of the finite element method for determining the stiffness constants as a function of the mesh refinement. We show the convergence only for coupling terms which arise from initial twist and curvature. The error taken is defined as

$$\text{Relative Error} = \left| \frac{S_{VABS} - S_{exact}}{S_{exact}} \right| \tag{29}$$

where S_{exact} is the exact stiffnesses for an isotropic beam.

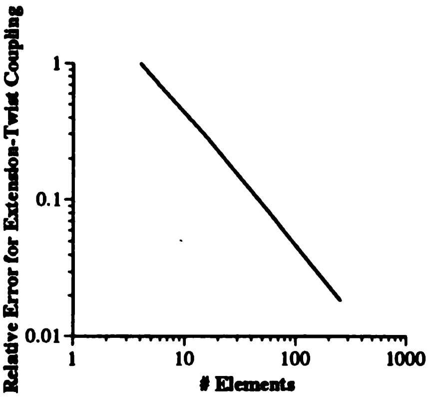

FIG 2. Convergence history of the extension-twist stiffness term due to initial twist.

Fig 2 describes the convergence behavior of the extension-twist coupling term for nonzero initial twist. Similarly, Fig 3 deals with the extension-bending coupling term for nonzero initial curvature. For these plots, S_{exact} in Eq (29) is taken from Eq (28). As one can see from the results, the relative errors decrese linearly on a logarithmic scale with respect to the number of elements. The slope of the line indicates a relative error that is approximately inversely proportional to the number of elements. The extension-twist coupling involves the torsional stiffness, which is less accurate than the bending stiffness for the same number of elements in the mesh. This is reflected in the larger error in the calculation of the extension-twist coupling. However, the relative error for all the terms is still smaller than 2% for 100 elements (a 10×10 mesh).

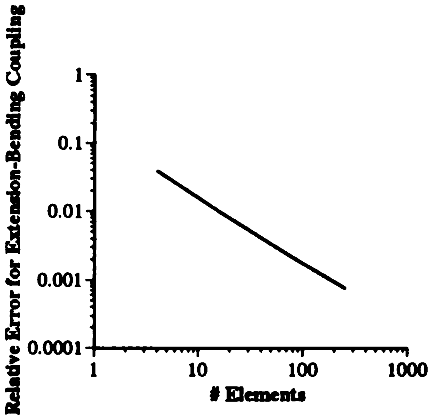

FIG 3. Convergence history of the extension-bending stiffness due to initial curvature.

Now, let us consider two composite beams studied both experimentally and theoretically by Minguet (1989). The two layups for these beams are defined as

(BT): $[45°/0°]_{3s}$

(ET): $[20°/-70°/-70°/20°]_{2a}$

where BT reflects the fact that the prismatic beam has bending-twist coupling and ET that the prismatic beam has extension-twist coupling. The beams have thin rectangular cross sections of width 30.023 mm and of thickness 1.4712 mm and 1.9215 mm, respectively. The material used is AS4/3501-6 Graphite/Epoxy, the properties of which are given in Table I.

TABLE I. Properties of AS4/3501-6 Graphite/Epoxy ("L" direction is along the fibers and "N" is normal to the laminate)

$E_{LL} = 142$ GPa	$E_{TT} = E_{NN} = 9.80$ GPa
$G_{LT} = G_{LN} = 6.00$ GPa	$G_{TN} = 4.80$ GPa
$\nu_{LT} = \nu_{LN} = 0.3$	$\nu_{TN} = 0.34$

The resulting stiffness constants are given in Tables II and III. The first column contains the results for a prismatic beam from NABSA (*N*onhomogeneous *A*nisotropic *B*eam *S*ection *A*nalysis), which is based in Giavotto *et al.* (1983). The second column contains similar results from VABS. Notice that the stiffnesses for the prismatic case are all very close to each other except the shear stiffness constants. This is already expected considering the fact that VABS ignores terms in the strain energy of first and higher orders in $\frac{h}{l}$ while NABSA treats the Saint-Venant flexure solution, equivalent to retaining terms of second order in $\frac{h}{l}$. Based on the study of the effects of these terms by Hodges *et al.* (1992) for static behavior of certain composite beams, it is believed that these differences will not make any noticeable differences in the results for static and low-frequency dynamic analysis of composite beams.

Now consider the remaining three columns. These are results from VABS for the coefficients of k_i in the stiffness constants. To get the stiffness coefficient for any given element of the stiffness matrix, multiply the value of k_i times the appropriate column, *i.e.*,

$$\hat{S} = \hat{S}^0 + k_i\,\hat{S}^\Delta \tag{30}$$

where $\hat{S}^0$ is the stiffness contribution from the prismatic solution and $\hat{S}^\Delta$ is the one correspondent to the Δ $\mathbf{VABS}_{k_i}$ column.

As one can see, Tables II and III show that the presence of initial twist and curvature introduces new couplings among the one-dimensional deformation measures. Beams of this size have h about 30 mm; so that $\frac{h}{R}$ does not exceed about 0.12, and, therefore, $\sqrt{k^T k}$ should not exceed about 4.0 rad/m. Even though the new terms are of lower orders of magnitude when compared to the main diagonal terms (keeping in mind the unit system used herein), their presence can have important effects when larger pretwist is considered (see Kosmatka 1991). For example, note the contribution of the extension-twist coupling due to the presence of the pretwist in Table III. Even for small pretwist, the extension-twist coupling can be increased by 10%. Not only is it possible to alter *existing* couplings, new couplings can appear where there were no couplings present at all in the prismatic beam. For example, extension-twist coupling shows up in Table II, and extension-bending coupling shows up in Table III.

The most important issue in evaluation of the contribution of the first-order correction terms to the stiffness constants is whether these terms have any noticeable effects on the predicted deformation of the beam. Consider the beams, which are essentially thin strips, with fixed-free boundary conditions and with two possible load cases: a transverse force applied perpendicular to the strip, and an axial load applied along the strip, both at the beam tip. Two levels of load are applied: one small (in the linear range) and one large (in the geometrically nonlinear range). A representative sample of the results obtained are presented herein.

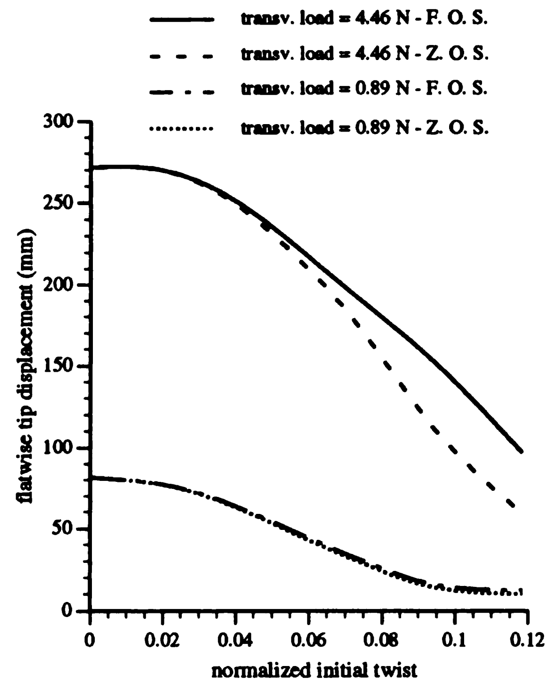

FIG 5. Flatwise tip displacement due to transverse load for BT beam.
Note: F.O.S. = first-order stiffness matrix.
Z.O.S. = zeroth-order stiffness matrix.

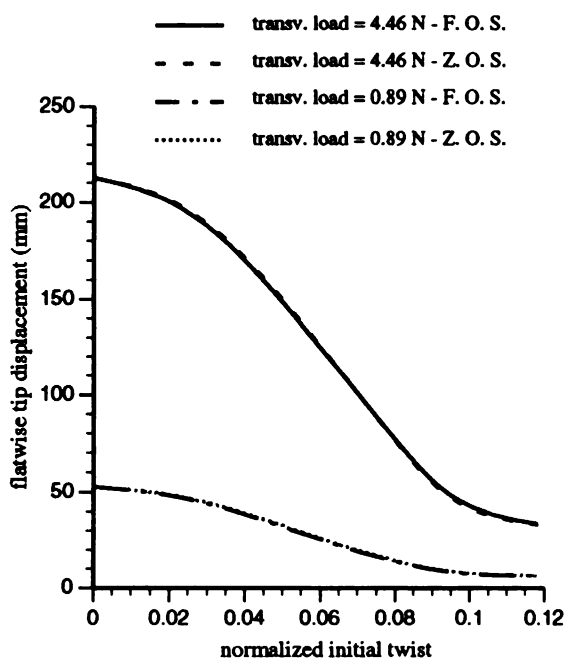

FIG 4. Flatwise tip displacement due to transverse load for ET beam.
Note: F.O.S. = first-order stiffness matrix.
Z.O.S. = zeroth-order stiffness matrix.

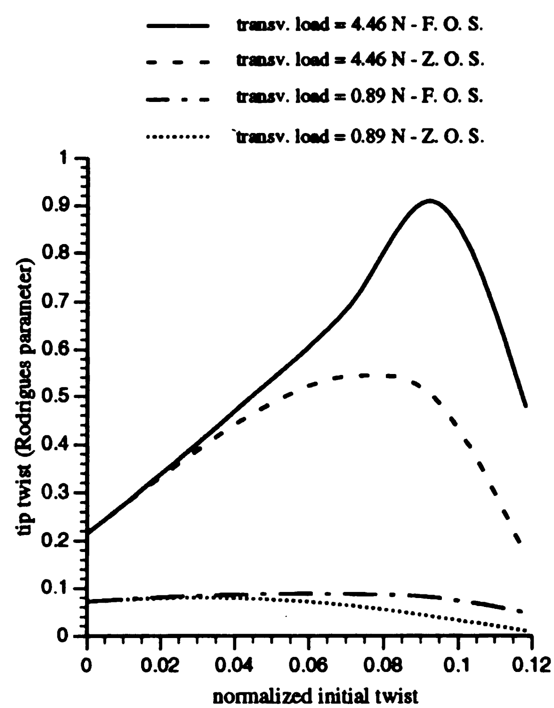

FIG 6. Rodrigues parameter corresponding to tip twist due to transverse load for BT beam.
Note: F.O.S. = first-order stiffness matrix.
Z.O.S. = zeroth-order stiffness matrix.

Figs 4 and 5 show the flatwise tip displacement for the ET and BT beams, respectively, for both transverse loads – with and without the first-order correction to the stiffness matrix – versus the normalized initial twist hk_1. According to Fig 4, the effect of the first-order correction to the stiffness model is negligibly small for both small and large loading. However, according to Fig 5, the effect of the first-order correction to the stiffness in the BT beam cannot be ignored for the large load, in the geometrically nonlinear range. The twist deformation seems to be more sensitive to these terms. In Fig 6 the Rodrigues parameter which corresponds to the twist of the tip (which is the twist angle for small deformation) is shown versus the normalized initial twist hk_1. Here we see that even small loading, in the linear range, is strongly affected by the first-order correction terms in the stiffness matrix.

In the case of initial curvature, one of the worst cases appears to be the effect of inplane curvature (k_3) on the edgewise displacement, in the presence of an axial force. In Fig 7 the edgewise displacement at the tip of the ET beam is shown for two levels of axial force applied at the tip versus the normalized initial inplane curvature of the beam hk_3. Here the error is smaller than with the initial twist, but not negligible, and is worse for the larger load.

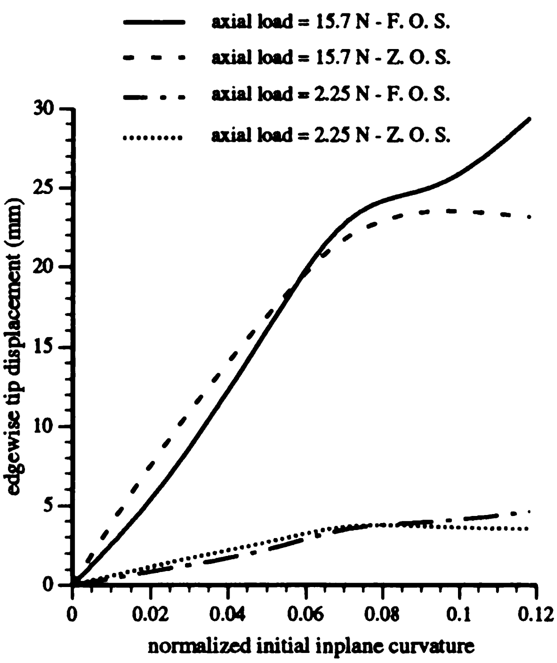

FIG 7. Edgewise tip displacement due to axial load for ET beam.
Note: F.O.S. = first-order stiffness matrix.
Z.O.S. = zeroth-order stiffness matrix.

the total energy remains less than 3% for the ET beam, while for the BT beam it reaches approximately 30%.

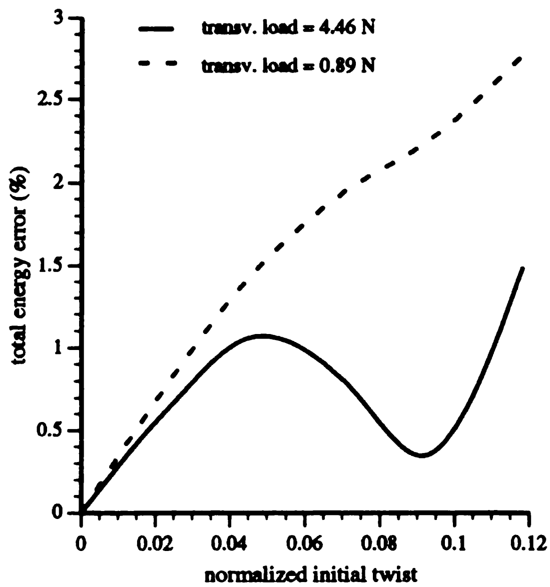

FIG 8. Total energy due to transverse load for ET beam.

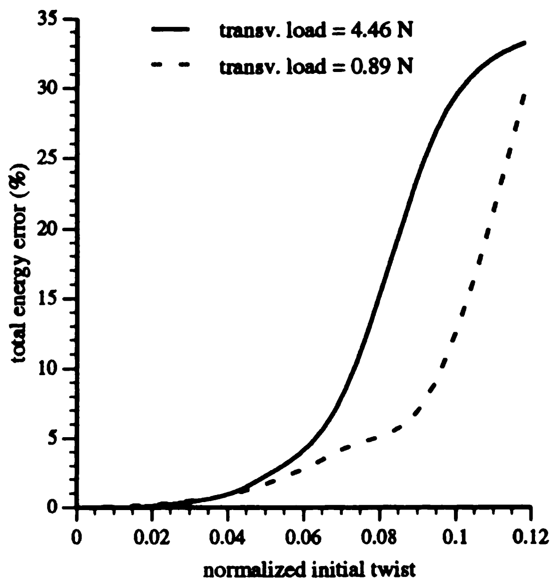

FIG 9. Total energy due to transverse load for EB beam.

The total strain and potential energy in the loaded beam is a convenient way to quantify the effects of initial curvature and twist. Figs 8 and 9 show the total energy of the ET and BT beams, respectively, versus the normalized initial twist hk_1. The error in

These results clearly show that a naïve approach in which one uses stiffness constants from a prismatic beam sectional analysis in the geometrically-exact one-dimensional equilibrium and kinematical equations for initially curved and twisted beams, the results will not be correct in general. The section constants must include the first-order correction terms due to initial curvature and twist. Judging from the size of the errors from initial twist, it is noted that second-order corrections to the stiffness may be needed for it.

CONCLUDING REMARKS

An asymptotically exact methodology, based on geometrically nonlinear, three-dimensional elasticity, is presented for analysis of initially curved and twisted, nonhomogeneous, anisotropic beams. The analysis is subject only to the restrictions that the strain is small relative to unity and that the maximum dimension of the cross section is small relative to a length parameter (thus, restrained warping effects are not considered) and to the minimum radius of curvature and/or twist. A two-dimensional functional is derived which enables the determination of sectional elastic constants, as well as relations between the beam (*i.e.*, one-dimensional) displacement and generalized strain measures and the three-dimensional displacement and strain fields. The initial twist and curvature not only appear in the equilibrium and kinematical equations, but they also influence the sectional modeling, as shown in the final form of the stiffness matrix. A cross-sectional analysis code called VABS (*V*ariational-*A*symptotical *B*eam *S*ectional Analysis) has been developed based upon the theoretical formulation presented herein, from which one gets an asymptotically correct stiffness matrix and warping displacements for a general, nonhomogeneous, anisotropic beam cross section. Numerical results were obtained first for an isotropic beam, which converge to the asymptotic closed-form solution for the stiffnesses. Then, two laminated cases were analyzed, showing the influence of the initial twist and curvature in the elastic constants. It is concluded that for any general-purpose analysis of composite beams, the effects of initial curvature and twist need to be included in all aspects of the analysis. That is, one cannot simply use the geometrically-exact equilibrium and kinematical equations for initially curved and twisted beams with sectional constants calculated from a prismatic beam.

Compressive strength and failure time based on local buckling in viscoelastic composites

RA Schapery

Department of Aerospace Engineering and Engineering Mechanics
University of Texas, Austin TX 78712

The axial compressive strength and failure time of unidirectional, viscoelastic composites are investigated. Effects of nonlinear shear behavior and fiber misalignment are emphasized because they are important strength-limiting factors in those strongly anisotropic composites which fail by local buckling in the shear mode of deformation. We first describe the basic buckling model and then, neglecting hereditary effects, predict the compressive strengths of an untoughened and a rubber-toughened carbon/epoxy composite. Next, using a nonlinear viscoelastic constitutive equation for shear behavior, failure time for constant load and compressive strength for increasing load history are predicted by a numerical method. Additionally, approximate analytical formulas are developed which enable one to easily estimate buckling response as a function of initial fiber misalignment angle as well as loading and material parameters.

INTRODUCTION

Microbuckling appears to be the primary strength-limiting mechanism in modern, highly anisotropic composites (Fleck and Budiansky, 1990), such as carbon fiber-reinforced plastic. Over the past three decades, investigators have used linear theory of varying degrees of complexity in studies of failure by fiber buckling (e.g. Rosen, 1965 and Waas, et al 1990). For the commonly used levels of fiber volume fraction, the dominant deformation mode is one in which the wave length is long compared to the fiber diameter and is characterized locally by simple shearing deformation. These linear analyses predict a strength which is approximately or exactly equal to the principal shear modulus G_{12}. Measured strengths are commonly one-third to one-fifth of this modulus. Kink bands are observed in compression failed specimens and, as a result, elastic and plastic buckling analyses of kink bands have been made in an effort to resolve this discrepancy (e.g. Fleck and Budiansky, 1990 and Budiansky, 1983). Assuming a state of local, simple shear deformation, Wisnom (1990) and Schapery (1991) independently showed that the combined effects of shear nonlinearity and realistic amounts of initial fiber misalignment are sufficient to reduce the compressive strength from the linear theory value of G_{12} to observed levels. (In earlier work, Hahn and Williams (1986), among others, also demonstrated that these effects lead to a significant loss in strength.). One may interpret the shear analysis as applying to a kink band which is normal to the fibers. Alternatively, distributed shear buckling may trigger a local failure initiation event, which is followed by a kink band propagating from the site of the initial event.

The strength model used here is based on the shear stress-strain behavior of the composite, and thus it is a modified version of Wisnom's shear buckling model, which uses an approximate micromechanical prediction of shear behavior. Not only does it lead to realistic strength predictions, but it also is sufficiently simple that nonlinear viscoelastic behavior is easily taken into account.

Finally, the reader is referred to a recent review of compressive strength of composites and kink band models (Budiansky and Fleck, 1993). Also, see Slaughter et al (1993) for a study of the effects of multiaxial loading and creep of nonlinear viscous composites.

SHEAR BUCKLING MODEL

Figure 1 illustrates the shear deformation and tractions acting on a local material element. The axial force/area, σ, in the right figure is decomposed into a traction σ_t which acts in the instantaneous fiber direction, ϕ_t , and a horizontal shear traction τ. If $|\phi_t| << 1$, then

$$\tau = \sigma\phi_t \qquad (1)$$

part of "MECHANICS PAN-AMERICA 1993" edited by MRM Crespo da Silva and CEN Mazzilli ASME Reprint No AMR134

Equilibrium considerations imply the same shear traction acts parallel to the fibers and that the traction normal to the fibers, to the first order in ϕ_t, is zero. Prior to application of σ , the local fiber angle is ϕ_0 (assumed small). The shear strain due to the loading is therefore $\gamma \equiv \phi_t - \phi_0$. Combining these results we obtain

$$\sigma = \tau/(\gamma + \phi_0) \tag{2}$$

where τ is, in general, a constitutive function of the shear strain history $\gamma(t)$; we assume the fiber axial modulus is so relatively high that the effect of σ on this constitutive relation can be neglected. Wisnom (1990) used $\tau = G_m\gamma/v_m$, where G_m is the (strain-dependent) secant shear modulus of the (resin) matrix and v_m is the matrix volume fraction; this result is based on a two-dimensional layer model in which fiber shear deformation is neglected. We do not employ this idealization here. Instead, we use the composite constitutive equation to relate τ and γ , which at least implicitly accounts for three-dimensional microstresses and fiber-shear effects.

QUASI-ELASTIC STRENGTH PREDICTION

Viscoelastic effects in structural composites under constant or monotonically increasing loading are often weak enough to either neglect them or to account for them simply through a time-dependent stress-strain equation. This is the case for Hexcel's carbon/epoxy composite, T2C145/F155, characterized by Mignery and Schapery (1991); for simple shear,

$$\gamma = S_0\tau + S_m t^m \tau^q \quad \text{when } \tau > \tau_1 \tag{3}$$

where $m = 0.05, q = 2.4$, S_0 and S_m are positive constants, and t is the time under load. In the linear range, $\tau \leq \tau_1$, the equation is similar, with $q = 1$. The epoxy matrix (designated as F155) is toughened with rubber particles, and exhibits noticeable time-dependence, as reflected in the t^m factor. In contrast, Hercules' carbon/epoxy composite, AS4/3502, characterized by Schapery (1989), has an untoughened matrix (designated as 3502); its time-dependence at room temperature is very weak and is usually neglected. Figure 2 shows the shear stress-strain curves for both composites, in which we use the resin designation to identify the two composites; note that $t = 1$ second and $t = 1$ year (extrapolated) curves are shown for the F155 composite. (Although t varies for each case, a constant value was used in drawing the curves for F155 since m is so small.) The stress-strain curve for the 3502 composite is from Schapery's (1989) data; it was not possible to fit the data with a power law like that in Eq (3).

Figure 3 illustrates behavior predicted by Eq (2) for the 3502 composite. The axial stress is divided by the zero-strain shear modulus, $G_{12}(0)$, and thus linear strength theory corresponds to an ordinate value of unity. The axial compressive strength is the maximum stress on these curves, and corresponds to the onset of failure by shear buckling. Figure 4 shows how these maxima vary with the initial fiber angle ϕ_0. Although the stress-strain curves in Fig 2 are quite different, the strengths in Fig 4 are remarkably close. As mentioned previously, typically measured strength $> G_{12}(0)/5$, which implies $\phi_0 < 2^0$ (cf. Fig 4); also, if $\phi_0 \to 0$, then the strength is $G_{12}(0)$, which is the result from linear theory. (For F155, $G_{12}(0)$ is time-dependent.) Although not shown here, when $\phi_0 < 2^0$, the shear strain at which the maximum stress is reached

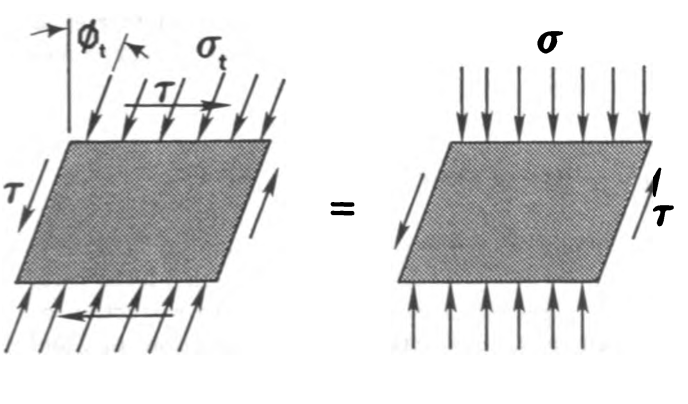

FIG 1. Representative comp... ...nt in compression and...

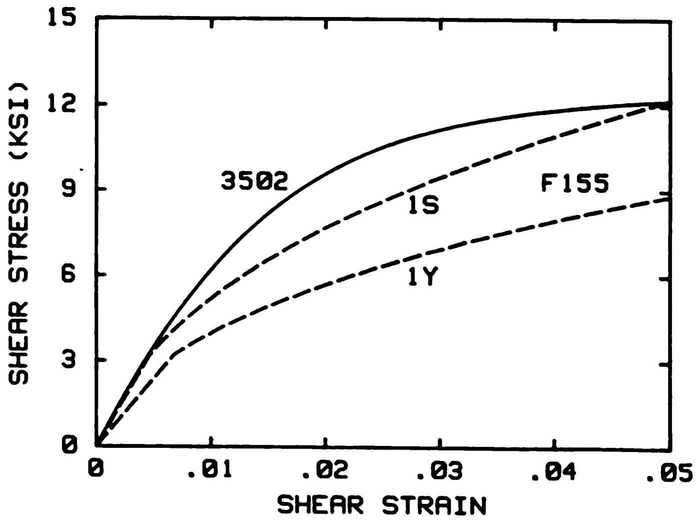

FIG 2. Stress vs strain for two composites.

is less than 0.02 for both composites; this strain is well below the ultimate strain in simple shear (cf. Fig 2).

Finally, it is readily shown that the maximum of Eq (2) is given by $\sigma_{max} = \partial\tau/\partial\gamma = (\partial\gamma/\partial\tau)^{-1}$ where $\tau = \tau(\gamma, t)$, and thus the strength is equal to the tangent modulus. The corresponding shear stress and strain may be found analytically when Eq (3) applies. Specifically, using Eqs (2) and (3) along with the condition $\partial\sigma/\partial\tau = 0$ yields

$$\tau = [\phi_0/S_m t^m (q-1)]^{1/q} \tag{4}$$

at the point $\sigma = \sigma_{max}$. Then, using this shear stress,

$$\sigma_{max} = \{S_0 + q(S_m t^m)^{1/q}[\phi_0/(q-1)]^{(q-1)/q}\}^{-1} \tag{5}$$

VISCOELASTIC MODEL

Constitutive equation

The shear stress-strain equation in the linear viscoelastic range may be written in the form

$$\gamma = \int_{0^-}^{t} S(t-t')\frac{d\tau}{d\tau'}dt' \tag{6}$$

providing that $\tau = \gamma = 0$ for $t < 0$ and the material does not age. The lower integration limit is 0^-, rather than 0, which allows for a stepwise applied stress at $t = 0$. For a creep test, $\tau = \tau_c H(t)$ (where τ_c is a constant and $H(t) \equiv 0$ when $t < 0$ and $H(t) \equiv 1$ when $t > 0$), then with the help of the Dirac delta function Eq (6) gives for $t > 0$,

$$\gamma = S(t)\tau_c \tag{7}$$

showing that $S(t)$ is the linear viscoelastic creep compliance, since this compliance is defined as γ/τ_c.

For the nonlinear range of behavior we shall use the constitutive equation

$$\gamma = S_0\tau + \int_{0^-}^{t} \Delta S(t-t')\frac{df}{dt'}dt' \tag{8}$$

where $S_0 \equiv S(0^+)$ is the initial creep compliance and $\Delta S(t) \equiv S(t) - S_0$ is the transient component of the linear viscoelastic creep compliance.

Also, $f = f(\tau)$ is an odd function of shear stress. By using $S = S_0 + \Delta S$ in (6), it is seen that it is a special case of Eq (8) if $f(\tau) = \tau$ at sufficiently low stress levels.Equation (8) was introduced by Leaderman (1943), and has met with limited success over the years (Findley et al , 1976). For some materials, including some fiber-reinforced plastics, both ΔS and f obey power laws. Specifically, with $\rho \equiv t/t_1$,

$$\Delta S = S_1\rho^m \tag{9}$$

Also,

$$f = S_2 \mid \tau \mid^q Sgn(\tau) \tag{10}$$

when $\mid \tau \mid > \tau_1$ and $f = \tau$ when $\mid \tau \mid \le \tau_1$, where t_1, S_1, S_2, m, q and τ_1 are positive constants; $Sgn(\tau)$ is

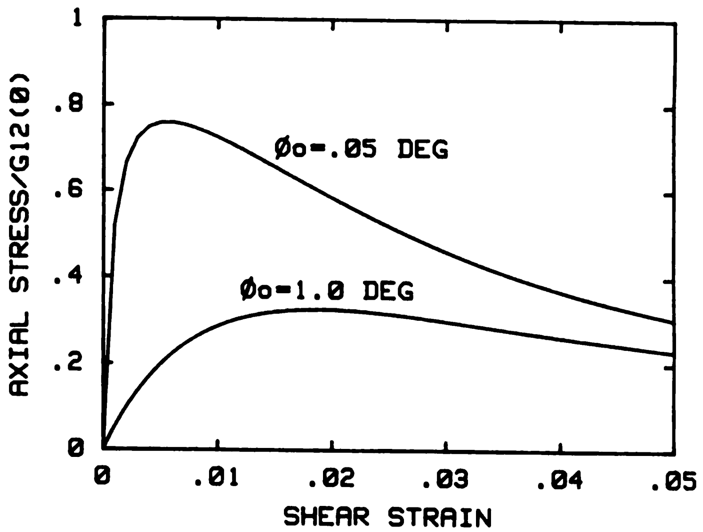

FIG 3. Effect of initial angle ϕ_0 for the 3502 composite.

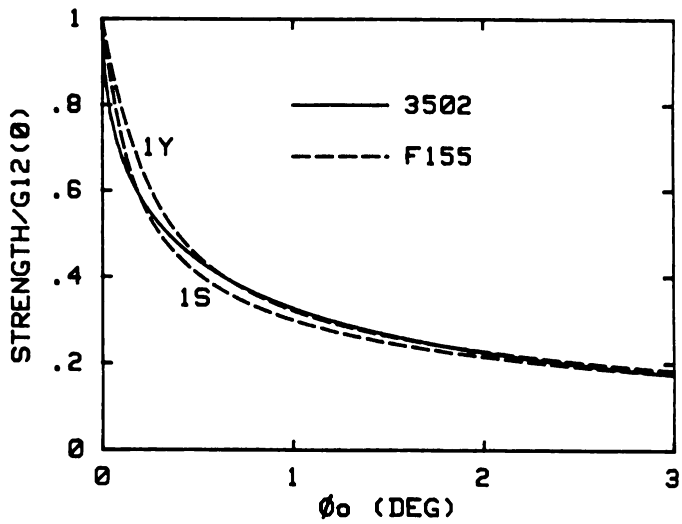

FIG 4. Effect of initial fiber angle ϕ_0 on strength.

the sign of τ and $|\ |$ denotes absolute value. For notational simplicity, we shall suppose $\tau \geq 0$ in what follows. (Observe that this formulation was used earlier in the quasi-elastic strain representation, Eq (3).) The function f will be continuous if we use

$$S_2 = \tau_1^{1-q} \tag{11}$$

On the other hand t_1 is a free constant since it may be combined with S_1; but this time constant is retained to express results in terms of a dimensionless time. Equations (9) and (10) were used by Mignery and Schapery (1991) in characterizing the behavior of a carbon fiber/rubber-toughened composite under constant and increasing loads.

For application to the fiber microbuckling problem, it will be helpful to write the constitutive equation using a normalized strain γ/ϕ_0 and other dimensionless ratios,

$$Y \equiv (S_1\tau/\phi_0)^q \quad , \quad k_0 \equiv S_0/S_1 \tag{12}$$
$$k_1 \equiv (\phi_0/S_1\tau_1)^{q-1} \quad , \quad \rho \equiv t/t_1$$

Then, with the assumption that $\tau_1 << \tau_{max}$,

$$\gamma/\phi_0 = k_0 Y^{1/q} + k_1 \int_{0-}^{\rho} (\rho - \rho')^m \frac{dY}{d\rho'} d\rho' \tag{13}$$

The linear viscoelastic case is recovered by using $q = 1$.

Buckling equation

The shear strain may be eliminated by combining Eqs (2) and (13) to obtain an integral equation for Y in terms of the applied axial stress for $\rho > 0$,

$$\frac{1 - k_0 x}{x} Y^{1/q} - k_1 \int_{0-}^{\rho} (\rho - \rho')^m \frac{dY}{d\rho'}\, d\rho' = 1 \tag{14}$$

where $x \equiv S_1\sigma$ is a dimensionless axial stress. An alternative form, which is useful when $k_0 \neq 0$, is

$$\frac{1 - \hat{\sigma}}{\hat{\sigma}}\, \hat{\tau}^{1/q} - \int_{0-}^{\hat{t}} (\hat{t} - \hat{t}')^m \frac{d\hat{\tau}}{d\hat{t}'}\, d\hat{t}' = 1 \tag{15}$$

where

$$\hat{\sigma} \equiv k_0 x = S_0\sigma \quad , \quad \hat{\tau} \equiv k_0^q Y \tag{16}$$

$$\hat{t} \equiv (k_1/k_0^q)^{1/m} t/t_1 \tag{17}$$

When the axial stress is expressed in the form $\hat{\sigma} = \hat{\sigma}(\hat{t})$, the solution $\hat{\tau} = \hat{\tau}(\hat{t})$ depends on only the exponents, m and q.

The normalized fiber misalignment angle, $\phi \equiv \phi_t/\phi_0$ may be expressed simply in terms of Y or $\hat{\tau}$ by using Eq (1),

$$\phi = Y^{1/q}/x \tag{18}$$

or

$$\phi = \hat{\tau}^{1/q}/\hat{\sigma} \tag{19}$$

If $\hat{\sigma}$ vanishes at any time, then Eq (13) may be used to predict ϕ by recognizing that

$$\phi = \gamma/\phi_0 + 1 \tag{20}$$

CREEP BUCKLING (σ = constant)

Quasi-elastic solution

For many linear viscoelasticity problems, the convolution integral may be approximated quite well by a simple product (Schapery, 1965); for example, the quasi-elastic approximation to Eq (6) is $\gamma(t) \simeq S(t)\tau(t)$. Here, we shall use this simplification in nonlinear Eq (15), and later compare the result with numerical solutions. Thus

$$\frac{1 - \hat{\sigma}}{\hat{\sigma}} \hat{\tau}^{1/q} - \hat{t}^m \hat{\tau} = 1 \tag{21}$$

or, by using Eq (19) for ϕ,

$$(1 - \hat{\sigma})\phi - \hat{t}^m \phi^q \hat{\sigma}^q = 1 \tag{22}$$

This nonlinear equation may be readily solved numerically for $\phi = \phi(\hat{t})$, given the constant stress $\hat{\sigma}$. It can be shown that the quasi-elastic solution approaches the exact solution to Eq (15) as $\hat{t} \to 0$; it is helpful to use the quasi-elastic solution at short times in developing the numerical solution to Eq (15). When $\hat{\sigma} < 1$ and $q > 1$, Eq (22) has a double-valued solution, with the lower branch providing the stable solution. Instability or failure occurs when the condition $d\hat{t}/d\phi = 0$ is satisfied; we find at this point that

$$\phi = q/(q-1)(1-\hat{\sigma}) \tag{23}$$

which, together with Eq (22), provides the quasi-elastic, normalized failure time $\hat{t}_q$,

$$\hat{t}_q = \left[\left(\frac{1-\hat{\sigma}}{\hat{\sigma}}\right)^q \left(\frac{q-1}{q}\right)^q \frac{1}{q-1}\right]^{1/m} \tag{24}$$

The effect of initial angle ϕ_0 and other parameters on the physical failure time t_q is obtained by noting that $\hat{t}_q$ is independent of ϕ_0, and thus from (12) and (17),

$$t_q = \hat{t}_q t_1 \left[\frac{k_0^q (S_1\tau_1)^{q-1}}{\phi_0^{q-1}}\right]^{1/m} \tag{25}$$

When $\hat{\sigma} = 1$ then $t_q = 0$, which corresponds to elastic buckling; certainly, for even higher loads, $\hat{\sigma} > 1$, failure occurs immediately upon loading.

Exact and numerical solutions

Equation (15) may be simplified for creep buckling by introducing one more change of variables. Specifically, use

$$S_r \equiv \tau/\tau_0 \quad , \quad t_r \equiv t/t_q \tag{26}$$

where τ_0 is the shear stress at $t = 0^+$,

$$\tau_0 \equiv \sigma\phi_0/(1 - \sigma S_0) \tag{27}$$

and t_q is given by Eq (25). Then the integral equation for $S_r = S_r(t_r)$ is

$$S_r - k\int_{0^-}^{t_r} (t_r - t_r')^m \frac{dS_r^q}{dt_r'} dt_r' = 1 \tag{28}$$

where

$$k \equiv [(q-1)/q]^{q-1}/q \tag{29}$$

Thus, $S_r(t_r)$ is independent of applied stress σ and all other parameters, except for m and q. This result is very helpful since an analytical solution to Eq (28) has not been obtained except for a Maxwell model ($m = 1$). For $m = 1$ we find that

$$S_r = [1 - (q-1)kt_r]^{1/(1-q)} \tag{30}$$

which provides a finite failure time when $q > 1$,

$$t_r = [q/(q-1)]^q \tag{31}$$

This time ratio t/t_q increases monotonically (with decreasing q) from e at $q = \infty$ to ∞ at $q = 1$. The same behavior of the failure time has been obtained from the numerical solution of Eq (28) for $0 < m < 1$. For the linear viscoelastic case, $q = 1$, the exact solution diverges exponentially in time (Schapery, 1991), so that $t_r = \infty$ for all $m > 0$.

Equation (28) was solved numerically after removing the discontinuity at $t = 0$. Noting that $S_r = 0$ when $t_r < 0$ and $S_r = 1$ at $t_r = 0^+$, Eq (28) becomes, for $t_r > 0$,

$$S_r - kt_r^m - k\int_{0+}^{t_r} (t_r - t_r')^m \frac{dS_r^q}{dt_r'} dt_r' = 1 \tag{32}$$

This integral equation was solved numerically by converting it to a matrix equation by using a piecewise linear representation of $S_r^q(t_r)$; excellent accuracy was obtained with 100 time intervals.

Figures 5 and 6 give results for $m = 0.05$ and $m = 0.5$, respectively, using $q = 2.4$; the Maxwell model solution, Eq (30), is also shown in both figures. Numerical solutions to Eq (28) are designated as *viscoelastic.*

It is seen that the quasi-elastic approximation provides a conservative solution to the failure time. Moreover, even for the extreme case of highly rate-dependent behavior ($m = 1$), the failure time is not much greater. Considering the scatter in actual failure time that one can expect (probably greater than the spread of the different cases in Figs 5 and 6) in view of its sensitivity to the initial fiber angle as inferred from Eq (25), a quasi-elastic prediction

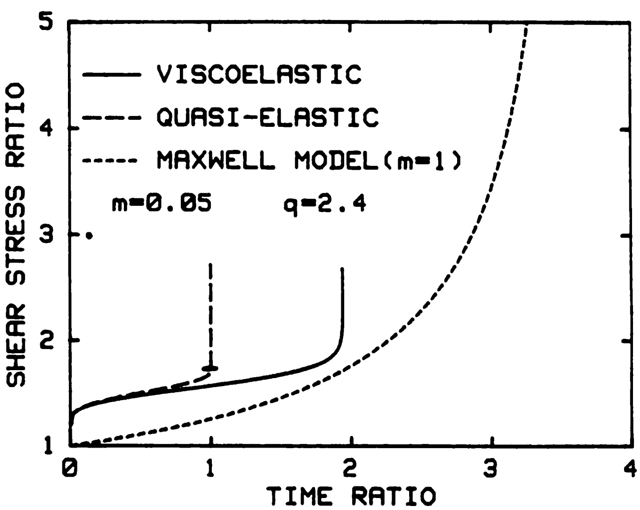

FIG 5. Shear stress ratio τ/τ_0 vs time ratio t/t_q

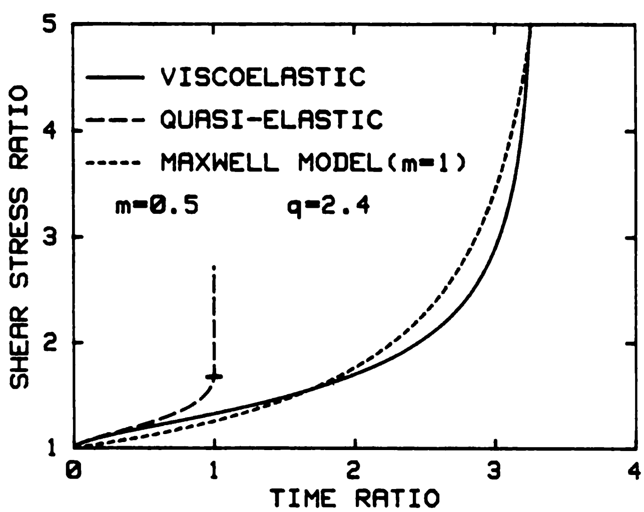

FIG 6. Shear stress ratio τ/τ_0 vs time ratio t/t_q

may be adequate for engineering applications, especially for small m.

Finally, we mention that the overall axial strain is practically independent of the amount of local shearing up to failure, and thus is not a good indicator of impending creep failure.

BUCKLING UNDER INCREASING STRESS

The axial stress is taken as a power law in time for $t > 0$,

$$\sigma = \sigma_n (t/t_1)^n \tag{33}$$

where σ_n and n are positive constants. In terms of normalized variables in Eqs (16) and (17),

$$\hat{\sigma} = k_n \hat{t}^n \tag{34}$$

where

$$k_n = S_0 \sigma_n (k_0^q / k_1)^{n/m} \tag{35}$$

In order to simplify the solution to Eq (15), it is helpful to introduce another change in dependent variable. Specifically, define a new time variable,

$$T \equiv k_n^{1/n} \hat{t} \tag{36}$$

Then

$$\hat{\sigma} = T^n \tag{37}$$

and Eq (15) becomes

$$\frac{1-\hat{\sigma}}{\hat{\sigma}} \hat{\tau}^{1/q} - k_2 \int_{0^-}^{T} (T - T')^m \frac{d\hat{\tau}}{dT'} dT' = 1 \tag{38}$$

where

$$k_2 \equiv k_n^{-m/n} = k_1 / k_0^q (S_0 \sigma_n)^{m/n} \tag{39}$$

Note that since $n > 0$ the lower integration limit may be taken as 0 since the solution will be continuous at $T = 0$. The solution $\hat{\tau} = \hat{\tau}(T)$ to Eq (38) is seen to depend on the load rate-dependent dimensionless parameter, k_2, as well as the exponents m, n and q. The higher the loading rate, as specified by increasing values of σ_n, the smaller will be k_2, and thus, as expected, the effect of viscoelasticity will decrease.

Quasi-elastic solution

For this case Eq (38) becomes,

$$\frac{1-\hat{\sigma}}{\hat{\sigma}} \hat{\tau}^{1/q} - k_2 T^m \hat{\tau} = 1 \tag{40}$$

or, in terms of normalized fiber angle using Eq (19),

$$(1-\hat{\sigma})\phi - k_2 T^m \phi^q \hat{\sigma}^q = 1 \tag{41}$$

As in the creep case, the failure (initiation) time is obtained from the condition $d\hat{T}/d\phi = 0$. The angle at failure initiation ϕ_q is the same as in Eq (23), except now $\hat{\sigma}$ depends on the failure time T_q. Denote the stress at failure by $\hat{\sigma}_q$, and then substitute Eq (23) into (41) to obtain a nonlinear algebraic equation for $\hat{\sigma}_q$,

$$\hat{\sigma}_q (1 + k_3 \hat{\sigma}_q^p) = 1 \tag{42}$$

where

$$p \equiv m/qn \quad , \quad k_3 \equiv q \left[k_2 / (q-1)^{(q-1)} \right]^{1/q} \tag{43}$$

and Eq (37) has been used to eliminate T in favor of $\hat{\sigma}$. In many cases $p << 1$; thus, as a first approximation use $\hat{\sigma}_q^p = 1$, which yields

$$\hat{\sigma}_{q1} = 1/(1 + k_3) \tag{44}$$

A better approximation may be obtained by examining the behavior of $\hat{\sigma}_q$ for small values of p and for the cases in which k_3 is very large and very small. We obtain

$$\hat{\sigma}_q \simeq \hat{\sigma}_{q1}^{\alpha} \tag{45}$$

where

$$\alpha \equiv \left(1 + \frac{k_3 p}{1 + k_3} \right)^{-1} \tag{46}$$

This result has been found to agree with numerical solutions to Eq (42) to within 3% for all cases of practical interest which were studied; for all $p, k_3 > 0$, a maximum error of only 10% was found.

An equation for $\phi = \phi(\hat{\sigma})$ prior to failure may be obtained by using Eq (37) to express (41) entirely in terms of ϕ and $\hat{\sigma}$,

$$\phi - k_2 \frac{\hat{\sigma}^{q+(m/n)}}{1-\hat{\sigma}} \phi^q = (1-\hat{\sigma})^{-1} \tag{47}$$

Numerical solution

A numerical method similar to that used for the creep problem was used to solve Eq (38). As before, it is helpful to use the quasi-elastic solution to provide the very short time response. However, in order that the short time quasi-elastic solution approach the exact solution as $T \to 0$, it is found necessary to modify the constant k_2. Specifically, replace k_2 in Eqs (40) and (41) by

$$k_2' \equiv I_r k_2 \tag{48}$$

where k_2 is given by Eq (39) and, with $r = nq$,

$$I_r \equiv \Gamma(r+1)\Gamma(m+1)/\Gamma(r+m+1) \tag{49}$$

in which $\Gamma(x)$ is the Gamma function of x. When $m << 1$ or $r << 1$, then $I_r \simeq 1$.

Figures 7 and 8 provide results for $m = 0.05$ and $m = 0.5$, respectively, using $q = 2.4$; the value of $k_2 = 10$ was used to emphasize viscoelastic effects. The Maxwell model solution ($m = 1$) was found numerically, and is shown for comparison. *Viscoelastic* in the figures refers to the numerical solution to Eq (38). The horizontal axis is the axial stress ratio $\hat{\sigma}/\hat{\sigma}_q = \sigma/\sigma_q$, where σ_q is the quasi-elastic failure stress. The k_2', Eq (48), was used in place of k_2 to predict all quasi-elastic solutions from Eqs (41) and (42). It is observed in these figures that the quasi-elastic solution for $m = 0.05$ and $m = 0.5$ is close to the numerical solution of Eq (38) for most of the time; when $m = 0.05$, the quasi-elastic strength is very close to the viscoelastic strength.

CONCLUDING REMARKS

The importance of the effect of initial fiber angle and shear nonlinearity on strength has been shown. In a previous study (Schapery, 1991) linear theory was used to predict the growth of the fiber angle under cyclic loading. One may combine the present and earlier analyses to predict the influence of low-level cyclic loading on the residual compressive strength (Schapery, 1993); specifically, the initial fiber angle in the present nonlinear analysis would be taken as the residual fiber angle following cyclic loading.

We have not accounted for the spacewise distribution of initial fiber angles, the free surfaces, and resulting nonuniform stress and strain distributions. However, it is believed that the primary factors which influence compressive strength are contained in the simple shear model. Initial fiber angles have been reported to range from about 1/3 to 3 degrees (Wisnom, 1990 and Yurgartis, 1987), depending on the composite, which through the present theory is consistent with the range of experimental strengths. What is needed at this time in order to check the theory and develop a more detailed, realistic model is experimental work which combines knowledge of initial fiber angle distributions, shear stress-strain behavior and compressive strengths, all on one or more composites. Experimental studies, in which changes in shear strain-strain behavior due to temperature, loading history, etc., are correlated with compressive strength would also be useful in assessing the model.

Estimation of Lyapunov exponents using a semi-discrete formulation

Josef S Török

Department of Mechanical Engineering
Rochester Institute of Technology, Rochester NY 14623

Lyaponov exponents are a generalization of the eigenvalues of a dynamical system at an equilibrium point. They are used to determine the stability of any type of steady-state behavior, including chaotic solutions. More specifically, Lyapunov exponents measure the exponential rates of divergence or convergence associated with nearby trajectories. This paper presents an efficient method of estimating the Lyapunov spectrum of continuous dynamical systems. Based on the Lie series expansion of the flow, the technique can be readily implemented to estimate the Lyapunov exponents of dynamical systems governed by ordinary differential equations.

INTRODUCTION

For periodic motion, the spectrum of exponents contains only zero or negative values, indicating convergence to a highly predictable motion. At the other extreme, a chaotic system will exhibit at least one positive exponent. A positive exponent is significant, because it gives an indication of the rate at which one loses the ability to predict the system response. This is closely related to the property of sensitive dependence on initial conditions, which is characteristic of chaotic systems. Therefore, one way to determine if a system is behaving in a chaotic manner is to calculate the Lyapunov exponents. A further motivation for calculating these exponents is that a knowledge of the entire spectrum of Lyapunov exponents can be used to calculate an approximate fractal dimension of the attractor (Holmes and Moon, 1983). Unfortunately, there is no general analytical way to determine the Lyapunov exponents for a general system of equations. The Lyapunov spectrum must be numerically approximated.

It is a simple calculation to determine the Lyapunov exponents of a linear system. Linear differential equations can in principle be solved exactly, and thus the exponents can be determined by an inspection of the solution. For example, the unforced equation

$$\ddot{q} + 5\dot{q} + 6q = 0$$

has the general solution

$$q = Ae^{\lambda_1 t} + Be^{\lambda_2 t}$$

in which the Lyapunov exponents, λ_1 and λ_2, are equal to -2 and -3, respectively.

A forced system such as

$$\ddot{q} + 5\dot{q} + 6q = F\cos(\omega t)$$

has the same exponents, but with an additional exponent that has a zero real part, i.e. purely imaginary. This fact is apparent from the general solution of the problem, which is readily computed as

$$q = Ae^{\lambda_1 t} + Be^{\lambda_2 t} + C(e^{i\omega t} + e^{-i\omega t})$$

It is interesting to note that the exponents in this example are constant, in that they do not depend on initial conditions. Furthermore, since the forcing function does not alter the complementary solution, λ_1 and λ_2 are independent of F and ω. This makes the computation of Lyapunov exponents for linear systems very easy.

There are no analytical methods available to precisely determine the Lyapunov spectrum for nonlinear systems. Nonlinearities can cause repeated stretching and folding of a small region of initial conditions as it evolves in its state space (Wolf et al, 1985). This causes the locally-determined Lyapunov exponents to vary considerably over a trajectory. Thus, it is necessary to examine the long-time average of the exponents. Furthermore, unlike the case for linear systems, the Lyapunov exponents change with forcing amplitude and frequency. This important fact is the motivation of this investigation.

Even for a relatively simple nonlinear differential equation, such as the Duffing equation, a periodic or even a chaotic response can be obtained for a given set of system parameters merely by changing the forcing amplitude and frequency. For example, the forced Duffing equation

$$\ddot{q} + 0.1\dot{q} - q + q^3 = 3.2\cos(\omega t)$$

yields a periodic response for $\omega = 0.482$, but exhibits chaotic behavior for $\omega = 0.475$. This indicates that one of the exponents has shifted from negative to positive over a very small change in the forcing frequency ω.

ESTIMATION OF LYAPUNOV EXPONENTS

In higher order systems, Lyapunov exponents are determined by examining the long-term evolution of an infinitesimal n-sphere of initial conditions, with 'n' being the order of the dynamical system. As the system evolves, the initial n-sphere will expand or contract along its n principal axes, resulting in a deformed n-ellipsoid.

The general method of numerically calculating the exponents of a dynamical system proceeds in the following manner. First, a point that lies near the steady-state attractor of the system of interest is selected. This means that the system must first be integrated well into its post-transient state. Initially, a vector of magnitude ϵ and arbitrary direction is chosen and is attached to a point on the trajectory. It is important that this ϵ be small because as pointed out above, a repeated stretching and folding can take place in the state space. Only the stretching of the space is of interest here. A small test vector is better able to avoid any effects of folding. A second vector, perpendicular to the first, but equal in magnitude, is also constructed at the test point.

Additional vectors are added in a similar fashion until the vector set forms an orthogonal basis $\{b_i\}$ for the state space in the region of the test point. The test point and nearby initial conditions determined by the vector set are then integrated ahead for a short length of time.

After integration, the largest vector is used to calculate the largest local exponent from the equation

$$\lambda_1 = (\ 1/\Delta t\ )\ \ln(\ l_f/\epsilon\ )$$

where Δt is the time interval over which the system is integrated and l_f is the length of the largest vector after integration. This vector will automatically tend toward the direction of greatest divergence (or convergence). The second vector is not free to tend toward the direction associated with the second largest exponent because of the effect of the largest exponent upon its evolution. Instead, the second exponent is determined from the calculation of the sum of the first two exponents, which measures the rate of contraction of an area in state space. This is obtained from the equation

$$\lambda_1 + \lambda_2 = (\ 1/\Delta t\ )\ \ln(A_f/\epsilon^2)$$

in which A_f is the final area of the space determined by the first two vectors. Subsequent exponent sums are computed in a similar fashion for higher dimensional systems (Wolf et al, 1985).

The largest vector is then normalized to a magnitude of ϵ, while its direction is preserved, enabling this vector to continue converging to the direction associated with the largest exponent. Additional vectors are again constructed perpendicular to the first. This is repeated over a long time in the simulation and the exponents are then calculated as a long-time average over the steaty-state motion. This long-time average is extremely important, as even very close trajectories leading to periodic motion can temporarily diverge from each other over short time intervals. This phenomenon is what characterizes transient chaos.

This procedure is based directly on the definition of the Lyapunov spectrum. The one drawback is that the collection of initial conditions must be repeatedly integrated over short time intervals. The evolution of an n-sphere must be carefully tracked to determine the divergence (convergence) rates along the attractor. In the following section, a more convenient method is proposed based on the concept of a forward-advance mapping.

COMPUTATION OF LYAPUNOV EXPONENTS

The determination of the Lyapunov exponents for ordinary differential equations will be accomplished using a semi-discrete formulation. The dynamics of the system will be discretized by the introduction of a time-advance mapping. Consequently, Lyapunov exponents can be calculated by using techniques that work well for discrete dynamical systems, as addressed below.

Consider a nonlinear point mapping defined on R^n by the equation

$$\mathbf{x}_{n+1} = \mathbf{F}(\mathbf{x}_n),\ n > 1 \tag{1}$$

Then to the first order,

$$\delta\mathbf{x}_{n+1} = \mathbf{F}\ (\mathbf{x}_n + \delta\mathbf{x}_n) - \mathbf{F}(\mathbf{x}_n) \tag{2}$$

$$= [\mathbf{DF}]_n \delta\mathbf{x}_n \tag{3}$$

in which $[\mathbf{DF}]_n$ is the Jacobian of $\mathbf{F}(\mathbf{x})$ evaluated at $\mathbf{x} = \mathbf{x}_n$. From the usual definition

$$\mathrm{DF}_{ij} = \partial F_i/\partial x_j \tag{4}$$

Thus equation (3) gives an estimate of the variation at the $(n+1)^{st}$ step of the iteration in term of the variation at the n^{th} step. Repeatedly applying equation (3) results in

$$\delta x_{n+1} = DF_n * DF_{n-1} * DF_{n-2} * \ldots\ldots * DF_1(\delta x_1) \quad (5)$$

Equation (5) represents the variation at the $(n+1)^{st}$ step in terms of the initial variation δx_1. To avoid divergence of the vector norms, due to repeated application of the Jacobian matricees, it is more convenient to express equation (5) as

$$\delta x_{n+1} = DF_n[DF_{n-1} \ldots\ldots\ldots DF_1(\delta x_1)] \quad (6)$$

In equation (6), the latest Jacobian is applied to the current set of vectors. To avoid divergence of the variations, due to stretching of orbits, a Gram-Schmidt orthonormalization procedure is applied at each step to accomplish two things:

(i) estimate the local growth rate of the vectors

(ii) replace the vectors with a renormalized set as described in the previous section.

The vector with a largest growth rate is always renormalized and used as the first replacement vector. It should be noted that the growth rate of the local basis vectors is governed by the absolute values of the eigenvalues at each iteration. Denote the eigenvalues of $[DF]_n$ at the n^{th} iteration by

$$\Lambda_1(n),\ \Lambda_2(n),\ \ldots\ldots\ ,\Lambda_n(n). \quad (7)$$

For non-degenerate cases, the magnitude of each eigenvalue can be expressed as

$$\Lambda_1(n) = \exp(\lambda_{loc,i}(n)) \quad (8)$$

so that

$$\lambda_{loc,i}(n) = \log \Lambda_i(n) \quad (9)$$

represents the local convergence (or divergence) rate.

The Lyapunov exponents are computed as a long-time average, consequently the global behavior of the mapping is determined by the eigenvalues of the product Jacobian

$$[JP] = [DF_n][DF_{n-1}] \ldots\ldots [DF_1] \quad (10)$$

as $n \to \infty$. Thus the Lyapunov exponents for mappings such as (1) are defined as

$$\lambda_i = \lim_{n\to\infty} (1/n) \textstyle\sum_{k=1} \log \Lambda_i(k) \quad (11)$$

In order to apply the above to continuous dynamical systems, the flow must be discretized. That is, the governing equations must be integrated forward, for arbitrary initial conditions, to a specified time in order to construct a time-advance mapping. The procedure is outlined as follows.

An initial value problem defined by a system of differential equations

$$\dot{x} = X(x,t),\ \ x(0) = x_0$$

is integrated from the initial condition x_o. Denote this solution as $x(t;x_0)$. Since the initial condition, x_0, is arbitrary, a sequence of points is defined inductively as

$$x_{n+1} = F(x_n) \quad (13)$$

in which

$$x_{n+1} = x(h;x_n) \quad (14)$$

At each step, the initial point x_0 in (12) is replaced by the current state vector x_n. That is, x_{n+1} is obtained by advancing the solution of (12) over a time $\Delta t = h$, from an initial point x_n.

Since most differential equations cannot be integrated analytically, the time-advance mapping must be constructed with the aid of numerical integration schemes. The drawback of using a numerical routine such as Runge-Kutta, is that an explicit form of the time-advance mapping (13) is not obtained.

The standard method of estimating local divergence (or convergence) rates entails the comparison of the time-evolution of two trajectories at neighboring points (Wolf et al, 1985). The neighboring trajectories are tracked by solving the associated variational equation

$$\frac{d}{dt}(\delta x) = [J]\ \delta x$$
$$\delta x(0) = \delta x_0 \quad (15)$$

simultaneously with the original differential equation (12). The variational equations (15) are obtained by applying the variational operator to equation (12).

Although equation (15) is linear, the coupled system is now twice the order of the original system (12). This makes the numerical integration more tedious. Essentially, the differential equations along with the coupled set of local variational equations must be numerically integrated over small displacements in the phase space. The local divergence (or convergence) are determined by analyzing the evolution of the variations δx.

A more attractive approach is to construct an approximate, yet explicit, form of the time-advance map

$$x_{n+1} = F(x_n) \tag{16}$$

The objective is to develop an explicit mapping with no worse of an error than a corresponding numerical integration scheme. Since errors are typically based on Taylor series expansions, a truncated Taylor expansion of the solution will not introduce any more errors than numerical integration of the differential equations.

Series solutions to an initial value problem can be conveniently and efficiently developed from the theory of continuous transformation groups (Torok and Advani, 1985). Briefly, the coefficients of the series expansion can be computed from the associated infinitesimal generator of the system of differential equations. Specifically, given an initial value problem

$$\begin{aligned} \dot{x}_1 &= X_1(x_1, x_2, \ldots\ldots, x_n), \;\; x_1(0) = \dot{x}_1 \\ \dot{x}_2 &= X_2(x_1, x_2, \ldots\ldots, x_n), \;\; x_2(0) = \dot{x}_2 \\ &\vdots \\ \dot{x}_n &= X_n(x_1, x_2, \ldots\ldots, x_n), \; x_n(0) = \dot{x}_n \end{aligned} \tag{17}$$

the infinitesimal generator is defined as the operator

$$U = X_1\, \partial/\partial x_1 + X_2\, \partial/\partial x_2 + \ldots\ldots + X_n\, \partial/\partial x_n \tag{18}$$

in which the coefficients in (18) are given as the right hand sides of equation (17). It can be shown that the series representation of the solution $x_i{}^t = x_i(t)$ is given by

$$x_i{}^t = x_i + (Ux_i)t + (U^2x_i)t^2/2 + \ldots + (U^kx_i)\, t^k/k! + \ldots$$

in which the variable, x_i, represents an arbitrary initial value.

Thus, the explicit time-advance mapping is developed as

$$\begin{aligned} (x_i)_{n+1} &= F((x_i)_n) \\ &= x_i{}^h \end{aligned} \tag{19}$$

That is,

$$\begin{aligned} (x_i)_{n+1} &= x_i{}^h \\ &= x_i + (Ux_i)h + (U^2x_i)h^2/2 + \ldots \end{aligned} \tag{20}$$

in which $(x_i)_n$ is substituted for the initial condition x_i.

As an example, consider the problem

$$\begin{aligned} \dot{x} &= x^2, \;\; x(0) = x_o \\ \dot{y} &= xy, \;\; y(0) = y_o \end{aligned} \tag{21}$$

The infinitesimal generator associated with this system of differential equations is given as the operator

$$U = x^2\, \partial/\partial x + xy\, \partial/\partial y \tag{22}$$

The powers of the operator U are computed successively as

$$\begin{array}{ll} Ux = x^2 & Uy = xy \\ U^2x = 2x^3 & U^2y = 2x^2y \\ U^3x = 6x^4 & U^3y = 6x^3y \\ U^4x = 24x^5 & U^4y = 24x^4y \\ \vdots & \vdots \end{array} \tag{23}$$

and the series representations of the solutions are

$$x^t = x + x^2t + 2x^3t^2/2 + 6x^4t^3/3! + 24x^5t^4/4! + .. \tag{24}$$

$$y^t = y + xyt + 2x^2yt^2/2 + 6x^3yt^3/3! + 24x^4yt^4/4! + .. \tag{25}$$

in which x and y are arbitrary initial conditions.

By inspection, the solutions (24) and (25) are found to converge to

$$x^t = x/(1-xt) \tag{26}$$

$$y^t = y/(1-xt) \tag{27}$$

As mentioned above, the variables x and y in equations (26) and (27) represent arbitrary initial conditions. Hence substitution the initial conditions from equations (21), results in the solutions

$$x(t) = x_o/(1-x_ot) \tag{28}$$

$$y(t) = y_o/(1-x_ot) \tag{29}$$

Furthermore, the time-advance solution for arbitrary h is given by

$$x^h = x_o/(1-x_oh) \tag{30}$$

$$y^h = y_o/(1-x_oh) \tag{31}$$

Alternatively, since x_o and y_o are abitrary, the time-advance mapping is explicitly deduced as

$$x_{n+1} = x_n/(1-hx_n) \tag{32}$$

$$y_{n+1} = y_n/(1-hx_n) \tag{33}$$

Hence the conti[illegible] dynamics of the system (12) are equivalently, [illegible]sely, represented by the discrete [illegible]ing [illegible] (33). Thus point mapping techniques are applicable, eliminating the cumbersome numerical tracking of trajectories.

Most nonlinear systems, however do not admit solutions which are expressible in terms of elementary functions as in (28) and (29). In such cases, a truncated series representation is used to construct the time-advance mapping. Using this discretized version of the dynamics, equations (1) through (11) are used to estimate the Lyapunov spectrum.

SUMMARY

A semi-discrete algorithm for the computation of Lyapunov exponents associated with continuous dynamical systems has been discussed. The proposed method consists of developing formal power series solutions based on Lie series expansions of the flow. The truncated power series can be used to construct forward advanced mappings, thereby converting a continuous dynamical system to a discrete one. Methods known to be reliable for discrete systems can then be utilized, eliminating the necessity of integrating the associated variational equations simultaneously with the original equations of motion.

Table 1. illustrates the results obtained by applying the proposed method to estimate the Lyapunov spectrum of the Lorenz system (Wolf et al, 1985). The complete spectrum of exponents of the Lorenz system is approximately (2.16, 0.0, -32.4) bits per second. The parameter h represents the time-advance used for the forward advance mapping. The integer N represents the number of time steps (in thousands) used for the averaging process. Excellent agreement is implied, especially for smaller time steps. It appears that the proposed algorithm is sensitive to the particular time step used, but does not vary considerably with the number of averaging steps.

A procedure for simulating aerodynamic/dynamic interactions is described. The equations of motion of the flowing air and the lifting structure are integrated numerically by an iterative technique based on Hamming's predictor-corrector method. The solution provides the flowfield and the motion of the lifting body simultaneously. The technique is modular and different models of the flow and the structure can be incorporated by simply changing subroutines. For the current examples of wingrock of highly swept delta wings and flutter of very flexible, very high-aspect-ratio wings, the flowfields are considered incompressible and modeled by vortex-lattice and continuous vorticity-panel methods. These models are inherently nonlinear and provide a force-free wake as part of the solution. It is shown that the instabilities can be easily suppressed by means of actively controlled flaps.

INTRODUCTION

In this article we discuss one aspect of the problem of modelling fluid-structure interactions, namely the numerical simulation of the motion of a lifting structure in a uniform, subsonic stream. We consider the spontaneous motion that develops as the angle of attack of a highly swept delta wing mounted on a free-to-roll sting in a uniform stream is steadily increased; the phenomenon is known as wing rock. Then we consider the spontaneous motion that develops when the speed of a uniform stream flowing past a thin, high-aspect-ratio, very flexible wing increases while the angle of attack decreases in such a way that the lift force remains constant. Both spontaneous motions are manifestations of a loss of dynamic stability, and both are forms of flutter. We refer to the former as rigid-body flutter and to the latter as aeroelastic flutter.

Wing rock can be a problem for a highly maneuverable military aircraft when it is performing tactical, high-alpha maneuvers and even when it is landing. Highly flexible, large-aspect-ratio wings are often found on the high-altitude, long-endurance (HALE) aircraft now intended for atmospheric monitoring and previously intended for observation platforms to verify some of the provisions of the strategic-arms-reduction treaty (START). Thus, both phenomena occur well within the subsonic-flow regime. We consider the flow to be incompressible.

The simulations of such phenomena involve equations of motion for both the lifting bodies and the flowing air. An apparent impasse develops: In order to integrate the equations of motion of the body, one must know the aerodynamic forces acting on the body; and in order to integrate the equations of motion of the flowing air and subsequently find the aerodynamic forces, one must know the motion of the body (for the boundary conditions on the flowfield). The difficulty can be resolved by an iteration scheme; to obtain the present results, we developed an algorithm based on Hamming's predictor-corrector method.

The remainder of the article is divided into five sections: In the second section, we describe the numerical model used to simulate the flowfield. In the third section, we discuss the simulation of wing rock and its suppression by feedback-controlled flaperons. In the fourth section, we discuss aeroelastic flutter and its suppression by feedback-controlled flaperons. Finally, in the last section, we present some concluding remarks.

AERODYNAMIC MODEL

The flowfield is modelled by either the general unsteady vortex-lattice method or the general unsteady vorticity-panel method. The basis for the methods is the definitions of incompressible flow, Div $\vec{v}=0$ (where $\vec{v}$ is the velocity), and vorticity, $\vec{\Omega}=$ Curl $\vec{v}$. These two equations can be manipulated to provide $\vec{v}$ as a function of $\vec{\Omega}$:

part of "MECHANICS PAN-AMERICA 1993" edited by M[illegible] [illegible]ilva and CEN Mazzilli ASME Reprint No AMR134
Appl Mech Rev vol 46, no 11, part 2, November 1993

$$\vec{v}(\vec{r}_p, t) = \frac{1}{4\pi} \iiint_{\text{volume}} \frac{\vec{\Omega}(\vec{r}_s, t) \times (\vec{r}_p - \vec{r}_s) d\tau(\vec{r}_s)}{|\vec{r}_p - \vec{r}_s|^2} \quad (1)$$

where $d\tau$ is the volume element at position $\vec{r}_s$ in the flowfield $\vec{v}$ is the velocity at position $\vec{r}_p$ in the flowfield, and $\times$ denotes the vector product.

There are six characteristics of the velocity given by Eq. (1) that are worth mentioning:

1. When the vorticity is confined to a straight line segment, Eq. (1) reduces to the Biot-Savart law.

2. The volume of the "flowfield", over which the integration in Eq. (1) is carried out, includes the interiors of solid objects in the actual flow.

3. The vorticity, $\vec{\Omega}$, may be zero in large parts of the flowfield, and the velocity, $\vec{v}$, is irrotational there.

4. Vorticity any where in the flowfield generates velocity everywhere.

5. The velocity, $\vec{v}$, decays as the reciprocal of the distance from the vorticity-containing regions.

6. Equation (1) is a purely kinematic relationship and, consequently, is valid for "viscous" as well as "inviscid" models of incompressible flowfields.

In the actual flow over a wing, the vorticity in the boundary layers on the upper and lower surfaces and the vorticity in the wake generate a velocity field that disturbs the freestream to the extent that the no-slip and no-penetration conditions are satisfied. We consider thin wings and merge the boundary layers on the upper and lower surfaces, into a single vortex sheet, which is called a lifting surface here. And we also consider the wake to be a vortex sheet. Because the position of the vortex sheet representing the wing is prescribed, a pressure jump across the sheet exists. The sheet representing the wake is allowed to deform freely in such a way as to eliminate the pressure jump.

To facilitate the computations in one procedure, Konstadinopoulos et al. (1985), we represent the lifting surface as a lattice of discrete vortex lines, which divides the sheet into a system of closed four-sided elements. Each discrete vortex segment of a given element is a straight line. The quadrilateral elements are not, in general, planar. To satisfy the requirement of spatial conservation of circulation, the circulations around the segments along the four sides of a given element are equal. The discrete vortex arrangement for a given element produces the same velocity field as a panel of constant-strength doublets when the panel is planar.

In the other procedure, Mracek et al. (1993) and Mracek (1988), we represent the lifting surface as a system of triangular panels over which the two in-plane components of vorticity vary linearly. This vorticity field is divergenceless. As a consequence discrete vortex lines form along the edges of the lifting surface.

To use either of the methods, one must specify where separation occurs; usually this means that one must specify the edges of the lifting surface from which the wakes emanate. The rate at which vorticity is shed into the wakes is determined by forcing the pressures on the upper and lower sides of the lifting surface to be equal along the edges where the wakes are attached. After the vorticity has been shed, it convects with the local fluid-particle velocity and the circulation around a given segment remains constant. The procedure generates a wake in the force-free position for an inviscid fluid as part of the solution. Hence, the wake is modelled as a region of rotational, inviscid flow. Two computed wakes are shown in Figs. 1 and 2.

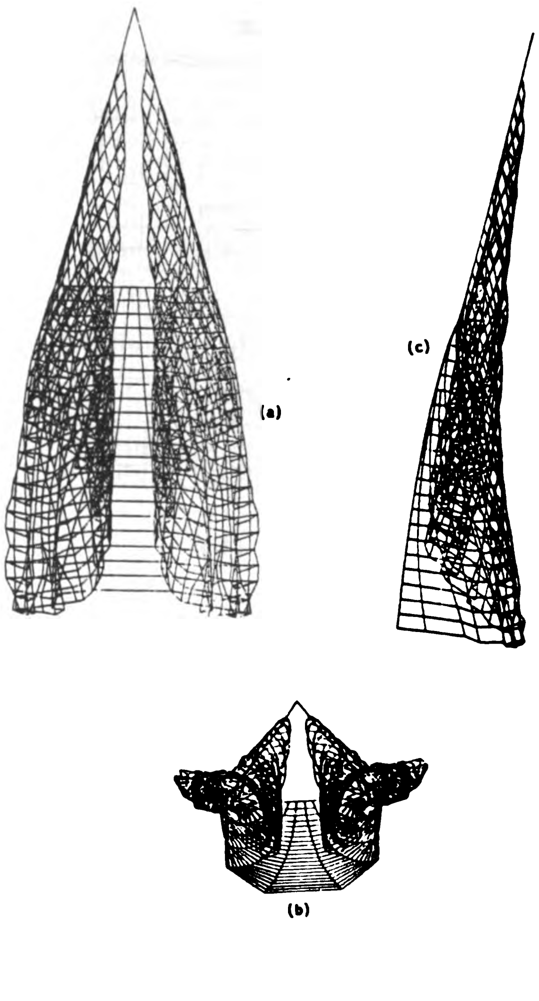

Fig. 1. Computed steady-state wake for flow past a unit-aspect-ratio delta wing at 20° angle of attack. (a) Top view, (b) rear view, and (c) side view.

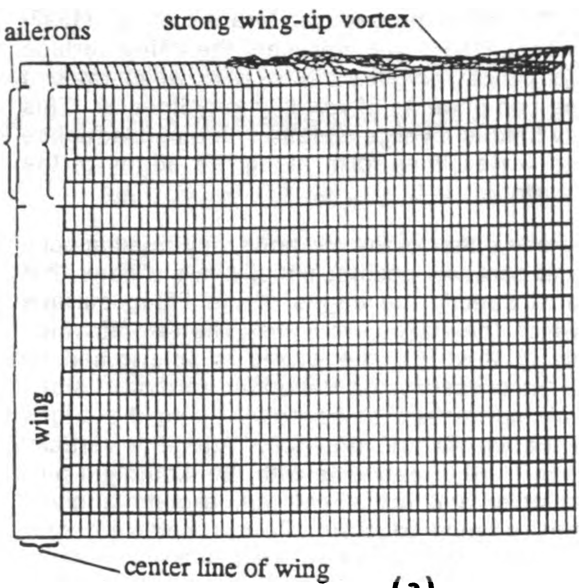

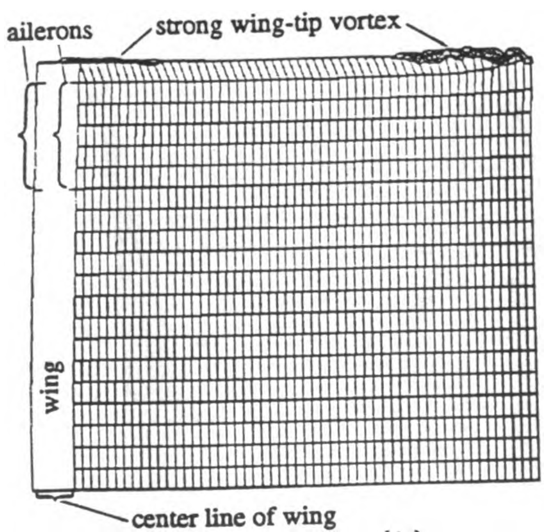

Fig. 2. Computed wake for unsteady flow past an aspect-ratio 20 rectangular wing. The wing is oscillating in bending and twist. In part (a) the wing tip is moving upward and nearly no vorticity is generated at the wing-tip. In part (b) the upward motion of the wing tip is slowing and strong wing-tip vorticity is beginning to develop.

The vorticity in the wake influences the flow over the wing. At any given instant, the vorticity in the wake was shed from the edges of the wing at an earlier time; hence, the current flowfield is influenced by what happened earlier. In other words, the current flowfield depends on the history of the flow, and the historian is the wake. Typically, the vorticity most recently shed is closest to the wing and has the strongest influence on the flow over the wing; hence, the historian has a fading memory.

In both procedures, the vorticity on the lifting surface is determined by imposing the no-penetration condition, and there is one point in each element of the lifting surface, called the control point, where this condition is imposed. In both procedures, the control point is the centroid of the corners.

The pressures are computed with the unsteady Bernoulli equation. The difference between the pressures on the two sides of the element is multiplied by the area of, and the unit vector normal to, the element to produce the elemental force. Then the elemental forces and their moments are summed.

WING ROCK

In Fig. 3, a delta wing mounted on a free-to-roll sting is shown. Here we consider the case where the distance d is zero. The equation governing the roll angle ϕ is

$$I_{xx}\ddot{\phi} = \frac{1}{2}\rho v_{\infty}^{2} S b C_R - \mu_x \dot{\phi} \tag{2}$$

where I_{xx} is the moment of inertia of the wing, ρ is the density of the air, v_∞ is speed of the freestream, S is the area of the planform, b is the span, C_R is the roll-moment coefficient which depends on the current values of ϕ and $\dot{\phi}$ and their histories, and μ_x is the damping coefficient for the roller bearing in the string.

The flaperons are operated by a servo mechanism and a feedback control law. The commanded deflections, δ_c, are given by

$$\delta_c = K_1\phi_1 + K_2\dot{\phi} \tag{3}$$

the servo-mechanism is governed by

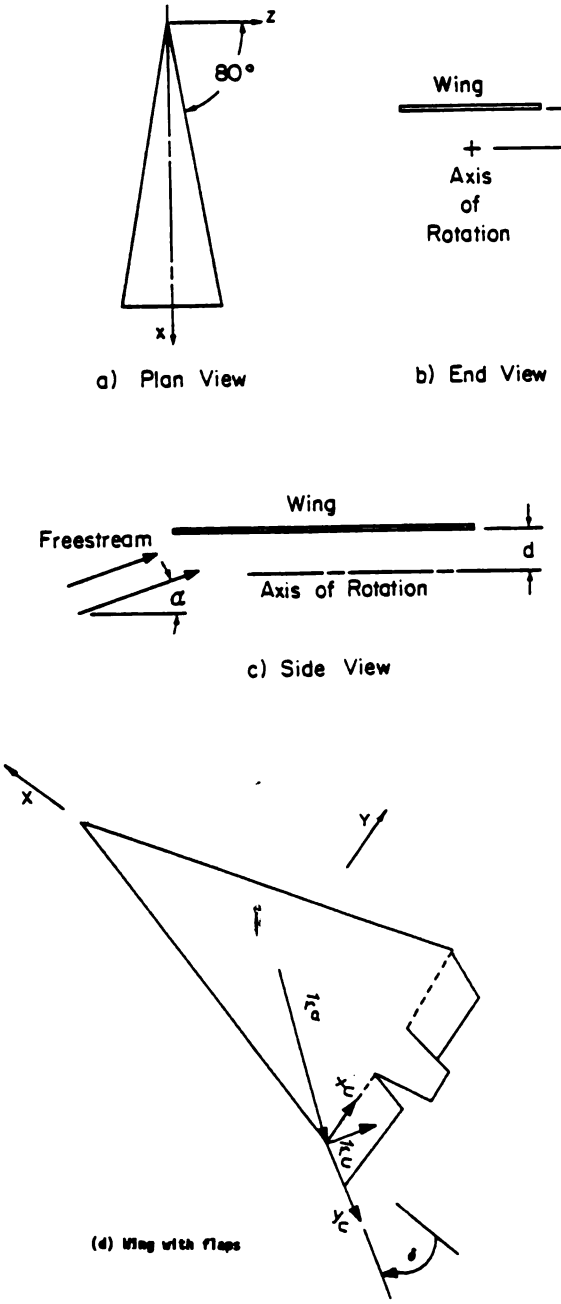
$$\ddot{\delta} = -K_3\dot{\delta} - K_4(\delta - \delta_c) \tag{4}$$

and finally,

$$\delta_p = -\delta_s = \delta \tag{5}$$

where K_1 .and K_2 are constant gains, K_3 and K_4 are constant characteristic parameters of the servo-mechanism, δ_p is the port-side deflection, and δ_s is the starboard-side deflection. In the present examples, Eqs. (3)-(5) are linear with constant coefficients, but the method is not restricted to such equations.

We wish to integrate Eqs. (2)-(5) and the equations governing the flowfield simultaneously to produce ϕ, C_R, δ_c, and δ. The flow-chart of the algorithm is shown in Fig. 4.



Quantity	Magnitude	Units
ρ	1.2000	kg/m³
U	15.000	m/s
S	0.0321	m²
b	0.1500	m
μ_x	0.5×10^{-4}	
I_{xx}	1.3×10^{-4}	kg-m²

(e) Physical properties

Fig. 3. A schematic drawing of the delta wing used in the numerical simulation of wing rock.

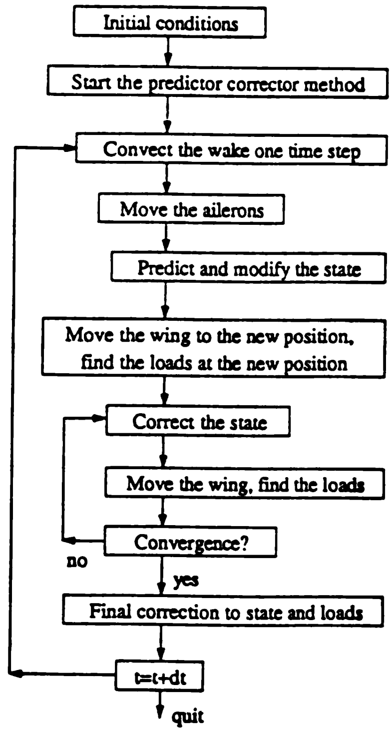


Fig. 4. Flow-chart for the predictor-corrector method.

To produce a simulation of an uncontrolled response, we first fix δ and exclude Eqs. (3)-(5); fix the wing at $\phi = 5°$ and allow a steady state to develop; and then the wing is released. When the angle of attack is below 25 degrees approximately, ϕ oscillates and decays to zero. When the angle of attack is greater than 25 degrees, ϕ grows and reaches a limit cycle. The results for 27.5 degrees angle of attack are shown in Fig. 5. The amplitude of the limit cycle is 29.6 degrees and its period is 0.3 sec; both agree well with the observations of Levin and Katz (1982).

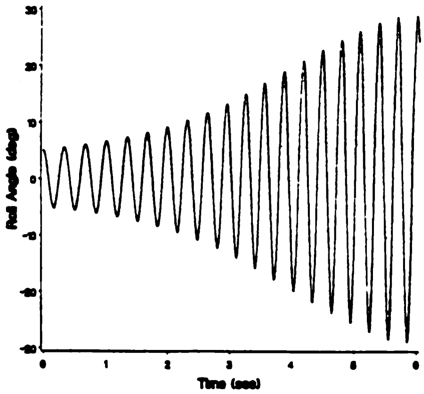

Fig. 5. The uncontrolled response in roll for a unit-aspect-ratio delta wing at 27.5° angle of attack.

Numerical simulations of wing rock were first obtained by Konstadinopoulos (1985) and

Konstadinopoulos (1984). They were able to simulate the experiments of Nguyen et al. (1983) and Levin and Katz accurately. They also were able to develop analytical expressions for the roll moment, which enabled Nayfeh et al. (1989) and Elzebda et al. (1989) to develop analytical models of wing rock. Luo and Lan (1993), working independently, also developed an analytical model.

To produce a simulation of a controlled response, we add Eqs. (3)-(5) to the system of equations being solved. The controlled response at 27.5 degrees angle of attack are shown in Fig. 6. After some trial and error, we chose $K_1 = 1.$ and $K_2 = 20$. The deflection of the port-side aileron is shown in Fig. 7. The unstable motion is quickly damped. The aileron deflection appears to decay, but if the control is shut off ϕ will begin to grow.

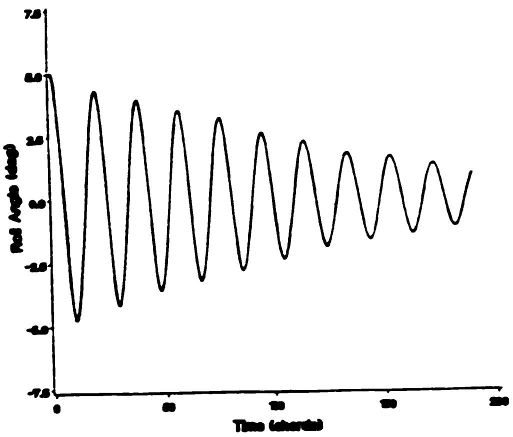

Fig. 6. The controlled response in roll for a unit-aspect-ratio delta wing at 27.5° angle of attack.

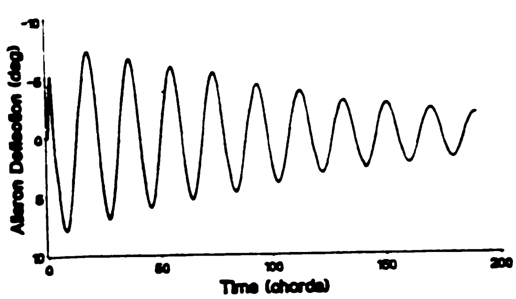

Fig. 7. Controlled aileron deflection as a function of time.

FLUTTER

In this example we consider a high-as very flexible, uniform wing, such as t presented in Fig. 8. (The method car wise variations of the properties.) H

chosen the elastic and inertial axes to be coincident. All of the twist/bending coupling is produced by the aerodynamic loads.

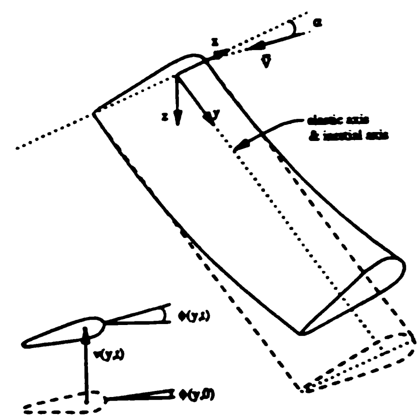

Fig. 8. A schematic of the high-aspect-ratio rectangular wing.

The dimensionless equations of motion of the wing are

$$\ddot{\phi} - D_t\phi'' = q_t Q_t \tag{6a}$$

$$\ddot{v} + D_b v'''' - D_b(2v'^2 v'''' + 10v'v''v''' + 3v''^3) = q_b Q_b - w - \frac{1}{2} q_b Q_b v'^2 \tag{6b}$$

$$u(y,t) = -\frac{1}{2}\int_0^y v'^2 dy \tag{6c}$$

where $D_b = \frac{EI}{mL_c^2V^2}$, $D_t = \frac{GJ}{V^2J_0}$, $q_b = \frac{\rho L_c^2}{2m}$,

$q_t = \frac{\rho L_c}{2J_0}$, and $w = \frac{gL_c}{V^2}$. Here EI is the flexural stiffness, GJ is the torsional stiffness, ρ is the density of the air, L_c is a characteristic length, J_0 is the mass polar moment of inertia, V is the speed of the freestream and m is the mass per unit of span. The dimensionless aerodynamic loads, Q_b and Q_t, are functions of the current shape and motion of the wing as well as the histories of these quantities. The nonlinear terms come from the curvature.

The boundary conditions are

$$\phi(0,t) = 0 \quad \phi'(L,t) = 0 \tag{7a}$$

$$v(0,t) = 0 \quad v''(L,t) = 0 \tag{7b}$$

$$v'(0,t) = 0 \quad v'''(L,t) = 0 \tag{7c}$$

Now the goal is to solve Eqs. (6) and (7) as well as those governing the flow for u, v, ϕ, Q_t, and Q_b simultaneously. The first step is to discretize, or convert, the partial-differential equations into a set of ordinary-differential equations. To this end, we represent v and ϕ as expansions in terms of the linear, free-vibration modes:

$$\phi(y,t) = \sum_{m=1}^{M} C_m(t)\chi_m(y) \tag{8a}$$

$$v(y,t) = \sum_{m=1}^{N} B_m(t)\psi_m(y) \tag{8b}$$

For the present results, four flexural and three torsional modes are used. The modes (χ_m and ψ_m) can be obtained analytically or numerically. The expansions are substituted into Eqs. (6) and Galerkin's procedure is applied to produce a set of $N+M$ second-order ordinary differential equations (see Luton, 1991) governing the time-dependent coefficients. These equations are integrated by the same algorithm used in the simulation of wing rock.

To control the anticipated flutter, we add flaps near the wing tips, a feedback-control system, and a servo-mechanism to move the flaps. The control law for the commanded flap deflection has the form:

$$\delta_c = G_1\dot{v}(0.95L, t) + G_2\dot{\phi}(0.95L,t) \tag{9}$$

and the actual flap deflection is given by

$$\ddot{\delta} = G_3(\delta_c - \delta) + G_4\dot{\delta} \tag{10}$$

where G_1, G_2, G_3, and G_4 are constants. The deflection, δ, is limited to $\pm$ 12 degrees and has zero velocity at these extreme positions. The control law and servo equation need not be linear nor have constant coefficients.

In Figs. 9-11, the responses of the uncontrolled wing to an initial disturbance are shown for three speeds near the flutter speed. The angles of attack are adjusted so that the lift forces are the same. In Fig. 9, the speed in the freestream is 75 m/s and α is 2.4 degrees; the motion of the wing decays very slowly to the static equilibrium position. In this simulation, all damping is due to the aerodynamic loads. Though the aerodynamic model is 'inviscid', there is still 'damping' as a result of the transfer of energy from the wing to the flowing air. In Fig. 11, the speed is 80 m/s and the response grows slowly. The appearance of the torsional response is similar to that of the flexural response in both cases. In Fig. 10, the speed is 77.5 m/s and the response to the initial disturbance is a limit cycle. Dong (1991) also found limit cycles near the flutter speed in his two-dimensional simulations of flutter. For a small range of speeds limit cycles exist and their amplitudes increase with the freestream speed. The nonlinear terms in the bending equation were deleted for these results, so all nonlinear effects are from the aerodynamic model.

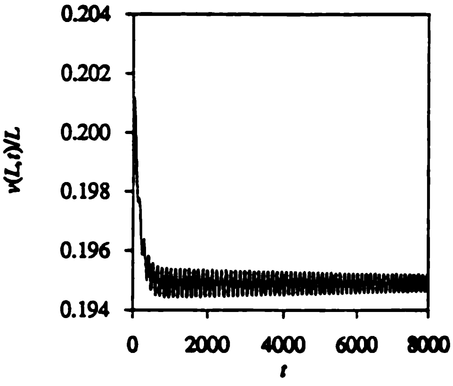

Fig. 9. Wing-tip deflection as a function of time for the rectangular wing when the speed in the freestream is 75 m/s and α is 2.4 degrees.

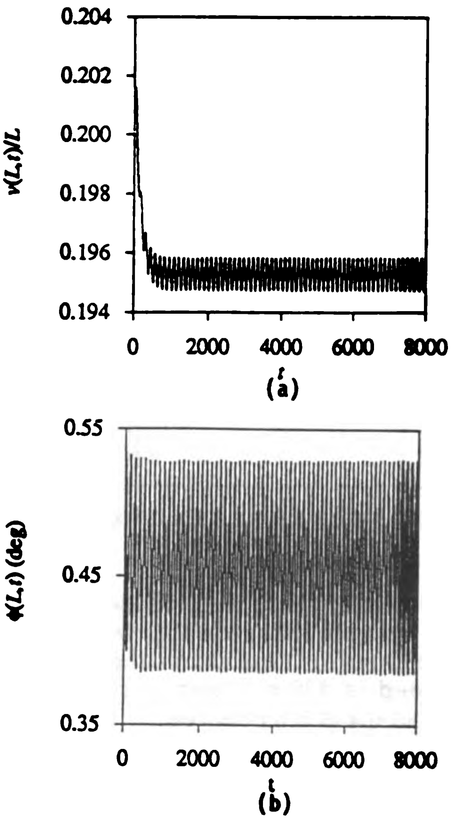

Fig. 10. (a) Wing-tip deflection and (b) wing-tip twist angle as functions of time for the rectangular wing when the speed in the freestream is 77.5 m/s.

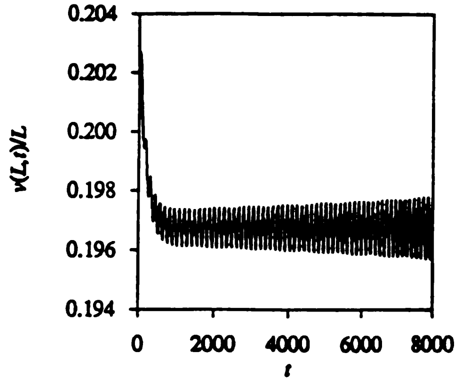

Fig. 11. Wing-tip deflection as a function of time for the rectangular wing when the speed in the freestream is 80 m/s.

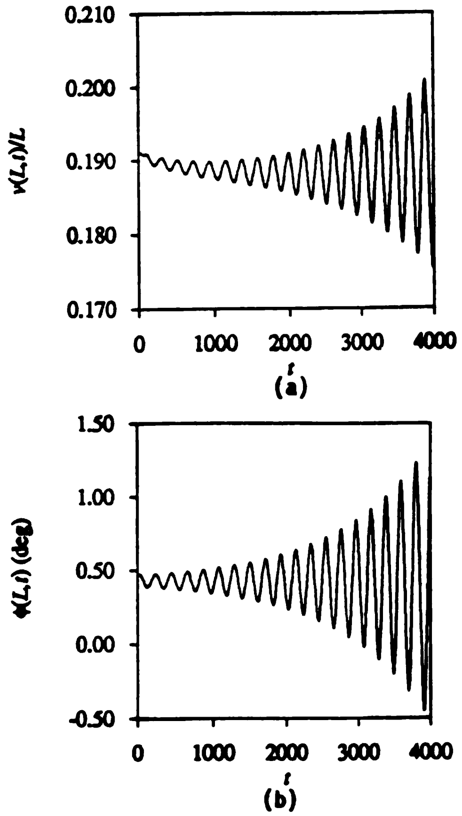

Fig. 12. (a) Uncontrolled wing-tip deflection and (b) uncontrolled wing-tip twist angle as functions of time when the freestream speed is 125 m/s and α and the angle of attack is 0.65 degree.

In Fig. 12, we show a supercritical response; here the speed is 125 m/s and α is 0.65 degree. The response oscillates while its amplitude appears to be growing exponentially. Bending and twist respond at the same frequency. In Fig. 13, we show the response under the same conditions as those used in Fig. 12 after the control system has been activated at the nondimensional time of 2000. The gains are $G_1 = -5$ and $G_2 = 500$. Although the oscillation has already developed a moderately large amplitude, the actively controlled aileron quickly suppresses the motion. When the control system is activated at a very early stage, flutter can be suppressed at speeds of 150 m/s or more, twice the critical speed.

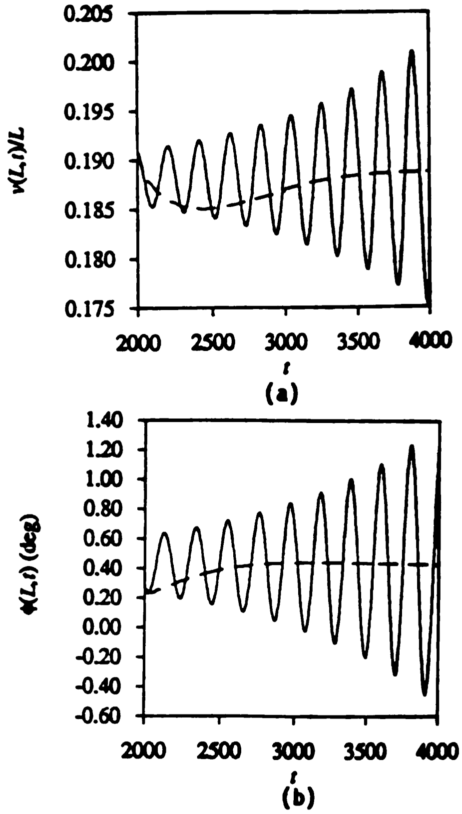

Fig. 13. (a) Controlled wing-tip deflection and b) controlled wing-tip twist angle as functions of time when the freestream speed is 125 m/s and α and the angle of attack is 0.65 degree. The control system is activated at time step 2000.

CONCLUDING REMARKS

A general formulation for simulating dynamic/aerodynamic interactions has been presented. The general formulation is modular and, consequently, different methods for simulating the flowfield and different dynamic and structural models can be used without changing the basic algorithm. Aerodynamic, material, inertial, and geometric nonlinear effects may be included. Motions in the subcritical, critical, and supercritical regimes can be simulated with no prior assumptions as to the form of the solution (e.g., periodic motions).

A relatively simple, linear feedback control system has been successfully used to suppress flutter in the present simulation. The control system consists of one or more ailerons as well as a servo motor. The present simulation is also capable of incorporating nonlinear control laws and variable gains. The gains for the current study were selected by a trial-and-error procedure. It was found that a wide range of gains is effective in the suppression of the instability. The control system can suppress flutter at almost twice the flutter speed. Although no attempt has been made to find the power requirements necessary for the aileron motion, it appears that only very small deflections and low frequencies are needed, especially when there is little or no delay in activating the control system.

Large-amplitude plate vibration in an elevated thermal environment

Jon Lee

Wright Laboratory (FIB), Wright-Patterson AFB, OH 45433

At elevated temperatures the dynamics of vibrating plate (or shell) must include the three thermal effects: (i) the global expansion by uniform plate temperature, (ii) the local expansion by temperature variation over the plate, and (iii) the thermal moment induced by temperature gradient across the plate thickness. For the single-mode prototype model of Galerkin representation, (i) and (ii) give rise to the combined stiffness that is responsible for thermal buckling, whereas (iii) contributes to the combined forcing of acoustic and thermal excitations. For the high-temperature sonic fatigue test facility at the Wright Lab, the present study is devoted to the mean square estimates on transverse displacement and normal stress/strain by the equivalent linearization technique.

1. INTRODUCTION

Transatmospheric vehicle (National Aero-Space Plane) technology presents a grand challenge of the rest of this century and the next for aerospace science and engineering communities. In contrast to the ballistic re-entry vehicles (space shuttles) piercing through the atmosphere nearly vertically, the transatmospheric vehicle will remain in the dense layer of the atmosphere for a good portion of its flight, and hence the air near the moving vehicle is heated to very high temperatures (aerodynamic heating). According to computational fluid dynamic simulations of hypersonic lifting body, the skin temperature can readily reach 2000°F and, in particular, the nose cone and external skin panels near the jet efflux are estimated to have temperatures over 3500°F (Barthelemy, 1991). At these high-temperature hypersonic flights, acoustic fatigue becomes a severe structural problem because not only are the pressure fluctuations anticipated in the range of 160-180 dB, but also the skin panels can vibrate chaotically about the thermally buckled positions whose amplitudes increase as the square root of temperature above the critical buckling temperature, i.e., the snap-through phenomena (Seide and Adami, 1983). Realizing the importance of elevated temperature on acoustic fatigue, work has begun as early as in the 70's to establish fatigue failure criteria in a combined thermal-acoustic environment (Schneider, 1974).

Sonic fatigue is a fluid-structure interaction problem requiring simultaneous solution of the Navier-Stokes equations for pressure/temperature and the structural dynamic equation for ensuing stress/strain. For large-amplitude deflections, the shape of structures defining the fluid-structure interface is not known *a priori*, hence must be determined from the solution of the fluid and structure equations. However, much progress has been made in the past by decoupling the structural part of the problem from solving the Navier-Stokes equations for pressure fluctuations. Following in this tradition, we shall in this paper investigate dynamics of a piece of hypersonic vehicle structure modeled by the so-called von Karman-Herrmann-Chu plate equation under prescribed pressure and temperature variations.

Although Bolotin (1963) derived the basic plate/shell equation for large-amplitude deflection subjected to temperature variation in the late 50's (Sec 2), the role of thermal effects has not yet been elucidated in their full generality. To exhibit the essential features, we expand the transverse displacement, Airy's stress function, and temperature distributions in trigonometric functions, and obtain the modal equations for the simply-supported and clamped plates (Sec 3).By a suitable nondimensionalization the modal equations of both the simply-supported and clamped plates are found to have three thermal terms. The first is global thermal expansion by a uniform plate temperature, the second corresponds to local thermal expansion by temperature variation over the plate, and the third term represents the thermal moment induced by temperature gradient through the plate thickness (Sec 4).

To proceed further, it is necessary to specify a typical temperature variation over the plate and temperature gradient across the plate (Sec 5). Much insight into the role of thermal terms can be gained by the prototype single-mode equation for both the simply-supported and clamped plates (Sec 6). The uniform temperature and temperature variation over the plate represent a kind of thermal stiffness which counteracts the structural stiffness. Hence, the combined thermal-structural stiffness is positive when the sum of uniform and local temperatures is less than the critical buckling temperature (pre-buckling), whereas it becomes negative when the sum exceeds the critical buckling temperature (post-buckling). In contrast, the temperature gradient gives rise to thermal moment, representing an additional loading (Boley and Weiner, 1960). Therefore, this together with external pressure constitute the combined thermal-acoustic forcing.

Under the acoustic loading, it is straightforward to estimate the mean response of a single-mode equation. However, the equivalent linearization technique (Caughey, 1963) cannot be applied when the temperature gradient

part of "MECHANICS PAN-AMERICA 1993" edited by MRM Crespo da Silva and CEN Mazzilli — ASME Reprint No AMR134
Appl Mech Rev vol 46, no 11, part 2, November 1993

represents a constant forcing. This therefore calls for reformulation to remove the constant thermal forcing. The main conclusion of this paper is that the uniform temperature, temperature variation over the plate, and temperature gradient across the plate can contribute additively to the mean square displacement (Sec 7) and also to the normal stress and strain (Sec 8). Yet, the thermal effects are felt most strongly when the acoustic loading is weak.

2. LARGE-DISPLACEMENT PLATE EQUATIONS

Let us begin with the following strain-stress relations

$$\varepsilon_x = \frac{1}{E}(\sigma_x - \mu\sigma_y) + \alpha T, \quad \varepsilon_y = \frac{1}{E}(\sigma_y - \mu\sigma_x) + \alpha T, \quad \varepsilon_{xy} = \frac{1+\mu}{E}\sigma_{xy}, \tag{1}$$

where E is the modulus of elasticity, μ Poisson's ratio, T the local plate temperature, and α the thermal expansion coefficient. In the absence of αT, Eq (1) is the usual relationship of strain (ε_x, ε_y, ε_{xy}) and stress (σ_x, σ_y, σ_{xy}). For $\alpha>0$, raising T would result in increased strain, in conformity with the physical notion of thermal expansion. The inverse relation is

$$\sigma_x = \frac{E}{(1-\mu^2)}\left[\varepsilon_x + \mu\varepsilon_y - (1+\mu)\alpha T\right],$$
$$\sigma_y = \frac{E}{(1-\mu^2)}\left[\varepsilon_y + \mu\varepsilon_x - (1+\mu)\alpha T\right], \quad \sigma_{xy} = \frac{E}{(1+\mu)}\varepsilon_{xy}. \tag{2}$$

Since the sign for αT is negative, the stress may in fact decrease as T is raised.

Following Bolotin (1963) we decompose T into

$$T(x,y,z) = \bar{T}(x,y) + z\theta(x,y), \tag{3}$$

where $\bar{T}(x,y)=h^{-1}\int_{-h/2}^{h/2}T(x,y,z)dz$ is temperature averaged over the plate thickness h, and $\theta(x,y)$ is the temperature gradient across h. Note that only the linear temperature variation in z is included in (3), according to the thin plate theory. We now summarize the compatibility, transverse displacement equation, and immovable edge and boundary conditions (see, Lee (1992) for the detail). It is however more convenient to measure x and y in units of a and b, the respective sides of plate, so that x and y now range over [0, 1]. First, the compatibility condition is

$$\hat{\nabla}^4 F + Eh\alpha b^2\hat{\nabla}^2\bar{T} = Eh\beta^2\left[\left(\frac{\partial^2 w}{\partial x\partial y}\right)^2 - \left(\frac{\partial^2 w}{\partial x^2}\right)\left(\frac{\partial^2 w}{\partial y^2}\right)\right], \tag{4}$$

where $\beta=b/a$ and $\hat{\nabla}^2=\beta^2\partial^2/\partial x^2+\partial^2/\partial y^2$. Note that the biharmonic operator applies to Airy's stress function F, and the transverse displacement w is governed by the von Karman type of large-deflection plate equation, written in the following symbolic form

$$R_1 + R_2 + R_3 + R_4 = 0, \tag{5}$$

where

$$R_1=\rho h\frac{\partial^2 w}{\partial t^2} + \rho h\xi\frac{\partial w}{\partial t} - p, \quad R_2=Db^{-4}\hat{\nabla}^4 w, \quad R_3=\alpha(1+\mu)Db^{-2}\hat{\nabla}^2\theta,$$

$$R_4=\frac{\beta^2}{b^4}\left[\left(\frac{\partial^2 w}{\partial x^2}\right)\left(\frac{\partial^2 F}{\partial y^2}\right) + \left(\frac{\partial^2 w}{\partial y^2}\right)\left(\frac{\partial^2 F}{\partial x^2}\right) - 2\left(\frac{\partial^2 w}{\partial x\partial y}\right)\left(\frac{\partial^2 F}{\partial x\partial y}\right)\right].$$

Here, ρ is the cross-sectional mass density, ξ the damping coefficient, p the external pressure, and $D=Eh^3/12(1-\mu^2)$ the flexural rigidity. The $\rho h\xi(\partial w/\partial t)$ is introduced to R_1 for viscous damping, but a more appropriate damping model would be $\xi D\hat{\nabla}^4(\partial w/\partial t)$ of Maekawa (1982). Eqs (4) and (5) are essentially Eqs (4.131) and (4.132) of Bolotin (1963), and also agree in form with Eqs (13.7.1) and (13.11.3) of Boley and Weiner (1960).

The compatibility states force balances at the mid-plate. Hence, it constrains the in-plane displacements u and v in x and y axes, respectively. Let us assume a homogeneous solution of $\hat{\nabla}^4 G=0$

$$G = P_x b^2 y^2/2 + P_y a^2 x^2/2 - P_{xy}abxy. \tag{6}$$

Here, the constants P_x, P_y, and P_{xy} representing the membrane stresses can be evaluated through the immovable edge conditions (Mei, 1980)

$$\frac{\partial^2 F}{\partial x\partial y} = 0 \text{ and } \int_0^1\int_0^1\left(\frac{\partial u}{\partial x}\right)dxdy = 0 \text{ at } x=0,\ 1$$
$$\frac{\partial^2 F}{\partial x\partial y} = 0 \text{ and } \int_0^1\int_0^1\left(\frac{\partial v}{\partial y}\right)dxdy = 0 \text{ at } y=0,\ 1 \tag{7}$$

Note that the edge displacements are suppressed only in the average sense. The integrands expressed in F and w are given by Eq (4.140) of Bolotin (1963)

$$b\beta\left(\frac{\partial u}{\partial x}\right) = \frac{1}{Eh}\left[\frac{\partial^2 F}{\partial y^2} - \mu\beta^2\frac{\partial^2 F}{\partial x^2}\right] + \alpha b^2\bar{T} - \frac{\beta^2}{2}\left(\frac{\partial w}{\partial x}\right)^2,$$
$$b\left(\frac{\partial v}{\partial y}\right) = \frac{1}{Eh}\left[\beta^2\frac{\partial^2 F}{\partial x^2} - \mu\frac{\partial^2 F}{\partial y^2}\right] + \alpha b^2\bar{T} - \frac{1}{2}\left(\frac{\partial w}{\partial y}\right)^2, \tag{8}$$

as given by Eq (4.140) of Bolotin (1963). For the boundary conditions, we first assume no transverse displacement

$$w(0,y) = w(1,y) = w(x,0) = w(x,1) = 0. \tag{9}$$

For a simply-supported plate, the tangential components of the bending moment being zero implies (Eq (12.4.2) of Boley and Weiner, 1963)

$$\beta^2\frac{\partial^2 w}{\partial x^2} + \alpha b^2(1+\mu)\theta = 0 \text{ at } x=0,\ 1$$
$$\frac{\partial^2 w}{\partial y^2} + \alpha b^2(1+\mu)\theta = 0 \text{ at } y=0,\ 1 \tag{10}$$

Whereas, we have for a clamped plate

$$\frac{\partial w}{\partial x} = 0 \text{ at } x=0,\ 1 \text{ and } \frac{\partial w}{\partial y} = 0 \text{ at } y=0,\ 1. \tag{11}$$

For an isotropic plate, the assumption that $\partial u/\partial x$, $\partial v/\partial y$, $\partial w/\partial x$, ... are constant across the plate leads to the following stress tensor

$$\sigma_x = \frac{1}{hb^2}\frac{\partial^2 F}{\partial y^2} - \frac{zE}{b^2(1-\mu^2)}\left(\beta^2\frac{\partial^2 w}{\partial x^2} + \mu\frac{\partial^2 w}{\partial y^2}\right) - \frac{zE\alpha\theta}{(1-\mu)},$$
$$\sigma_y = \frac{1}{hb^2}\frac{\partial^2 F}{\partial x^2} - \frac{zE}{b^2(1-\mu^2)}\left(\frac{\partial^2 w}{\partial y^2} + \mu\beta^2\frac{\partial^2 w}{\partial x^2}\right) - \frac{zE\alpha\theta}{(1-\mu)},$$
$$\sigma_{xy} = -\frac{\beta}{h\beta^2}\frac{\partial^2 F}{\partial x\partial y} - \frac{\beta zE}{b^2(1+\mu)}\frac{\partial^2 w}{\partial x\partial} \tag{12}$$

also given by Eqs (29-31) of Choi and Vaicaitis (1989). Inserting Eq (12) to (1) yields

$$\varepsilon_x = \frac{1}{Ehb^2}\left(\frac{\partial^2 F}{\partial y^2} - \mu\beta^2\frac{\partial^2 F}{\partial x^2}\right) - z\beta^2\frac{\partial^2 w}{\partial x^2} + \alpha T,$$

$$\varepsilon_y = \frac{1}{Ehb^2}\left(\beta^2\frac{\partial^2 F}{\partial x^2} - \mu\frac{\partial^2 F}{\partial y^2}\right) - z\frac{\partial^2 w}{\partial y^2} + \alpha T,$$

$$\varepsilon_{xy} = -\frac{(1+\mu)\beta}{Ehb^2}\frac{\partial^2 F}{\partial x\partial y} - \frac{\beta}{b^2}\frac{\partial^2 w}{\partial x\partial y}\ . \tag{13}$$

Eqs (12-13) will be used for the stress/strain computation in Sec 8.

3. THE DERIVATION OF MODAL EQUATIONS

Since $P_{xy}=0$ for the immovable edge (7), we construct F from homogeneous solution (6) and the particular solution expanded in cosines

$$F=-P_xb^2y^2/2 - P_ya^2x^2/2 + Eh\sum_{p=0}^{\infty}\sum_{q=0}^{\infty}F_{pq}\cos p\pi x\,\cos q\pi y. \tag{14}$$

And, a similar expansion is introduced for $\bar{T}$(Sunakawa and Uemura, 1960)

$$\bar{T} = t_o + \sum_{p=0}^{\infty}\sum_{q=0}^{\infty}t_{pq}\cos p\pi x\,\cos q\pi y. \tag{15}$$

Note that the term for p=q=0 is excluded from Eqs (14-15). To evaluate F_{pq} one must further assume an expansion for w.

For a simply-supported plate, it is standard to expand w in $\Psi_m(x)=\sin(m\pi x)$ with the desired properties that they are orthogonal and $\Psi_m(x)\Psi_n(y)$ is an eigenfunction of the biharmonic operator, i.e, the Helmholtz problem. We therefore adopt for a simply-supported plate

$$w(x,y)=\sum_{m=0}^{\infty}\sum_{n=0}^{\infty}w_{mn}\psi_m(x)\psi_n(y), \tag{16}$$

where $\psi_m(x)=\sqrt{2}\Psi_m(x)$ are orthonormal. On the other hand, $\Phi_m(x)=\cos(m+1)\pi x-\cos(m-1)\pi x$ have been used for the clamped plate problems (e.g., Maekawa, 1982, and Paul, 1982). However, they lack the desired properties so that the inertial and stiffness matrices become nondiagonal. Although one can readily construct orthonormal bases from $\Phi_m(x)$, as will be done shortly, the $\Phi_m(x)\Phi_n(y)$ is not an eigenfunction of the Helmholtz problem. Hence, a nondiagonal stiffness matrix is still unavoidable.

Let us rewrite $\Phi_m(x)=2S_m(x)$, where $S_m(x)=\sin(m\pi x)x\sin\pi x$, and construct the orthonormal φ_m from Φ_m by the Gram-Schmidt procedure (Luenberger, 1969). Since $S_1(x)$, $S_3(x)$, ... are even and $S_2(x)$, $S_4(x)$, ... are odd, one finds that $\varphi_m(x)$ also split into the even $\varphi_1=\sqrt{8/3}S_1(x)$, $\varphi_3=\sqrt{24/5}S_3(x)+\sqrt{8/15}S_1(x)$, ... and odd components $\varphi_2=2S_2(x)$, $\varphi_4=\sqrt{16/3}S_4(x)+\sqrt{4/3}S_2(x)$, ... Summing up, we then have

$$\varphi_m(x)=\sum_{1}^{m} \tag{17}$$

where

$$a_{mi} = \begin{bmatrix} \sqrt{8/3} & 0 & 0 & 0 & 0 & 0 & \cdots \\ 0 & 2 & 0 & 0 & 0 & 0 & \cdots \\ \sqrt{8/15} & 0 & \sqrt{24/5} & 0 & 0 & 0 & \cdots \\ 0 & \sqrt{4/3} & 0 & \sqrt{16/3} & 0 & 0 & \cdots \\ \sqrt{8/35} & 0 & 3\sqrt{8/35} & 0 & \sqrt{40/7} & 0 & \cdots \\ 0 & \sqrt{2/3} & 0 & \sqrt{8/3} & 0 & \sqrt{6} & \cdots \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \end{bmatrix}$$

The expansion for a clamped plate has the form

$$w(x,y)=\sum_{m=0}^{\infty}\sum_{n=0}^{\infty}w_{mn}\varphi_m(x)\varphi_n(y), \tag{18}$$

where φ_m are orthonormal.

Simply-Supported Plate: By inserting Eqs (14-16) into (4) and collecting the coefficients for F_{pq}, we have

$$F_{pq} = \frac{\alpha b^2 t_{pq}}{\pi^2(p^2\beta^2+q^2)} + \frac{A_{pq}}{(p^2\beta+q^2/\beta)^2}\ , \tag{19}$$

where A_{pq} given in Appendix A consists of nine sums B_1-B_9 of Levy (1942). In parallel to (16), we also expand

$$\begin{pmatrix}\theta(x,y)\\ p(x,y)\end{pmatrix} = \sum_{m=0}^{\infty}\sum_{n=0}^{\infty}\begin{pmatrix}\theta_{mn}\\ p_{mn}\end{pmatrix}\psi_m(x)\psi_n(y). \tag{20}$$

Now, introduce Eqs (14), (16) and (20) into (5) and sort out the coefficients for w_{rs} by the Galerkin procedure. Because of the orthonormality, one can write down at once

$$\int_0^1\int_0^1 R_1\psi_r(x)\psi_s(y)dxdy= \rho h\frac{\partial^2 w_{rs}}{\partial t^2} + \rho h\xi\frac{\partial w_{rs}}{\partial t} - p_{rs},$$

$$\int_0^1\int_0^1 R_2\psi_r(x)\psi_s(y)dxdy= \frac{D\pi^4}{b^4}(\beta^2r^2 + s^2)^2 w_{rs},$$

$$\int_0^1\int_0^1 R_3\psi_r(x)\psi_s(y)dxdy= -\frac{\alpha(1+\mu)D\pi^2}{b^2}(\beta^2r^2 + s^2)\theta_{rs}. \tag{21}$$

On the other hand, the integral for R_4 is complicated due to the product of F and w. After some algebra, we have

$$\begin{aligned}\int_0^1\int_0^1 R_4\psi_r(x)\psi_s(y)dxdy= &-\frac{\pi^2\alpha Eht_o}{b^2(1-\mu)}(\beta^2r^2 + s^2)\,w_{rs}\\ &-\frac{\pi^2\beta^2\alpha Eh}{4b^2}B_{rs}\left(w_{mn}, \frac{t_{pq}}{(\beta^2p^2+q^2)}\right) + \frac{\pi^4\beta^2 Eh}{2b^4(1-\mu^2)}K_1 w_{rs}\\ &-\frac{\pi^4\beta^2 Eh}{4b^4}B_{rs}\left(w_{mn}, \frac{A_{pq}}{(\beta p^2+q^2/\beta)^2}\right),\end{aligned} \tag{22}$$

where

$$K_1=\sum_{m,n=1}^{\infty}\left\{r^2(\beta^2 m^2w_{mn}^2+\mu n^2w_{mn}^2)+s^2(\mu m^2w_{mn}^2+\beta^{-2}n^2w_{mn}^2)\right\}.$$

The B_{rs} is given in Appendix B. By equating the sum of four integrals in Eqs (21-22) to zero, the modal equation is obtained for w_{rs}.

Clamped Plate: Inserting Eqs (14-15) and (18) into (4), we obtain

$$F_{pq} = \frac{\alpha b^2 t_{pq}}{\pi^2(p^2\beta^2+q^2)} + \frac{C_{pq}}{(p^2\beta+q^2/\beta)^2}, \tag{23}$$

where C_{pq} is given in Appendix C. Similar to (20) we let

$$\begin{pmatrix}\theta(x,y)\\ p(x,y)\end{pmatrix} = \sum_{m=0}^{\infty}\sum_{n=0}^{\infty}\begin{pmatrix}\theta_{mn}\\ p_{mn}\end{pmatrix}\varphi_m(x)\varphi_n(y). \tag{24}$$

Because of the orthonormality, one finds at once

$$\int_0^1\int_0^1 R_1\varphi_r(x)\varphi_s(y)dxdy = \rho h\frac{\partial^2 w_{rs}}{\partial t^2} + \rho h\xi\frac{\partial w_{rs}}{\partial t} - p_{rs}. \tag{25}$$

For the biharmonic term, we obtain

$$\int_0^1\int_0^1 R_2\varphi_r(x)\varphi_s(y)dxdy = \frac{D\pi^4}{b^4}K_2, \tag{26}$$

where

$$K_2 = -\frac{\beta^4}{8}\sum_{m=1}^{\infty} w_{ms}\sum_{i=1}^{m} a_{mi}\sum_I{}' \sum_J{}' IJ a_{r(i+I+J)}(i+I)^4 - \frac{1}{8}\sum_{n=1}^{\infty} w_{rn}\sum_{j=1}^{n} a_{nj}\sum_I{}' \sum_J{}' IJ a_{s(i+I+J)}(i+I)^4$$
$$+\frac{\beta^2}{32}\sum_{m,n=1}^{\infty} w_{mn}\Big\{\sum_{i=1}^{m} a_{mi}\sum_I{}' \sum_J{}' IJ a_{r(i+I+J)}(i+I)^2\Big\} \times\Big\{\sum_{j=1}^{n} a_{nj}\sum_I{}' \sum_J{}' IJ a_{s(i+I+J)}(i+I)^2\Big\}.$$

Here, the notation $\sum_I{}' f(I)=f(1)+f(-1)$ of Maekawa (1982) is used to consolidate the shifted summands. Similarly, we find

$$\int_0^1\int_0^1 R_3\varphi_r(x)\varphi_s(y)dxdy = -\frac{\alpha(1+\mu)D\pi^2}{b^2}K_3, \tag{27}$$

where

$$K_3 = -\frac{\beta^2}{8}\sum_{m=1}^{\infty}\theta_{ms}\sum_{i=1}^{m} a_{mi}\sum_I{}' \sum_J{}' IJ a_{r(i+I+J)}(i+I)^2 - \frac{1}{8}\sum_{n=1}^{\infty}\theta_{rn}\sum_{j=1}^{n} a_{nj}\sum_I{}' \sum_J{}' IJ a_{s(i+I+J)}(i+I)^2.$$

Finally, the integral for R_4 can be put in the form

$$\int_0^1\int_0^1 R_4\varphi_r(x)\varphi_s(y)dxdy = -\frac{\pi^2\alpha Eht_o}{b^2(1-\mu)}(\beta^2K_4+K_5) - \frac{\pi^2\beta^2\alpha Eh}{4b^2}D_{rs}\Big(w_{mn}, \frac{t_{pq}}{(\beta^2p^2+q^2)}\Big)$$
$$+\frac{\pi^4\beta^2 Eh}{2b^4(1-\mu^2)}\Big\{(\beta^2K_6+\mu K_7)K_4 + (\mu K_6+\beta^{-2}K_7)K_5\Big\} - \frac{\pi^4\beta^2 Eh}{4b^4}D_{rs}\Big(w_{mn}, \frac{C_{pq}}{(\beta p^2+q^2/\beta)^2}\Big). \tag{28}$$

The D_{rs} and K_4 - K_7 are given in Appendix D. Again, the modal equations for a clamped plate are formed from the four integrals in Eqs (25-28).

4. UNIFIED MODAL EQUATIONS

For unified representation we put the modal equations in a dimensionless form by scaling the length by h, the time by $\gamma=(\rho hb^4/\pi^4 D)^{1/2}$, the force by $(\rho h^2/\gamma^2)$, and the temperature by T^*, to be defined shortly. Accordingly, the dimensionless mechanical variables are

$$\tau = t/\gamma,\ P_{rs} = (\gamma^2/\rho h^2)p_{rs},\ W_{rs} = w_{rs}/h, \tag{29}$$

and thermal variables are

$$T_o = t_o/T^*,\ T_{pq} = t_{pq}/T^*,\ \Theta_{rs} = h\theta_{rs}/T^*. \tag{30}$$

Simply-Supported Plate: The modal equation for W_{rs} follows by equating the sum of four integrals (21-22) to zero. For a simply-supported plate, the appropriate T^* is the critical buckling temperature $T_s^*=\pi^2h^2(\beta^2+1)/12\alpha b^2(1+\mu)$, at which the global thermal expansion cancels out the structural stiffness for W_{11} (Wilcox and Clemmer, 1964, and Schneider, 1974). Using the variables (29-30), the dimensionless modal equation becomes

$$\underbrace{\frac{\partial^2 W_{rs}}{\partial\tau^2}}_{\text{(SP-1)}} + \underbrace{\gamma\xi\frac{\partial W_{rs}}{\partial\tau}}_{\text{(SP-2)}} \underbrace{- P_{rs}}_{\text{(SP-3)}} + \underbrace{(\beta^2r^2+s^2)^2 W_{rs}}_{\text{(SP-4)}} + \underbrace{6\beta^2K_1W_{rs}}_{\text{(SP-5a)}}$$
$$\underbrace{-3\beta^2(1-\mu^2)B_{rs}\Big(W_{mn}, \frac{A_{pq}}{(\beta p^2+q^2/\beta)^2}\Big)}_{\text{(SP-5b)}} \underbrace{-(\beta^2+1)(\beta^2r^2+s^2)T_oW_{rs}}_{\text{(SP-6)}}$$
$$\underbrace{-\frac{(1-\mu)\beta^2(\beta^2+1)}{4}B_{rs}\Big(W_{mn}, \frac{T_{pq}}{(\beta^2p^2+q^2)}\Big)}_{\text{(SP-7)}}$$
$$\underbrace{-\frac{(\beta^2+1)(\beta^2r^2+s^2)}{12}\Theta_{rs}}_{\text{(SP-8)}} = 0. \tag{31}$$

We may interpret the terms labeled by SP (simply-supported plate) 1 - 8 as follows: SP-1 is the inertial term, SP-2 represents viscous damping, SP-3 is the external forcing, SP-4 is the usual stiffness term, and SP-5a and 5b represent the cubic stiffness. Note that SP-5a is the immovable edge contribution, whereas SP-5b is derived from the product of w and F. The thermal effects are embodied by the last three terms. That is, SP-6 is the global thermal expansion owing to uniform plate temperature, SP-7 is the local thermal expansion by temperature variation over the plate, and SP-8 represents the thermal moment induced by temperature gradient across the plate thickness.

Clamped Plate: Using $T_c^*=\pi^2h^2(\beta^4+2\beta^2/3+1)/3\alpha b^2(1+\mu)\times(\beta^2+1)$ for the clamped plate, the modal equation becomes

$$\underbrace{\frac{\partial^2 W_{rs}}{\partial\tau^2}}_{\text{(CP-1)}} + \underbrace{\gamma\xi\frac{\partial W_{rs}}{\partial\tau}}_{\text{(CP-2)}} \underbrace{- P_{rs}}_{\text{(CP-3)}} + \underbrace{[K_2(W_{mn})]_{rs}}_{\text{(CP-4)}}$$
$$\underbrace{+6\beta^2[(\beta^2K_6+\mu K_7)K_4+(\mu K_6+\beta^{-2}K_7)K_5]_{rs}}_{\text{(CP-5a)}}$$
$$\underbrace{-3\beta^2(1-\mu^2)D_{rs}\Big(W_{mn}, \frac{C_{pq}}{(\beta p^2+q^2/\beta)^2}\Big)}_{\text{(CP-5b)}}$$
$$\underbrace{-\frac{4(\beta^4+2\beta^2/3+1)}{(\beta^2+1)}T_o[\beta^2K_4(W_{mn})+K_5(W_{mn})]_{rs}}_{\text{(CP-6)}}$$
$$\underbrace{-\frac{(1-\mu)\beta^2(\beta^4+2\beta^2/3+1)}{(\beta^2+1)}D_{rs}\Big(W_{mn}, \frac{T_{pq}}{(\beta^2p^2+q^2)}\Big)}_{\text{(CP-7)}}$$

$$-\frac{(\beta^4+2\beta^2/3+1)}{3(\beta^2+1)}[K_3(\Theta_{mn})]_{rs}=0. \tag{32}$$

(CP-8)

The CP (clamped plate) 1-8 have the same meaning as SP 1-8.

The enumeration of (31) and (32) has been carried out by Lee(1992) for the lowest order W_{11}, W_{13}, W_{31}, and W_{33} to provide a comparison with Levy's (1942) simply-supported plate case and the clamped plate result of Paul (1982). Even with only four W_{rs}, the modal equations have a bewildering number of constant, linear, and cubic terms. Therefore, as a check on the internal consistency, we construct the Hamiltonian H(p,q), where $p_1=\dot{W}_{11}$, $p_2=\dot{W}_{13}$, $p_3=\dot{W}_{31}$, $p_4=\dot{W}_{33}$, $q_1=W_{11}$, $q_2=W_{13}$, $q_3=W_{31}$, $q_4=W_{33}$, from which the equations for W_{rs} have been recovered by

$$\dot{p}_i=-\frac{\partial H}{\partial q_i},\quad \dot{q}_i=\frac{\partial H}{\partial p_i}, \tag{33}$$

for the simply-supported (Lee, 1986) and clamped (Lee, 1992) plates.

5. TEMPERATURE VARIATION AND GRADIENT

To proceed further, it is necessary to specify T_{pq} and Θ_{rs} in Eqs (31-32). We split the averaged temperature into uniform t_o and variation $t_v(x,y)$

$$\bar{T}=t_o+t_v(x,y), \tag{34}$$

as in (15). Hence, Eq (3) has the form

$$T=t_o+t_v(x,y)+Z\Theta(x,y), \tag{35}$$

where $Z=z/h$ ranges over [1/2, -1/2]. Since t_o is assumed nonzero, the magnitude of (t_v, Θ) will be measured by multiples (δ_v, δ_g) of t_o

$$t_v=\delta_v t_o f_v(x,y),\quad \Theta=\delta_g t_o f_g(x,y). \tag{36}$$

In words, ($\delta_v t_o$,$\delta_v t_o$) is the magnitude of temperature (variation, gradient) with the distribution ($f_v(x,y)$, $f_g(x,y)$). Upon inserting (36) into (35) we have the dimensionless form

$$T/T^*=T_o+(\delta_v T_o)f_v(x,y)+(\delta_g T_o)Zf_g(x,y), \tag{37}$$

where $T^*=(T_s^*, T_c^*)$ for the (simply-supported, clamped) plate.

First, by comparing (37) with (15) we have

$$(\delta_v T_o)f_v(x,y)=\sum_{p=0}^{\infty}\sum_{q=0}^{\infty}T_{pq}\cos p\pi x\cos q\pi y. \tag{38}$$

Let us examine a few examples. If $f_v=\sin\pi x\sin\pi y$ we find from (38) that

$$T_{pq}=\frac{16\delta_v T_o}{\pi^2(p^2-1)(q^2-1)} \quad \text{[illegible]} q\neq 0) \tag{39}$$

For the second example $f_v=\sin\pi x^2\sin\pi y^2$, the sum in (38) reduces to a finite sum (1/4)(1-cos2πx)(1-cos2πy). Hence,

$$T_{20}=T_{02}=-T_{22}=-\delta_v T_o/4,\quad T_{pq}=0 \text{ (for other p, q)}. \tag{40}$$

Now, for the temperature gradient we write in view of (20) and (24)

$$(\delta_g T_o)f_g(x,y)=\sum_{m=0}^{\infty}\sum_{n=0}^{\infty}\Theta_{mn}\eta_m(x)\eta_n(y), \tag{41}$$

where $\eta_m=(\psi_m, \varphi_m)$ for the (simply-supported, clamped) plate. For simplicity we shall suppose $f_g=\sin\pi x\sin\pi y$ for the simply-supported plate and obtain

$$\Theta_{11}=\delta_g T_o/2,\quad \Theta_{mn}=0 \text{ (for other m, n)} \tag{42}$$

Whereas, $f_g=\sin\pi x^2\sin\pi y^2$ gives rise to

$$\Theta_{11}=3\delta_g T_o/8,\quad \Theta_{mn}=0 \text{ (for other m, n)} \tag{43}$$

for a simple temperature gradient for the clamped plate.

Although it appears at first sight that δ_v and δ_g can be chosen arbitrarily, this is not the case when the temperature variation and gradient are nonuniform. Note that a nonuniform Θ cannot exist unless t_v is also nonuniform; i.e, $\delta_v=0$ implies $\delta_g=0$. What is then the maximum value of δ_g, denoted by $(\delta_g)_{max}$, for a given δ_v? This cannot be answered in general without knowing the f_v and f_g. However, in the case $f_v=f_g$, one may infer $(\delta_g)_{max}=2\delta_v$. Sunakawa and Uemura (1960) have used a parabolic distribution for f_v and f_g, and prescribed $(\delta_g)_{max}=(4/3)\delta_v$, for which the lower plate temperature is half the upper plate temperature. In view of the recent attempts (Kehoe and Synder, 1991; Richards and Thompson, 1991) to generate various temperature profiles over a panel by radiant heating, the sorts of f_v that we have discussed here are not unphysical. Yet, to the best of our knowledge no attempt has yet been made to either measure or control f_g over a plate.

6. SINGLE-MODE EQUATION FOR W_{11}

Let us examine the simplest case of a single mode W_{11} when all others are suppressed. Under (40) and (42), the simply-supported plate equation (31) gives

$$\ddot{W}_{11}+\gamma\xi\dot{W}_{11}+(\beta^2+1)^2\left\{1-T_o\left[1+\frac{1}{8}(1-\mu)\delta_v\right]\right\}W_{11}+4e(\mu,\beta)W_{11}^3$$
$$-\left[P_{11}+\frac{1}{24}(\beta^2+1)^2\delta_g T_o\right]=0, \tag{44}$$

where $e(\mu,\beta)=(3/4)[(1-\mu^2)(\beta^4+1)+2(\beta^4+1+2\mu\beta^2)]$. Under (40) and (43) Eq (32) similarly reduces to

$$\ddot{W}_{11}+\gamma\xi\dot{W}_{11}+$$
$$+\frac{16}{3}(\beta^4+2\beta^2/3+1)\left\{1-T_o\left[1+\frac{1}{6}(1-\mu)\delta_v\left(1+\beta^2(\beta^2+1)^{-2}\right)\right]\right\}W_{11}$$
$$+\frac{128}{9}d(\mu,\beta)W_{11}^3-\left[P_{11}+\frac{1}{6}(\beta^4+2\beta^2/3+1)\delta_g T_o\right]=0, \tag{45}$$

where $d(\mu,\beta)=(3\beta^2/4)\{(\beta^2+\beta^{-2}+2\mu)+(1-\mu^2)(4/9)[17(\beta^2+$

$\beta^{-2})/8+4(\beta+\beta^{-1})^{-2}+(\beta+4\beta^{-1})^{-2}+(4\beta+\beta^{-1})^{-2}]\}$. The eight terms in Eqs (31-32) are now regrouped into five. The first two inertial and damping terms are retained intact. However, the third term of Eq (44, 45) is the combined stiffness which subsumes the stiffness (SP-6, CP-4), global thermal expansion (SP-6, CP-6), and local thermal expansion (SP-7, CP-7). And, the fourth term represents the cubic stiffness (SP-5, CP-5). Finally, the last term in Eq (44, 45) is the combined forcing of the external pressure (SP-3, CP-3) and thermal moment (SP-8, CP-8).

Since Eqs (44) and (45) are similar, we present them in a prototype form ($q=W_{11}$ and $f=P_{11}$)

$$\ddot{q} + \omega_0\xi\dot{q} + \omega_0^2(1-s)q + \kappa q^3 = f_o + f(t), \tag{46}$$

where $\omega_o=(\beta^2+1)$, $s=T_o[1+(1-\mu)\delta_v/8]$, $\kappa=4e$, $f_o=(\beta^2+1)^2\delta_g T_o/24$ for the simply-supported plate; and $\omega_o=16(\beta^4+2\beta^2/3+1)/3$, $s=T_o[1+(1-\mu)\delta_v(1+\beta^2(\beta^2+1)^{-2})/6]$, $\kappa=128d/9$, $f_o=(\beta^4+2\beta^2/3+1)\delta_g T_o/6$ for the clamped plate. Also, $\gamma=\omega_o$ is introduced. Note that the combined stiffness $\omega_0^2(1-s)$ is positive when the thermal loading is weak ($s<1$ for pre-buckling), whereas it becomes negative under a strong thermal loading ($s>1$ for post-buckling).

Without damping and forcing, the Hamiltonian $H=K+U$ for Eq (46) has the kinetic energy $K=p^2/2$ and potential (strain) energy $U=\omega_0^2(1-s)q^2/2+\kappa q^4/4-f_oq$. When $f_o=0$ the potential energy is even, $U(q)=U(-q)$. Hence, f_o has a very significant effect of destroying the symmetry property of Duffing oscillator as defined by Räty (1984). Fig 1(a) shows the symmetric U of a simply-supported plate under $f_o=0$. Note that the single well potential develops a double well as $s>1$. Although δ_vT_o has been lumped into a parameter s, one must specify δ_g and T_o for f_o. For qualitative discussions, we let $\delta_v=\delta_g=1$ and express T_o in terms of s

$$T_o=s/[1+(1-\mu)/8],\ T_o=s/[1+(1-\mu)(1+\beta^2(\beta^2+1)^{-2})/6], \tag{47}$$

for the simply-supported and clamped plates. In this way, the three thermal terms can all be quantified by s. Shown in Fig 2 are the potentials of Fig 1(a) being asymmetrized by the temperature gradient. Note that an asymmetric U has also been observed in an electrical power system model (Nayfeh et al., 1990) and imperfect structural model (Souza and Mook, 1991).

A. Thermally Buckled Modal Amplitude

The static problem of (46) is governed by

$$\kappa Q^3 + \omega_0^2(1-s)Q - f_o = 0. \tag{48}$$

For $f_o=0$ the two regimes of (48) are $Q_1=0$ for $s<1$ and

$$Q_2 = \pm\omega_o\sqrt{(s-1)/\kappa}, \tag{49}$$

for $s>1$. Since (48) is nothing but $\partial U/\partial q=0$, the Q_1 and Q_2 represent the trough of symmetric U, shown in Fig 1(b). When $f_o\neq0$ Eq (48) again has two regimes. For $s<s^*$ it has only one real root

$$Q_3=\left[\frac{f_o}{2\kappa}+\sqrt{\left(\frac{f_o}{2\kappa}\right)^2+\left(\frac{\omega_0^2(1-s)}{3\kappa}\right)^3}\,\right]^{1/3} - \left[-\frac{f_o}{2\kappa}+\sqrt{\left(\frac{f_o}{2\kappa}\right)^2+\left(\frac{\omega_0^2(1-s)}{3\kappa}\right)^3}\,\right]^{1/3}, \tag{50}$$

for the radicand is positive. In fact, the critical s^* is determined by the zero radicand

$$s^* = 1 + \left(\frac{3\kappa}{\omega_0^2}\right)\left(\frac{f_o}{2\kappa}\right)^{2/3}. \tag{51}$$

For $s>s^*$ the radicand is negative, so that the two real roots representing the trough of asymmetric double well potential are

$$Q_{4,n}=2\left(\frac{\omega_0^2(s-1)}{3\kappa}\right)^{1/2}\cos\left(\frac{\vartheta}{3}+\frac{2\pi n}{3}\right),\ (n=0,\ 1) \tag{52}$$

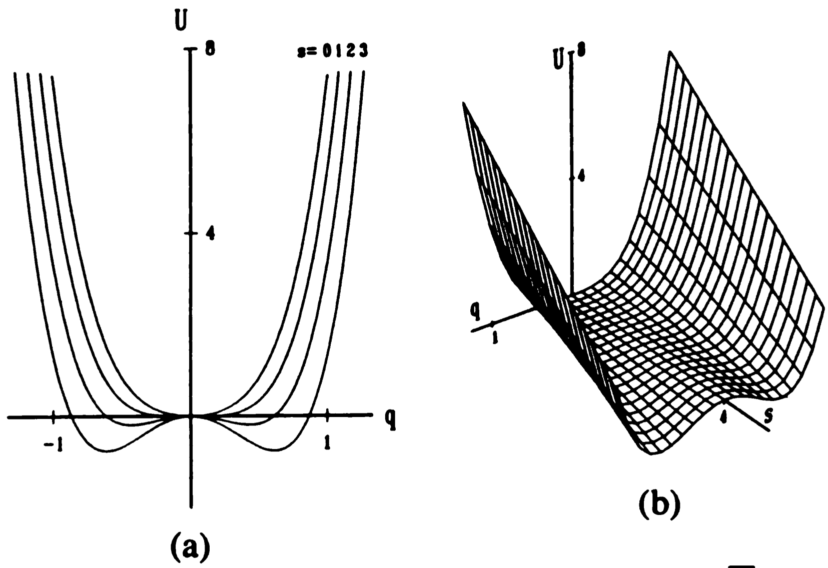

Fig 1. The potential energy U of a simply-supported plate under $\beta=1$ and $\mu=\sqrt{0.1}$. (a) Discrete increments of s =0, 1, 2, 3. (b) Single well potential developing a symmetric double well.

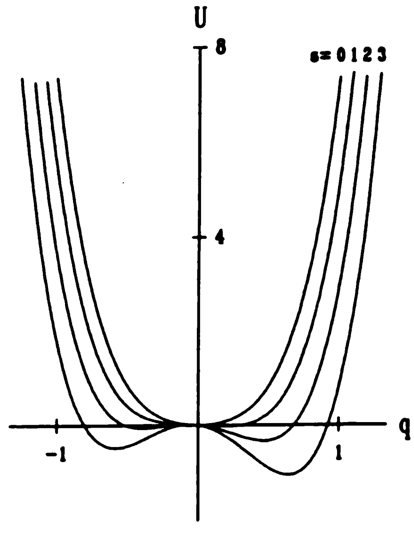

Fig 2. Asymmetrized potentials due to $f_o=s/6[1+(1-\mu)/8]$ of the simply-supported plate under $\beta=1$ and $\mu=\sqrt{0.1}$

where $\cos\vartheta = \left((f_0/2\kappa)^2/(\omega_0^2(s-1)/3\kappa)^3\right)^{1/2}$. In Fig 3 we compare the pairs (Q_1, Q_2) and (Q_3, Q_4) under the relation (47). Note that the emergence of two roots (52) is quite sudden, and Q_3 and $Q_{4,0}$ are joined smoothly at $s=s^*$. As expected, the (Q_3, Q_4) degenerate to (Q_1, Q_2) when $f_0=0$.

B. Dynamic Considerations

The equilibrium Q_3 is stable for $s<s^*$ and becomes unstable at $s=s^*$. On the other hand, the stable equilibrium states are given by Q_4 for $s>s^*$. The local dynamic can best be examined by the change of variable $q=Q+r$ in (46)

$$\ddot{r} + \omega_0\xi\dot{r} + [\omega_0^2(1-s)+3\kappa Q^2]r + 3\kappa Qr^2 + \kappa r^3 = f(t), \qquad (53)$$

by virtue of (48). Eq (53) now describes oscillations about the state Q. In fact, we have traded Eq (46) with the right-hand side f_0 term with a pair of (48) and (53). Under $f_0=0$, we have $Q_1=0$ for $s<1$, so that (48) and (53) reduce to the original equation (46). And, for $s>1$ we have, since $Q=Q_2$

$$\ddot{r} + \omega_0\xi\dot{r} + 2\omega_0^2(s-1)r + 3\kappa Q_2 r^2 + \kappa r^3 = f(t). \qquad (54)$$

This therefore has led Schneider (1974) to conclude that the natural frequency is increased by the $\sqrt{2}$ factor after thermal buckling. Although (46) and (53) are equivalent, the latter system is better suited for a local analysis about the Q (Sec 7).

For the global analysis, one must deal directly with (46). This equation, however, does not appear studied in its entirety, although there is no dearth of investigations pertaining to certain subsystems of it. Of course, the most notable is when $f_0=0$. Introducing $f(t)=M\cos\Omega t$(where M and Ω are the forcing amplitude and frequency), (46) is has the well-known Duffing's equation

$$\ddot{q} + \omega_0\xi\dot{q} + \omega_0^2(1-s)q + \kappa q^3 = M\cos\Omega t, \qquad (55)$$

with a hard ($\kappa>0$) and soft ($\kappa>0$) spring (Stoker, 1950). For $s<1$ the equilibrium $Q_1=0$ represents the trough of single well potential in Fig 1(b). As s passes through unity, Q_1 becomes unstable and Q_2 is now the stable equilibrium state. Let us rewrite (55) for $s>1$

$$\ddot{q} + \omega_0\xi\dot{q} - \omega_0^2(s-1)q + \kappa q^3 = M\cos\Omega t. \qquad (56)$$

This is the so-called buckled beam equation of Holmes (1979). The dynamics of Duffing and Holmes oscillators have been investigated extensively (see, for instance, Huberman and Crutchfield (1979), Räty et al. (1984), and Nayfeh and Sanchez (1989) for soft Duffing oscillator; Novak and Frehlick (1982) for hard Duffing oscillator; and Guckenheimer and Holmes (1983) for Holmes oscillator). The general observation is that the development of chaos in these oscillators can be ascribed to the symmetry breaking, thereby engendering even modes consistent with the period doubling scenario of Feigenbaum (Kalafati and Malakhov, 1983).

Under $f_0\neq 0$ Duffing's equation that Ueda (1981) has originally investigated is Eq (46) with $f=M\cos\Omega t$, but $s=1$ so that only the cubic stiffness term is present. On the other hand, the systems of Nayfeh et al. (1990) and Souza and Mook (1991) have a nonzero forcing term; however, their cosine potential represents a nonlinear pendulum.

7. RANDOM DISPLACEMENT ESTIMATION

The combined forcing $g=f_0+f$ is a nonzero-mean Gaussian process when f(t) is assumed zero-mean Gaussian. The

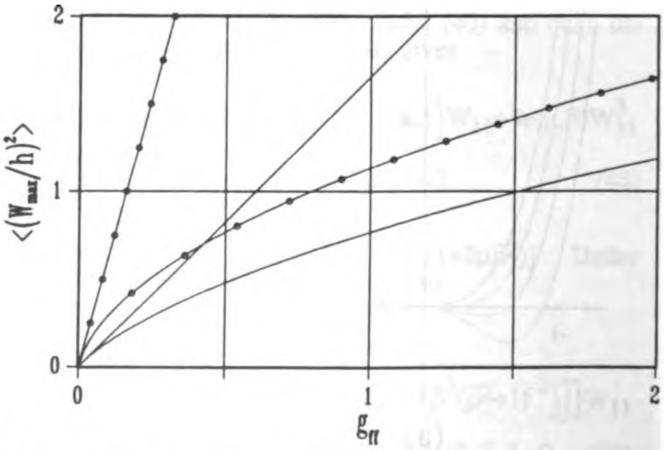

Fig 4. Linear and nonlinear estimates of the maximum mean square displacement under $\beta=1$, $\mu=\sqrt{0.1}$, $\xi=0.04$. The simply-supported plate is denoted by a line with circles, and the clamped plate without circles.

equivalent linearization technique was formulated (Caughey, 1963) for a zero-mean Gaussian excitation, hence it is necessary to reformulate the problem so that f_0 does not appear in the forcing term. We shall first consider $f_0=0$ in Sec 7A and the general case $f_0 \neq 0$ will be presented in Sec 7B.

A. Acoustic Loading ($g=f(t)$)

Pre-buckling ($s<1$): Let us denote by q_{lin} the amplitude of linearized Eq (46) under $f_0=0$. The mean square amplitude is given by Eq (E3) of Appendix E

$$<q_{lin}^2> \approx \frac{g_{ff}(f)}{2\xi\omega_0^3(1-s)}, \tag{57}$$

where < > is the statistical (time) average and $g_{ff}(f)$ is the power spectral density in frequency. Now, for (46) the equivalent linearization technique yields

$$<q^2> = \frac{\omega_0^2(1-s)}{6\kappa}\left[\sqrt{1+\frac{12\kappa<q_{lin}^2>}{\omega_0^2(1-s)}}-1\right], \tag{58}$$

as given by Eq (E9). For small κ, (58) reduces to $<q^2> \approx <q_{lin}^2>$ as expected, and $<q^2> \approx <q_{lin}^2>^{1/2}$ when κ is large.

For the nonthermal ($s=0$) reference, we have evaluated $<q_{lin}^2>$ and $<q^2>$ for $\beta=1$, $\mu^2=0.1$, $\xi=0.04$, and presented in Fig 4 the maximum displacement

$$<(W_{max}/h)^2> = c<q_{lin}^2> \text{ or } c<q^2>, \tag{59}$$

where $c=(4, 64/9)$ for the (simply-supported, clamped) plate. In the figure, the straight lines originating from the origin are linear input-output relations. However, the mean square displacement (58) increases more gradually due to a nonlinear saturation provided by the equivalent linearization. For a given g_{ff}, the simply-supported plate has a larger mean displacement than the corresponding clamped plate, as already noted by Mei (1980).

In the thermal case ($s>0$), the mean square displacement increases with s, as evidenced by the three $s=0$, 0.5 and 0.9 in Fig 5. However, the net thermal contribution diminishes as g_{ff} becomes large. This may be inferred from the limiting form of (58), $<q^2> \approx (g_{ff}/6\xi\kappa\omega_0)^{1/2}$, as $g_{ff} \to \infty$, which is independent of s. In other words, the uniform temperature and temperature variation will have no effect on the mean square displacement when the acoustic loading is large.

Post-buckling ($s>1$): Denoting by r_{lin} the amplitude of linearized Eq (54), we have in parallel to (57)

$$<r_{lin}^2> \approx \frac{g_{ff}}{4\xi\omega_0^3(s-1)}. \tag{60}$$

The equivalent linearization procedure goes through just as in the pre-buckled case, for the quadratic term in (54) has no consequence under the Gaussian assumption. Hence,

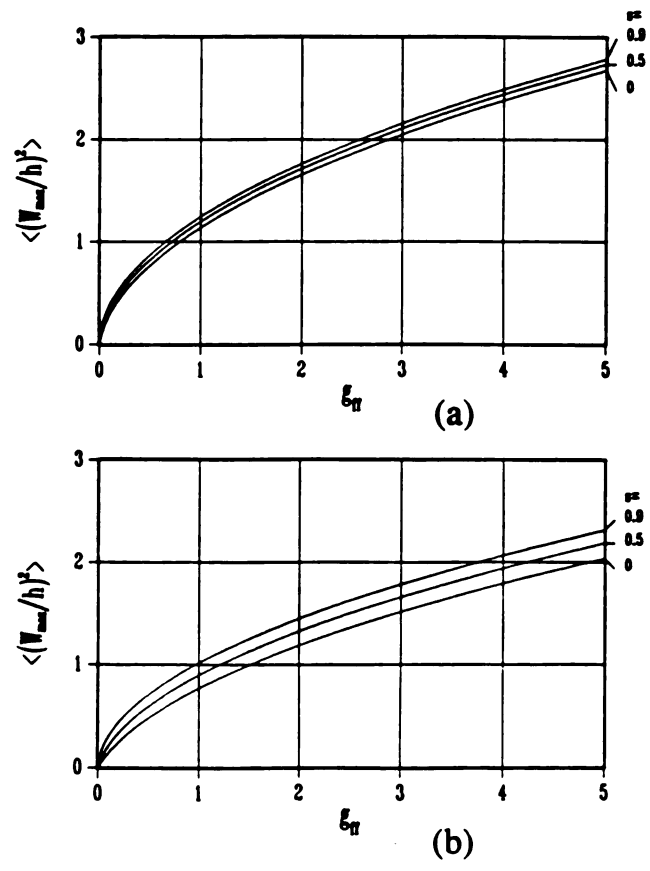

Fig 5. Maximum mean square displacement of a pre-buckled plate ($s<1$) under $\beta=1$, $\mu=\sqrt{0.1}$, $\xi=0.04$. (a) Simply-supported plate; (b) clamped plate.

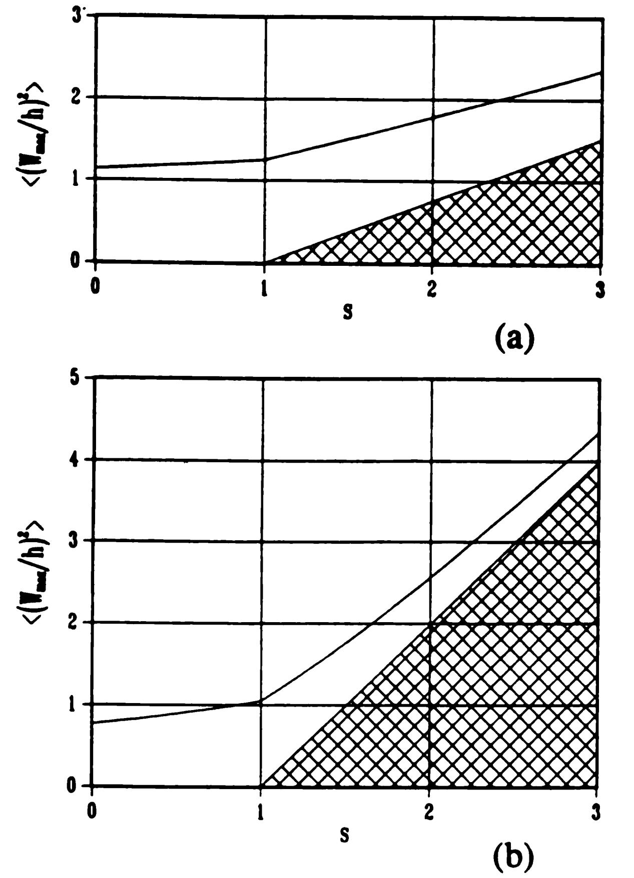

Fig 7. Maximum mean square displacement under $\beta=1$, $\mu=\sqrt{0.1}$, $\xi=0.04$, and $g_{ff}=1$. The cross-hatched triangle represents the squared buckled plate amplitude. (a) Simply-supported plate; (b) clamped plate.

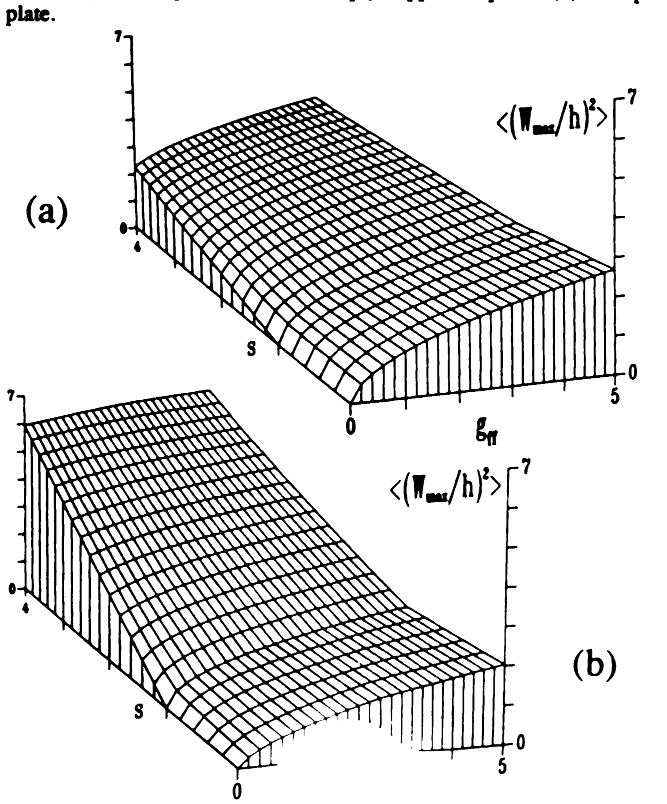

Fig 8. The composite vi[...] re displacements of Figs 5 and 6. (a) Simply-su[...] ped plate.

$$\langle r^2\rangle = \frac{\omega_0^2(s-1)}{3\kappa}\left[\sqrt{1+\frac{6\kappa\langle r_{lin}^2\rangle}{\omega_0^2(s-1)}}-1\right]. \tag{61}$$

And, the total mean square amplitude is given by

$$\langle q^2\rangle = Q_2^2 + \langle r^2\rangle, \tag{62}$$

since $\langle r\rangle=0$.

Fig 6 shows that the total mean square displacement increases greatly with s. However, the increase is largely due to the contribution of Q_2. To show this, we have presented in Fig 7 the separate contributions of Q_2 and $\langle r^2\rangle$ at $g_{ff}=1$. We see the squared Q_2 increasing linearly with (s-1), but $\langle r^2\rangle$ actually falls off with s. This is again supported by the asymptotic form of (61), $\langle r^2\rangle \propto 1/s$, as $s \to \infty$. Hence, the mean square amplitude due to fluctuations is smaller in a post-buckled state than in the pre-buckled. This has also been borne out by the Monte Carlo simulation of Choi and Vaicaitis (1989), in which the magnitude of stress fluctuations is considerably smaller whenever the stress time history shifts to buckled states. The composite of Figs 5 and 6 is shown by the surface plot of total mean displacement in Fig 8.

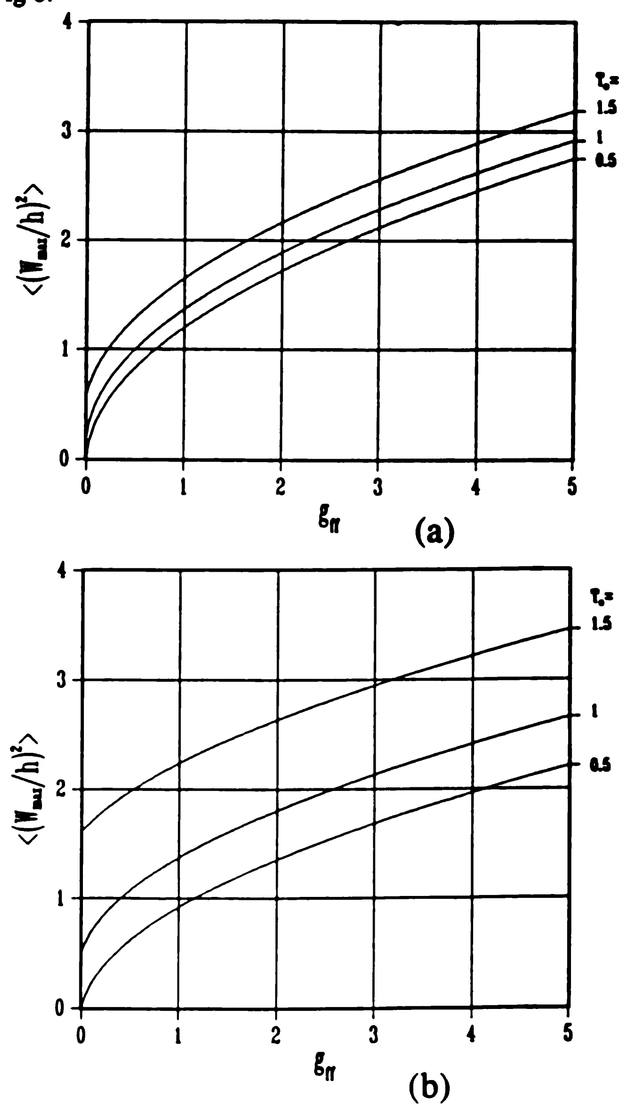

Fig 9. Total mean square displacement under the combined forcing. Here, $\beta=1$, $\mu=\sqrt{0.1}$, $\xi=0.04$, $\delta_v=\delta_g=1$. The range of T_0 includes the critical s* of (a) simply-supported plate and (b) clamped plate.

B. Combined Acoustic and Thermal Loading ($g=f_0+f(t)$)

The analysis of Sec 7A is valid when there is no heat flux through the plate thickness. This may occur, for instance, when the temperature gradient vanishes due to one side of the plate being insulated. Under a nonuniform heat flux, the temperature gradient will be neither constant nor linear over the plate. One must then retain f_0 as a nonzero-mean on which the Gaussian excitations are superposed. Instead of (46), it is more appropriate to use the local dynamical equation (53). Denoting the combined linear stiffness by $k_c=\omega_0^2(1-s)+3\kappa Q^2$, the mean square amplitude of linearized equation (53) is

$$<r_{lin}^2> = \frac{g_{ff}}{2\xi\omega_0 k_c}. \tag{63}$$

And, the equivalent linearization procedure yields

$$<r^2> = \frac{k_c}{6\kappa}\left[\sqrt{1+\frac{12\kappa<r_{lin}^2>}{k_c}} - 1\right], \tag{64}$$

together with

$$<q^2> = Q^2 + <r^2>. \tag{65}$$

Eqs (63-65) are analogous to Eqs (60-62) of the post-buckled case; however, Q is now given by Q_3 and $Q_{4,n}$.

Again, for simplicity we let $\delta_g=\delta_v=1$. We then present in Fig 9 the total mean square response computed by joining Q_3 and $Q_{4,0}$ smoothly at $s=s^*$. That Q>0 indicates that the thermal moment induced by f_0 increases the mean square displacement above the level of Fig 8. As in Fig 6, the clamped plate responds more favorably to the temperature gradient than a simply-supported plate (Fig 9).

8. RMS STRESS AND STRAIN

Let us put the normal stress (12) and strain (13) in dimensionless form, $\begin{pmatrix}\sigma_x\\ \sigma_y\end{pmatrix}=\frac{\pi^2Eh^2}{b^2}\begin{pmatrix}\hat\sigma_x\\ \hat\sigma_y\end{pmatrix}$, $\begin{pmatrix}\varepsilon_x\\ \varepsilon_y\end{pmatrix}=\frac{\pi^2h^2}{b^2}\begin{pmatrix}\hat\varepsilon_x\\ \hat\varepsilon_y\end{pmatrix}$.

For the single-mode representation, we shall present the stress and strain as a function x at y=1/2

Simply-Supported Plate:

$$\hat\sigma_x=-\frac{(\beta^2+1)T_0}{12(1-\mu^2)}\left\{1+\frac{(1-\mu)\delta_v}{4}\left[1-\frac{\cos2\pi x}{(\beta^2+1)}\right]+Z\delta_g\sin\pi x\right\}+$$
$$+\frac{2Z(\beta^2+\mu)}{(1-\mu^2)}(\sin\pi x)q+\left[\frac{(\beta^2+\mu)}{(1-\mu^2)}+\beta^2\right]\frac{q^2}{2}, \tag{66}$$

$$\hat\varepsilon_x=\frac{(\beta^2+1)\delta_vT_0}{12(1+\mu)}\left\{f_v-\frac{1}{4}\left[(1+\mu\cos2\pi x)-\frac{(1-\mu\beta^2)}{(\beta^2+1)}\cos2\pi x\right]\right\}+$$
$$+2Z\beta^2(\sin\pi x)q+(2\beta^2+\mu\cos2\pi x)q^2/2, \tag{67}$$

Clamped Plate:

$$\hat\sigma_x=-\frac{(\beta^4+2\beta^2/3+1)T_0}{3(1-\mu^2)(\beta^2+1)}\left\{1+\frac{(1-\mu)\delta_v}{4}\left[1-\frac{\cos2\pi x}{(\beta^2+1)}\right]+Z\delta_g\sin^2\pi x\right\}-$$
$$-\frac{16Z}{3(1-\mu^2)}[\beta^2\cos2\pi x+\mu\sin^2\pi x]q+\frac{32}{9}\left\{\frac{3(\beta^2+\mu)}{16(1-\mu^2)}+\frac{5\beta^2}{16}\right.$$
$$\left.+\frac{\cos2\pi x}{2(\beta+\beta^{-1})^2}-\frac{\cos2\pi x}{(\beta+4\beta^{-1})^2}+\frac{\cos4\pi x}{4(4\beta+\beta^{-1})^2}\right\}q^2, \tag{68}$$

$$\hat\varepsilon_x=\frac{(\beta^4+2\beta^2/3+1)\delta_vT_0}{3(1+\mu)(\beta^2+1)}\left\{\sin^2\pi x-\right.$$
$$\left.-\frac{1}{4}\left[(1+\mu\cos2\pi x)-\frac{(1-\mu\beta^2)}{(\beta^2+1)}\cos2\pi x\right]\right\}-\frac{16Z\beta^2}{3}(\cos2\pi x)q$$
$$+\frac{32}{9}\left\{\frac{3\beta^2}{16}+\frac{1}{4}(\beta^2+\mu\cos2\pi x)+\frac{1}{16}(\beta^2-\mu\cos4\pi x)+\frac{\cos2\pi x}{2(\beta+\beta^{-1})^2}\right.$$
$$\left.\times(1-\mu\beta^2)-\frac{\cos2\pi x}{(\beta+4\beta^{-1})^2}\left(1-\frac{\mu\beta^2}{4}\right)+\frac{\cos4\pi x}{4(4\beta+\beta^{-1})^2}\left(\frac{1}{4}-\mu\beta^2\right)\right\}q^2. \tag{69}$$

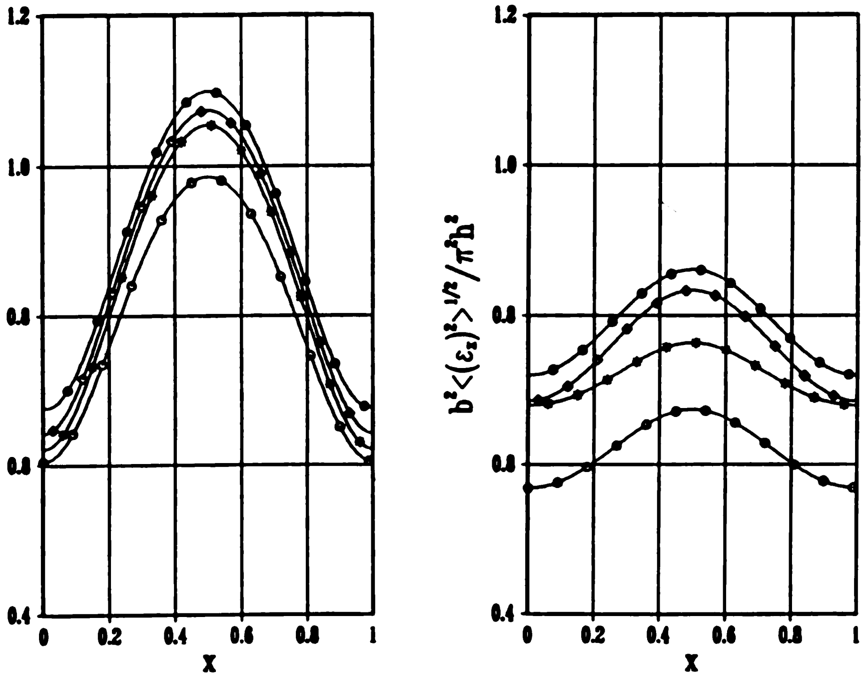

Fig 10. RMS extreme-fiber stress and strain of a simply-supported plate under $\beta=1$, $\mu=\sqrt{0.1}$, $\xi=0.04$, and $g_{ff}=1$. o for $T_0=\delta_v=\delta_g=0$; * for $T_0=1.2$, $\delta_v=\delta_g=0$; ◊ for $T_0=1.2$, $\delta_v=1$, $\delta_g=0$; • for $T_0=1.2$, $\delta_v=\delta_g=1$.

Eqs (63-66) have the symbolic form

$$\wp = C_0 + C_1q + C_2q^2, \tag{70}$$

where $\wp$ represents ($\hat\sigma_{x,y}$, $\hat\varepsilon_{x,y}$) and C's are the coefficients involving x. Under the assumption of zero-mean Gaussian, we obtain by squaring and averaging

$$<\wp^2>=C_0^2+(C_1^2+2C_0C_2)<q^2>+$$
$$+3C_3^2(<q^2>)^2. \tag{71}$$

To be specific, we consider the parameter values $T_0=1.2$, $\delta_v=\delta_g=1$, and $g_{ff}=1$. After computing the extreme-fiber stress and strain (at Z=1/2), we estimate the mean square value by (71). To quantify the thermal contributions, we have shown four plots in each of Figs 10 and 11. The first (open circle) is the nonthermal case ($T_0=\delta_v=\delta_g=0$); the second (asterisk) in[...] only the uniform tempera[...]

1.2, $\delta_v=\delta_g=0$); the third (diamond) involves both the uniform temperature and temperature variation over the plate ($T_0=1.2$, $\delta_v=1$, $\delta_g=0$); and the last (solid circle) represents the fully thermal case ($T_0=1.2$, $\delta_v=\delta_g=1$). Figs 10 and 11 show that the three thermal terms contribute additively over the entire x. Moreover, the contribution by the uniform temperature (asterisk) is at least a half the total thermal contribution for both the normal stress and strain. The parameter values of the figures are meant to be typical; however, a variant may be noticed under a different parameter choice.

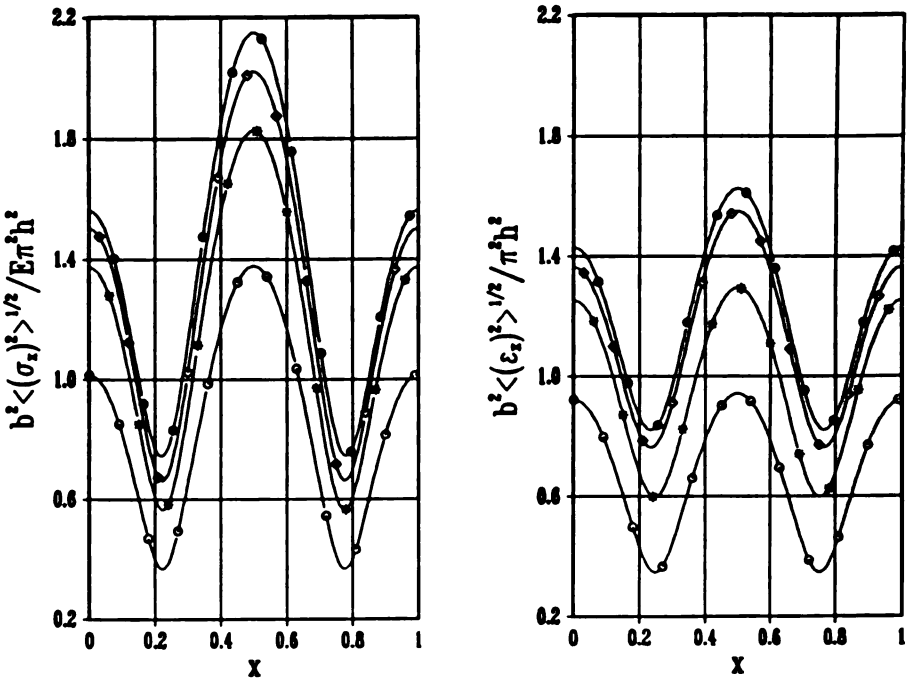

Fig 11. RMS extreme-fiber stress and strain of a clamped plate under $\beta=1$, $\mu=\sqrt{0.1}$, $\xi=0.04$, and $g_{ff}=1$. o for $T_0=\delta_v=\delta_g=0$; * for $T_0=1.2$, $\delta_v=\delta_g=0$; ◊ for $T_0=1.2$, $\delta_v=1$, $\delta_g=0$; • for $T_0=1.2$, $\delta_v=\delta_g=1$.

9. ASSESSMENT OF SINGLE-MODE DYNAMICS

The parameter reaches the critical value s=1 when thermal expansion is sufficient to induce buckling under the immovable edge condition. For a pre-buckled plate (s<1) the thermal expansion brings about increased mean square amplitude over the nonthermal (s=0) level. However, the relative increase diminishes as the acoustic loading becomes large. On the other hand, for a post-buckled plate (s>1) the total mean square displacement is sum of the square of buckled plate amplitude and mean square displacement due to the acoustic excitation only. Note that the square of buckled plate amplitude increases with (s-1), but the mean square displacement due to fluctuations falls off by 1/s, as s becomes large. Hence, the total mean square displacement is dominated by the buckled plate amplitude in the high-temperature limit.

It is important to point out that the temperature gradient across the plate introduces a qualitative change in overall dynamics. For a positive temperature gradient, there appears another critical value s=s* by which the thermal buckling is now characterized. Quantitatively, however, the thermal loading brings about additive contributions of the three thermal terms to the mean square amplitude as well as the rms normal stress and strain.

At this juncture, one may ask: How good is the random dynamics of a single-mode equation? Clearly, we cannot answer this fully without a detailed investigation of multi-mode equations. In the nonthermal case, however, Mei and Paul (1986) have shown that the single-mode analysis can provide an adequate approximation when the external forcing is weak. In fact, this is a good news in that the thermal effects show up most poignantly in the weak forcing range. Hence, the peculiarities of thermal effects might have already been captured by the single-mode analysis presented here. In any event, because of the Hamiltonian equations (33) of motion, it behooves us to investigate the multimode systems by Fokker-Planck formulation (Heuer et al., 1992).

APPENDIX E: Equivalent Linearization Technique

Let us begin with a damped linear oscillator

$$\ddot{x} + \beta\dot{x} + kx = f(t), \tag{E1}$$

where β is the damping coefficient and k the stiffness. Assume that f(t) is a stationary Gaussian with the power spectral density $\phi_{ff}(\omega)$, where ω is the angular frequency. The mean square response is

$$<x^2> = \frac{\pi\phi_{ff}(\sqrt{k}\,)}{\beta k},$$

where $\langle\ \rangle$ denotes an ensemble (or time) average. Note the sign $\approx$ is used because $\phi_{ff}(\omega)$ is assumed constant over the narrow resonance peaks at $\omega = \pm\sqrt{k}$ (see, Fig 5.3 of Lin, 1976). Rewrite (E2) by using $\phi_{ff}(\omega) = g_{ff}(f)/2\pi$, where f is frequency

$$\langle x^2\rangle \approx \frac{g_{ff}}{2\beta k}. \tag{E3}$$

Here, the argument of g_{ff} is suppressed for a constant spectrum.

Now consider a damped Duffing oscillator

$$\ddot{x} + \beta\dot{x} + kx + \gamma x^3 = f(t), \tag{E4}$$

where γ denotes the strenght of hard spring. Rather than solving (E4) by perturbation, the aim is to replace it by a linear system of the form

$$\ddot{x} + \beta\dot{x} + k_e x + e = f(t). \tag{E5}$$

By a judicious choice of the equivalent stiffness k_e, one attempts to capture the nonlinearity in a statistical sense. And,

attempts to capture the nonlinearity in a statistical sense. And,
the degree of failure is quantified by the error $e = (-k_e + k)x + \gamma x^3$. In the equivalent linearization technique, k_e is found by minimizing the mean square error, i.e., $d\langle e^2\rangle/dk_e = 0$. When x is zero-mean Gaussian, a simple expression follows

$$k_e = k + 3\gamma\langle x^2\rangle. \tag{E6}$$

By suppressing the error term, (E5) is linear so that

$$\langle x^2\rangle \approx \frac{g_{ff}}{2\beta k_e}, \tag{E7}$$

in view of (E3). Inserting (E6) into (E7) and identifying $\langle x^2_{lin}\rangle = g_{ff}/2\beta k$, we have (Caughey, 1963)

$$\frac{3\gamma}{k}(\langle x^2\rangle)^2 + \langle x^2\rangle - \langle x^2_{lin}\rangle = 0, \tag{E8}$$

the positive root is

$$\langle x^2\rangle = \frac{k}{6\gamma}\left[\sqrt{1+\frac{12\gamma\langle x^2_{lin}\rangle}{k}} - 1\right]. \tag{E9}$$

Hybrid Padé-Galerkin technique for differential equations

James F Geer

Department of Systems Science, Watson School of Engineering and Applied Science State University of New York, Binghamton NY 13902

Carl M Andersen

Department of Mathematics, College of William and Mary, Williamsburg VA 23185

A three-step hybrid analysis technique, which successively uses the regular perturbation expansion method, the Padé expansion method, and then a Galerkin approximation, is presented and applied to some model boundary value problems. In the first step of the method, the regular perturbation method is used to construct an approximation to the solution in the form of a finite power series in a small parameter ϵ associated with the problem. In the second step of the method, the series approximation obtained in step one is used to construct a Padé approximation in the form of a rational function in the parameter ϵ. In the third step, the various powers of ϵ which appear in the Padé approximation are replaced by new (unknown) parameters $\{\delta_j\}$. These new parameters are determined by requiring that the residual formed by substituting the new approximation into the governing differential equation is orthogonal to each of the perturbation coordinate functions used in step one. The technique is applied to model problems involving ordinary or partial differential equations. In general, the technique appears to provide good approximations to the solution even when the perturbation and Padé approximations fail to do so. The method is discussed and topics for future investigations are indicated.

INTRODUCTION

We have introduced and applied a hybrid perturbation-Galerkin technique to a variety of problems involving ordinary differential equations (Andersen and Geer, 1991; Geer and Andersen, 1989b, 1990, 1991b), partial differential equations (Geer and Andersen, 1991a; Singler and Geer, 1993), and integral equations (Geer and Andersen, 1989a), which contain a parameter ϵ. For many different classes of problems, this technique appears to significantly improve the usefulness of perturbation expansions over a wide range of parameter values.

In this paper, we show how some of these hybrid ideas can be combined with Padé (or rational function) approximations to provide approximate solutions of even greater accuracy. The hybrid technique we shall describe successively uses the regular perturbation expansion method (see, e.g., Nayfeh, 1973), the Padé expansion method (see, e.g. Baker, 1975), and then a Galerkin approximation (see, e.g., Galerkin, 1915). In the first step of the method, the regular perturbation method is used to construct an approximate solution in the form of a finite power series in a small parameter ϵ associated with the problem. In the second step of the method, the series approximation obtained in step one is used to construct a Padé approximation in the form of a rational function in the parameter ϵ. In the third step, the various powers of ϵ which appear in the Padé approximation are replaced by new (unknown) parameters $\{\delta_j\}$. These new parameters are determined by requiring that the residual formed by substituting the new approximation into the original governing differential equation is orthogonal to each of the perturbation coordinate functions used in step one. This hybrid method has the potential of overcoming some of the drawbacks of the perturbation method, the Padé method, and the Galerkin method when they are applied by themselves, while combining some of the good features of each.

Padé approximants have been popular among physicists for improving the convergence of series or for obtaining information from divergent series (see, e.g., Baker, 1975; Gaunt and Guttmann, 1974; and Hunter, 1973). They are easily constructed from the first few terms of a power series representation of a function, requiring only the solution of a system of linear algebraic equations. From a mathematical point of view, the power series representation of a function fails to converge because of the presence of one or more (real or complex) singularities of

part of "MECHANICS PAN-AMERICA 1993" edited by MRM Crespo da Silva and CEN Mazzilli ASME Reprint No AMR134

CONTENTS

the function, which the series representation is unable to adequately approximate. The more general Padé, or rational function, approximation of the function can better simulate the presence, or at least the effect, of these singularities. This is accomplished through the presence of zeros in the denominator of the approximation (the simulation of poles) or the combination of zeros of the numerator and denominator at nearly the same locations (which can simulate certain branch cuts) (see, e.g., Andersen and Geer, 1982; Dadfar, et al, 1984; or Van Dyke, 1974). However, the region of convergence of a sequence of Padé approximants is, in general, not closely related to the region of convergence of the power series on which the approximations are based. In fact, the construction of Padé approximants in the usual way may lead to approximations which fail to converge at points where the Taylor series of the function does converge. Often this is due to the appearance of spurious poles or zeros in the approximants which are not present in the original function. (See, e.g., Bender and Orszag, 1978, for some simple, but very interesting, examples which illustrate this phenomena.) As we shall demonstrate below, the hybrid method we will describe appears to overcome this drawback of the Padé method by "adjusting" the location of the poles and zeros of the approximants to simulate better the true analytical structure of the function being modeled.

Some general observations about the hybrid technique we are proposing are the following. First, in many perturbation problems, much effort has to be expended to compute each additional term in a perturbation expansion. Through the use of the proposed hybrid method, the "information" contained in the known perturbation terms can be exploited more fully. In particular, more of the analytical structure of the solution can be "uncovered" using a rational function approximation. Secondly, another way of viewing the technique is to recognize that in many perturbation expansions the functional form of the higher order terms can be well approximated by a linear combination of the lower order terms. Thus, much of the effect of the higher order terms may be included by applying the technique to the lower order terms. Finally, preliminary unpublished investigations indicate that, while the use of a Taylor series expansion is frequently limited by a finite radius of convergence, the proposed hybrid method can sometimes yield good results even well outside the radius of convergence.

In Sec 2 we shall describe our method in more detail and then apply it to two model boundary value problems involving ordinary differential equations (Sec 3) and to two model problems involving partial differential equations (Sec 4). Finally, we shall discuss observations about the method in Sec 5, and also indicate topics for further investigation.

DESCRIPTION OF THE METHOD

We consider the problem of finding approximations to the solution $u(x,\epsilon)$ to the problem

$$L(u,\epsilon)=0,\ x\in D,\quad \text{with } B(u,\epsilon)=0,\quad x\in\partial D. \tag{1}$$

Here L represents a (linear or nonlinear) differential operator, x is a scalar or a vector, D is the domain in which the differential equation is to hold, ∂D denotes the boundary of D, and ϵ is a small parameter. For simplicity we shall assume that the operator B, which defines the boundary conditions of the problem, is linear and homogeneous in u.

The hybrid Padé-Galerkin technique we present can be conveniently described as the following three-step process.

Step one: For small values of the parameter ϵ, we assume that u can be expanded in a (convergent or asymptotic) perturbation series of the form

$$u(x,\epsilon)=\sum_{j=0}^{n}u_j(x)\epsilon^j+O(\epsilon^{n+1}). \tag{2}$$

Here each of the perturbation coordinate functions u_j is determined in a straightforward manner using the regular perturbation method.

Step two: We now use the functions $\{u_j\}$ determined in step one to construct the Padé approximant $P[M,N]$ defined by

$$P[M,N](x,\epsilon)\equiv\frac{\sum_{j=0}^{M}v_j(x)\epsilon^j}{\sum_{j=0}^{N}w_j(x)\epsilon^j},\quad w_0(x)\equiv 1. \tag{3}$$

Here the functions $\{v_j(x)\}$ and $\{w_j(x)\}$ are determined by the condition that $P[M,N](x,\epsilon)=u(x,\epsilon)+O(\epsilon^{M+N+1})$, as $\epsilon\to 0$. This condition leads to the requirements

$$v_j(x)=\sum_{k=0}^{j}w_k(x)u_{j-k}(x),\quad j=0,1,...,M, \tag{4}$$

$$\sum_{k=1}^{\min(p,N)} u_{p-k}(x) w_k(x) = -u_p(x), \qquad p = M+1, M+2, \ldots, M+N. \tag{5}$$

Step three: Once $P[M, N]$ has been determined, we define the hybrid Padé-Galerkin approximation $H[M, N]$ by

$$H[M, N](x, \epsilon) = \frac{\sum_{j=0}^{M} v_j(x) \delta_j}{1 + \sum_{j=1}^{N} w_j(x) \delta_{M+j}}. \tag{6}$$

Here $H[M, N]$ has the *same functional form* as $P[M, N]$ except that each power of ϵ in the definition of $P[M, N]$ (except the coefficient of w_0) has been replaced by a new (unknown) parameter, or amplitude, $\delta_j = \delta_j(\epsilon)$. The $M + N + 1$ amplitudes $\{\delta_j\}$ are determined by requiring that the residual formed by substituting $H[M, N]$ into the governing differential equation is orthogonal to each of the perturbation coordinate functions used in step one. Thus, the new amplitudes $\{\delta_j\}$ are determined from the Galerkin conditions

$$\int_D L\left(H[M, N](x, \epsilon), \epsilon\right) u_k \, dx = 0, \quad k = 0, 1, \ldots, M + N. \tag{7}$$

Conditions (7) are a system of $M+N+1$ equations for the $M + N + 1$ amplitudes $\{\delta_j\}$. In general, these equations are nonlinear and must be solved numerically. However, we note that they can be solved efficiently using Newton's method, starting with small values of ϵ, where we expect $\delta_j \cong \epsilon^j$, for $0 \le j \le M$, and $\delta_{M+j} \cong \epsilon^j$, for $1 \le j \le N$, and then incrementally proceeding to larger values of ϵ.

Before applying this technique, we make a few observations. In step one of the method, i.e., the perturbation step, the solution to a particular problem involving a small parameter is developed in terms of a series of *unknown functions* with *preassigned coefficients*, i.e. gauge functions. The unknown functions are usually determined by solving a recursive set of differential equations which are, in general, simpler than the original governing differential equation. Using these perturbation coordinate functions, a new approximation in the form of a rational function of ϵ can be constructed in a straightforward manner. (We note that the Padé approximant $P[M, 0]$ as defined above is the same as the perturbation approximation of order M, while $P[M, N]$ with $N > 0$ is a truly new approximation.) By contrast, using the Galerkin technique in the standard manner, one seeks an approximate solution to the problem in the form of a series of *specified* (known) *coordinate functions* with *unknown coefficients*. The coefficients are determined by requiring that the residual formed by substituting the trial solution into the governing differential equation is orthogonal to each of the coordinate functions. The technique we are proposing simply replaces the power series form of the approximation in the Galerkin step by a more general rational function approximation to the solution.

We also observe that the perturbation, Padé, and Galerkin methods have each been useful when applied by themselves in providing approximate solutions to a wide variety of nonlinear (and otherwise difficult) problems. However, each of these techniques has certain drawbacks. The perturbation method has at least two major drawbacks. First, as the number of terms in the perturbation expansion increases, the mathematical complexity of the equations which determine the unknown functions increases rapidly. Thus, in most practical applications, the perturbation series is limited to only a few terms. A second drawback to the perturbation method is the requirement of restricting the perturbation parameter to small values in order to obtain solutions of acceptable accuracy. (These drawbacks of the perturbation method have been recognized and several modifications or extensions have been proposed, as, e.g., in Andersen and Geer, 1982, and Van Dyke, 1974.) One of the main drawbacks of the Padé method is that it often has to be applied "blindly", with little or no assurance that the approximations obtained will converge to the solution as the number of terms is increased. Also, a rational function obviously has (real or complex) poles which may or may not improve the quality of the approximations obtained. The main shortcoming of the Galerkin method is the difficulty, from a practical point of view, of selecting a small number of good coordinate functions.

By basing our technique on a formal perturbation expansion of the solution, we should note that our particular choice of coordinate functions overcomes the main drawback of the Galerkin method (at least for the case when $N = 0$.) By the way they are constructed, the perturbation coordinate functions are (under certain assumptions) elements of a set of functions which span the space of solutions in a neighborhood of their point of generation. Thus, they should fully characterize the solution u in that neighborhood. Also, in many applications, the functions $\{u_j\}$ are determined by solving a set of linear equations, even though the original operator L may be nonlinear. The first property is necessary for the convergence of the Galerkin method, while the second property enhances the effectiveness of the proposed hybrid method for solving nonlinear problems. In addition, for $N > 0$, we shall demonstrate below that the Galerkin method appears to determine the parameters of the Padé approximants in such a manner that the poles of $H[M, N]$ tend to *improve* and not degrade the quality of the approximations obtained.

In the following sections we shall apply our method to several model boundary value problems involving ordinary or partial differential equations. These examples will serve to illustrate the application of the method, and will also provide insights into some of the mathematical properties of the method. A more thorough and detailed analysis of some of the mathematical properties of the technique, as well as the application of the method to certain singular perturbation problems, will be presented elsewhere.

APPLICATIONS TO ORDINARY DIFFERENTIAL EQUATIONS

In this section we shall apply our method to two model boundary value problems involving second order ordinary differential equations.

Example 1: We consider first the two-point boundary value problem

$$\begin{gathered} L(u,\epsilon) \equiv u''(x) - \epsilon u'(x) - \epsilon = 0, \quad 0 < x < 1, \\ \text{with } B(u,\epsilon) \equiv u = 0, \quad \text{for } x = 0 \text{ and } x = 1. \end{gathered} \tag{8}$$

To help evaluate the accuracy of our proposed hybrid method, we note that this simple problem has the exact solution

$$u = \frac{1 - e^{\epsilon x}}{1 - e^{\epsilon}} - x. \tag{9}$$

The Taylor series expansion of $u(x,\epsilon)$ about $\epsilon = 0$ converges for $|\epsilon| < 2\pi$, since the singularities of u which lie closest to the origin in the complex ϵ−plane are located at $\epsilon = \pm 2\pi i$. We also note that u develops a boundary layer at $x = 1$ as ϵ becomes large.

Step one: Using the regular perturbation method we find that each of the perturbation coefficient functions u_j in Eq (2) is a polynomial of degree $j+1$ which vanishes at $x = 0$ and $x = 1$. In particular, we find $u_0 = 0$, $u_1 = x(x-1)/2$, $u_2 = x(x-1)(2x-1)/12$, $u_3 = x^2(1-x)^2/24$, and $u_4 = x(x-1)(2x-1)(3x^2-3x-1)/720$.

Step two: We now use the perturbation coordinate functions $\{u_j(x)\}$ determined in step one to calculate Padé approximations $P[M,N]$ for various values of M and N. In particular for $M+N=2$, using Eqs (4) and (5), we find

$$P[2,0] = \epsilon\, u_1(x) + \epsilon^2 u_2(x), \tag{10}$$

which is the second order perturbation solution, and

$$P[1,1] = \frac{\epsilon\, x(x-1)/2}{1+\epsilon(1-2x)/6}, \tag{11}$$

since $v_0 \equiv 0$, $v_1 = x(x-1)/6$, and $w_1 = (1-2x)/6$. We note that $P[1,1]$ has a pole at $x = 1/2 + 3/\epsilon$, which lies *inside* the interval $[0,1]$ for $\epsilon > 6$. Thus, we do not expect $P[1,1]$ to be a good approximation to $u(x,\epsilon)$ for $\epsilon > 6$. In Figs 1 and 2, we have plotted $P[2,0]$ and $P[1,1]$, along with the exact solution, for $\epsilon = 5$ and $\epsilon = 10$, respectively. The influence of the pole of $P[1,1]$ is evident in Fig 2.

Step three: We now use the *form* of the Padé approximations determined in step two to define the hybrid approximations

$$H[2,0] = \delta_1\, u_1(x) + \delta_2\, u_2(x), \tag{12}$$

and

$$H[1,1] = \frac{\delta_1\, x(x-1)/2}{1+\delta_2\,(1-2x)/6}, \tag{13}$$

where the amplitudes $\delta_1 = \delta_1(\epsilon)$ and $\delta_2 = \delta_2(\epsilon)$ are determined from the Galerkin conditions (7), which for this example become

$$\int_0^1 \left(H''[M,N] - \epsilon H'[M,N] - \epsilon\right) u_k\, dx = 0, \text{ for } k = 1,2. \tag{14}$$

When $M = 2$ and $N = 0$, Eqs (14) are the *linear* equations

$$\begin{gathered} (1/12)\delta_1 + (\epsilon/720)\delta_2 = \epsilon/12, \\ (\epsilon/720)\delta_1 - (1/720)\delta_2 = 0, \end{gathered} \tag{15}$$

from which we find

$$\delta_1 = \frac{\epsilon}{1+\epsilon^2/60}, \quad \delta_2 = \frac{\epsilon^2}{1+\epsilon^2/60}. \tag{16}$$

When $M = 1$ and $N = 1$, from Eqs (14) we find that δ_1 and δ_2 satisfy the *nonlinear* equations

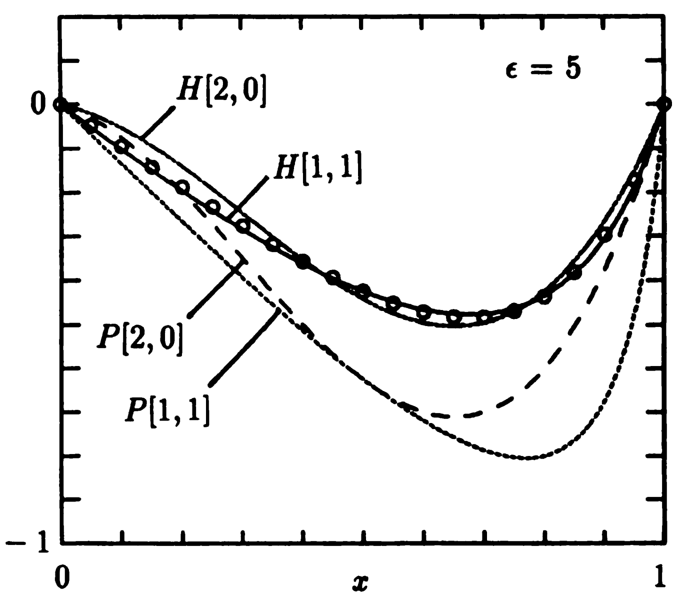

FIG 1. The Padé approximations $P[2,0]$ and $P[1,1]$, the hybrid approximations $H[2,0]$ and $H[1,1]$, and the exact solution (circles) for Ex 1 with $\epsilon = 5$.

$$\delta_1 = \frac{2\epsilon\,\delta_2^4}{9(3\epsilon+\delta_2)(36-\delta_2^2)\log(\frac{6+\delta_2}{6-\delta_2}) - 324\epsilon\,\delta_2 - 108\delta_2^2 + 6\epsilon\,\delta_2^3}, \tag{17}$$

$$\log\left(\frac{6+\delta_2}{6-\delta_2}\right) - \frac{4\,\delta_2(324\,\epsilon + 216\,\delta_2 - 9\,\epsilon\,\delta_2^2 - 4\,\delta_2^3)}{(36-\delta_2^2)(108\,\epsilon + 72\,\delta_2 - \epsilon\,\delta_2^2)} = 0. \tag{18}$$

Equation (17) expresses δ_1 in terms of δ_2, while Eq (18) is an equation for δ_2 as a function of ϵ, which must be solved numerically. In Figs 1 and 2 we have also plotted $H[2,0]$ and $H[1,1]$ for $\epsilon = 5$ and $\epsilon = 10$, respectively. As these figures illustrate, the hybrid approximations are more accurate than the Padé approximations on which they are based.

Although we shall discuss, more fully, insights about our method provided by this example (as well as our other examples) in the Discussion section, we make a few preliminary observations at this point. First, from Eqs (16) and Eqs (17)-(18) it follows that

$$\begin{aligned} &\delta_1 = \epsilon + O(\epsilon^3) \text{ and } \delta_2 = \epsilon^2 + O(\epsilon^3), \\ &\qquad \text{as } \epsilon \to 0, \text{ for } M = 2 \text{ and } N = 0, \\ &\delta_1 = \epsilon + O(\epsilon^2) \text{ and } \delta_2 = \epsilon + O(\epsilon^2), \\ &\qquad \text{as } \epsilon \to 0, \text{ for } M = 1 \text{ and } N = 1. \end{aligned} \tag{19}$$

Thus $H[2,0]$ reduces to $P[2,0]$ and $H[1,1]$ reduces to $P[1,1]$, as $\epsilon \to 0$. In addition, as $\epsilon \to \infty$, we find from Eqs (17) and (18) that, for the case $M = 1$ and $N = 1$,

$$\begin{aligned} &\delta_1 = 4 + O(\gamma(\epsilon)), \\ &\delta_2 = 6 - \gamma(\epsilon) + o(\gamma(\epsilon)), \quad \text{as } \epsilon \to \infty. \end{aligned} \tag{20}$$

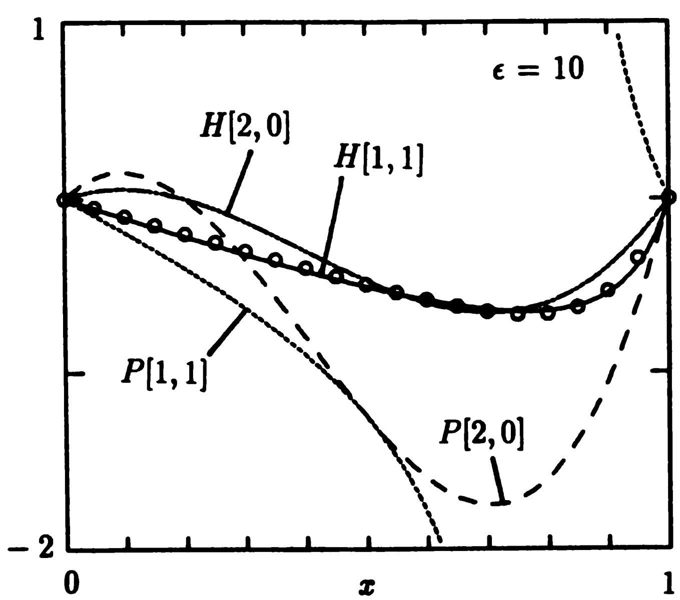

FIG 2. The Padé approximations $P[2,0]$ and $P[1,1]$, the hybrid approximations $H[2,0]$ and $H[1,1]$, and the exact solution (circles) for Ex 1 with $\epsilon = 10$. For this value of ϵ, the pole of $P[1,1]$ lies at $x = 0.8$.

Here $\gamma(\epsilon) \to 0^+$ as $\epsilon \to +\infty$ and is defined by $\gamma\log(\gamma) = -12/\epsilon$. From these results, as well as the numerical solution of Eqs (17) and (18) for "intermediate" values of ϵ, we find that the pole of $H[1,1]$, which is located at $x = 1/2 + 3/\delta_2$, lies *outside* the interval [0,1] for all positive values of ϵ. (The location of the pole approaches 1 from above as ϵ becomes large, with the pole lying, for example, at about 1.008 when $\epsilon = 50$.)

It is straightforward to use the procedure and formulas outlined above to construct Padé and hybrid approximations to $u(x,\epsilon)$ for other (larger) values of M and N. For example, we find

$$\begin{aligned} P[4,0](x,\epsilon) &= \epsilon\,u_1(x) + \epsilon^2\,u_2(x) + \epsilon^3\,u_3(x) + \epsilon^4\,u_4(x), \\ H[4,0](x,\epsilon) &= \delta_1\,u_1(x) + \delta_2\,u_2(x) + \delta_3\,u_3(x) + \delta_4\,u_4(x), \end{aligned} \tag{21}$$

where

$$\begin{aligned} \delta_1 &= \frac{15120\,\epsilon + 420\,\epsilon^3}{15120 + 420\,\epsilon^2 + \epsilon^4}, \quad \delta_2 = \epsilon\delta_1, \\ \delta_3 &= \frac{15120\,\epsilon^3}{15120 + 420\,\epsilon^2 + \epsilon^4}, \quad \delta_4 = \epsilon\delta_3; \end{aligned} \tag{22}$$

and

$$\begin{aligned} P[2,2] &= \frac{\epsilon\,v_1(x) + \epsilon^2\,v_2(x)}{1 + \epsilon\,w_1(x) + \epsilon^2\,w_2(x)}, \\ H[2,2] &= \frac{\delta_1\,v_1(x) + \delta_2\,v_2(x)}{1 + \delta_3\,w_1(x) + \delta_4\,w_2(x)}, \end{aligned} \tag{23}$$

with

$$\begin{aligned} v_1 &= \frac{x(x-1)}{2}, \\ v_2 &= -\frac{x(x-1)(2x-1)(x+1)(x-2)}{60(x^2-x+1)}, \\ w_1 &= -\frac{(2x-1)(2x^2-2x+1)}{10(x^2-x+1)}, \\ w_2 &= \frac{3x^4 - 6x^3 + 4x^2 - x + 1}{x^2 - x + 1}. \end{aligned} \tag{24}$$

In Fig 3 we have plotted the Padé approximation $P[2,2]$, the hybrid approximations $H[4,0]$ and $H[2,2]$, as well as the exact solution, for $\epsilon = 50$. Here $H[2,2]$ is clearly the "best" of the approximations shown and does a good job of simulating the boundary layer behavior of the exact solution, even at this moderately large value of ϵ where the boundary layer is well formed.

Example 2: We consider now the two-point boundary value problem

$$\begin{aligned} L(u,\epsilon) \equiv u''(x) + \epsilon\sin(2x)\,u'(x) + \\ 2\,\epsilon\cos(2x)u - 2\,\epsilon\cos(2x) = 0, \qquad 0 < x < \pi, \\ \text{with } B(u,\epsilon) \equiv u = 0, \text{ for } x = 0 \text{ and } x = \pi. \end{aligned} \tag{25}$$

The exact solution to this problem is

$$u = 1 - e^{-\epsilon \sin^2(x)}. \tag{26}$$

The Taylor series expansion of $u(x, \epsilon)$ about $\epsilon = 0$ converges for all $|\epsilon| < \infty$, since u has no singularities in the finite part of the complex ϵ−plane. For this example, u develops boundary layers at both $x = 0$ and $x = \pi$ as ϵ becomes large.

Step one: Using the regular perturbation method we find the u_j in Eq (2) are given by $u_0(x) = 0$ and $u_j(x) = (-1)^{j+1} \sin^{2j}(x)/j!$, for $j \geq 1$.

Step two: Using the perturbation coordinate functions $\{u_j(x)\}$ determined in step one, we can calculate Padé approximations $P[M, N]$ for various values of M and N. In particular for $M + N = 2$, using Eqs (4) and (5), we find

$$P[2, 0](x, \epsilon) = \epsilon \sin^2(x) - \epsilon^2 \sin^4(x)/2, \tag{27}$$

which is the second order perturbation solution, and

$$P[1, 1](x, \epsilon) = \frac{\epsilon \sin^2(x)}{1 + (\epsilon/2)\sin^2(x)}. \tag{28}$$

We note that, for $\epsilon > 0$, the poles of $P[1, 1]$ are all complex and, hence, lie *outside* the interval $D \equiv [0, 1]$. In particular, the poles which lie closest to D are at $x = \pm i \sinh^{-1}(\sqrt{2/\epsilon})$ and $x = \pi \pm i \sinh^{-1}(\sqrt{2/\epsilon})$, which approach $x = 0$ and $x = \pi$, respectively, as $\epsilon \to +\infty$. In Fig 4, we have plotted $P[2, 0]$ and $P[1, 1]$, along with the exact solution, for $\epsilon = 10$. The influence of the (complex) poles of $P[1, 1]$ in helping to simulate the steep slope of the solution near the ends of the interval is evident in Fig 4.

Step three: We now use the form of the Padé approximations determined in step two to define the hybrid approximations

$$H[2, 0] = \delta_1 \sin^2(x) - \delta_2 \sin^4(x)/2, \tag{29}$$

and

$$H[1, 1] = \frac{\delta_1 \sin^2(x)}{1 + (\delta_2/2)\sin^2(x)}, \tag{30}$$

where the amplitudes δ_1 and δ_2 are determined from the Galerkin conditions (7), which for this example become

$$\int_0^1 \{H[M, N]'' + \epsilon \sin(2x) H[M, N]' + 2\epsilon \cos(2x) H[M, N] - 2\epsilon \cos(2x)\} u_k \, dx = 0, \quad k = 1, 2. \tag{31}$$

When $M = 2$ and $N = 0$ Eqs (31) are *linear* and their solution is

$$\delta_1 = \frac{16\epsilon(2 + \epsilon)}{32 + 16\epsilon + 3\epsilon^2}, \quad \delta_2 = \frac{32\epsilon^2}{32 + 16\epsilon + 3\epsilon^2}. \tag{32}$$

When $M = 1$ and $N = 1$, Eqs (31) are *nonlinear* and must be solved numerically. In Fig 4 we have also plotted $H[2, 0]$ and $H[1, 1]$ for $\epsilon = 10$. As the figure illustrates, the hybrid approximations are again more accurate than the Padé approximations on which they are based. Using Eqs (31), we can again show that the relations (19) hold for this example as well. Also, it is straightforward to use the procedure and formulas outlined above to construct Padé and hybrid approximations to $u(x, \epsilon)$ for other (larger) values of M and N.

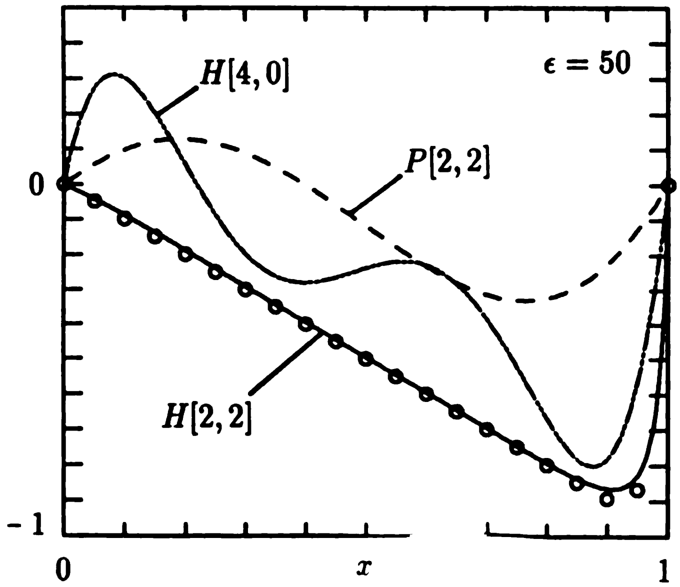

FIG 3. The Padé approxim... hybrid approximations $H[4, 0]$ and H... act solution (circles) for Ex 1 with $\epsilon = 5$...

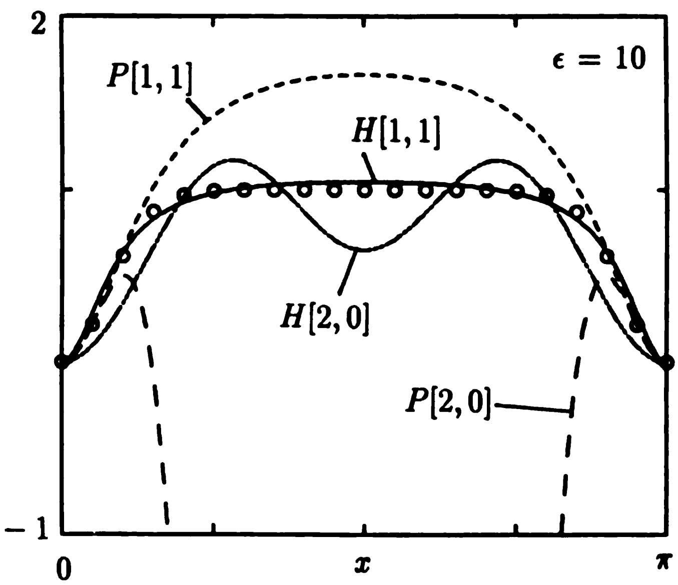

FIG 4. The Padé approximations $P[2, 0]$ and $P[1, 1]$, the hybrid approximations $H[2, 0]$ and $H[1, 1]$, and the exact solution (circles) for Ex 2 with $\epsilon = 10$.

APPLICATIONS TO PARTIAL DIFFERENTIAL EQUATIONS

In this section, we shall apply our method to two model elliptic boundary value problems in two space dimensions.

Example 3: We consider the elliptic boundary value problem

$$L(u,\epsilon) \equiv \nabla^2 u + \epsilon\cos(x)\sin(y)u_x + \epsilon\sin(x)\cos(y)u_y \\ -2\epsilon\sin(x)\sin(y)u + 2\epsilon\sin(x)\sin(y) = 0, \tag{33}$$

for $(x,y) \in D \equiv \{(x,y) : 0 < x < \pi, 0 < y < \pi\}$, with $B(u,\epsilon) \equiv u = 0$ for $(x,y) \in \partial D$. Here ∇^2 denotes the usual (two dimensional) Laplacian operator. This problem has the exact solution

$$u = 1 - e^{-\epsilon\sin(x)\sin(y)}, \tag{34}$$

and hence its Taylor series expansion about $\epsilon = 0$ converges for all $|\epsilon| < \infty$. We also note that, as $\epsilon \to +\infty$, u develops a boundary layer around the entire boundary of D, and approaches the value of 1 at each point in the interior of D. Figure 5 depicts a surface plot of the exact solution for $\epsilon = 10$.

Step one: Using the regular perturbation method we find $u_0 \equiv 0$ and

$$u_j = \frac{(-1)^{j+1}}{j!}\sin^j(x)\sin^j(y), \text{ for } j \geq 1. \tag{35}$$

Step two: Using the perturbation coordinate functions in Eqs (35) we find

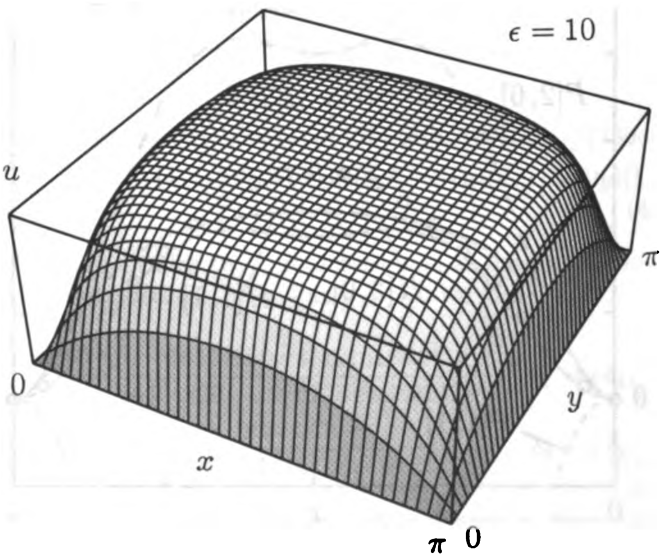

FIG 5. A surface plot of the exact solution, Eq (34), for Ex 3 with $\epsilon = 10$. Note the rather steep boundary layer around the entire boundary of D.

$$P[2,0] = \epsilon\sin(x)\sin(y) - (\epsilon^2/2)\sin^2(x)\sin^2(y), \\ P[1,1] = \frac{\epsilon\sin(x)\sin(y)}{1+(\epsilon/2)\sin(x)\sin(y)}. \tag{36}$$

We note that $P[1,1]$ has real poles for $\epsilon \geq 2$ where $\sin(x)\sin(y) = -2/\epsilon$, and hence these poles lie *outside* of D for all values of $\epsilon > 0$. In Fig 6 we have plotted a cross-section of the approximate solutions $P[2,0]$ and $P[1,1]$, along with the exact solution, at $y = \pi/2$ for $0 \leq x \leq \pi$ for $\epsilon = 10$.

Step three: Using the form of the Padé approximants above, we define

$$H[2,0] = \delta_1\sin(x)\sin(y) - (\delta_2/2)\sin^2(x)\sin^2(y), \\ H[1,1] = \frac{\delta_1\sin(x)\sin(y)}{1+(\delta_2/2)\sin(x)\sin(y)}, \tag{37}$$

where δ_1 and δ_2 are determined from the Galerkin conditions (7), which for this example become

$$\int_0^\pi\int_0^\pi L(H[M,N],\epsilon)\,u_k(x,y)\,dx\,dy = 0, \text{ for } k = 1,2. \tag{38}$$

For $N = 2$ and $N = 0$, these equations are linear and yield the solutions

$$\delta_1 = 32\epsilon(6075\pi^4 + 7632\pi^2\epsilon - 409600)/\Delta, \\ \delta_2 = 800\epsilon^2(243\pi^4 - 16384)/\Delta, \\ \Delta \equiv 194400\pi^4 - 13107200 + 244224\pi^2\epsilon \\ + (2097152 - 18225\pi^4)\epsilon^2. \tag{39}$$

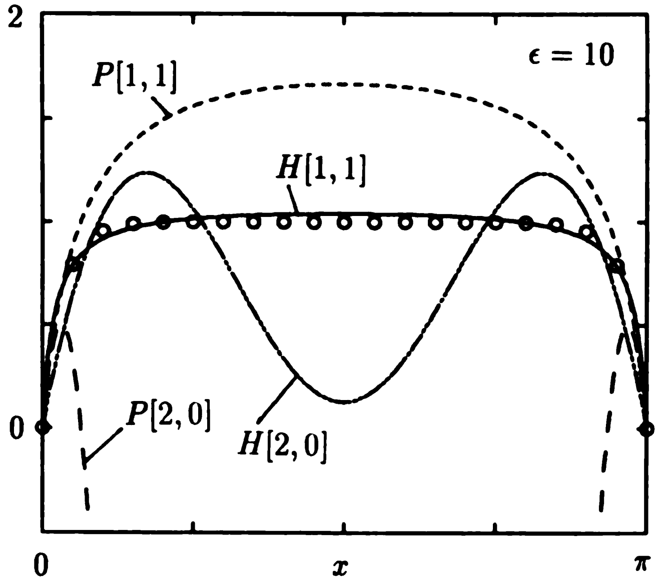

FIG 6. The Padé approximations $P[2,0]$ and $P[1,1]$, the hybrid approximations $H[2,0]$ and $H[1,1]$, and the exact solution (circles) for Ex 3 along the cross section $y = \pi/2$ with $\epsilon = 10$. Note the very "poor" quality of the perturbation solution $P[2,0]$, on which all of the other (much better!) approximations are ultimately based

From Eqs (38) and (39) it follows that δ_1 and δ_2 satisfy the conditions (19) as $\epsilon \to 0$. In Fig 6 we have also plotted the approximate solutions $H[2,0]$ and $H[1,1]$ at $y = \pi/2$ for $0 \le x \le \pi$. The improvement of the hybrid solutions over the corresponding perturbation solutions is evident from the figure.

Example 4: We consider the problem

$$L(u,\epsilon) \equiv \nabla^2 u + \epsilon \sin(x)\cos(y) u_x + 2\,\epsilon \sin(x)\sin(y) = 0, \tag{40}$$

for $(x,y) \in D \equiv \{(x,y) : 0 < x < \pi, 0 < y < \pi\}$, with $B(u,\epsilon) \equiv u = 0$ for $(x,y) \in \partial D$. Although there appears to be no closed form solution for this problem, it is straightforward to show that its solution $u(x,y)$ exhibits a number of interesting properties. The solution is positive over the entire domain D for positive values of ϵ and is invariant under the 180° rotation $x \to \pi - x$, $y \to \pi - y$. Since Eq (40) is also invariant under the transformation $\epsilon \to -\epsilon$, and $u(x,y) \to -u(x, \pi - y)$, we may focus our attention on solutions for positive ϵ. Figure 7 depicts a surface plot of the "exact" solution, obtained by purely numerical means, for $\epsilon = 12$. The solution has a regular perturbation expansion about $\epsilon = 0$, which converges for values of ϵ with $|\epsilon| < \epsilon_0 \cong 6.7$. (See Geer and Andersen, 1991a, where this equation was discussed in some detail.) In addition, as $\epsilon \to +\infty$, the solution develops a number of boundary layers over *portions* of ∂D, but not over the entire boundary.

Step one: Using the regular perturbation method, we find

$$\begin{aligned}
u_0 &\equiv 0,\\
u_1 &= \sin(x)\sin(y),\\
u_2 &= (1/32)\sin(2x)\sin(2y),\\
u_3 &= \frac{1}{128}\left\{\frac{1}{9}\sin(3x)\sin(3y) + \frac{1}{5}\sin(3x)\sin(y)\right.\\
&\quad \left. -\frac{1}{5}\sin(x)\sin(3y) - \sin(x)\sin(y)\right\},\\
u_4 &= \frac{1}{49152}\sin(4x)\sin(4y) + \frac{7}{76800}\sin(4x)\sin(2y)\\
&\quad - \frac{1}{19200}\sin(2x)\sin(4y) - \frac{1}{1920}\sin(2x)\sin(2y).
\end{aligned} \tag{41}$$

Step two: Using Eqs (41) we find

$$\begin{aligned}
P[2,0] &= \epsilon\sin(x)\sin(y) + (\epsilon^2/32)\sin(2x)\sin(2y),\\
P[1,1] &= \frac{\epsilon\sin(x)\sin(y)}{1 - (\epsilon/8)\cos(x)\cos(y)}.
\end{aligned} \tag{42}$$

We note that the poles of $P[1,1]$ lie inside D for $\epsilon > 8$. In Fig 8 we have plotted approximations to the diagonal cross-section $y = x$ of the solution at $\epsilon = 12$ using $P[2,0]$, $P[1,1]$, and the numerical solution.

Step three: Using the expressions in (42) we define

$$\begin{aligned}
H[2,0] &= \delta_1\sin(x)\sin(y) + (\delta_2/32)\sin(2x)\sin(2y),\\
H[1,1] &= \frac{\delta_1\sin(x)\sin(y)}{1 - (\delta_2/8)\cos(x)\cos(y)}.
\end{aligned} \tag{43}$$

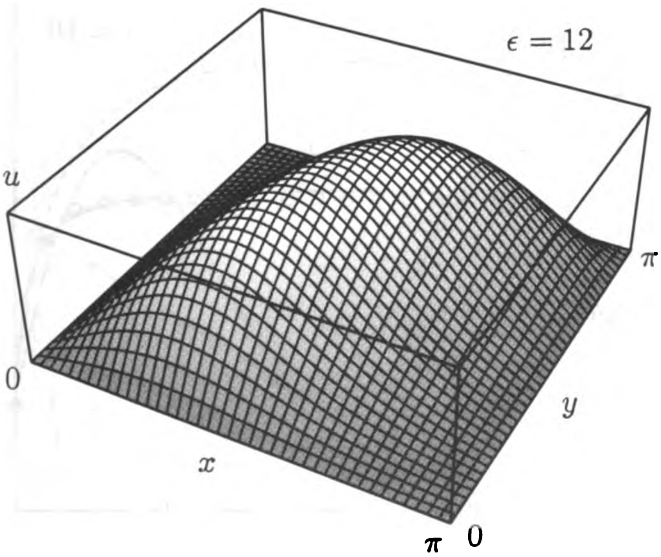

FIG 7. A surface plot of the "exact" solution for Ex 3 obtained by purely numerical means for $\epsilon = 12$. Note the boundary layers beg... to form around portions of the boundary of D ... ar $(x,y) = (0,0)$ and $(x,y) = (\pi,\pi)$, a... rnal "rise" forming near the diagonal $x =$

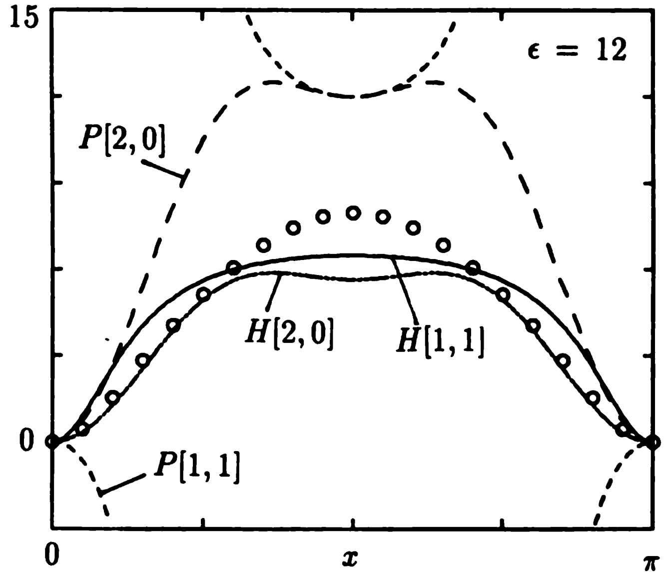

FIG 8. The Padé approximations $P[2,0]$ and $P[1,1]$, the hybrid approximations $H[2,0]$ and $H[1,1]$, and the exact solution (circles) for Ex 4 along the diagonal cross section $x = y$ with $\epsilon = 12$.

For $M = 2$ and $N = 0$, the Galerkin conditions (7) are linear and give

$$\delta_1 = \frac{\epsilon}{1+\epsilon^2/128}, \quad \delta_2 = \frac{\epsilon^2}{1+\epsilon^2/128}. \tag{44}$$

For $M = 1$ and $N = 1$, these conditions are nonlinear and must be solved numerically. Using these numerically computed solutions, it appears that the poles of $H[1,1]$ always lie outside of D. In Fig 8 we have also plotted approximations to the diagonal cross-section $y = x$ of the solution at $\epsilon = 12$ using $H[2,0]$ and $H[1,1]$.

The quality of the hybrid approximations improves as the order of the Padé approximants is increased. In particular, we find

$$P[4,0] = \sum_{j=1}^{4} \epsilon^j u_j(x,y), \quad H[4,0] = \sum_{j=1}^{4} \delta_j u_j(x,y), \tag{45}$$

and

$$P[2,2] = \frac{\epsilon\, v_1 + \epsilon^2\, v_2}{1+\epsilon\, w_1 + \epsilon^2\, w_2}, \quad H[2,2] = \frac{\delta_1\, v_1 + \delta_2\, v_2}{1+\delta_3\, w_1 + \delta_4\, w_2}, \tag{46}$$

where

$$\begin{aligned}
v_1 &= \sin(x)\sin(y),\\
v_2 &= [65 + \cos(2x) + 193\cos(2y) - 25\cos(2x)\cos(2y)]\\
&\quad \sin(2x)\sin(2y)/\{160[125 - 11\cos(2x) + 61\cos(2y)\\
&\quad + 5\cos(2x)\cos(2y)]\},\\
w_1 &= -\{1201\cos(x)\cos(y) - 31\cos(3x)\cos(y)\\
&\quad + 137\cos(x)\cos(3y) + 25\cos(3x)\cos(3y)\} \;/\; \{80\\
&\quad [125 - 11\cos(2x) + 61\cos(2y) + 5\cos(2x)\cos(2y)]\},\\
w_2 &= \{32301 - 7590\cos(2x) + 237\cos(4x)\\
&\quad + 25962\cos(2y) - 4396\cos(2x)\cos(2y)\\
&\quad + 106\cos(4x)\cos(2y) + 2109\cos(4y)\\
&\quad - 902\cos(2x)\cos(4y) + 125\cos(4x)\cos(4y)\}/\{23040\\
&\quad [125 - 11\cos(2x) + 61\cos(2y) + 5\cos(2x)\cos(2y)]\}.
\end{aligned} \tag{47}$$

The amplitudes $\{\delta_j\}$ are determined as indicated above. In particular, for $M = 4$ and $N = 0$ we find

$$\begin{aligned}
\delta_1 &= \frac{56524800\,\epsilon + 1216128\,\epsilon^3}{56524800 + 1216128\,\epsilon^2 + 2141\,\epsilon^4}, \quad \delta_2 = \epsilon\,\delta_1,\\
\delta_3 &= \frac{56524800\,\epsilon^3}{56524800 + 1216128\,\epsilon^2 + 2141\,\epsilon^4}, \quad \delta_4 = \epsilon\,\delta_3,
\end{aligned} \tag{48}$$

while the amplitudes for $M = N = 2$ must be determined numerically.

In Fig 9 we have plotted approximations to the diagonal cross-section $y = x$ of the solution at $\epsilon = 12$ using $P[4,0]$, $H[4,0]$, $P[2,2]$,and $H[2,2]$. From the figure we see that each hybrid approximation is an improvement over the Padé approximation on which it is based, while $H[2,2]$ appears to be the "best" of all of the hybrid approximations.

DISCUSSION AND OBSERVATIONS

We now make some observations concerning our method as related to the examples we have presented.

In Ex 1 we considered a simple two point boundary value problem. The hybrid solutions presented provide approximations which are consistently more accurate than the perturbation or Padé approximations on which they are based, and they appear to be converging to the exact solution as the number of terms is increased. This is true for small values of ϵ, for which the perturbation and Padé solutions give reasonable approximations to the solution, as well as for larger values of ϵ, where the perturbation and Padé solutions fail to give reasonable approximations. Part of the reason for this behavior is related to the convergence properties of the original perturbation series. The Taylor series expansion (and, hence, the regular perturbation expansion) of the solution converges only for values of ϵ with $|\epsilon| < 2\pi$. Thus, the perturbation solution, by itself, is useless for computing approximations to $u(x,\epsilon)$ for values of ϵ with $|\epsilon| > 2\pi$. However, we have shown (Andersen and Geer, 1991) that the sequence of approximations $\{H[M,0]\}$ converges to the exact solution as $M \to \infty$ for each $0 \le x \le 1$ and for each $0 \le \epsilon < \infty$. In addition, for $N \ge 1$, each Padé approximation $P[M,N]$ fails to give a reasonable approximation to the solution when one or more of its poles moves inside the domain (interval) $D = (0,1)$. The presence of a pole in a Padé approximation is undoubtedly related to the formation of the boundary layer at $x = 1$ as ϵ increases.

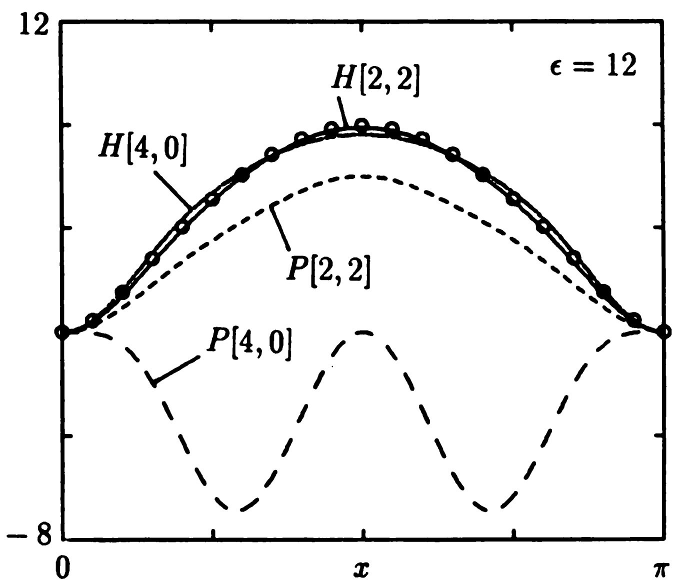

FIG 9. The Padé approximations $P[4,0]$ and $P[2,2]$, the hybrid approximations $H[4,0]$ and $H[2,2]$, and the exact solution (circles) for Ex 4 along the diagonal cross section $x = y$ with $\epsilon = 12$.

When this pole lies *outside* of D, but "close to" $x = 1$, it helps to simulate the steep slope of the solution forming within the boundary layer. When a pole moves *inside* D, however, it creates a singularity in the approximation which is not present in the exact solution. It appears that the poles of the hybrid approximations $H[M, N]$ always lie *outside* of D and hence $H[M, N]$ has the potential of providing at least a reasonable approximation to the exact solution, even when the corresponding Padé approximation cannot do so. In Fig 10 we have plotted the location of the pole of $P[1,1]$ and of $H[1,1]$ for $0 \le \epsilon \le 30$. As the figure illustrates, the pole of $H[1,1]$ asymptotically approaches 1 from *outside* of D, as $\epsilon \to \infty$.

In Ex 2, the perturbation solutions converge to the exact solution for all finite values of ϵ, as the number of terms in the approximation is increased. However, as ϵ increases, boundary layers form at each end of the domain (interval) D, and, consequently, more terms are required in the perturbation expansion to provide approximations of "acceptable" accuracy. In this case, the poles of the Padé and hybrid approximations lie in the complex plane and hence outside of D for all real values of ϵ. Some of these poles do approach the ends of the interval $D = [0, 1]$, however, as $\epsilon \to \infty$, and hence help to simulate the actual behavior of the exact solutions in these regions. In Fig 11 we have indicated the location of these poles of $P[1,1]$ and $H[1,1]$ as a function of ϵ. From the figure it is clear that the poles of $H[1,1]$ lie closer to the boundary of D than do the corresponding poles of $P[1,1]$. This helps to explain the increased accuracy of the hybrid approximations.

In our third example, we examined a two dimensional, elliptic boundary value problem involving a simple partial differential equation. As in Ex 2, the perturbation solution converges to the exact solution for all finite values of ϵ, as the number of terms in the approximation is increased. However, as ϵ increases, boundary layers now form over the *entire boundary* of the domain D. Consequently, more terms in the perturbation expansion are again required to provide approximations of "acceptable" accuracy as ϵ increases. In this case, all of the real poles of the Padé and hybrid approximations $P[1,1]$ and $H[1,1]$ lie *outside* of D for all real values of ϵ. In Fig 12 we have plotted the location of the real poles of these approximations for selected values of $\epsilon > 2$. From the figure we see that, as in Ex 2, the poles of $H[1,1]$ lie closer to the boundary of D than do the corresponding poles of $P[1,1]$.

In Ex 4 we considered another two dimensional, elliptic boundary value problem, whose exact solution develops a more complicated boundary layer structure as ϵ increases. In this case the perturbation solution has a *finite* radius of convergence, and hence the classical perturbation approximations are useless for values of ϵ with magnitude greater than the radius of convergence. However, all of the hybrid solutions appear to give reasonable approximations even for values of ϵ moderately above the radius of convergence (see Figs 8 and 9). In this case, the poles of $P[1,1]$ move inside D for values of $\epsilon > 8$. The location of these poles are indicated in Fig 13. The corresponding poles of $H[1,1]$ are purely imaginary (since $|\delta_2| < 8$) and hence they lie outside of D.

The observations we have indicated above, as well as experience we have had with the method for other examples, motivate us to make the following conjecture. It appears that, if the original perturbation expansion has a *finite* radius of convergence, then the poles of the Padé approximations constructed from this expansion will move

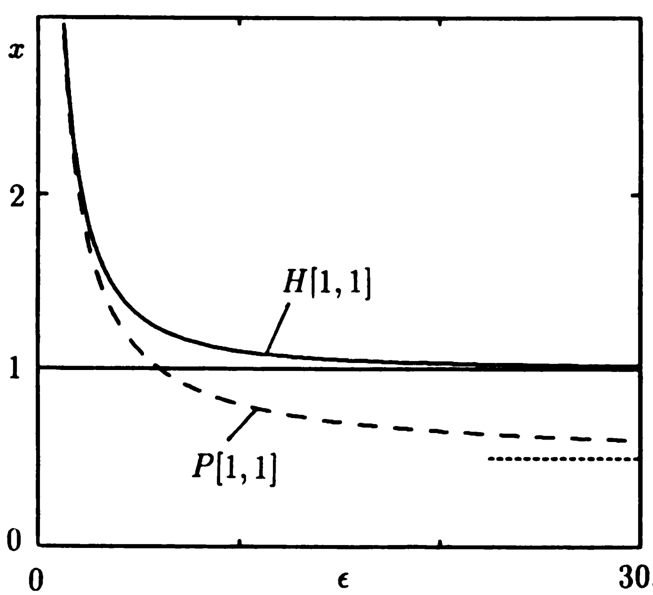

FIG 10. A plot of the location of the poles (vertical axis) of $P[1,1]$ and $H[1,1]$ for Ex 1 as ϵ (horizontal axis) varies between 0 and 30. The "critical" value of $x = 1$ is indicated, as well as the asymptotic value (short dashed line) of the pole of $P[1,1]$ as $\epsilon \to \infty$.

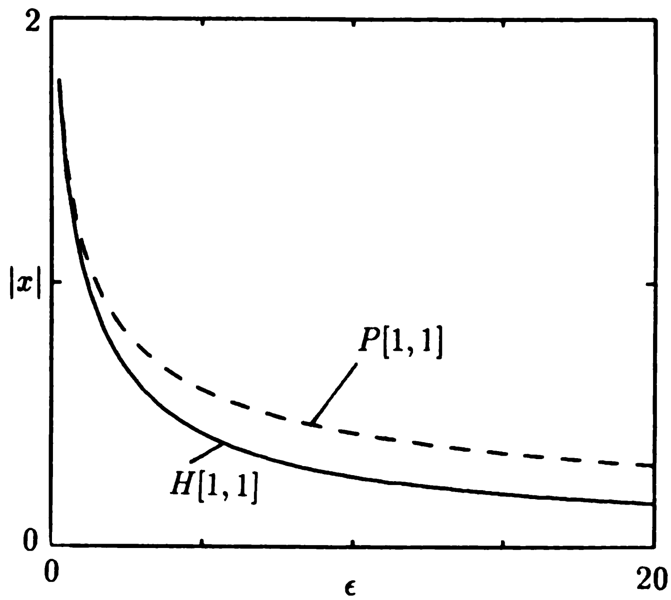

FIG 11. A plot of the magnitude (vertical axis) of the poles of $P[1,1]$ and $H[1,1]$ for Ex 2 which lie closest to $x = 0$ as ϵ (horizontal axis) varies between 0 and 20. These poles are purely imaginary and lie at $x = \pm i \sinh^{-1}(\sqrt{2/\epsilon})$ and $x = \pm i \sinh^{-1}(\sqrt{2/\delta_2})$ for $P[1,1]$ and $H[1,1]$, respectively.

inside the domain D as ϵ increases. If the original perturbation expansion has an *infinite* radius of convergence, then the poles of the Padé approximations will remain *outside* of D. In the first case, the hybrid approximations we have described appear to keep the corresponding poles outside of D for all values of ϵ, while in the second case the hybrid solutions appear to move the poles closer to the boundary of D. In either case, the hybrid technique appears to "adjust" the location of the poles in such a manner as to provide approximate solutions of greater accuracy than the corresponding Padé approximation. Obviously, this conjecture needs to be studied in more detail and is the subject of some of our current investigations.

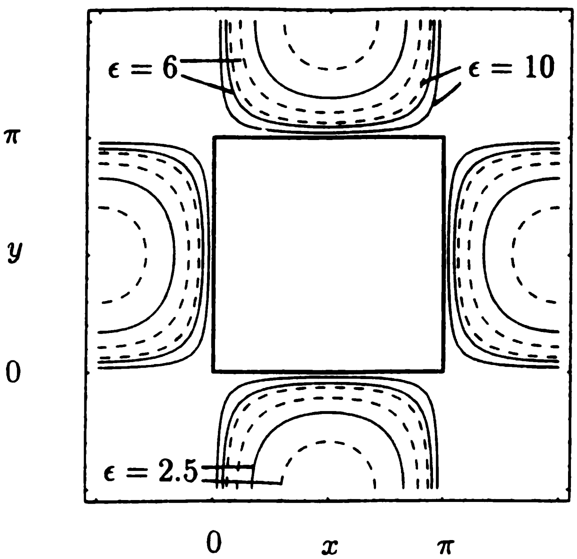

FIG 12. A plot of the locations of some of the poles of $P[1,1]$ (dashed lines) and $H[1,1]$ (solid lines) in the $x, y-$plane which lie closest to D for Ex 3 with $\epsilon = 2.5$, 6, and 10. The boundary of D is also indicated. Note that the poles of $H[1,1]$ lie closer to the boundary of D than do the corresponding poles of $P[1,1]$.

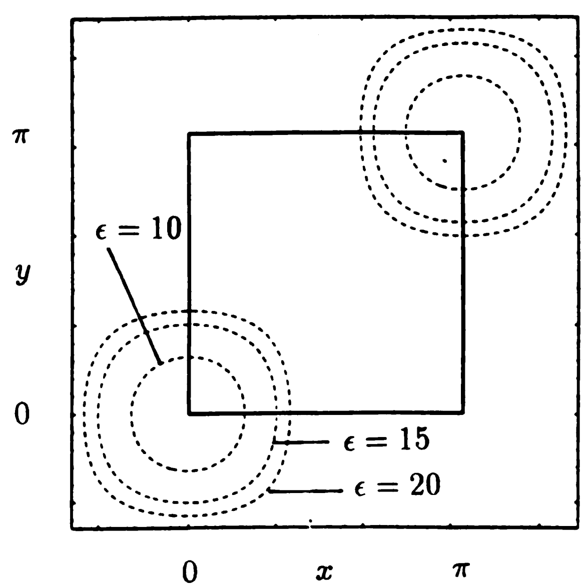

FIG 13. A plot of the locations of some of the poles of $P[1,1]$ (dashed lines) in the $x, y-$plane which lie closest to D for Ex 4 with $\epsilon = 10$, 15, and 20. The boundary of D is also indicated. The influence of the pole of $P[1,1]$ at $\epsilon = 12$ is also evident in Fig 8.

In general, the basic idea of using the original perturbation expansion to construct one or more Padé approximations seems to be justified, and, in fact, is recommended when the solution tends to exhibit some kind of boundary layer behavior as ϵ increases. The increased ability of the Padé solutions to simulate boundary layer behavior appears to provide more accurate approximations, even for "smaller" values of ϵ, for which the boundary layer is not yet well formed (see, e.g., Figs 1 and 2). For "any" value of ϵ, however, the hybrid solutions are consistently more accurate than the Padé solutions on which they are based, and it is recommended that the additional step of computing the new amplitudes $\{\delta_j\}$ be undertaken, especially when only a few perturbation coordinate functions are known.

Method of virtual power applied to Cosserat surfaces with deformable directors

Boris Krajnc Alves

Department of Informatics, Federal University of Espírito Santo, Vitória ES, Brazil 29069

Jacob Lubliner

Department of Civil Engineering, University of California, Berkeley CA 94720

Following a brief outline of the method of virtual power, the local equations of motion for a Cosserat surface with inextensible directors are derived by means of this method. The model obtained coincides with the results derived from three-dimensional theory by Simo and Fox. Subsequently the model is extended so as to account for deformable directors. Besides the linear-momentum and moment-of-momentum balance equations, one additional scalar equation is derived. This equation replaces the director-momentum balance equation of Naghdi and therefore eliminates the necessity of introducing constitutive restrictions. The equivalence between the model derived by the virtual-power method and the results from the direct method of Naghdi are finally noted.

INTRODUCTION

It is the purpose of this paper to show how the method of virtual power, as introduced by Germain (1973) and modified by Lubliner (1983a), can be applied to the derivation of the local equations of motion for a Cosserat surface. Initially the application is restricted to a Cosserat surface with inextensible directors. The basic equations derived are not novel but their derivation by the virtual power method does not seem to have been proposed in the literature. In contrast with the direct approach of Naghdi (1972), where kinematics plays a fundamental role in the definition of the model, the derivation using the virtual power method is intrinsically based on the physics of the problem where meaningful forces and moments, a priori assumed, are placed in duality with velocities and rates of rotations. As a result, a physically sound model is obtained with the degree of kinematic indeterminacy as a direct consequence of its duality with the assumed forces and moments.

The restricted model is then extended to account for deformable directors. In Naghdi's direct method, the approach is to derive the basic field equations in accordance with the results of the asymptotic expansion of the three-dimensional equations. Thus Naghdi's model, besides assuming balance of linear momentum and moment of momentum, postulates an additional equation of balance of director momentum. The overdeterminacy in the theory is overcome by introducing constitutive restrictions such that the moment-of-momentum balance equation becomes identically satisfied. The physical interpretation of the equation of balance of director momentum has been a major subject of research in the works of Naghdi and co-authors. Ericksen and Truesdell (1958) also derived the basic field equations for a Cosserat surface but, not assuming balance of director momentum, obtained an incomplete theory. Green, Naghdi and Wainwright (1965) also did not postulate it but latter assumed it to hold in order to solve the indeterminacies of the model (see Naghdi, 1972, page 490, footnote 17).

As shown in the present paper, the method of virtual power is an effective way of deriving the appropriate equations. The local linear-momentum and moment-of-momentum balance equations are derived from the fundamental axiom of the method of virtual power. An additional scalar equation is derived with the help of a physically reasonable hypothesis and the principle of virtual power. The resulting set of equations eliminates the need for constitutive restrictions. It is finally shown that in the sense of the virtual-power method this model is nonetheless equivalent to that of Naghdi's direct method.

THE METHOD OF VIRTUAL POWER

As originally proposed by Germain (1973), the method of virtual power may be summarized by the following two statements:

Axiom of virtual power of internal forces:

> *The virtual power of the internal forces on any virtual rigid-body velocity field is zero.*

Principle of virtual power:

> *For a body in equilibrium with respect to a Galilean frame, the virtual power of the internal and external forces on any virtual velocity field is zero.*

The axiom of virtual power of internal forces is simply a restatement of the laws of motion. In an alternative formulation which dispenses with the a priori introduction of internal forces, the words *internal forces* in the statement of the axiom are replaced by *external and inertial force systems* (for the definition of the inertial force system and additional considerations see Lubliner (1983a-b, 1984)). The principle of virtual power is then used to define the *internal force system* (a generalization of the notion of *stress field* in classical continuum mechanics) with the help of the *principle of localization* (for details and an application, see Lubliner (1986)). The modified axiom is referred to as the *fundamental axiom of the method of virtual power.*

In the remainder of this section the method of virtual power is formalized in a manner appropriate to its application to Cosserat surfaces.

A body is modeled as a smooth, compact, orientable manifold $\mathcal{B}$ with smooth boundary and dimension at most 3. Configurations are mappings $\kappa : \mathcal{B} \to \mathcal{M}$, where $\mathcal{M}$ is a smooth finite-dimensional affine manifold without boundary, belonging to a *configuration space* $\mathcal{C}$ which is itself a smooth infinite-dimensional manifold modeled on a Banach space (Marsden and Hughes, 1983). Following previously introduced terminology (Lubliner, 1986), we call a body model *simple* if $\mathcal{M}$ is the Euclidean affine space modeled on $\mathbf{R}^3$ (as is commonly done, the Euclidean affine space will often be denoted simply $\mathbf{R}^3$) and *generalized* otherwise. A Cosserat surface is a generalized body model where $\mathcal{B}$ is a surface or 2-manifold and $\mathcal{M} = T\mathbf{R}^3$, the tangent bundle of $\mathbf{R}^3$, which may be identified with $\mathbf{R}^3 \times \mathbf{R}^3$ and whose elements are ordered pairs of vectors in $\mathbf{R}^3$.

Motions are one-parameter families of configurations, describing curves in the space of configurations $\mathcal{C}$:

$$\tilde{\kappa} : I \to \mathcal{C}, \quad \text{for } \tilde{\kappa}(t) \in \mathcal{C} \text{ and } I \text{ an interval of } \mathbf{R}.$$

For convenience, the configuration at time t, $\tilde{\kappa}(t)$, will be denoted κ_t.

If, at a given point $p \in \mathcal{B}$, the mapping $t \to \kappa_t(p)$ is differentiable, then the derivative, denoted $\boldsymbol{v}_t(p)$, is the material velocity of $p \in \mathcal{B}$ at time $t \in I$, and is a vector tangent to the curve $t \to \kappa_t(p)$ at $\kappa_t(p)$ (that is, $\boldsymbol{v}_t(p) \in T\mathcal{C}_{\kappa_t(p)}$). A material velocity field at a configuration κ is thus a mapping $\boldsymbol{v} : \mathcal{B} \to T\mathcal{C}_\kappa$, and is in a sense a tangent vector to the curve $t \to \kappa_t$ at κ_t. The concept of a tangent to a curve in a finite dimensional manifold is thus naturally generalized. In manifold terminology, the material velocity field is an element of $T\mathcal{C}$, the tangent bundle to the configuration space $\mathcal{C}$. In the remainder it is assumed that both the configuration manifold $\mathcal{C}$ and its tangent bundle are modeled on appropriate Banach spaces (for additional definitions, see Hirsch (1976), Spivak (1979), Abraham and Marsden (1983)).

In the application of the method of virtual power it is useful to assume that all rigid-body motions from a given configuration $\kappa \in \mathcal{C}$ are a priori possible (any external constraints are applied afterwards).[1] The velocity-field space $T\mathcal{C}_\kappa$ thus contains the space of all rigid-body velocity fields as a closed finite-dimensional subspace, to be denoted $T\mathcal{C}^r_\kappa$.

A force system is naturally defined as a continuous linear functional on the space of virtual velocity fields and hence is characterized by its virtual power on a virtual velocity field. A force system is consequently an element of the topological dual of the tangent space $T\mathcal{C}$, denoted $T^*\mathcal{C}$ and denoted the cotangent bundle of $\mathcal{C}$. In the application of the method of virtual power, the crucial step is the choice of the physically meaningful force systems that describe the model being studied. Following physical intuition, at each configuration $\kappa \in \mathcal{C}$ a subspace $\mathcal{F}_\kappa$ of $T^*\mathcal{C}_\kappa$, consisting of the physically meaningful force systems at the configuration κ, is chosen, generating the subbundle $\mathcal{F}$ of $T^*\mathcal{C}$. If $\boldsymbol{f} \in \mathcal{F}_\kappa$ and $\boldsymbol{\eta} \in T\mathcal{C}_\kappa$ then the value of $\boldsymbol{f}$ at $\boldsymbol{\eta}$ will be denoted by $< \boldsymbol{f}, \boldsymbol{\eta} >$ and represents the virtual power of the force system $\boldsymbol{f}$ on the virtual velocity field $\boldsymbol{\eta}$.

We now define

$\boldsymbol{f}^e_t$: external force system exerted on $\mathcal{B}$ by other bodies at time t in a motion, $t \to \kappa_t$,

$\boldsymbol{f}^i_t$: inertial force system at time t;

then the fundamental axiom of virtual power may be written as

$$< \boldsymbol{f}^e_t + \boldsymbol{f}^i_t, \eta > = 0 \quad \forall\, \eta \in T\mathcal{C}^r_\kappa.$$

[1] In a simple body model, a rigid-body motion is one in which all configurations can be derived from one another by a Euclidean mapping. The definition must be extended appropriately for a generalized body model.

$$\begin{tikzcd} TC_\kappa \arrow[r, phantom, "< f, \eta >"] \arrow[d, "Tl_\kappa"'] & TC^*_\kappa \\ T\mathcal{D}_{l(\kappa)} \arrow[r, phantom, "\ll \sigma, \epsilon \gg"] & T\mathcal{D}^*_{l(\kappa)} \arrow[u, "Tl^*_\kappa"'] \end{tikzcd}$$

FIG 1: Commutative Diagram for a Simple Body Model

Therefore, if $(TC^r)^\perp$ denotes the orthogonal complement of (TC^r), then we may write $f^e_t + f^i_t \in (TC^r)^\perp \cap \mathcal{F}_\kappa$, the space of equilibrated force systems at the configuration κ.

The application of the principle of virtual power requires the notion of internal force system, which does work when a body is deformed. A deformed state (or *deformation*) of the body may be described by an equivalence class of configurations that differ by a (*generalized*) rigid-body displacement. If $\mathcal{R}$ denotes the corresponding equivalence relation, then the space of deformations is the quotient set $\mathcal{C}/\mathcal{R}$. Quotient sets do not, in general, inherit a manifold structure; it is also preferable not to work with quotient sets but with manifolds where an appropriate physical interpretation is possible. Thus we postulate the existence of a deformation manifold $\mathcal{D}$, modeled on a Banach space, and an injection $k : \mathcal{C}/\mathcal{R} \rightarrow \mathcal{D}$ such that if $j : \mathcal{C} \rightarrow \mathcal{C}/\mathcal{R}$ is the canonical surjection of $\mathcal{C}$ onto $\mathcal{C}/\mathcal{R}$, then the mapping

$$l = k \circ j : \mathcal{C} \rightarrow \mathcal{D},$$

is differentiable in some appropriate sense.[2] Clearly, the appropriate notion of differentiability must be determined by the specific model being studied.

If $Tl_\kappa : TC_\kappa \rightarrow T\mathcal{D}_{l(\kappa)}$ denotes the derivative of l at the configuration κ and $T\mathcal{D}_{l(\kappa)}$ the image of TC_κ by Tl_κ (by hypothesis a Banach space and in a sense the tangent space to the deformation manifold $\mathcal{D}$ at $l(\kappa)$), then the commutative diagram in Figure 1 holds. Here $\ll \sigma, \epsilon \gg$ denotes the duality pairing in $T\mathcal{D}_\kappa \times T\mathcal{D}^*_\kappa$, and Tl^*_κ is the adjoint mapping to Tl_κ, defined by

$$< Tl^*_\kappa \sigma, \eta > = \ll \sigma, Tl_\kappa \eta \gg \quad \forall \eta \in TC_\kappa.$$

The space $T\mathcal{D}_{l(\kappa)}$ is the deformation-rate space, and its dual, $T\mathcal{D}^*_{l(\kappa)}$, the internal force-system space. The linear mapping $Tl_\kappa : TC_\kappa \rightarrow T\mathcal{D}_{l(\kappa)}$ is such that Kernel $[Tl_\kappa] = TC^r_\kappa$.

Finally, the principle of virtual power defines uniquely (for the given choice of $\mathcal{D}$) the internal force system[3] σ compatible with the model being studied and associated with an equilibrated external force system $f \in F_\kappa \cap (TC^r_\kappa)^\perp$. Thus

$$\ll \sigma, Tl_\kappa \eta \gg = < Tl^*_\kappa \sigma, \eta > = < f, \eta > \quad \forall \eta \in TC_\kappa.$$

The space of internal force systems may consequently be described by $(Tl^*_\kappa)^{-1}(\mathcal{F}_\kappa)$.[4]

Finally, if $t \rightarrow \kappa_t$ is a motion and σ the internal force system acting at time t, the *deformation power* at time t is defined by

$$P^*_t = \ll \sigma, Tl_\kappa v_t \gg,$$

that is, the value of the internal virtual power at the actual velocity field v_t of the body.

COSSERAT SURFACE. BASIC DEFINITIONS

A Cosserat surface may be regarded as a smooth, compact and orientable two-dimensional manifold $\mathcal{B}$, with a smooth boundary and a vector-bundle structure associated with it. As previously indicated, the configuration manifold $\mathcal{M}$ is TR^3 (the tangent bundle of R^3), which may be identified with $R^3 \times R^3$, so that a configuration κ may be identified with the pair of mappings $(r : \mathcal{B} \rightarrow R^3, d : \mathcal{B} \rightarrow R^3)$. Here $r : \mathcal{B} \rightarrow R^3$ is an embedding, and $\mathcal{N} = r(\mathcal{B})$ is the surface occupied by $\mathcal{B}$ in the configuration κ, while the mapping $d \circ r^{-1} : \mathcal{N} \rightarrow TR^3_{r(\mathcal{B})}$ defines a *director* at each point of $\mathcal{N}$; d is called the *director field.*

In order to apply the method of virtual power to Cosserat surfaces it is necessary to provide an appropriate definition of rigid-body motions. This may be done by temporarily identifying the Cosserat surface with a shell, a three-dimensional simple body. Following this reasoning, the Cosserat surface at a given configuration $\kappa = (r, d)$ may be identified with the set

$$W_\kappa = \{X \in R^3 | X = r(p) + \zeta d(p); \;\; p \in \mathcal{B}; \zeta \in [-\tfrac{1}{2}, \tfrac{1}{2}]\},$$

while $D(p) = \| d(p) \|$, the Euclidean norm of $d(p)$, is identified with the thickness of the shell at $p \in \mathcal{B}$. To guarantee the uniqueness of the above representation, the following restrictions are imposed for all $p \in \mathcal{B}$:

(i) $d(p) \notin T\mathcal{N}_{r(p)}$,

(ii) $D(p) < 2 \times \min\{R_\alpha(p), \quad \alpha = 1, 2\}$,

where $T\mathcal{N}_{r(p)} \subset TR^3_{r(p)}$ is the tangent plane to $\mathcal{N}$ at $r(p)$, and $R_\alpha(p)$ $(\alpha = 1, 2)$ are the principal radii of curvature of the embedded surface $\mathcal{N}$ at $r(p)$.

---

[2] In general, more than one choice [illegible] possible; witness the many possible strain tensors in [illegible] um mechanics.

[3] In the work of Germain (197[illegible] [illegible] e system is the negative of the one defined here

[4] By hypothesis TC_κ is a Banach space, TC^r_κ a closed subspace and Tl_κ a linear map from TC_κ onto $T\mathcal{D}_{l_\kappa} \sim TC_\kappa / TC^r_\kappa$; it follows (Horvath, 1968) that $Tl^*_\kappa : T\mathcal{D}_{l_\kappa} \rightarrow (TC^r_\kappa)^\perp$ is a bijection.

We may now assert that two configurations $\kappa = (\boldsymbol{r}, \boldsymbol{d})$ and $\kappa^* = (\boldsymbol{r}^*, \boldsymbol{d}^*)$ of a Cosserat surface $\mathcal{B}$ are equivalent to within a rigid-body displacement if the respective sets W_κ and W_{κ^*} are so equivalent in the classical sense, that is, they are related to each other by a Euclidean mapping. This assertion leads to

$$\begin{aligned}\boldsymbol{r}^*(p) &= \boldsymbol{x}_0 + \boldsymbol{v} + \boldsymbol{Q}(\boldsymbol{r}(p) - \boldsymbol{x}_0),\\ \boldsymbol{d}^*(p) &= \boldsymbol{Q}(\boldsymbol{d}(p)),\end{aligned}$$

for $\boldsymbol{x}_0, \boldsymbol{v} \in \boldsymbol{R}^3$ and $\boldsymbol{Q} \in SO(3)$ (the rotation group on $\boldsymbol{R}^3$, that is, the set of proper orthogonal second-rank tensors).

In what follows we assume that the manifold $\mathcal{B}$ is diffeomorphic to a subset of $\boldsymbol{R}^2$ and may without loss of generality be identified with such a subset. The configuration space under this assumption may be described by mappings $(\boldsymbol{r} : \mathcal{B} \subset \boldsymbol{R}^2 \to \boldsymbol{R}^3, \boldsymbol{d} : \mathcal{B} \subset \boldsymbol{R}^2 \to \boldsymbol{R}^3)$. The mapping $\boldsymbol{r}$ induces a parametrization of the reference surface $\mathcal{N} \subset \boldsymbol{R}^3$ following the coordinate lines (θ_1, θ_2) in $\boldsymbol{R}^2$. Vectors tangent to the coordinate lines (convected coordinates) on $\mathcal{N}$ and forming a natural basis for the tangent space, at each point of $\mathcal{N}$, are given by

$$\boldsymbol{a}_\alpha = \frac{\partial \boldsymbol{r}}{\partial \theta_\alpha} \qquad \text{for } \alpha = 1, 2. \tag{1}$$

It follows from hypothesis (i) that $(\boldsymbol{a}_1, \boldsymbol{a}_2, \boldsymbol{d})$ form a basis for $T\boldsymbol{R}^3_{r(p)}$ at all $p \in \mathcal{B}$.

A physically meaningful force system in a Cosserat surface is given by force and moment distributions on $\mathcal{N}$, together with boundary forces and moments along the edge $\partial\mathcal{N}$. Since the power of a force and a moment is, respectively, on a linear and an angular velocity, the natural kinematic quantities in the Cosserat surface that may be placed in duality with the aforementioned force system are the velocity field of points in the reference surface, contributing to the power of distributed and boundary forces, and the director angular velocity field naturally contributing to the power of distributed and boundary moments.

COSSERAT SURFACE WITH INEXTENSIBLE DIRECTORS

In a two-dimensional Cosserat continuum, the physically meaningful moments form a two-dimensional fiber bundle described by the bending and twisting moments. Sufficient kinematic structure to account for those components is contained in the restricted theory of Cosserat surfaces with inextensible directors, which is treated in the present section. An extension that takes into account forces associated with changes in length of the directors is considered in the next section.

Kinematics of the restricted Cosserat Surface

Configurations of the restricted Cosserat surface are given by mappings

$$\kappa : \mathcal{B} \subset \boldsymbol{R}^2 \to \boldsymbol{R}^3, \qquad \kappa(p) = (\boldsymbol{r}(p), \boldsymbol{d}(p)),$$

where $\boldsymbol{r} : \mathcal{B} \subset \boldsymbol{R}^2 \to \boldsymbol{R}^3$ is an embedding. Without loss of generality, it is moreover assumed that

$$D(p) = \| \boldsymbol{d}(p) \| = 1,$$

for all $p \in \mathcal{B}$.[5]

If (θ_1, θ_2) defines a coordinate chart on $\boldsymbol{R}^2$ then it induces a parametrization on the surface $\boldsymbol{r}(\mathcal{B}) = \mathcal{N} \subset \boldsymbol{R}^3$. The reference configuration is represented by $\kappa_0 = (\boldsymbol{r}_0, \boldsymbol{d}_0)$, with $\boldsymbol{r}_0(\mathcal{B}) = \mathcal{N}_0$.

The base vectors tangent to the coordinate lines on $\mathcal{N}$ and $\mathcal{N}_0$ are respectively denoted by

$$\begin{aligned}\boldsymbol{a}_\alpha &= \frac{\partial}{\partial \theta_\alpha} \boldsymbol{r} \ \in T\boldsymbol{R}^3_{\mathcal{N}},\\ \boldsymbol{A}_\alpha &= \frac{\partial}{\partial \theta_\alpha} \boldsymbol{r}_0 \ \in T\boldsymbol{R}^3_{\mathcal{N}_0},\end{aligned}$$

and the components of the metric tensor by

$$\begin{aligned}a_{\alpha\beta} &= \boldsymbol{a}_\alpha \cdot \boldsymbol{a}_\beta,\\ A_{\alpha\beta} &= \boldsymbol{A}_\alpha \cdot \boldsymbol{A}_\beta\end{aligned}$$

(for additional details see Flugge (1970), Marsden and Hughes (1983)).

As indicated in the previous section, at each point $p \in \mathcal{M}$, $(\boldsymbol{a}_1, \boldsymbol{a}_2, \boldsymbol{a}_3)$, where $\boldsymbol{a}_3 = \boldsymbol{d}$, form a local curvilinear basis for $T\boldsymbol{R}^3_{r(p)}$. The dual base vectors are defined by $\boldsymbol{a}_i \cdot \boldsymbol{a}^j = \delta_i^j$ (Kronecker delta) for $1 \le i, j \le 3$ and clearly $\boldsymbol{a}^3 = (\boldsymbol{a}_1 \times \boldsymbol{a}_2)/a$, with $a = \det(a_{ij})$, $a_{ij} = \boldsymbol{a}_i \cdot \boldsymbol{a}_j$.

We assume the summation convention with repeated greek indices representing summations of indices over 1,2 and repeated latin indices over 1,2,3.

Rigid-body motions $t \to \kappa_t^* = (\boldsymbol{r}_t^*, \boldsymbol{d}_t^*)$ from a configuration $\kappa = (\boldsymbol{r}, \boldsymbol{d})$ are given by

$$\begin{aligned}\boldsymbol{r}_t^*(p) &= \boldsymbol{x}_0 + \boldsymbol{c}_t + \boldsymbol{Q}_t(\boldsymbol{r}(p) - \boldsymbol{x}_0),\\ \boldsymbol{d}_t^*(p) &= \boldsymbol{Q}_t \boldsymbol{d}(p),\end{aligned}$$

where $\boldsymbol{x}_0$ is a fixed point in $\boldsymbol{R}^3$, $t \to \boldsymbol{c}_t$ and $t \to \boldsymbol{Q}_t$ map $I \subset \boldsymbol{R}$ into $\boldsymbol{R}^3$ and $SO(3)$, respectively. If these mappings are differentiable, then the velocity field at $t \in I$ in a rigid-body motion is given by $(\dot{\boldsymbol{r}}_t^*, \dot{\boldsymbol{d}}_t^*)$, where

$$\begin{aligned}\dot{\boldsymbol{r}}_t^*(p) &= \boldsymbol{v} + \boldsymbol{w} \times (\boldsymbol{r}_t^*(p) - \boldsymbol{x}_0 - \boldsymbol{c}_t),\\ \dot{\boldsymbol{d}}_t^*(p) &= \boldsymbol{w} \times \boldsymbol{d}_t^*.\end{aligned}$$

[5]The assumption $D(p) = 1$ does not imply that the shell analyzed as a Cosserat surface has uniform thickness. It is merely a statement that the thickness plays no role at all in the two-dimensional theory of inextensible directors.

Here $\boldsymbol{v} = \dot{\boldsymbol{c}}_t$ and $\boldsymbol{w}$ is the axial vector of $\dot{\boldsymbol{Q}}_t\boldsymbol{Q}_t^{\mathrm{T}}$, where $(\cdot)^{\mathrm{T}}$ denotes the transpose operator.

If virtual velocity fields on $\mathcal{B}$ are denoted by $\delta\kappa = (\delta\boldsymbol{r}, \delta\boldsymbol{d})$, then rigid-body velocity fields or distributors — that is, the elements of $TC^r_{\kappa(p)}$ — are characterized by

$$(\delta\boldsymbol{r}, \delta\boldsymbol{d})(p) = (\boldsymbol{v} + \boldsymbol{w} \times (\boldsymbol{r}(p) - \boldsymbol{c}), \boldsymbol{w} \times \boldsymbol{d}(p)),$$

with $\boldsymbol{c}, \boldsymbol{v}, \boldsymbol{w} \in \boldsymbol{R}^3$. Clearly,

$$\delta\boldsymbol{d} \cdot \boldsymbol{d} = 0 \quad \text{for all } (\delta\boldsymbol{r}, \delta\boldsymbol{d}) \in TC^r_\kappa. \tag{2}$$

If $t \to \kappa_t = (\boldsymbol{r}_t, \boldsymbol{d}_t)$ is an arbitrary motion, then the hypothesis of inextensible directors leads to the following identities:

$$\dot{\boldsymbol{d}}_t \cdot \boldsymbol{d}_t = 0, \tag{3}$$

$$\boldsymbol{d}_t|_\alpha \cdot \boldsymbol{d}_t = 0, \tag{4}$$

$$\dot{\boldsymbol{d}}_t|_\alpha \cdot \boldsymbol{d}_t = -\boldsymbol{d}_t|_\alpha \cdot \dot{\boldsymbol{d}}_t. \tag{5}$$

where $(\cdot)|_\alpha$ denotes covariant differentiation along θ_α.

In what follows, the subscript t will be dropped from $\kappa_t = (\boldsymbol{r}_t, \boldsymbol{d}_t)$ as well as from $(\dot{\boldsymbol{r}}_t, \dot{\boldsymbol{d}}_t)$ in order to simplify the writing. Decomposing the covariant derivative of the director field with respect to the curvilinear basis $(\boldsymbol{a}_1, \boldsymbol{a}_2, \boldsymbol{a}_3)$, we define the quantities $\lambda^i_{\cdot\alpha}$ by

$$\boldsymbol{d}|_\alpha = \lambda^\mu_{\cdot\alpha}\boldsymbol{a}_\mu + \lambda^3_{\cdot\alpha}\boldsymbol{d}. \tag{6}$$

Since $\boldsymbol{d}|_\alpha \cdot \boldsymbol{d} = 0$, it follows that

$$\lambda^3_{\cdot\alpha} = -\lambda^\mu_{\cdot\alpha}a_{\mu 3}, \tag{7}$$

and

$$\boldsymbol{d}|_\alpha = \lambda^\mu_{\cdot\alpha}\tilde{\boldsymbol{a}}_\mu,$$

where $\tilde{\boldsymbol{a}}_\alpha = \boldsymbol{a}_\mu - (\boldsymbol{a}_\mu \cdot \boldsymbol{d})\boldsymbol{d}$ is the projection of $\boldsymbol{a}_\mu$ onto the plane perpendicular to $\boldsymbol{d}$.

Equations of motion

Following the method of virtual power, the basic equations of motion are obtained from the fundamental axiom of the method of virtual power,

$$< \boldsymbol{f}^e_t + \boldsymbol{f}^i_t, \boldsymbol{\eta} > = 0 \qquad \forall\boldsymbol{\eta} \in TC^r_{\kappa_t}.$$

We assume that the inertial force system consists of forces and couples that are continuously distributed over the reference surface $\mathcal{N}$, with the forces representing the classical inertia of the particles and the couples the rotatory inertia of the directors. This assumption is consistent, to the first order, with the asymptotic expansion of the shell as a three-dimensional simple body, and is also adopted by Naghdi (1972) in his direct method. Such a hypothesis leads to the following expression for the inertial force system:

$$< \boldsymbol{f}^i_t, \boldsymbol{\eta} > = -\iint_{\mathcal{N}} (\rho\dot{\boldsymbol{v}} \cdot \delta\boldsymbol{r} +$$

where $\boldsymbol{v} = \dot{\boldsymbol{r}}$ is the velocity field of points in the reference surface, $\boldsymbol{w}$ the angular velocity of the director field, ρ the mass density per unit area and I a parameter determining the contribution to the inertia of the director field. On the basis of the above assumptions, the axiom may be written as

$$< \boldsymbol{f}^e_t + \boldsymbol{f}^i_t, \boldsymbol{\eta} > = \iint_{\mathcal{N}} \rho(\boldsymbol{f} \cdot \delta\boldsymbol{r} + \boldsymbol{m} \cdot \delta\boldsymbol{d}) \; d\mathcal{N}$$
$$+ \int_{\partial\mathcal{N}} (\boldsymbol{N} \cdot \delta\boldsymbol{r} + \boldsymbol{M} \cdot \delta\boldsymbol{d}) \; d\partial\mathcal{N}$$
$$- \iint_{\mathcal{N}} \rho(\dot{\boldsymbol{v}} \cdot \delta\boldsymbol{r} + I\dot{\boldsymbol{w}} \cdot \delta\boldsymbol{d}) \; d\mathcal{N} = 0$$
$$\forall\boldsymbol{\eta} = (\delta\boldsymbol{r}, \delta\boldsymbol{d}) \in TC^r_{\kappa^t}, \tag{8}$$

where $\boldsymbol{f}, \boldsymbol{m}$ are respectively the distributed external forces and moments on $\mathcal{N}$. The boundary forces and moments $\boldsymbol{N}, \boldsymbol{M}$ are implicitly dependent on the outward unit normal $\boldsymbol{\nu}_p \in T\partial\mathcal{N}^\perp_{r(p)} \subset T\mathcal{N}_{r(p)}$ to the boundary $\partial\mathcal{N}$, i.e.

$$\boldsymbol{N} = \boldsymbol{N}(p, t, \boldsymbol{\nu}_p), \qquad \boldsymbol{M} = \boldsymbol{M}(p, t, \boldsymbol{\nu}_p).$$

Remark I: The moment $\boldsymbol{M}$ may be decomposed into:

$$\boldsymbol{M} = (\boldsymbol{M} \cdot \boldsymbol{d})\,\boldsymbol{d} + \tilde{\boldsymbol{M}},$$

where $\tilde{\boldsymbol{M}} = (\boldsymbol{1} - \boldsymbol{d} \otimes \boldsymbol{d})\boldsymbol{M}$ and $\boldsymbol{1}$ is the identity on $\boldsymbol{R}^3$. From (2) it follows that

$$\boldsymbol{M} \cdot \delta\boldsymbol{d} = \tilde{\boldsymbol{M}} \cdot \delta\boldsymbol{d} \qquad \forall\,(\delta\boldsymbol{r}, \delta\boldsymbol{d}) \in TC^r_\kappa.$$

Moreover, the component $(\boldsymbol{M} \cdot \boldsymbol{d})\,\boldsymbol{d}$ of the boundary moment is a reaction in the restricted Cosserat theory, since its virtual power in an arbitrary virtual velocity field is zero. Without loss of generality we assume that $\boldsymbol{M} \cdot \boldsymbol{d} = 0$.

Finally we define

$$\bar{\boldsymbol{M}} = \boldsymbol{d} \times \boldsymbol{M} \tag{9}$$

and note that $\boldsymbol{M} = \bar{\boldsymbol{M}} \times \boldsymbol{d}$. ■

If we assume a distributor of the form

$$\delta\boldsymbol{r} = \boldsymbol{c} \in \boldsymbol{R}^3, \qquad \delta\boldsymbol{d} = 0,$$

corresponding to a virtual rigid-body translation, then from the arbitrariness of $\boldsymbol{c}$ it follows that

$$\iint_{\mathcal{N}} \rho(\boldsymbol{f} - \dot{\boldsymbol{v}}) \; d\mathcal{N} + \int_{\partial\mathcal{N}} \boldsymbol{N} \; d\partial\mathcal{N} = 0. \tag{10}$$

Equation (10) expresses the balance of linear momentum (Naghdi, 1972). If the vector fields in (10) are smooth then it can be shown that $\boldsymbol{N}$ depends linearly on the unit normal $\boldsymbol{\nu}_p = \nu_\alpha \boldsymbol{a}^\alpha$ to the boundary $\partial\mathcal{N}$ (see Naghdi, 1972, pages 492-494) and finally that $\boldsymbol{N}$ may be decomposed into

$$\boldsymbol{N}(p, t, \boldsymbol{\nu}_p) = \boldsymbol{N}^\alpha \nu_\alpha. \tag{11}$$

Following the application of the divergence theorem for surfaces,

$$\int_{\partial\mathcal{N}} \boldsymbol{N}^\alpha \nu_\alpha \; d\partial\mathcal{N} = \iint_{\mathcal{N}} \boldsymbol{N}^\alpha|_\alpha \; d\mathcal{N}, \tag{12}$$

in Equation (10), we obtain the localized expression for the conservation of linear momentum:

$$\boldsymbol{N}^\alpha|_\alpha + \rho \boldsymbol{f} = \rho \dot{\boldsymbol{v}}. \tag{13}$$

Similarly, a distributor of the form

$$\delta \boldsymbol{r} = \boldsymbol{\Omega} \times \boldsymbol{r}, \qquad \delta \boldsymbol{d} = \boldsymbol{\Omega} \times \boldsymbol{d},$$

with $\boldsymbol{\Omega} \in \boldsymbol{R}^3$, corresponding to a virtual rigid-body rotation, when substituted in (8) yields

$$\iint_{\mathcal{N}} [\rho(\boldsymbol{f} - \dot{\boldsymbol{v}}) \cdot (\boldsymbol{\Omega} \times \boldsymbol{r}) + \rho(\boldsymbol{m} - I\dot{\boldsymbol{w}}) \cdot (\boldsymbol{\Omega} \times \boldsymbol{d})] \; d\mathcal{N} + \int_{\partial\mathcal{N}} [\boldsymbol{N} \cdot (\boldsymbol{\Omega} \times \boldsymbol{r}) + \boldsymbol{M} \cdot (\boldsymbol{\Omega} \times \boldsymbol{d})] \; d\partial\mathcal{N} = 0. \tag{14}$$

Using the vector identity $\boldsymbol{a} \cdot (\boldsymbol{b} \times \boldsymbol{c}) = \boldsymbol{b} \cdot (\boldsymbol{c} \times \boldsymbol{a})$, recalling that $\boldsymbol{N} = \boldsymbol{N}^\alpha \nu_\alpha$, $\boldsymbol{r}_{,\alpha} = \boldsymbol{a}_\alpha$, and applying the divergence theorem for surfaces, we obtain

$$\int_{\partial\mathcal{N}} (\boldsymbol{r} \times \boldsymbol{N}^\alpha) \nu_\alpha \; d\partial\mathcal{N} = \iint_{\mathcal{N}} (\boldsymbol{r} \times \boldsymbol{N}^\alpha|_\alpha + \boldsymbol{a}_\alpha \times \boldsymbol{N}^\alpha) \; d\mathcal{N}.$$

Equation (14) then reduces to

$$\iint_{\mathcal{N}} \{\boldsymbol{r} \times [\boldsymbol{N}^\alpha|_\alpha + \rho(\boldsymbol{f} - \dot{\boldsymbol{v}})] + \boldsymbol{d} \times \rho(\boldsymbol{m} - I\dot{\boldsymbol{w}})\} \; d\mathcal{N} + \iint_{\mathcal{N}} \boldsymbol{a}_\alpha \times \boldsymbol{N}^\alpha \; d\mathcal{N} = \int_{\partial\mathcal{N}} \boldsymbol{d} \times \boldsymbol{M} \; d\partial\mathcal{N}.$$

From the balance of linear momentum (13) and the definition (9), the above equation leads to the balance of moment of momentum,

$$\iint_{\mathcal{N}} (\boldsymbol{d} \times \rho(\boldsymbol{m} - I\dot{\boldsymbol{w}}) + \boldsymbol{a}_\alpha \times \boldsymbol{N}^\alpha) \; d\mathcal{N} + \int_{\partial\mathcal{N}} \bar{\boldsymbol{M}} \; d\partial\mathcal{N} = 0. \tag{15}$$

Using similar arguments to those employed in Equations (10)-(13), we conclude that

$$\bar{\boldsymbol{M}} = \bar{\boldsymbol{M}}^\alpha \nu_\alpha, \tag{16}$$

$$\int_{\partial\mathcal{N}} \bar{\boldsymbol{M}} \; d\partial\mathcal{N} = \iint_{\mathcal{N}} \bar{\boldsymbol{M}}^\alpha|_\alpha \; d\mathcal{N}, \tag{17}$$

and finally

$$\bar{\boldsymbol{M}}^\alpha|_\alpha + \boldsymbol{d} \times \rho \boldsymbol{m} + \boldsymbol{a}_\alpha \times \boldsymbol{N}^\alpha = \boldsymbol{d} \times \rho I \dot{\boldsymbol{w}}. \tag{18}$$

Equations (13) and (18) are the classical equations of motion for a Cosserat surface with inextensible directors (Naghdi, 1972; Simo and Fox, 1987).

Internal virtual power

From (9), (11), (16) and the divergence theorem for surfaces we obtain

$$\int_{\partial\mathcal{N}} (\boldsymbol{N} \cdot \delta\boldsymbol{r} + \boldsymbol{M} \cdot \delta\boldsymbol{d}) \; d\partial\mathcal{N} = \iint_{\mathcal{N}} (\boldsymbol{N}^\alpha|_\alpha \cdot \delta\boldsymbol{r} + \boldsymbol{N}^\alpha \cdot \delta\boldsymbol{r}|_\alpha + \bar{\boldsymbol{M}}^\alpha|_\alpha \times \boldsymbol{d} \cdot \delta\boldsymbol{d} + \bar{\boldsymbol{M}}^\alpha \times \boldsymbol{d}|_\alpha \cdot \delta\boldsymbol{d} + \bar{\boldsymbol{M}}^\alpha \times \boldsymbol{d} \cdot \delta\boldsymbol{d}|_\alpha) \; d\mathcal{N}. \tag{19}$$

Replacing (19) in (8), the virtual power of the external and inertial force systems reduces to:

$$< \boldsymbol{f}^e_t + \boldsymbol{f}^i_t, \eta > = \iint_{\mathcal{N}} \{[\boldsymbol{N}^\alpha|_\alpha + \rho(\boldsymbol{f} - \dot{\boldsymbol{v}})] \cdot \delta\boldsymbol{r} + \bar{\boldsymbol{M}}^\alpha \times \boldsymbol{d}|_\alpha \cdot \delta\boldsymbol{d} + [\bar{\boldsymbol{M}}^\alpha|_\alpha \times \boldsymbol{d} + \rho(\boldsymbol{m} - I\dot{\boldsymbol{w}})] \cdot \delta\boldsymbol{d} + \boldsymbol{N}^\alpha \cdot \delta\boldsymbol{r}|_\alpha + \bar{\boldsymbol{M}}^\alpha \times \boldsymbol{d} \cdot \delta\boldsymbol{d}|_\alpha\} \; d\mathcal{N}. \tag{20}$$

From the vector identity $(\boldsymbol{a} \times \boldsymbol{b}) \times \boldsymbol{c} = \boldsymbol{b}(\boldsymbol{a} \cdot \boldsymbol{c}) - \boldsymbol{a}(\boldsymbol{b} \cdot \boldsymbol{c})$ and the balance of angular momentum (18) it follows that

$$[\bar{\boldsymbol{M}}^\alpha|_\alpha + \boldsymbol{d} \times \rho(\boldsymbol{m} - I\dot{\boldsymbol{w}}) + \boldsymbol{a}_\alpha \times \boldsymbol{N}^\alpha] \times \boldsymbol{d} \cdot \delta\boldsymbol{d} = [\bar{\boldsymbol{M}}^\alpha|_\alpha \times \boldsymbol{d} + \rho(\boldsymbol{m} - I\dot{\boldsymbol{w}})] \cdot \delta\boldsymbol{d} + (\boldsymbol{N}^\alpha \cdot \boldsymbol{d})(\delta\boldsymbol{d} \cdot \boldsymbol{a}_\alpha) - (\boldsymbol{N}^\alpha \cdot \delta\boldsymbol{d})(\boldsymbol{a}_\alpha \cdot \boldsymbol{d}) = 0. \tag{21}$$

Moreover, if we define

$$\boldsymbol{M}^\alpha = \bar{\boldsymbol{M}}^\alpha \times \boldsymbol{d} \tag{22}$$

then Remark I implies that $\bar{\boldsymbol{M}}^\alpha = \boldsymbol{d} \times \boldsymbol{M}^\alpha$ and

$$\bar{\boldsymbol{M}}^\alpha \times \boldsymbol{d}|_\alpha \cdot \delta\boldsymbol{d} = (\boldsymbol{M}^\alpha \cdot \delta\boldsymbol{d})(\boldsymbol{d} \cdot \boldsymbol{d}|_\alpha) - (\boldsymbol{M}^\alpha \cdot \boldsymbol{d}|_\alpha)(\boldsymbol{d} \cdot \delta\boldsymbol{d}) = 0. \tag{23}$$

Replacing (21), (22) and the balance of linear momentum (13) in (20) yields

$$\begin{aligned} < \boldsymbol{f}^e_t + \boldsymbol{f}^i_t, \eta > &= \iint_{\mathcal{N}} \boldsymbol{N}^\alpha \cdot \delta\boldsymbol{r}|_\alpha + \boldsymbol{M}^\alpha \cdot \delta\boldsymbol{d}|_\alpha \; d\mathcal{N} \\ &\quad + \iint_{\mathcal{N}} (\boldsymbol{N}^\alpha \cdot \boldsymbol{d})(\delta\boldsymbol{d} \cdot \boldsymbol{a}_\alpha) - (\boldsymbol{N}^\alpha \cdot \delta\boldsymbol{d})(\boldsymbol{a}_\alpha \cdot \boldsymbol{d}) \; d\mathcal{N} \\ &= \iint_{\mathcal{N}} \boldsymbol{N}^\alpha \cdot \delta\boldsymbol{r}|_\alpha + \boldsymbol{M}^\alpha \cdot \delta\boldsymbol{d}|_\alpha \; d\mathcal{N} \\ &\quad - \iint_{\mathcal{N}} (\boldsymbol{a}_\alpha \times \boldsymbol{N}^\alpha) \times \boldsymbol{d} \cdot \delta\boldsymbol{d} \; d\mathcal{N}. \end{aligned} \tag{24}$$

Introduction of components

Decomposing the vector fields $\boldsymbol{N}^\alpha$ and $\boldsymbol{M}^\alpha$ with respect to the curvilinear basis $(\boldsymbol{a}_1, \boldsymbol{a}_2, \boldsymbol{a}_3)$, with $\boldsymbol{a}_3 = \boldsymbol{d}$, we define

$$\boldsymbol{N}^\alpha = N^{\beta\alpha} \boldsymbol{a}_\beta + Q^\alpha \boldsymbol{d}, \tag{25}$$

$$\boldsymbol{M}^\alpha = M^{\beta\alpha} \boldsymbol{a}_\beta + M^{3\alpha} \boldsymbol{d}. \tag{26}$$

By hypothesis $M^\alpha \cdot d = 0$, therefore

$$M^{3\alpha} = -M^{\beta\alpha} a_{3\beta}, \tag{27}$$

and consequently $M^\alpha = M^{\beta\alpha}\tilde{a}_\beta$, where

$$\tilde{a}_\beta = a_\beta - (a_\beta \cdot d)d. \tag{28}$$

Remark II: Replacing $\bar{M}^\alpha = d \times M^\alpha$ in the equation of balance of moment of momentum (18) and on taking the inner product of the above expression with d, we obtain

$$(d|_\alpha \times M^\alpha)\cdot d + (a_\alpha \times N^\alpha)\cdot d = 0. \tag{29}$$

Substituting (6), (25) and (26) in Equation (29) yields

$$\begin{aligned} & M^{\alpha\mu}\lambda^{\beta}_{.\mu} a_\beta \times a_\alpha \cdot d + N^{\beta\alpha} a_\alpha \times a_\beta \cdot d \\ &= (N^{\beta\alpha} - \lambda^{\beta}_{.\mu} M^{\alpha\mu})\, a_\alpha \times a_\beta \cdot d \\ &= (N^{\beta\alpha} - \lambda^{\beta}_{.\mu} M^{\alpha\mu}) a\, \epsilon_{\alpha\beta 3} = 0. \end{aligned}$$

Therefore $\epsilon_{\alpha\beta 3}(N^{\beta\alpha} - \lambda^{\beta}_{.\alpha} M^{\alpha\mu}) = 0$, where ϵ_{ijk} for $(1 \le i,j,k \le 3)$ denotes the permutation symbols.

Finally, if

$$N^{\beta\alpha}_{eff} = (N^{\beta\alpha} - \lambda^{\beta}_{.\mu} M^{\alpha\mu}), \tag{30}$$

then $N_{eff} = (N_{eff})^{\mathsf{T}}$, where $N_{eff} = N^{\alpha\beta}_{eff}(a_\alpha \otimes a_\beta)$. N_{eff} will be referred to as the effective membrane stress tensor and is related to the power of changes of length and distortion on the reference surface $\mathcal{N}$, measured by the metric tensor $a_{\alpha\beta}$ (see Lemma 1). ■

Remark II motivates the definition of the following deformation measures:

$$\begin{aligned} \varepsilon &= \varepsilon_{\alpha\beta} a^\alpha \otimes a^\beta, \\ \kappa &= \kappa_{\alpha\beta} a^\alpha \otimes a^\beta, \\ \gamma &= \gamma_\alpha a^\alpha, \end{aligned} \tag{31}$$

where

$$\begin{aligned} \varepsilon_{\alpha\beta} &= \frac{1}{2}(a_\alpha \cdot a_\beta - A_\alpha \cdot A_\beta), \\ \kappa_{\alpha\beta} &= (d|_\beta \cdot a_\alpha - d_0|_\beta \cdot A_\alpha), \\ \gamma_\alpha &= d \cdot a_\alpha - d_0 \cdot A_\alpha \end{aligned}$$

and A_α, d_0 are respectively the vector fields a_α, d at the reference configuration. The convected time derivatives (a special case of Lie derivatives) of the aforementioned deformation measures may be defined as follows (Marsden and Hughes, 1983; Simo and Fox, 1987):

$$\begin{aligned} \mathcal{L}_v \varepsilon &= \dot{\varepsilon}_{\alpha\beta} a^\alpha \otimes a^\beta, \\ \mathcal{L}_v \kappa &= \dot{\kappa}_{\alpha\beta} a^\alpha \otimes a^\beta, \\ \mathcal{L}_v \gamma &= \dot{\gamma}_\alpha a^\alpha. \end{aligned}$$

On the above Equations

$$\begin{aligned} \dot{\varepsilon}_{\alpha\beta} &= \frac{1}{2}(\dot{a}_\alpha \cdot a_\beta + a_\alpha \cdot \dot{a}_\beta), \\ \dot{\kappa}_{\alpha\beta} &= (\dot{d}|_\beta \cdot a_\alpha + d|_\beta \cdot \dot{a}_\alpha), \\ \dot{\gamma}_\alpha &= (\dot{d} \cdot a_\alpha + d.\dot{a}_\alpha). \end{aligned} \tag{32}$$

Component form of the internal virtual power

Lemma 1 *The deformation power is given by:*

$$\iint_{\mathcal{N}} (N^{\alpha\beta}_{eff}\dot{\varepsilon}_{\alpha\beta} + M^{\alpha\beta}\dot{\kappa}_{\alpha\beta} + Q^{\alpha}_{eff}\dot{\gamma}_\alpha)\ d\mathcal{N}, \tag{33}$$

where

$$Q^\alpha_{eff} = (Q^\alpha - \lambda^3_{.\beta} M^{\alpha\beta}). \tag{34}$$

Proof: We obtain the deformation power by replacing the virtual velocity field in the virtual power of the external and inertial force systems by the actual velocity field of the motion. Replacing $(\delta r, \delta d)$ in Equation (24) by $(\dot{r}, \dot{d})$ yields

$$\iint_{\mathcal{N}} N^\alpha \cdot \dot{a}_\alpha + M^\alpha \cdot \dot{d}|_\alpha\ d\mathcal{N} + \iint_{\mathcal{N}} (N^\alpha \cdot d)(\dot{d} \cdot a_\alpha) - (N^\alpha \cdot \dot{d})(a_\alpha \cdot d)\ d\mathcal{N}.$$

- Using (5), (6), (7) and (26) we find that

$$\begin{aligned} M^\alpha \cdot \dot{d}|_\alpha &= M^{\beta\alpha} a_\beta \cdot \dot{a}_{3,\alpha} - M^{3\alpha} a_{3,\alpha} \cdot \dot{a}_3 \\ &= M^{\beta\alpha}\dot{\kappa}_{\beta\alpha} - M^{\beta\alpha}\dot{a}_\beta \cdot a_{3,\alpha} - M^{3\alpha} a_{3,\alpha} \cdot \dot{a}_3 \\ &= M^{\beta\alpha}\dot{\kappa}_{\beta\alpha} - M^{\beta\alpha}\lambda^{\mu}_{.\alpha}\dot{a}_\beta \cdot a_\mu \\ &\quad - M^{\beta\alpha}\lambda^{3}_{.\alpha}\dot{a}_\beta \cdot a_3 - M^{3\alpha} a_{3,\alpha} \cdot \dot{a}_3. \end{aligned} \tag{35}$$

- From (25) and (35) we obtain

$$\begin{aligned} N^\alpha \cdot \dot{a}_\alpha + M^\alpha \cdot \dot{d}|_\alpha &= (N^{\beta\alpha} - M^{\alpha\mu}\lambda^{\beta}_{.\mu})\,\dot{a}_\alpha \cdot a_\beta \\ &\quad + M^{\beta\alpha}\dot{\kappa}_{\beta\alpha} + (Q^\alpha - \lambda^3_{.\beta} M^{\alpha\beta})\,\dot{a}_\alpha \cdot a_3 \\ &\quad - M^{3\alpha}\lambda^{\mu}_{.\alpha} a_\mu \cdot \dot{a}_3 - M^{3\alpha}\lambda^{3}_{.\alpha} a_3 \cdot \dot{a}_3. \end{aligned}$$

  From substituting (30), (32.a-b) and (34) in the above equation it follows that

$$\begin{aligned} N^\alpha \cdot \dot{a}_\alpha + M^\alpha \cdot \dot{d}|_\alpha &= N^{\alpha\beta}_{eff} \cdot \dot{\varepsilon}_{\alpha\beta} + M^{\alpha\beta} \cdot \dot{\kappa}_{\alpha\beta} \\ &\quad + Q^\alpha_{eff}\dot{a}_\alpha \cdot a_3 - M^{3\alpha}\lambda^{\mu}_{.\alpha} a_\mu \cdot \dot{a}_3. \end{aligned} \tag{36}$$

- Using (25) and (28) we obtain

$$\begin{aligned} & (N^\alpha \cdot d)(\dot{d} \cdot a_\alpha) - (N^\alpha \cdot \dot{d})(a_\alpha \cdot d) \\ &= [(N^{\beta\alpha} a_{\beta 3} + Q^\alpha) a_\alpha - a_{\alpha 3}(N^{\beta\alpha} a_\beta + Q^\alpha a_3)] \cdot \dot{a}_3 \\ &= [(N^{\beta\alpha} - \lambda^{\beta}_{.\mu} M^{\alpha\mu}) - (N^{\alpha\beta} - \lambda^{\alpha}_{.\mu} M^{\beta\mu}) \\ &\quad + \lambda^{\beta}_{.\mu} M^{\alpha\mu} - \lambda^{\alpha}_{.\mu} M^{\beta\mu}] a_{\beta 3} a_\alpha + Q^\alpha \tilde{a}_\alpha \cdot \dot{a}_3 \end{aligned} \tag{37}$$

From (30) and (34), the right-hand side of the above expression yields

$$\Big\{[(N^{\beta\alpha}_{eff} - N^{\alpha\beta}_{eff}) + (\lambda^{\beta}_{.\mu}M^{\alpha\mu} - \lambda^{\alpha}_{.\mu}M^{\beta\mu})]a_{\beta 3}\boldsymbol{a}_{\alpha} + (Q^{\alpha}_{eff} + \lambda^{3}_{.\beta}M^{\alpha\beta})\tilde{\boldsymbol{a}}_{\alpha}\Big\} \cdot \dot{\boldsymbol{a}}_3. \tag{38}$$

On substituting $N^{\alpha\beta}_{eff} = N^{\beta\alpha}_{eff}$, $M^{3\alpha} = -a_{3\beta}M^{\beta\alpha}$ and $\lambda^{3}_{.\beta} = -a_{3\alpha}\lambda^{\alpha}_{.\beta}$ in (38), Equation (37) reduces to

$$\begin{aligned}(\boldsymbol{N}^{\alpha} \cdot \boldsymbol{d})(\dot{\boldsymbol{d}} \cdot \boldsymbol{a}_{\alpha}) - (\boldsymbol{N}^{\alpha} \cdot \dot{\boldsymbol{d}})(\boldsymbol{a}_{\alpha} \cdot \boldsymbol{d}) &= (Q^{\alpha}_{eff} - a_{3\beta}\lambda^{\alpha}_{.\mu}M^{\beta\mu})\,\tilde{\boldsymbol{a}}_{\alpha} \cdot \dot{\boldsymbol{a}}_3. \\ &= (Q^{\alpha}_{eff} + \lambda^{\alpha}_{.\mu}M^{3\mu})\,\tilde{\boldsymbol{a}}_{\alpha} \cdot \dot{\boldsymbol{a}}_3. \end{aligned} \tag{39}$$

Note that from (3) and (28) it follows that

$$\tilde{\boldsymbol{a}}_{\alpha} \cdot \dot{\boldsymbol{a}}_3 = \boldsymbol{a}_{\alpha} \cdot \dot{\boldsymbol{a}}_3.$$

- Adding expressions (36) and (39), we finally obtain the deformation power per unit area

$$\begin{aligned}\boldsymbol{N}^{\alpha} \cdot \dot{\boldsymbol{a}}_{\alpha} + \boldsymbol{M}^{\alpha} \cdot \dot{\boldsymbol{d}}|_{\alpha} + (\boldsymbol{N}^{\alpha} \cdot \boldsymbol{d})(\dot{\boldsymbol{d}} \cdot \boldsymbol{a}_{\alpha}) \\ - (\boldsymbol{N}^{\alpha} \cdot \dot{\boldsymbol{d}})(\boldsymbol{a}_{\alpha} \cdot \boldsymbol{d}) \\ = N^{\alpha\beta}_{eff}\dot{\varepsilon}_{\alpha\beta} + M^{\alpha\beta}\dot{\kappa}_{\alpha\beta} + Q^{\alpha}_{eff}\dot{\gamma}_{\alpha}\end{aligned} \tag{40}$$

Integration of the right-hand side over the surface proves the lemma.

■

If κ is taken as the reference configuration and arbitrary motions from this configuration are considered, then the velocity fields generated by those motions at $\kappa \in \mathcal{C}$ form the tangent bundle $T\mathcal{C}_{\kappa}$. It follows that Equation (33) represents the internal virtual power if the actual deformation-rate components $\dot{\varepsilon}_{\alpha\beta}$, $\dot{\kappa}_{\alpha\beta}$, $\dot{\gamma}_{\alpha}$ are replaced by the virtual deformation rates $\delta\varepsilon_{\alpha\beta}$, $\delta\kappa_{\alpha\beta}$, $\delta\gamma_{\alpha}$.

Equations (13),(18) and appropriate constitutive relations for $N^{\alpha\beta}_{eff}$, $M^{\alpha\beta}$, Q^{α}_{eff} (and hence for $\boldsymbol{N}^{\alpha}$ and $\boldsymbol{M}^{\alpha}$) form a complete set of equations determining the motion of the Cosserat surface with inextensible directors. For elastic behavior, a strain energy function $\varphi(\boldsymbol{\varepsilon}, \boldsymbol{\kappa}, \boldsymbol{\gamma})$, whose dependence on the invariants of the reference surface is implicitly assumed (see Carroll and Naghdi, 1972, for additional details), is postulated to describe the constitutive relation in the functional form:

$$N^{\alpha\beta}_{eff} = \frac{\partial\varphi}{\partial\varepsilon_{\alpha\beta}}, \quad M^{\alpha\beta} = \frac{\partial\varphi}{\partial\kappa_{\alpha\beta}}, \quad Q^{\alpha} = \frac{\partial\varphi}{\partial\gamma_{\alpha}}.$$

For additional considerations on constitutive relations, see Naghdi (1972) and Niordson (1985).

COSSERAT SURFACE WITH DEFORMABLE DIRECTORS

Equations of motion and deformation power

An extension of the Cosserat-surface model with inextensible directors to one with deformable directors will be based on the following guidelines.

- The terms involving the force systems of the preceding model have the same physical motivation in their extension and therefore remain unchanged. Moments as physically understood are conjugate to angular velocity fields. A natural choice is given by the changes in orientation of the director field. If $\boldsymbol{d} = D\hat{\boldsymbol{d}}$, with $D^2 = \boldsymbol{d} \cdot \boldsymbol{d}$ and $\hat{\boldsymbol{d}}.\hat{\boldsymbol{d}} = 1$, then such changes in orientation are equivalently given by the variations of the unit director field $\hat{\boldsymbol{d}}$. This interpretation is at variance with the adopted by Naghdi (1972), as is seen in the next section.

- Changes in length of the directors are naturally associated with a scalar field expressing in an appropriate sense the pressure or squeezing forces applied along the director field. Such contributions may be conceived of as distributed on the surface as well as along the boundary.

- The inertia functional is assumed to have the same form as in the previous model but with additional terms due to the variations of the length of the director field.

In accordance with these guidelines, it may be assumed that the virtual power of the external and inertial force systems is given by

$$\begin{aligned}< \boldsymbol{f}^{e}_{t} + \boldsymbol{f}^{i}_{t}, \boldsymbol{\eta} > = \iint_{\mathcal{N}} \rho(\boldsymbol{f} \cdot \delta\boldsymbol{r} + \boldsymbol{m} \cdot \delta\hat{\boldsymbol{d}} + p\delta D)\ d\mathcal{N} \\ + \int_{\partial\mathcal{N}} (\boldsymbol{N} \cdot \delta\boldsymbol{r} + \boldsymbol{M} \cdot \delta\hat{\boldsymbol{d}} + P\delta D)\ d\partial\mathcal{N} \\ - \iint_{\mathcal{N}} \rho[\dot{\boldsymbol{v}} \cdot \delta\boldsymbol{r} + I\dot{\boldsymbol{w}} \cdot (D\delta\hat{\boldsymbol{d}} + \delta D\hat{\boldsymbol{d}})]\ d\mathcal{N} \\ \forall\boldsymbol{\eta} \in T\mathcal{C}_{\kappa}.\end{aligned} \tag{41}$$

The virtual velocity fields for the extended theory are conveniently denoted $\boldsymbol{\eta} = (\delta\boldsymbol{r}, \delta\hat{\boldsymbol{d}}, \delta D)$.

Because of the similarity of the virtual-power expression for the extended model with the one for the preceding model, Equation (8), most of the developments of the preceding section still hold if the director field is replaced, where appropriate, by the unit director field $\hat{\boldsymbol{d}}$. Equations (2)-(5) naturally hold for $\hat{\boldsymbol{d}}$ and definitions (6)-(7) expressing the covariant derivative of the unit director field are still valid. Thus

$$\hat{\boldsymbol{d}}|_{\alpha} = \lambda^{\mu}_{.\alpha}\boldsymbol{a}_{\alpha} + \lambda^{3}_{.\alpha}\boldsymbol{a}_3. \tag{42}$$

Clearly $\hat{d}|_\alpha \cdot \hat{d} = 0$, and again

$$\lambda^3_{.\alpha} = -\lambda^\mu_{.\alpha} a_{\mu 3}, \tag{43}$$

where by definition $a_3 = \hat{d}$.

To obtain the basic equations of motion we apply the fundamental axiom of the method of virtual power. As we shall see, one additional scalar equation is needed to describe the evolution of the length of the directors. Even though this equation is not obtained from the axiom, it has a clear and physically intuitive derivation. This aspect is indeed one of the great advantages of the method of virtual power.

The application of the fundamental axiom to the extended model leads to the linear-momentum equation,

$$N^\alpha|_\alpha + \rho f = \rho \dot{v}, \tag{44}$$

and the moment-of-momentum equation,

$$\bar{M}^\alpha|_\alpha + \hat{d} \times \rho m + a_\alpha \times N^\alpha = \hat{d} \times \rho I \dot{w}, \tag{45}$$

where by definition $N = N^\alpha \nu_\alpha$, $\bar{M} = \hat{d} \times M = \bar{M}^\alpha \nu_\alpha$ (see Remark I and Equations (11), (16) and (22) for the corresponding definitions in the restricted Cosserat theory of inextensible directors). The derivations of the above equations follow precisely the same steps as used in the preceding model and therefore will not be repeated. From Equations (44) and (45), the virtual power due to the external and inertial force systems (41) reduces to (see Equations (19-24))

$$\begin{aligned} < f^e_\iota + f^i_\iota, \eta > = & \iint_{\mathcal{N}} [N^\alpha \cdot \delta r|_\alpha + M^\alpha \cdot \delta \hat{d}|_\alpha \\ & - (a_\alpha \times N^\alpha) \times \hat{d} \cdot \delta \hat{d}]\, d\mathcal{N} \\ & + \iint_{\mathcal{N}} \rho (p - I\dot{w} \cdot \hat{d}) \delta D \; d\mathcal{N} \\ & + \int_{\partial \mathcal{N}} P \delta D \; d\partial\mathcal{N} \qquad \forall \eta \in TC_\kappa, \end{aligned} \tag{46}$$

where $M^\alpha = \bar{M}^\alpha \times \hat{d}$ and $\bar{M}^\alpha = \hat{d} \times M^\alpha$.

Assuming, for the purpose of deriving the basic equations of motion, that the Cosserat surface is in principle not subjected to constraints, we apply the virtual velocity field

$$\delta r = 0, \quad \delta \hat{d} = 0 \quad \text{and } \delta D = \delta \bar{D} \text{ (constant)},$$

corresponding to an uniform change in length of the directors, to (46). With this virtual velocity field, the power of the external and inertial force systems reduces to

$$\begin{aligned} < f^e_\iota + f^i_\iota, \eta > = \delta \bar{D} \Big\{ & \int_{\partial\mathcal{N}} P \; d\partial\mathcal{N} \\ & + \iint_{\mathcal{N}} \rho (p - I\dot{w} \cdot \hat{d}) \; d\mathcal{N} \Big\} \quad \forall \eta \end{aligned}$$

It follows from the principle of virtual [illegible] is external-cum-inertial force system the[illegible] in internal force system dual to changes in director length (that is, a linear functional in δD contributing to the internal virtual power associated with a virtual velocity field characterized by $(\delta r, \delta \hat{d}, \delta D)$). We assume a priori that this internal virtual power is given by

$$\ll \sigma, T d^*_\kappa \gg = \iint_{\mathcal{N}} H \delta D \; d\mathcal{N}.$$

Applying the principle of virtual power,

$$\ll \sigma, T d_\kappa \gg = < f^e_\iota + f^e_\iota, \eta > \qquad \forall \eta \in TC_\kappa,$$

to this particular virtual velocity field leads to

$$\iint_{\mathcal{N}} H \; d\mathcal{N} = \int_{\partial\mathcal{N}} P \; d\partial\mathcal{N} + \iint_{\mathcal{N}} \rho [p - I\dot{w} \cdot \hat{d}] \; d\mathcal{N},$$

and finally, under an appropriate smoothness hypothesis, it follows that

$$P = P^\alpha \nu_\alpha, \tag{47}$$

$$P^\alpha|_\alpha + \rho p - H = \rho I \dot{w} \cdot \hat{d}. \tag{48}$$

Moreover, applying Equations (47) and (48) to the expression for the virtual power (46), we obtain

$$\begin{aligned} < f^e_\iota + f^i_\iota, \eta > = & \iint_{\mathcal{N}} [N^\alpha \cdot \delta r|_\alpha + M^\alpha \cdot \delta \hat{d}|_\alpha \\ & - (a_\alpha \times N^\alpha) \times \hat{d} \cdot \delta \hat{d} + P^\alpha \delta D|_\alpha + H \delta D]\, d\mathcal{N}. \end{aligned} \tag{49}$$

Following the same developments as in Lemma 1, it can be shown that the deformation power is given by

$$\begin{aligned} \iint_{\mathcal{N}} (& N^{\alpha\beta}_{eff} \cdot \dot{\varepsilon}_{\alpha\beta} + M^{\alpha\beta} \cdot \dot{\kappa}_{\alpha\beta} + Q^\alpha_{eff} \cdot \dot{\gamma}_\alpha \\ & + P^\alpha \dot{\xi}_\alpha + H \dot{\Delta})\, d\mathcal{N}. \end{aligned} \tag{50}$$

The deformations ξ_α and Δ are defined by

$$\begin{aligned} \xi_\alpha &= D|_\alpha - D_0|_\alpha, & \dot{\xi}_\alpha &= \dot{D}|_\alpha, \\ \Delta &= D - D_0, & \dot{\Delta} &= \dot{D}, \end{aligned} \tag{51}$$

where $D_0 = ||d_0||$.

Equations (44), (45), (48) and appropriate constitutive relations for $N^{\alpha\beta}_{eff}$, $M^{\alpha\beta}$, Q^α_{eff}, P^α and H form a complete set of equations determining the motion of the Cosserat surface.

Note the appearance in Equation (48) of the internal force H dual to changes in director length. In the complete problem, H is constitutively determined by the motion and therefore should not be regarded as an additional unknown scalar field. As we shall see, this term is in a certain sense associated with the intrinsic director couple of Naghdi (1972) and the across-the-thickness stress resultant of Simo and Fox (1987).

The proposed theory includes essentially the same external and inertial force systems as the theory of Naghdi

(1972). Consequently, according to the principle of virtual power, they may be considered equivalent. The major differences lie in the identification of the internal forces and their corresponding constitutive relations.

Equation (48) does not follow directly from the director-momentum Equation of Naghdi (see Equation (56)). This is not surprising, in view of the intervention of internal forces in both equations and the natural differences between the internal force H and the intrinsic director couple of Naghdi. The similarities of the above model with the one proposed by Naghdi is analyzed in the next section.

NAGHDI'S COSSERAT SURFACE OF DEFORMABLE DIRECTORS

Equations of motion and internal virtual power

Naghdi's equations for a Cosserat surface with deformable directors may be obtained if the virtual power of the external and inertial force systems is assumed a priori to take the form

$$\begin{aligned} < \boldsymbol{f}_t^e + \boldsymbol{f}_t^i, \boldsymbol{\eta} > = & \iint_{\mathcal{N}} \rho(\boldsymbol{f} \cdot \delta\boldsymbol{r} + \boldsymbol{m}^* \cdot \delta\boldsymbol{d}) \; d\mathcal{N} \\ & + \int_{\partial\mathcal{N}} (\boldsymbol{N} \cdot \delta\boldsymbol{r} + \boldsymbol{M}^* \cdot \delta\boldsymbol{d}) \; d\partial\mathcal{N} \\ & - \iint_{\mathcal{N}} \rho[\dot{\boldsymbol{v}} \cdot \delta\boldsymbol{r} + I\dot{\boldsymbol{w}} \cdot \delta\boldsymbol{d}] \; d\mathcal{N} \\ & \qquad \forall \boldsymbol{\eta} = (\delta\boldsymbol{r}, \delta\boldsymbol{d}) \in TC_\kappa . \end{aligned} \tag{52}$$

Denoting

$$\tilde{\boldsymbol{m}}^* = (1 - \hat{\boldsymbol{d}} \otimes \hat{\boldsymbol{d}})\boldsymbol{m}^*, \qquad \boldsymbol{m}^* = (\boldsymbol{m}^* \cdot \hat{\boldsymbol{d}})\,\hat{\boldsymbol{d}} + \tilde{\boldsymbol{m}}^*,$$
$$\tilde{\boldsymbol{M}}^* = (1 - \hat{\boldsymbol{d}} \otimes \hat{\boldsymbol{d}})\boldsymbol{M}^*, \qquad \boldsymbol{M}^* = (\boldsymbol{M}^* \cdot \hat{\boldsymbol{d}})\,\hat{\boldsymbol{d}} + \tilde{\boldsymbol{M}}^*,$$

and observing that $\delta\boldsymbol{d} = \delta D\,\hat{\boldsymbol{d}} + D\,\delta\hat{\boldsymbol{d}}$, we may alternatively write Equation (52) as

$$\begin{aligned} < \boldsymbol{f}_t^e + \boldsymbol{f}_t^i, \boldsymbol{\eta} > = & \\ & \iint_{\mathcal{N}} \rho[\boldsymbol{f} \cdot \delta\boldsymbol{r} + (\boldsymbol{m}^* \cdot \hat{\boldsymbol{d}})\delta D + D\tilde{\boldsymbol{m}}^* \cdot \delta\hat{\boldsymbol{d}}] \; d\mathcal{N} \\ & + \int_{\partial\mathcal{N}} [\boldsymbol{N} \cdot \delta\boldsymbol{r} + D\tilde{\boldsymbol{M}}^* \cdot \delta\hat{\boldsymbol{d}} + (\boldsymbol{M}^* \cdot \hat{\boldsymbol{d}})\delta D] \; d\partial\mathcal{N} \\ & - \iint_{\mathcal{N}} \rho[\dot{\boldsymbol{v}} \cdot \delta\boldsymbol{r} + I\dot{\boldsymbol{w}} \cdot \delta\boldsymbol{d}] \; d\mathcal{N} \\ & \qquad \forall \boldsymbol{\eta} = (\delta\boldsymbol{r}, \delta\boldsymbol{d}) \in TC_\kappa . \end{aligned} \tag{53}$$

Finally, with the definitions

$$\begin{aligned} \boldsymbol{m} &= D\tilde{\boldsymbol{m}}^*, & \boldsymbol{M} &= D\tilde{\boldsymbol{M}}^*, \\ p &= \boldsymbol{m}^* \cdot \hat{\boldsymbol{d}}, & P &= \boldsymbol{M}^* \cdot \hat{\boldsymbol{d}}, \end{aligned} \tag{54}$$

Equation (53) takes the same form as (41). Hence both models account for basically the same inertial and external force systems. Note that the moment $\boldsymbol{M}^*$ in Naghdi's theory encompasses what in the present model are the distinct notions of moment and pressure, duals respectively to changes in director orientation and length.

Before invoking the fundamental axiom, we insert a virtual velocity field $\boldsymbol{\eta}^*$ such that $\delta\boldsymbol{r} = 0$ and $\delta\boldsymbol{d} = \delta\boldsymbol{d}^*$ (constant on the reference surface), into the expression (52) for the virtual power of the external and inertial force systems. By the same arguments as used in deriving Equation (48), we assume that to this virtual velocity field is associated the following internal virtual power:

$$\ll \boldsymbol{\sigma}, Td_\kappa\boldsymbol{\eta}^* \gg = \iint_{\mathcal{N}} \boldsymbol{H}^* \cdot \delta\boldsymbol{d} \; d\mathcal{N} .$$

Following the application of the principle of virtual power to this particular virtual velocity field, we obtain

$$\iint_{\mathcal{N}} \boldsymbol{H}^* \; d\mathcal{N} = \int_{\partial\mathcal{N}} \boldsymbol{M}^* \; d\partial\mathcal{N} + \iint_{\mathcal{N}} \rho(\boldsymbol{m}^* - I\dot{\boldsymbol{w}}) \; d\mathcal{N} ,$$

and, under an appropriate smoothness assumption,

$$\boldsymbol{M}^* = \boldsymbol{M}^{*\alpha}\nu_\alpha, \tag{55}$$

$$\boldsymbol{M}^{*\alpha}|_\alpha + \rho\boldsymbol{m}^* - \boldsymbol{H}^* = \rho I\dot{\boldsymbol{w}}. \tag{56}$$

Equation (56) describes the balance of director momentum. $\boldsymbol{H}^*$ is variously called the intrinsic director couple (Naghdi, 1972) or the across-the-thickness stress resultant (Simo and Fox, 1987).

From the fundamental axiom, we obtain

(i) **Balance of linear momentum**

$$\boldsymbol{N}^\alpha|_\alpha + \rho\boldsymbol{f} = \rho\dot{\boldsymbol{v}}, \tag{57}$$

(ii) **Balance of moment of momentum**

$$\begin{aligned} (\boldsymbol{d} \times \boldsymbol{M}^{*\alpha})|_\alpha + \boldsymbol{d} \times \rho\boldsymbol{m}^* + \boldsymbol{a}_\alpha \times \boldsymbol{N}^\alpha = & \\ \boldsymbol{d} \times \rho I\dot{\boldsymbol{w}}, & \end{aligned} \tag{58}$$

where by definition $\boldsymbol{N} = \boldsymbol{N}^\alpha\nu_\alpha$ and $\boldsymbol{M}^* = \boldsymbol{M}^{*\alpha}\nu_\alpha$. Substituting Equation (56) in (58) yields

$$\boldsymbol{d} \times \boldsymbol{H}^* = -(\boldsymbol{d}|_\alpha \times \boldsymbol{M}^{*\alpha} + \boldsymbol{a}_\alpha \times \boldsymbol{N}^\alpha), \tag{59}$$

and finally, replacing Equations (56) and (57) in (52), we obtain

$$< \boldsymbol{f}_t^e + \boldsymbol{f}_t^i, \boldsymbol{\eta} > = \iint_{\mathcal{N}} [\boldsymbol{N}^\alpha \cdot \delta\boldsymbol{r}|_\alpha + \boldsymbol{M}^{*\alpha} \cdot \delta\boldsymbol{d}|_\alpha + \boldsymbol{H}^* \cdot \delta\boldsymbol{d}] \; d\mathcal{N} . \tag{60}$$

Equations (56), (57) and appropriate constitutive relations for $\boldsymbol{N}^\alpha$, $\boldsymbol{M}^{*\alpha}$ and $\boldsymbol{H}^*$ form a complete set of equations determining the motion of the Cosserat surface. Equation (59) is regarded by Naghdi as a restriction on the admissible constitutive relations. Clearly, the moment-of-momentums balance Equation (58) is identically satisfied.

Relationship between the internal forces

The membrane stresses $\boldsymbol{N}^\alpha$ in both models are defined identically. From definitions (54.c-d) it follows that

$$\begin{aligned} P^\alpha &= \boldsymbol{M}^{*\alpha}\cdot\hat{\boldsymbol{d}}, \\ \boldsymbol{M}^\alpha &= D\tilde{\boldsymbol{M}}^{*\alpha} = D(\hat{\boldsymbol{d}}\times\boldsymbol{M}^{*\alpha})\times\hat{\boldsymbol{d}}, \\ \boldsymbol{M}^{*\alpha} &= \frac{1}{D}\boldsymbol{M}^\alpha + P^\alpha\hat{\boldsymbol{d}} = \frac{1}{D}M^{\beta\alpha}\tilde{\boldsymbol{a}}_\beta + P^\alpha\hat{\boldsymbol{d}}, \end{aligned} \tag{61}$$

where $\tilde{\boldsymbol{a}}_\beta = \boldsymbol{a}_\beta - (\boldsymbol{a}_\beta\cdot\hat{\boldsymbol{d}})\hat{\boldsymbol{d}}$. Equations (61) imply that once constitutive relations for $M^{\alpha\beta}$ and P^α are proposed then constitutive Equations for $\boldsymbol{M}^{*\alpha}$ may be obtained, and vice versa.

Remark III: From Equations (61) and (31), the relationship between $\boldsymbol{M}^{*\alpha}$ and the generalized deformations and internal forces of the proposed model may be readily established. Since

$$\begin{aligned} \boldsymbol{M}^{*\alpha}\cdot\boldsymbol{a}_\beta &= \frac{1}{D}M^{\mu\alpha}\tilde{\boldsymbol{a}}_\mu\cdot\boldsymbol{a}_\beta + P^\alpha a_{\beta 3} \\ &= \frac{1}{D}M^{\mu\alpha}(a_{\mu\beta} - a_{3\mu}a_{3\beta}) + P^\alpha a_{\beta 3}, \end{aligned}$$

it follows that

$$\begin{aligned} \boldsymbol{M}^{*\alpha}\cdot\boldsymbol{a}_\beta = {} & \frac{1}{\Delta + D_0}M^{\mu\alpha}[(2\epsilon_{\mu\beta} + A_{\mu\beta}) \\ & - (\gamma_\mu + \boldsymbol{A}_\mu\cdot\hat{\boldsymbol{d}}_0)(\gamma_\beta + \boldsymbol{A}_\beta\cdot\hat{\boldsymbol{d}}_0)] \\ & + P^\alpha(\gamma_\beta + \boldsymbol{A}_\beta\cdot\hat{\boldsymbol{d}}_0), \end{aligned} \tag{62}$$

where $\boldsymbol{A}_\alpha$ and $\hat{\boldsymbol{d}}_0$ are respectively the base vectors $\boldsymbol{a}_\alpha$ and the unit director field $\hat{\boldsymbol{d}}$ at the reference surface $\mathcal{N}_0$.

In general, the same conclusions hold conversely. This is clear from Equations (61) and the fact that whatever generalized deformations are defined for a Cosserat surface, the current configuration is determined, from the reference configuration, to within a Euclidean mapping. The last remark implies that $\boldsymbol{M}^{*\alpha}$, $\boldsymbol{a}_\alpha$ and $\hat{\boldsymbol{d}}$ are determined up to an orthogonal transformation, and clearly constitutive equations for P^α and $M^{\alpha\beta}$ may be established from an appropriate constitutive equation for $\boldsymbol{M}^*$ or its components. ■

From Equation (59) and the decomposition $\boldsymbol{H}^* = \tilde{\boldsymbol{H}}^* + (\boldsymbol{H}^*\cdot\hat{\boldsymbol{d}})\hat{\boldsymbol{d}}$, where $\tilde{\boldsymbol{H}}^* = (\hat{\boldsymbol{d}}\times\boldsymbol{H}^*)\times\hat{\boldsymbol{d}}$, it follows that

$$D\tilde{\boldsymbol{H}}^* = -(\boldsymbol{d}|_\alpha\times\boldsymbol{M}^{*\alpha})\times\hat{\boldsymbol{d}} - (\boldsymbol{a}_\alpha\times\boldsymbol{N}^\alpha)\times\hat{\boldsymbol{d}}. \tag{63}$$

Clearly,

$$\begin{aligned} & (\boldsymbol{d}|_\alpha\times\boldsymbol{M}^{*\alpha})\times\hat{\boldsymbol{d}} \\ &= [(D|_\alpha\hat{\boldsymbol{d}} + D\hat{\boldsymbol{d}}|_\alpha).\hat{\boldsymbol{d}}]\,\boldsymbol{M}^{*\alpha} \\ &\quad - (\boldsymbol{M}^{*\alpha}\cdot\hat{\boldsymbol{d}})(D|_\alpha\hat{\boldsymbol{d}} + D\hat{\boldsymbol{d}}|_\alpha) \\ &= D|_\alpha\tilde{\boldsymbol{M}}^{*\alpha} - (\boldsymbol{M}^{*\alpha}\cdot\hat{\boldsymbol{d}})\,D\hat{\boldsymbol{d}}|_\alpha, \end{aligned}$$

and after substituting (61.a-b) in the above equation, we obtain

$$\begin{aligned} (\boldsymbol{d}|_\alpha\times\boldsymbol{M}^{*\alpha})\times\hat{\boldsymbol{d}} &= \frac{1}{D}D|_\alpha\boldsymbol{M}^\alpha - DP^\alpha\hat{\boldsymbol{d}}|_\alpha \\ &= (\frac{1}{D}D|_\alpha M^{\beta\alpha} - DP^\alpha\lambda^\beta_{.\alpha})\tilde{\boldsymbol{a}}_\beta. \end{aligned} \tag{64}$$

From Equation (39) it follows that

$$(\boldsymbol{a}_\alpha\times\boldsymbol{N}^\alpha)\times\hat{\boldsymbol{d}} = -(Q^\beta_{eff} + \lambda^\beta_{.\alpha}M^{3\alpha})\tilde{\boldsymbol{a}}_\beta, \tag{65}$$

replacing (64) and (65) in (63) leads to

$$\begin{aligned} D\tilde{\boldsymbol{H}}^* = {} & (Q^\beta_{eff} - \frac{1}{D}D|_\alpha M^{\beta\alpha})\tilde{\boldsymbol{a}}_\beta \\ & + (DP^\alpha + M^{3\alpha})\lambda^\beta_{.\alpha}\tilde{\boldsymbol{a}}_\beta. \end{aligned} \tag{66}$$

The axial component $\boldsymbol{H}^{*\alpha}\cdot\hat{\boldsymbol{d}}$ may be obtained from the internal virtual-power expression (60) and (62). Since

$$\boldsymbol{H}^*\cdot\delta\boldsymbol{d} = D\tilde{\boldsymbol{H}}^*\cdot\delta\hat{\boldsymbol{d}} + (\boldsymbol{H}^*\cdot\hat{\boldsymbol{d}})\delta D,$$

and

$$\begin{aligned} \boldsymbol{M}^{*\alpha}\cdot\delta\boldsymbol{d}|_\alpha &= (\boldsymbol{M}^{*\alpha}\cdot\hat{\boldsymbol{d}})\,\delta D|_\alpha + (\tilde{\boldsymbol{M}}^{*\alpha}\cdot\hat{\boldsymbol{d}}|_\alpha)\,\delta D \\ &\quad + D|_\alpha\tilde{\boldsymbol{M}}^{*\alpha}\cdot\delta\hat{\boldsymbol{d}} + D\tilde{\boldsymbol{M}}^{*\alpha}\cdot\delta\hat{\boldsymbol{d}}|_\alpha \\ &\quad + D(\boldsymbol{M}^{*\alpha}\cdot\hat{\boldsymbol{d}})\hat{\boldsymbol{d}}\cdot\delta\hat{\boldsymbol{d}}|_\alpha \\ &= P^\alpha\delta D|_\alpha + \boldsymbol{M}^\alpha\cdot\delta\hat{\boldsymbol{d}}|_\alpha \\ &\quad + (\frac{1}{D}D|_\alpha\boldsymbol{M}^\alpha - DP^\alpha\hat{\boldsymbol{d}}|_\alpha)\cdot\delta\hat{\boldsymbol{d}} \\ &\quad + (\tilde{\boldsymbol{M}}^{*\alpha}\cdot\hat{\boldsymbol{d}}|_\alpha)\delta D, \end{aligned}$$

where the identity $\hat{\boldsymbol{d}}\cdot\delta\hat{\boldsymbol{d}}|_\alpha = -\hat{\boldsymbol{d}}|_\alpha\cdot\delta\hat{\boldsymbol{d}}$ was used, it follows that

$$\begin{aligned} \boldsymbol{H}^*\cdot\delta\boldsymbol{d} + \boldsymbol{M}^{*\alpha}\cdot\delta\boldsymbol{d}|_\alpha = {} & \boldsymbol{M}^\alpha\cdot\delta\hat{\boldsymbol{d}}|_\alpha + P^\alpha\delta D|_\alpha \\ & + (\boldsymbol{H}^*\cdot\hat{\boldsymbol{d}} + \tilde{\boldsymbol{M}}^{*\alpha}\cdot\hat{\boldsymbol{d}}|_\alpha)\,\delta D \\ & + (D\tilde{\boldsymbol{H}}^* + \frac{1}{D}D|_\alpha\boldsymbol{M}^\alpha - DP^\alpha\hat{\boldsymbol{d}}|_\alpha)\cdot\delta\hat{\boldsymbol{d}}. \end{aligned}$$

From Equations (63) and (64), clearly

$$\begin{aligned} & \left(D\tilde{\boldsymbol{H}}^* + \frac{1}{D}D|_\alpha\boldsymbol{M}^\alpha - DP^\alpha\hat{\boldsymbol{d}}|_\alpha\right)\cdot\delta\hat{\boldsymbol{d}} = \\ & \quad - (\boldsymbol{a}_\alpha\times\boldsymbol{N}^\alpha)\times\hat{\boldsymbol{d}}\cdot\delta\hat{\boldsymbol{d}}, \end{aligned}$$

and finally,

$$\begin{aligned} \boldsymbol{H}^*\cdot\delta\boldsymbol{d} + \boldsymbol{M}^{*\alpha}.\delta\boldsymbol{d}|_\alpha = {} & \boldsymbol{M}^\alpha\cdot\delta\hat{\boldsymbol{d}}|_\alpha + P^\alpha\delta D|_\alpha \\ & + (\boldsymbol{H}^*\cdot\hat{\boldsymbol{d}} + \tilde{\boldsymbol{M}}^{*\alpha}\cdot\hat{\boldsymbol{d}}|_\alpha)\delta D - (\boldsymbol{a}_\alpha\times\boldsymbol{N}^\alpha)\times\hat{\boldsymbol{d}}\cdot\delta\hat{\boldsymbol{d}}. \end{aligned}$$

If we define

$$H = \boldsymbol{H}^*\cdot\hat{\boldsymbol{d}} + \tilde{\boldsymbol{M}}^{*\alpha}\cdot\hat{\boldsymbol{d}}|_\alpha \tag{67}$$

then the internal virtual-power expression (60) reduces to (49). Obviously,

$$\boldsymbol{H}^*\cdot\hat{\boldsymbol{d}} = H - \frac{1}{D}\boldsymbol{M}^\alpha\cdot\hat{\boldsymbol{d}}|_\alpha, \tag{68}$$

or in components,

$$\boldsymbol{H}^* \cdot \hat{\boldsymbol{d}} = H - M^{\mu\alpha}\lambda^{\beta}_{.\alpha}(a_{\mu\beta} - a_{\mu3}a_{\beta3}). \tag{69}$$

Equations (66) and (69) finally lead to

$$\begin{aligned}\boldsymbol{H}^* &= \frac{1}{D}\left(Q^{\beta}_{eff} - \frac{1}{D}D|_{\alpha}M^{\beta\alpha}\right)\tilde{\boldsymbol{a}}_{\beta} \\ &+ \left(P^{\alpha} + \frac{1}{D}M^{3\alpha}\right)\lambda^{\beta}_{.\alpha}\tilde{\boldsymbol{a}}_{\beta} \\ &+ \left[H - M^{\mu\alpha}\lambda^{\beta}_{.\alpha}(a_{\mu\beta} - a_{\mu3}a_{\beta3})\right]\hat{\boldsymbol{d}}.\end{aligned} \tag{70}$$

Remark IV:

For a Cosserat surface of inextensible directors,

$$D = \|\boldsymbol{d}\| = 1, \qquad D|_{\alpha} = 0,$$

Equation (70) reduces to

$$\begin{aligned}\boldsymbol{H}^* &= [Q^{\beta}_{eff} + (P^{\alpha} + M^{3\alpha})\lambda^{\beta}_{.\alpha}]\,\tilde{\boldsymbol{a}}_{\beta} \\ &+ [H - M^{\mu\alpha}\lambda^{\beta}_{.\alpha}(a_{\mu\beta} - a_{\mu3}a_{\beta3})]\,\hat{\boldsymbol{d}}.\end{aligned}$$

Finally the internal force $(P^{\alpha}\hat{\boldsymbol{d}}|_{\alpha} + H\hat{\boldsymbol{d}})$ constitutes a reaction in the restricted model of inextensible directors and hence only the component $(\boldsymbol{H}^* - H\hat{\boldsymbol{d}} - P^{\alpha}\hat{\boldsymbol{d}}|_{\alpha})$ of $\boldsymbol{H}^*$ is determined from the motion of the Cosserat surface. ■

We observe that both Naghdi's and the proposed model assume essentially the same external and inertial force systems. The apparent differences should be regarded solely in terms of different physical interpretations of the vector fields involved. The fundamental fact is that both theories account for the same basic mechanisms. Regardless of the differences in definitions of the internal force systems, the internal virtual power associated with a given virtual velocity field is the same in both theories. This is consistent with the principle of virtual power and naturally follows from the equality of the external virtual power under appropriate identifications of the vector fields involved.

The relationship between the internal forces of both models was studied in detail in this section. As is seen, once constitutive equations for one model are postulated, corresponding constitutive equations for the other model may be directly obtained. This clearly shows the equivalence between both formulations.

One of the basic advantages of the proposed model is its relative simplicity compared with the developments of Naghdi. The necessity of considering restrictions on constitutive relations is completely eliminated and for elastostatic problems there is an uncoupling between the motion of the reference surface and the orientation of the director field with the deformation (changes in length) of the directors. Of course this uncoupling holds as long as the same is true with respect to the constitutive relations but clearly no such uncoupling is evident in Naghdi's equations whatever constitutive equations are used.

CONCLUSIONS

The equations of motion for a Cosserat surface were derived by means of the method of virtual power. Both the model with inextensible directors and its generalization to account for deformable directors were analyzed.

The equations derived for the Cosserat surface with inextensible directors coincides with the ones derived from the three-dimensional theory by Simo and Fox (1987). Our derivation shows the effectiveness of the method of virtual power in deriving such equations through a complete two-dimensional theory.

In the extension of the model to account for deformable directors a new set of equations is proposed. Besides the equations of linear and moment of momentum, one additional scalar equation is derived. This equation replaces the director-momentum equation of Naghdi and therefore eliminates the necessity of dealing with constitutive restrictions. One of the advantages of the proposed model is its direct connection with the constrained Cosserat surface of inextensible directors. The generalized deformations and internal forces are carried over invariantly. So far, most computer implementations of Cosserat surfaces have been restricted to the constrained model. The equations proposed here might furnish an efficient setting for the extension of those algorithms.

Clearly, some constitutive relations and a connection with the results of the asymptotic expansion of the three-dimensional equations are still needed in order to assess the usefulness of the theory presented here. The connection with the three-dimensional asymptotic expansion should be done first to identify the basic force systems in our model with equivalent resultants from the three-dimensional theory, and second to obtain constitutive relations that truly represent—to be sure, to the degree of approximation expected from a two-dimensional theory—the properties of the shell as a three-dimensional continuum. Since our objective was basically restricted to the derivation of the equations by means of the method of virtual power, this task is beyond the scope of this paper.

A final remark should be given with respect to the derivation of the equations for the Cosserat surface of deformable directors. As seen, the application of the fundamental axiom of the method of virtual power is alone not enough to solve the indeterminacies of the extended model. Even though the extension is straightforward, it does not truly reflect a pure application of the method of virtual power. The derivation should appropriately be regarded as an extension of the method of virtual power which reflects the three-dimensional nature of the additional force systems introduced in the model.

Jump phenomena, bifurcations, and chaos in a pressure loaded spherical cap under harmonic excitation

Paulo Batista Gonçalves

Department of Civil Engineering, Pontifical Catholic University
22453-900 Rio de Janeiro, Brazil

This paper investigates the dynamic non-linear behaviour of a pre-loaded shallow spherical shell under a harmonic excitation. For this, the Marguerre partial differential equations of motion for an imperfect, pre-loaded cap is reduced to a finite degree of freedom system using the Galerkin method. The displacements and stress functions are described by a linear combination of Bessel functions and modified Bessel functions that satisfy all the relevant boundary and continuity conditions. The resulting differential equations of motion are solved by the Galerkin-Urabe procedure, or, alternatively, by numerical integration. To study the response of the shallow cap under harmonic excitation, phase plane portraits, Poincaré maps, resonance curves, and bifurcation diagrams are plotted for a number of loading conditions. Results indicate that, for static load levels between the upper and lower limit point loads, the shell may display jumps due to the presence of competing potential wells and the presence of non-linear resonance curves within each well. Additionally, different physical situations are identified in which period-doubling phenomena and chaos can be observed.

INTRODUCTION

Due mainly to the discovery of chaotic motions in physical systems governed by deterministic equations, in a remarkably short time, the field of non-linear dynamics, as a topic of pure and applied mathematics, has experienced considerable development (Palis and de Melo, 1982; Arnold, 1982; Guckenheimer and Holmes, 1983; Wiggins, 1990). Engineering sciences have also benefited from these developments in that many non-linear dynamical problems have been treated and new classes of phenomena have been identified. Research in civil and mechanical engineering is well documented in the books of Thompson and Stewart (1987), Moon (1987) and Kapitaniak (1991), and in the review articles by Nayfeh and Balachandran (1989) and Holmes (1990). A detailed analysis of non-linear engineering problems, using traditional perturbation methods, can be found in Nayfeh and Mook (1979).

The consideration of non-linear effects on the modelling of structural systems is of particular concern in the static and dynamic analysis of structural elements liable to buckling. A particular feature of these systems is that, as parameters are changed, the stability of the equilibrium points can change as well as the number of equilibrium points (Thompson and Hunt, 1984). The existence of competing static equilibrium positions brings out, when the system is subjected to dynamic loads, a whole range of phenomena that are not found in linear systems. These include jumps, subharmonic and super-harmonic oscillations, period-multiplying bifurcations, co-existing small and large amplitude oscillations, combination resonances, modal interaction and chaotic motions (Nayfeh and Mook, 1979; Thompson and Stewart, 1987).

Among various non-linear problems analysed in literature, thin elastic shells have received a great deal of attention due to its complex non-linear behaviour. Analytical and experimental investigations of cylindrical and spherical shells have indicated that thin shells, when subjected to dynamic loads, may display a wealth of non-linear phenomena including chaotic motions (Chen and Babcock, 1975; Yasuda and Kushida, 1984; Nayfeh and Raouf, 1987; Raouf and Nayfeh, 1989). This is due to the presence of strong quadratic and cubic geometric non-linearities in the equations of motion. Nevertheless, the non-linear dynamic behaviour of thin shells is not completely understood and new phenomena are still coming to light.

Shallow spherical caps when subjected to static pressure loading often exhibit a highly non-linear response and may be subjected to either limit-point instability or bifurcational instability with unstable post-buckling response. As shown by Gonçalves and Croll (1992), the degree of non-linearity and the loading carrying capacity of these shell components are very sensitive to the geometric imperfections that are often induced during fabrication and installation procedures. For certain practical ranges of load levels and initial geometric imperfections, these shells may exhibit more than one point attractor. Also, the combined effects of initial geometric imperfections and compressive stresses will change substantially the natural frequencies and alter, consequently, the dynamic response and stability characteristics of these systems (Gonçalves, 1991). As a result, it is expected that pressure loaded imperfect spherical caps under dynamic loads may display complex dynamic phenomena such as those described earlier.

Although the effects of geometric imperfections on static buckling resistance of pressure loaded spherical caps have been the topic of numerous investigations in the past few decades (e. g. Budiansky, 1959; Huang, 1964, Yamada et al., 1983; Gonçalves and Croll, 1992), most of the studies of the linear and non-linear vibrations of these shells have, however, been limited to perfect (and usually unloaded) shells (e. g. Archer, 1962; Evesen and Evan-Iwanowski, 1967; Grossman et al., 1969; Yasuda and Kushida, 1984). In the present work a new non-linear modelling for the axisymmetric dynamic behaviour of clamped shallow spherical shells is presented, which considers the combined effects of pressure loading and geometric imperfections on the vibration characteristics and non-linear response of the cap. The basic approach in this work is to solve

part of "MECHANICS PAN-AMERICA 1993" edited by MRM Crespo da Silva and CEN Mazzilli
ASME Reprint No AMR134

the dynamic version of the fourth-order Marguerre equations by the Galerkin method. An accurate solution described by a linear combination of Bessel functions and modified Bessel functions based on the free vibration modes of the unloaded perfect cap is used to determine the non-linear pre-stress state of the imperfect cap and to examine its linear and non-linear vibration characteristics along the pre- and post-buckling paths. Each term of the modal expansions satisfies all the relevant boundary and continuity conditions.

Recently monographs on algorithms for simulating non-linear dynamical systems were written by Seydel (1988) and Parker and Chua (1989). Also, software packages are available for the analysis of non-linear differential equations, with emphasis on chaotic behaviour (Parker and Chua, 1989; Yorke, 1990). In order to study the non-linear behaviour of the cap, routines, based on these references, were used to integrate numerically the equations of motion and record time histories of the response, phase portraits, Poincaré maps, stable and unstable fixed points, Lyapunov exponents and bifurcation diagrams. Results show that, for static load levels between the upper and lower limit point loads, the shell may display jumps due to the presence of competing potential wells and the presence of non-linear resonance curves within each well. Additionally, different physical situations are identified in which period-doubling phenomena and chaos can be observed.

BASIC EQUATIONS

The geometry of a uniformly loaded shallow spherical cap with clamped edge conditions is presented in Fig. 1, where R, a, H and h are the principal radius of curvature of the sphere, the base radius of the cap, the rise of the mid-surface at the apex and the shell thickness, respectively. The polar co-ordinate system in the base plane is defined by r and θ, and the external uniform pressure distributed over the surface of the shell is denoted by q.

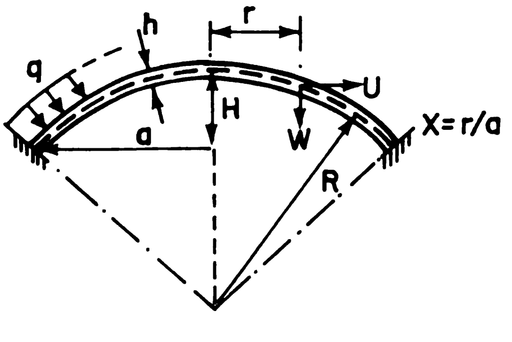

FIG 1. Shell geometry, displacements and co-ordinate system

Within the framework of shallow shell theory ($H/a < 0.25$), the tangential forces and displacements can be taken to be their projections onto the base plane of the shell. The basic equations governing large deformations, but small strains, of shallow spherical caps were formulated by Marguerre (1939). In the case of axisymmetric static deformations of a thin imperfect cap, the governing equations may be expressed in the non-dimensional form as

$$\nabla^4 w_s = \lambda^2\alpha^{1/2}\nabla^2 f_s + Q\frac{4\lambda^4}{\alpha^{1/2}} + \frac{\alpha}{x}\{f_{s,x}(w_{s,x}+\hat{w}_{,x})\} \tag{1.a}$$

$$\nabla^4 f_s = -\lambda^2\alpha^{-1/2}\nabla^2 w_s - \frac{1}{x}\{w_{s,x}w_{s,xx} + (\hat{w}_{,x}w_{s,x})_{,x}\} \tag{1.b}$$

where $()_{,x} = \partial/\partial x()$, $\alpha = 12(1-\nu^2)$ and λ is a geometrical parameter described by

$$\lambda = \alpha^{1/4}a/\sqrt{Rh} \tag{2}$$

The non-dimensional radial co-ordinate x, the vertical displacement w_s, imperfection shape $\hat{w}$, stress function f_s, and load parameter Q are related to the corresponding physical quantities by

$$x = \frac{r}{a} \qquad w_s = \frac{W_s}{h} \qquad \hat{w} = \frac{\hat{W}}{h}$$

$$f_s = \frac{F_s}{Eh^3} \qquad Q = \frac{q}{q_{cl}} \tag{3}$$

where $q_{cl} = 2E(h/R)^2/\sqrt{3(1-\nu^2)}$ is the classical buckling pressure of a complete spherical shell, E is the Young's modulus and ν is the Poisson's ratio.

The static stress resultants, couples and non-linear strain-displacement relations are given by

$$\frac{a^2N_r}{Eh^3} = \frac{1}{x}f_{s,x}$$

$$\frac{a^2N_\theta}{Eh^3} = f_{s,xx}$$

$$\frac{12(1-\nu^2)a^2M_r}{Eh^4} = \frac{1}{x}w_{s,x} + \nu w_{s,xx}$$

$$\frac{12(1-\nu^2)a^2M_\theta}{Eh^4} = w_{s,xx} + \frac{\nu}{x}w_{s,x}$$

$$\varepsilon_r = \frac{h}{a}u_{s,x} + \left(\frac{h}{a}\right)^2\left[\hat{w}_{,x}w_{s,x} + \frac{1}{2}w_{s,x}^2\right]$$

$$\varepsilon_\theta = \frac{h}{a}\frac{u_s}{x} \tag{4}$$

where $u_s(= U_s/h)$ is the non-dimensional displacement in the radial direction.

The boundary conditions at the clamped edge $x = 1$ of the shallow shell are

$$w_s = 0 \qquad w_{s,x} = 0 \qquad u_s = f_{s,xx} - \frac{\nu}{x}f_{s,x} = 0 \tag{5}$$

When a uniform static pressure is applied to the cap, it yields a basic static geometrically non-linear state of displacements and stresses. To represent the basic static axisymmetric response, the displacement w_s and the stress function f_s are assumed in the form

$$w_s(x) = \sum_{i=1}^{N} W_{0i}\phi_i(x) \tag{6.a}$$

$$f_s(x) = \sum_{i=1}^{N} F_{si}\psi_i(x) \tag{6.b}$$

where each separate generalized function

$$\phi_i(x) = J_0(K_i x) + \frac{J_1(K_i)}{I_1(K_i)} I_0(K_i x) - \left[J_1(K_i)\frac{I_0(K_i)}{I_1(K_i)} + J_0(K_i)\right] \tag{7.a}$$

$$\psi_i(x) = J_0(K_i x) - \frac{J_1(K_i)}{I_1(K_i)} I_0(K_i x) + \frac{K_i^2(\lambda^4 + K_i^4)}{4\lambda^4}\left[J_1(K_i)\frac{I_0(K_i)}{I_1(K_i)} + J_0(K_i)\right]x^2 \tag{7.b}$$

exactly satisfies the clamped boundary conditions at x=1 as well as the continuity requirements of displacements and stresses at the centre of the shell (x=0).

In equations (7.a) and (7.b) J_0 and J_1 are Bessel functions, and I_0, and I_1 modified Bessel functions of the first kind, and $K_n (0 < K_1 < K_2 < \ldots)$ are the roots of the equation

$$[J_0(K_n)I_1(K_n) + I_0(K_n)J_1(K_n)] \times K_n\left[\frac{\lambda^4 + K_n^4}{\lambda^4}\frac{(1-\nu)}{2} - 1\right] + 2J_1(K_n)I_1(K_n)(1+\nu) = 0 \tag{8}$$

It might be observed that the generalised functions (7.a) and (7.b) are also the linear vibration modes of an unloaded clamped shallow spherical shell (Yasuda and Kushida, 1984).

To facilitate a convenient representation of axisymmetric geometric imperfections of an arbitrarily specified shape and consequently allow an efficient modal analysis of the imperfect shell, a Fourier-Bessel series is used to describe the "general" imperfection, $\hat{w}(x)$. This Fourier-Bessel series may be written as

$$\hat{w}(x) = \hat{W}\left[\sum_{i=1}^{N} \hat{w}_i\phi_i(x) / \mathrm{MAX}\left(\sum_{i=1}^{N} \hat{w}_i\phi_i(x)\right)\right] \tag{9}$$

where $\hat{w}_i$ is the amplitude of the ith harmonic and $\phi_i(x)$ is the modal function given by (7.a). Note that $\{\phi_i(x)\}$ represents a complete set of orthogonal functions in [0,1] (Yasuda and Kushida, 1984).

For convenience, the expression between brackets in (9) is written in such a way that its maximum value is always equal to one. Consequently the magnitude and sign of the maximum amplitude will be given by $\hat{W}$.

Substituting expressions (6) and (9) into equations (1.a) and (1.b) and applying a Galerkin minimisation procedure one obtains a set of 2N non-linear algebraic equations characterizing the static behaviour of the cap. The expressions (7.a) and (7.b) are used as the weighting functions in this Galerkin procedure. These non-linear equations are unfortunately too long to be presented here; the interested reader will find them in Gonçalves and Croll (1990). These algebraic non-linear equations are solved by the Newton-Raphson method. The solution procedure is implemented in such a way that, without manual intervention, if convergence of the Newton-Raphson scheme fails in one step, the programme returns to the previous step and then chooses a new control parameter and modifies the Jacobian matrix accordingly.

In the further analysis the dynamic behaviour of the cap around the axisymmetric non-linear static state will be considered. For this, a dynamic perturbation is superimposed on the basic static state. In this case one has

$$W_p(x,t) = \hat{w}(x) + w_s(x) + w(x,t)$$
$$F_p(x,t) = f_s(x) + f(x,t) \tag{10}$$

where $w(x,t)$ denotes the incremental displacement component and $f(x,t)$, the corresponding incremental stress function.

Using expressions (10) and the dimensionless parameters, one obtains the following non-dimensional equation of motion

$$\nabla^4 w + w_{,\tau\tau} + \bar{c}w_{,\tau} = \lambda^2\alpha^{1/2}\nabla^2 f + \frac{\alpha}{x}\{f_{,x}(\hat{w} + w_s + w)_{,x} + f_{s,x}w_{,x}\}_{,x} + \frac{4\lambda^4}{\alpha^{1/2}}A_f\sin(\Omega\tau) \tag{11.a}$$

and the associated compatibility equation

$$\nabla^4 f = -\lambda^2\alpha^{-1/2}\nabla^2 w - \frac{1}{x}\{w_{,x}w_{,xx} + [(\hat{w}_{,x} + w_{s,x})w_{,x}]_{,x}\} \tag{11.b}$$

where $\tau = t/\gamma$, $\bar{c} = \gamma c/\rho h$, $\Omega = \gamma\omega$, $\gamma^2 = (\alpha a^4\rho/Eh^2)$, ρ is the mass density, t is time, ω is the driving frequency and c is the damping coefficient.

The incremental state is assumed in the separable form

$$w(x,t) = \sum_{i=1}^{N} W_i(t)\phi_i(x) \tag{12.a}$$

$$f(x,t) = \sum_{i=1}^{N} F_i(t)\psi_i(x) \tag{12.b}$$

The substitution of expressions (12) into equations (11.a) and (11.b), the use of the complete equations for the basic non-linear static state, and the application of the Galerkin method yields the required second-order ordinary differential equations of motion. To study the non-linear behaviour of the cap, these equations are reduced to a set of first order differential equations which are numerically integrated using the fourth-order Runge-Kutta method with double precision.

Alternatively, approximating in (12) the temporal functions $W_i(t)$ and $F_i(t)$ by

$$W_i(t) = W_i\cos(\omega t) + W_c \tag{13.a}$$

$$F_i(t) = F_{1i}\cos(\omega t) + F_{2i}(\cos(\omega t))^2 + F_c \tag{13.b}$$

substituting the resulting expressions in (11) and finally applying the Galerkin-Urabe method (Urabe, 1965), one obtains the required modal dynamic equations for the imperfect loaded cap. Neglecting non-linear terms in w and f a system of homogeneous linear algebraic equations is obtained. The solution of the resulting eigenvalue problem gives the vibration modes and the relationship between the load parameter and the square of the corresponding natural frequencies. The solution of the eigenvalue problem is obtained b[illegible] n of

Rutishauser's algorithm (Rutishauser, 1958). For the evaluation of the Bessel functions and modified Bessel functions, the polynomial expansions presented by Abramowitz and Stegun (1964) were used.

The constant terms in equations (13) are added due to the presence of quadratic non-linearity.

RESULTS AND DISCUSSION

In each of the non-linear paths reported in this section, care has been taken to achieve convergence through the use of a suitable number of terms N in the expansions (6) and (12). The number of terms N necessary to attain convergence to within 1% increases as the value of the geometrical parameter λ increase and, consequently, the waviness of the static solution and vibration modes increases.

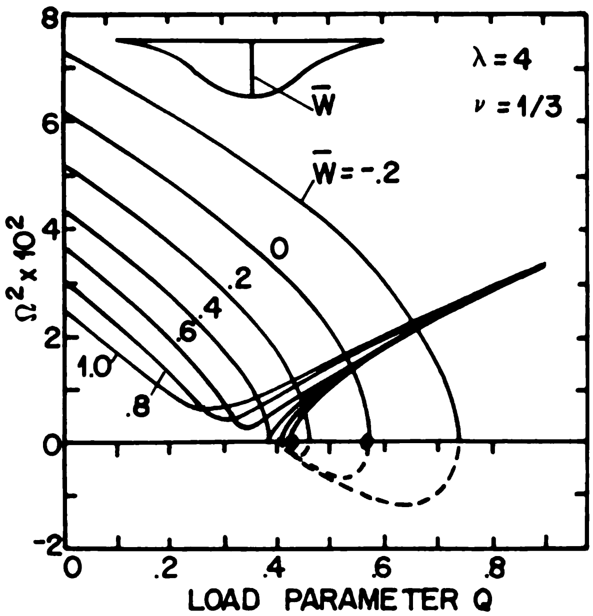

FIG 2. The square of the frequency versus applied load for the shell.

Figure 2 shows the relationship between the square of the frequency parameter Ω^2 ($\Omega = \gamma\omega$) associated with the lowest natural frequency and the load parameter Q for a shell with $\lambda = 4$ and $\nu = 1/3$. Figure 3 shows the variation of the load parameter Q with the central deflection of the cap $W_s(0)$. The dashed curves in these figures correspond to unstable regions. In Figs 2 and 3 the imperfection is taken in the form of the first vibration mode of the unloaded perfect cap (i=1, $K_1 = 4.3461$ in the modal expansion (9)). These results typify the effects of the non-linear pre-stress state and initial geometric imperfections on the axisymmetrical natural frequencies of the cap. This influence depends on the shape, magnitude and sign of the imperfections. In the pre-buckling region positive imperfections decrease the minimum frequency and the upper limit point load Q_U, whereas negative imperfections increase these two parameters. For relatively small positive and for negative values of $\hat{W}$ there is a gradual variation of the frequency parameter up to the neighbourhood of the buckling load after which the natural frequency begins to drop off sharply to zero as the buckling load is approached; similar behaviour is observed along the post-buckling path. These results and conclusions are typical of shallow caps with $\lambda \leq 5.5$ (Gonçalves, 1991; Gonçalves and Croll, 1992).

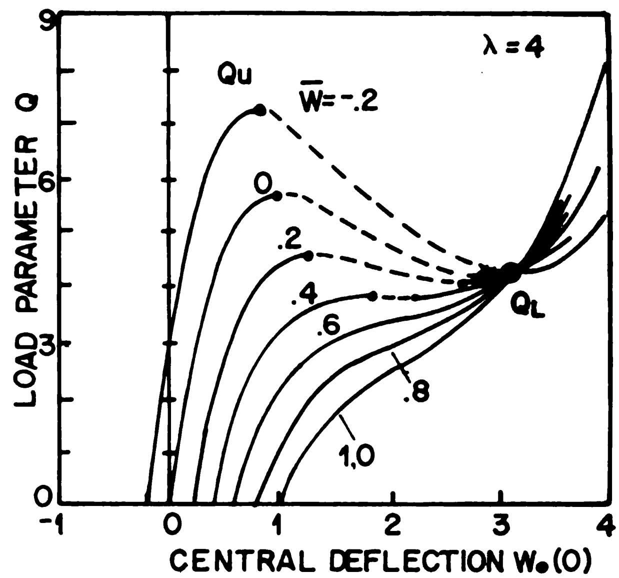

FIG 3. Non-linear equilibrium paths of perfect and imperfect caps.

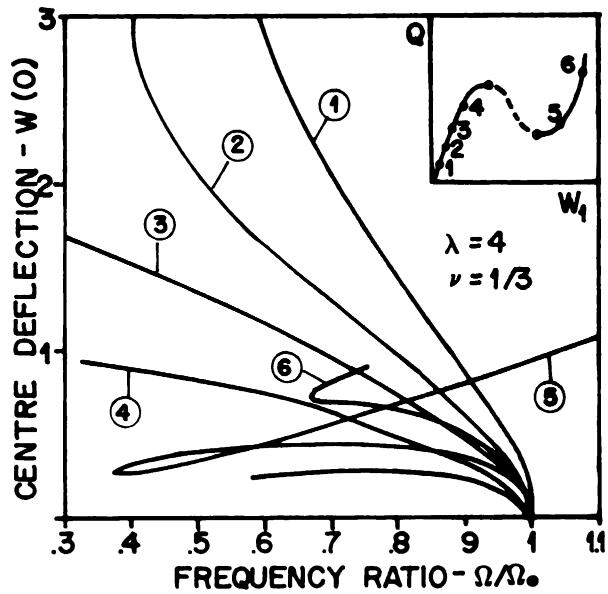

FIG 4. Influence of the static pre-stress state on the non-linear vibrations of the cap

The effect of the non-linear static stress state on the non-linear free-vibration frequencies is illustrated in Fig 4 where the displacement at the centre of the cap, $W(0)$, is plotted as a function of the frequency ratio Ω/Ω_0, for different load levels. Here Ω_0 is the fundamental free vibration frequency of the cap. Curves 1 to 4 are associated to increasing load levels along the pre-buckling path while curves 5 and 6 are related to post-buckling configurations. All response curves exhibit initial softening trends. As expected, the degree of softening increases with load along the pre-buckling path and decreases with load along the post buckling path. The curves associated with post-buckling configurations exhibit a high degree of non-linearity, presenting sometimes looping characteristics.

It is well known, both theoretically and experimentally, that for perfect and imperfect caps with $\lambda \leq 5.5$, the buckling pattern is always axisymmetric and the load-displacement curves are smooth both before and after buckling (e. g. Yamada et al., 1983). On the other hand, as shown by Huang (1964), for $\lambda > 5.5$ the perfect cap initially deforms symmetrically until it reaches a pressure slightly above $Q = 0.75$ where it bifurcates into an asymmetric mode. Whether the imperfect shell with $\lambda > 5.5$ will buckle symmetrically or asymmetrically it will depend on the imperfections. Several studies have shown that as the magnitude of the imperfection increases, the buckling pattern changes from asymmetric to axisymmetric. The value of the maximum imperfection magnitude required to produce this transition state is usually a small fraction of the shell thickness (Yamada et al., 1983). These facts indicate that the present results based on the axisymmetric formulation are particularly suited for the analysis of shallow caps with $\lambda \leq 5.5$. For higher values of λ the present analysis should be complemented by an analysis including asymmetric effects.

ONE-DEGREE-OF-FREEDOM MODEL

In a dissipative system energy is lost due to damping and the system may settle down to a final motion which can be described by only a few dimensions (Bishop et al., 1988). Numerical results have shown that for shallow spherical caps ($\lambda \leq 5.5$) the first mode is dominant and a simplified one-degree-of-freedom model is capable of describing with a reasonable degree of accuracy the non-linear behaviour of the cap. This allows one to use various mathematical and numerical tools recently developed for the investigation of the global behaviour of non-linear one-degree-of-freedom dynamical systems (Seydel, 1988; Parker and Chua, 1989; Yorke, 1990).

Using in (6) a number of terms N necessary to achieve convergence of the non-linear static state and using only one mode (i=1 in (12)) to describe the dynamic response, one obtains the following one-degree-of-freedom model for the cap

$$W_{1,\tau\tau}+\bar{c}W_{1,\tau}+\alpha_1 W_1+\alpha_2 W_1^2+\alpha_3 W_1^3=\beta A_f \sin(\Omega\tau) \qquad (14)$$

where the coefficients α_i and β are functions of the shell parameters and of the static pre-stress state.

As one can observe, Eq. (14), governing the motion of the pressure loaded cap, possesses both quadratic and cubic non-linearities.

Elimination of both damping and forcing will produce the equation

$$W_{1,\tau\tau}+\alpha_1 W_1+\alpha_2 W_1^2+\alpha_3 W_1^3=0 \qquad (15)$$

Multiplying Eq.(15) by $W_{1,\tau}$ and integrating will yield

$$\frac{1}{2}W_{1,\tau}^2+\frac{1}{2}\alpha_1 W_1^2+\frac{1}{3}\alpha_2 W_1^3+\frac{1}{4}\alpha_3 W_1^4=C \qquad (16)$$

where $T = 1/2W_{1,\tau}^2$ is recognized as the kinetic energy, $\Pi = 1\backslash 2\alpha_1 W_1^2 + 1\backslash 3\alpha_2 W_1^3 + 1\backslash 4\alpha_3 W_1^4$ is seen to be the potential energy and C is a constant.

Table 1 shows the values of the coefficients α_i for a perfect cap with $\lambda = 4$ and $\nu = 1/3$ under selected static load levels.

A schematic representation of the shell static non-linear response and of the damped unforced vibration response for representative load levels are shown in Fig. 5. For $Q < Q_L$, only one equilibrium point (a point attractor) exists. For $Q_L < Q < Q_U$ there are three equilibrium points: two stable equilibrium positions separated by a saddle. In this range one has a non-symmetric two-well potential function, as illustrated in Fig. 5.b. As the load increases from Q_L, well C, associated with the buckled state, becomes deeper, while well A, associated with the unbuckled state, becomes shallower and the corresponding basin of attraction shrinks and disappears for $Q > Q_U$. At $Q = Q_U$ and $Q = Q_L$ an attractor meets an unstable point and both are destroyed (saddle-node annihilation). As basin A shrinks the probability of occurrence of dynamic instability (jumps from well A into well C) increases greatly. The existence of these competing attractors for $Q_L < Q < Q_U$ is the main source of the complex non-linear dynamic behaviour shown herein.

Table 1

Load - Q	α_1	α_2	α_3
0.00	612.77	-581.51	154.24
0.01	552.16	-559.53	154.24
0.20	486.40	-534.34	154.24
0.30	413.34	-504.41	154.24
0.40	328.67	-466.48	154.24
0.50	219.87	-410.50	154.24

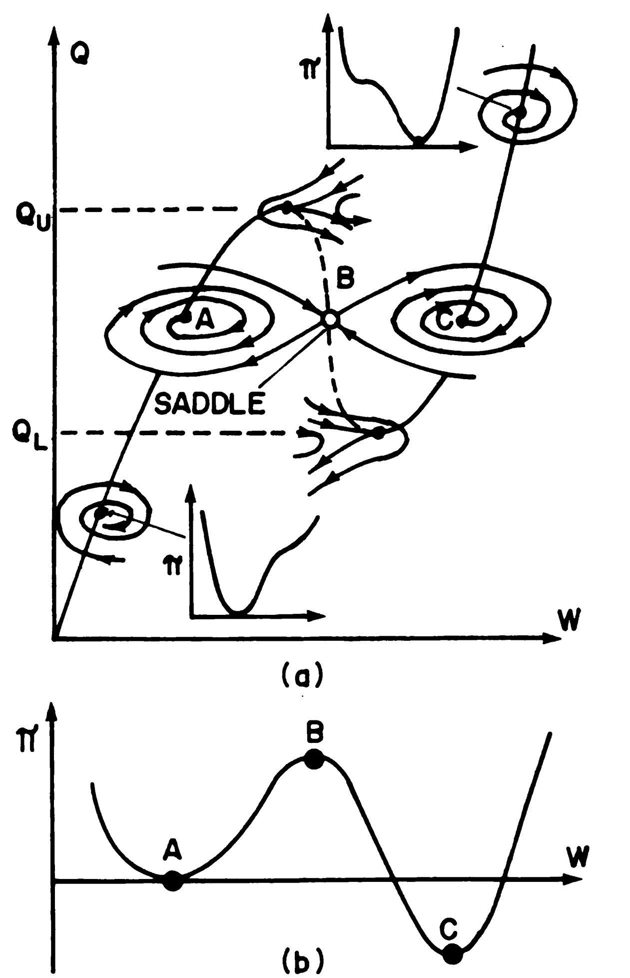

FIG 5. Schematic representation of the shell response, showing two saddle-node bifurcations

For a perfect cap with $\lambda = 4$ and $\nu = 1/3$ and $Q=0.5$, equation (14) reduces to

$$W_{1,\tau\tau}+\bar{c}W_{1,\tau}+219.87W_1-410.50W_1^2+$$

$$154.24W_1^3 = 358.88A_f\sin(\Omega\tau) \qquad (17)$$

The shape of the corresponding potential is illustrated in Fig. 6, showing two smooth minima at $W_1(0)=0$ and $W_1(0)=2.9734$ where the damped, unforced system has point attractors and a maximum at $W_1(0)=1.1518$, corresponding to a saddle point. A small external vibration converts these static equilibrium points to limit cycles in the forced system. The following results are related to this potential function.

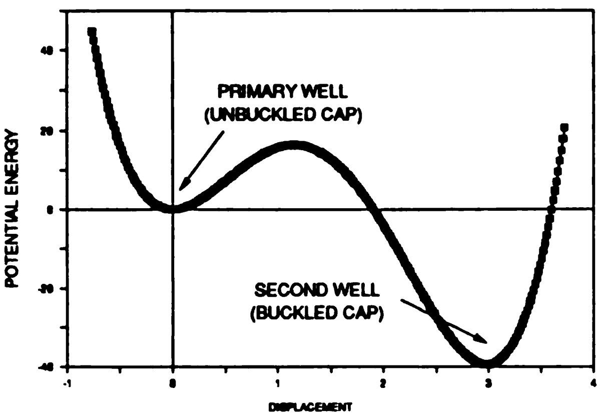

FIG 6. Non-symmetric two-well potential

One feature commonly found when modelling non-linear systems is the possibility of multiple coexisting periodic solutions. This may be due to the existence, for example, of multiple potential wells, resonance curves and competing subharmonic oscillations. In any of these cases, the final, steady state motion persisting after transients have decayed, depends crucially on the initial conditions given to the system. Here, for load levels between Q_U and Q_L and small values of the forcing amplitude A_f one has at least two stable, small amplitude periodic solutions and one unstable periodic solution which emanate from the three equilibrium points. For larger values of the forcing, other solutions may appear due to the presence of resonance curves within each well. The simultaneous presence of subharmonic oscillations is also possible. As an illustration Fig. 7 shows, for $A_f=-0.027$, $\Omega_f=12$ and $\bar{c}=1$, five stable periodic solutions, each of which is a possible long-term motion of the forced cap. Within each well there is one large amplitude period-one oscillation coexisting with a small period-one oscillation. They indicate the simultaneous presence of resonance curves, one within each well. The unbuckled cap also displays a subharmonic oscillation of order three, as shown in Fig. 7.b. The black dots are the stable fixed points of the Poincaré map. These points are calculated by a numerical scheme that combines a cell-mapping approach (Flashner and Guttalu, 1988) with the Newton-Raphson procedure.

For large forcing amplitudes there may also exist global oscillations about all three equilibria, as illustrated in Fig. 8. In addition to periodic response of various orders, the cap may display also chaotic motions.

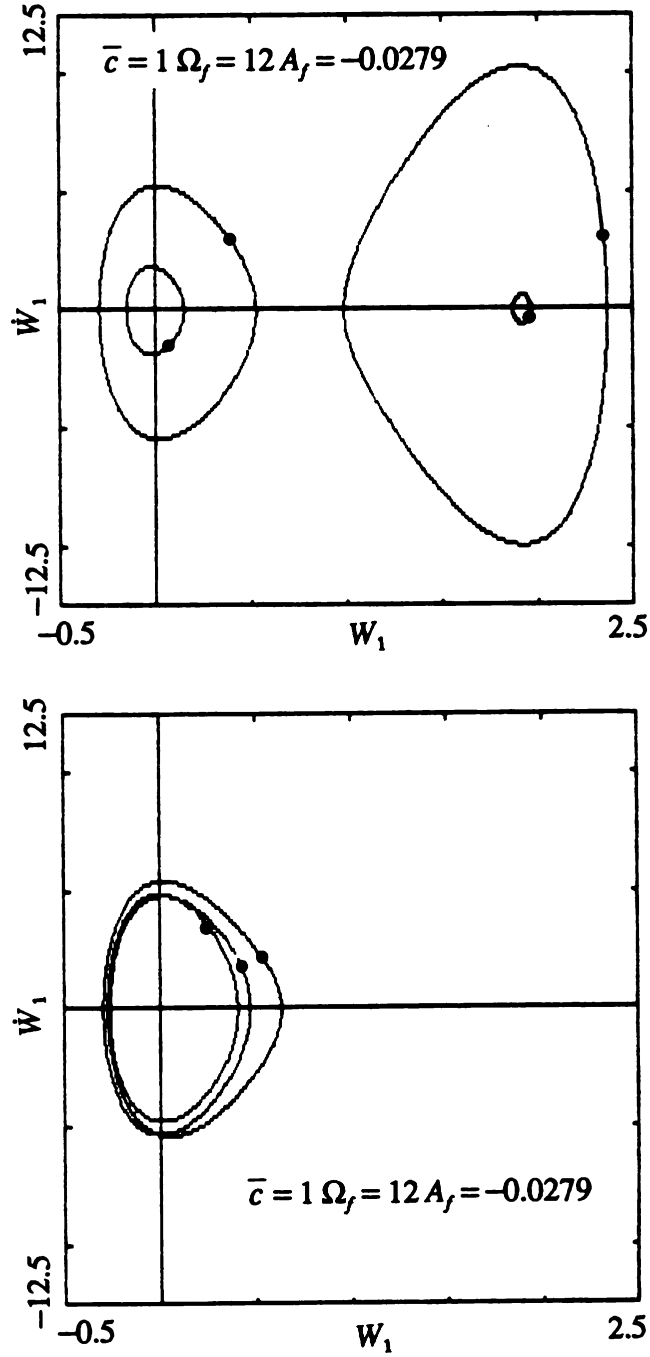

FIG 7. Phase projections of five coexisting stable periodic attractors

A detailed parametric analysis of Eq. (14) reveals that three different physical situations may arise in which the cap displays period doubling cascades leading to chaos. These are:

1- chaotic motions associated with softening spring effect in the resonance zone.

2- chaotic motions which appear just before escape from a potential well.

3- large amplitude chaotic motions in which the cap jumps back and forth between the two wells.

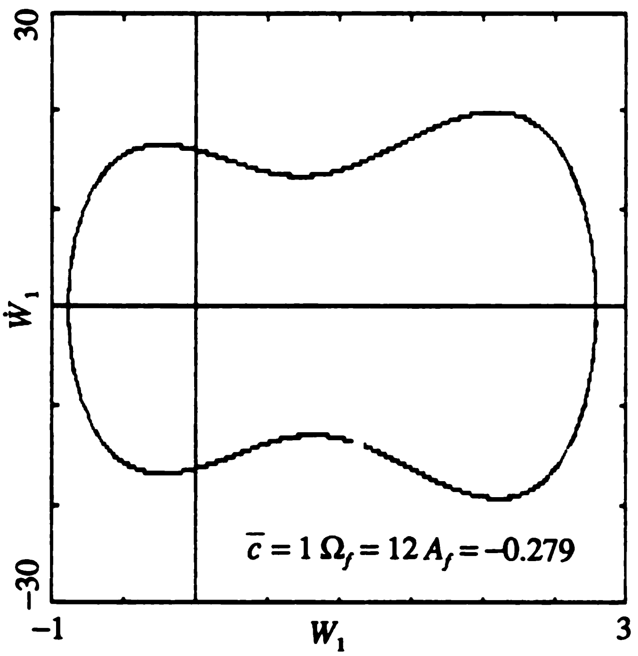

FIG 8. Large amplitude oscillations about all three equilibria

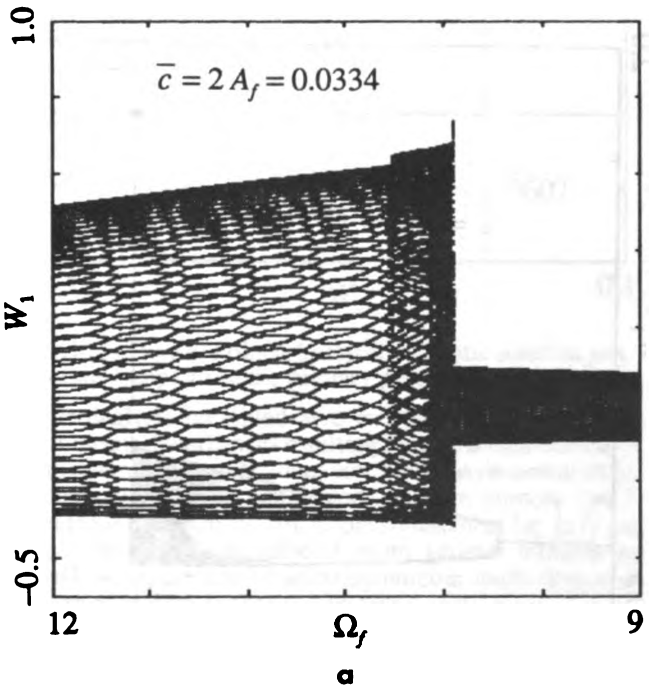
In the Duffing equation with softening type elastic characteristics, chaotic behaviour was observed by various authors at the region of the principal resonance. See, for example, Thompson and Stewart (1987) and Szemplinska-Stupnicka (1988). Taking $\bar{c}=2$ and $A_f=0.033$, using the driving frequency parameter as a control parameter, and plotting the projection of the phase curve onto the W_1 *vs*. Ω_f plane, one obtains, as Ω_f is decreased from 12 to 9, two branches of a resonance curve (see Fig. 9.a). Other stable segments of the curve can be obtained increasing Ω_f from 11 to 14, as shown in Fig. 9.b. These two pictures show clearly the softening nature of the frequency-response curves and the sudden increases and decreases in amplitude as the frequency is varied. This simple numerical procedure reveals that, instead of a smooth response as the one obtained from smooth variational equations (Nayfeh and Mook, 1979), the amplitude presents small fluctuations near the place where the upper cyclic fold should be. These fluctuations denote the region where flip bifurcations occur. A plot of the position of the Poincaré displacement co-ordinate W_1 versus the bifurcation parameter Ω_f leads to the bifurcation diagram depicted in Fig. 10. It confirms the existence of a cascade of period-doubling bifurcations leading eventually to chaos in a narrow zone of the frequency, just before the peak resonant amplitude. The zone of chaotic motion ends very sharply and is succeeded by a jump into the non-resonant, small-amplitude branch of the resonance curve. The phase portrait and the corresponding Poincaré section of a chaotic trajectory are recorded for $\Omega_f=10$in Figs. 11 and 12, respectively. The chaotic attractor exhibits the same simply-folded band structure observed by Thompson and Stewart (1987) for other softening spring oscillators. This chaotic response coexists with a smaller amplitude periodic limit cycle at the same control parameter value and within the same well. There is at least one more stable solution in the second well.

Now the behaviour of the unbuckled cap will be considered, when the amplitude of the forcing, A_f, is taken as a bifurcation parameter. For small values of A_f the motion may be confined into the shallower well, but for larger values of A_f the motion can no longer be confined into this well and the shell escapes, being trapped into the second, deeper well. With the proper choice of damping and excitation frequency, just before escape, the response goes through a cascade of period doubling bifurcations culminating in a chaotic behaviour, as illustrated by the bifurcation diagram shown in Fig. 13. Again the chaotic zone ends very sharply and the response, after some transients, jumps into the second well. This phenomenon is usually called dynamic snap-through buckling.



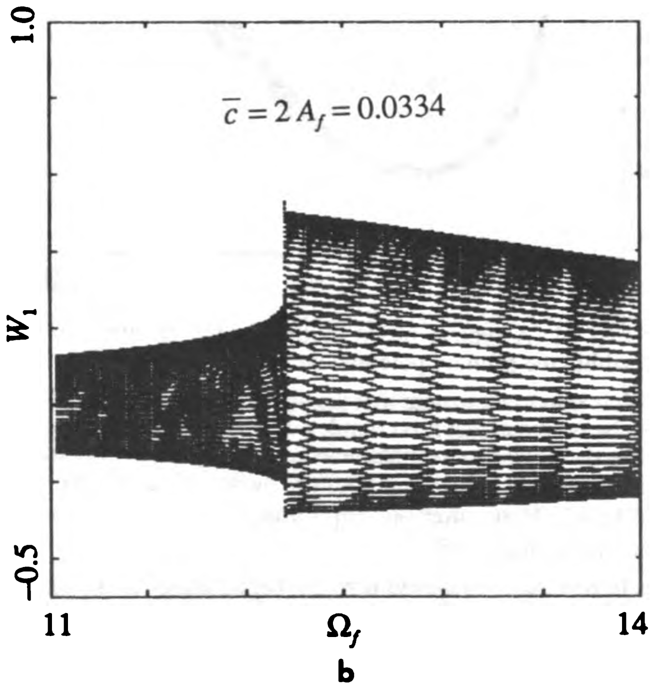


FIG 9. Numerically obtained resonance curves within the primary potential well, showing softening t

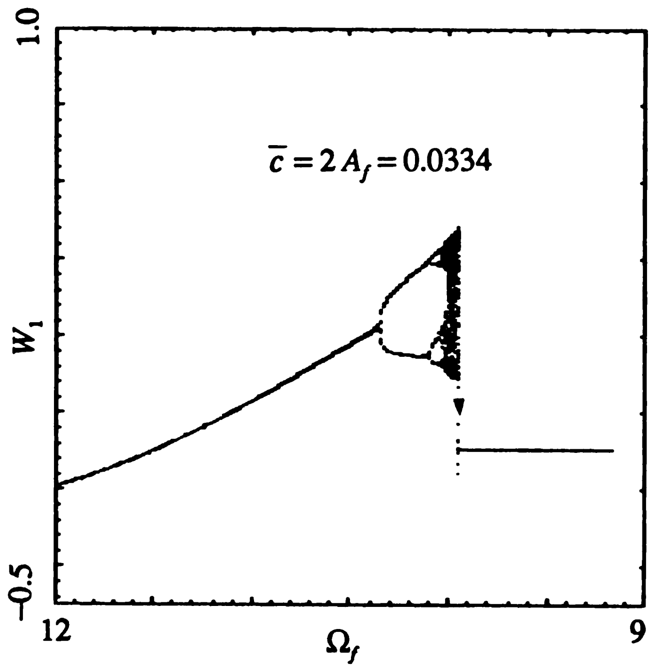

FIG 10. Bifurcation diagram. Poincaré co-ordinate, W_1, as a function of the forcing frequency.

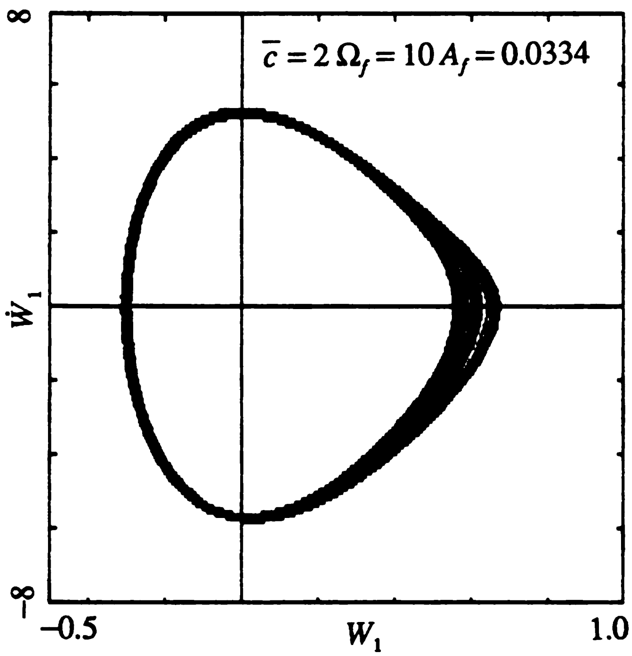

FIG 11. A typical phase portrait in the chaotic zone within the primary potential well

It is important to note that the beginning of a cascade does not always mean that it is completed; depending on the values of the shell and forcing parameters, the jump may occur after a finite number of flip bifurcations as shown in Fig. 14 for $\overline{c} = 2$ and $\Omega_f = 7$. Here, after one flip bifurcation, the cap escapes from the primary well.

In both cases analysed here the beginning of a cascade is a clear indication that an unsafe region is being approached. This fact could probably be used to control the behaviour of the structure and prevent unwanted jumps. These results also show that, for certain static load values, even low excitation vels can produce period-multiplying bifurcations and chaotic tions in the single-degree-of-freedom model.

In Fig. 15 the chaotic attractor for parameter values $\overline{c} = 3, A_f = 0.06$ and $\Omega_f = 12$ is shown. The nature of the chaotic attractors are verified by evaluating Lyapunov exponents.

In addition to the chaotic responses within one potential well, another type of chaotic response can be found in which the cap jumps back and forth between the two wells in a erratic manner. A typical chaotic attractor for large amplitude oscillations is depicted in Fig. 16. This type of chaotic response is associated with moderate to large forcing amplitudes and is well documented in literature.

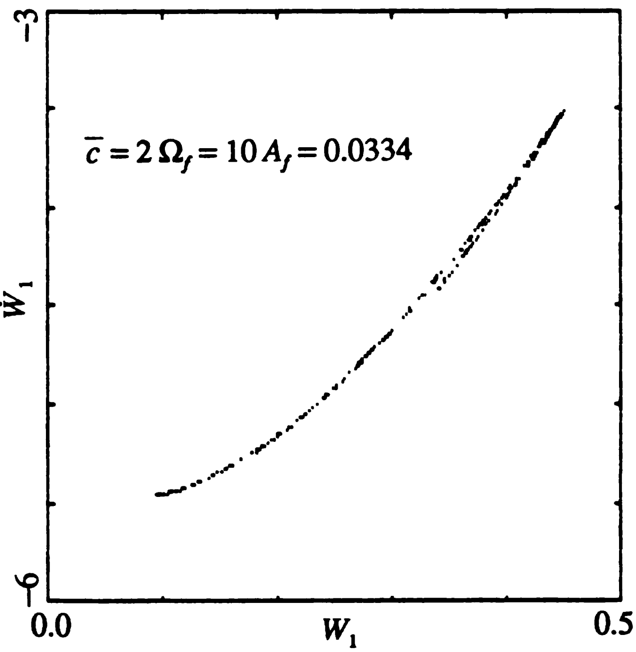

FIG 12. Poincaré map of the cap.

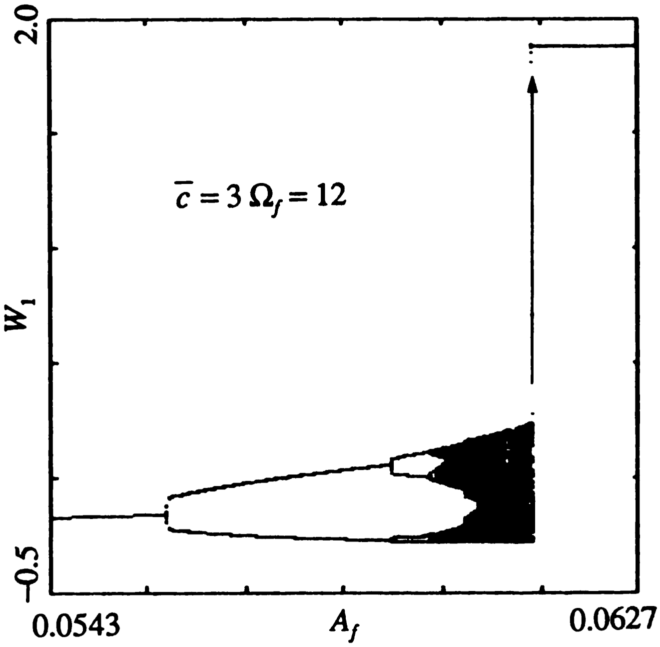

FIG 13. Period-doubling bifurcations leading to chaos and escape from the primary potential well.

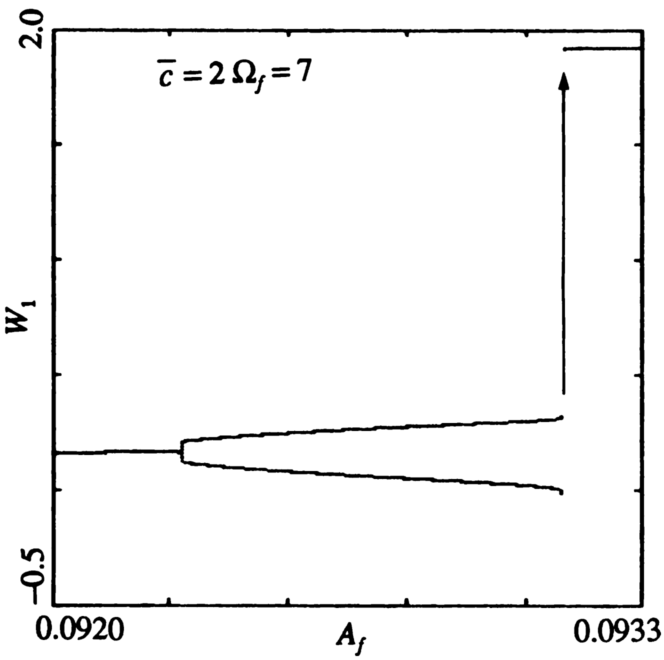

FIG 14. Bifurcation diagram.

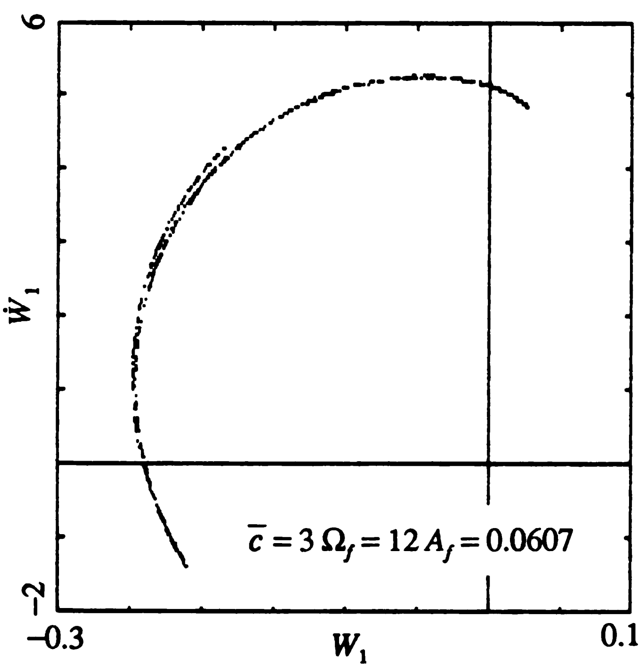

FIG 15. Typical Poincaré map of a chaotic solution just before escape from the primary potential well

The analysis presented here is with respect to spatially axisymmetric disturbances resulting in axisymmetric motions. The mathematical model does not allow asymmetric deformations and hence no conclusions on such motions can be drawn from this analysis. So, stable solutions of Eq. (17) may not be physically realizable if more general motions are allowed. Also, the use of an axisymmetric multi-degree-of-freedom model may change the parameter values at which bifurcations occur. Preliminary results using the multi-degree-of-freedom model presented at the beginning of this work have shown that, in spite of some changes in global behaviour, the basic features observed using this one-degree-of-freedom model still remains.

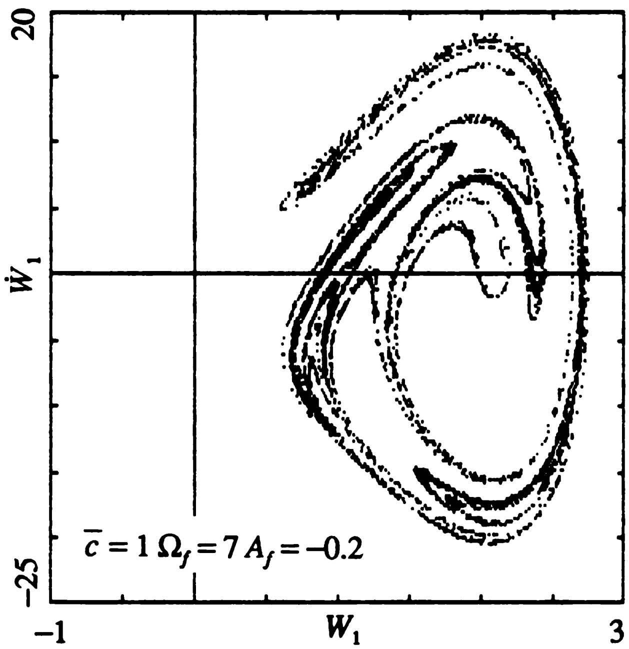

FIG 16. Chaotic attractor. Response associated with large forcing amplitudes.

CONCLUSIONS

Based on Marguerre's shallow shell equations, an accurate multi-mode solution is formulated and applied to study the non-linear vibration characteristics of a pressure-loaded geometrically imperfect spherical cap along its non-linear pre-and-post-buckling paths. It is shown both analytically and by computer simulation that pressure loaded shallow spherical shell exhibit a high degree of non-linearity and that the pre-stress state may alter significantly the natural frequencies and non-linear vibration characteristics of perfect and imperfect shells.

A detailed parametric study, using computer simulations, shows that the cap under harmonic excitation may display complex non-linear behaviour, including jumps and multiple coexisting periodic solutions due to the existence of competing potential wells and the presence of non-linear resonance curves within each well. Additionally, different physical situations are identified in which period-doubling phenomena and chaos can be observed.

Although the present analysis is restricted to clamped spherical caps, the conclusions could perhaps be extended to thin-walled structural elements liable to fold type buckling such as conical caps, cylindrical panels and shallow arches.

Transformation of liposomes: Mechanical behavior and stability

D Pamplona

Departamento de Engenharia Civil Pontifícia Universidade Católica do Rio de Janeiro
Rua Marquês de São Vicente, 225, Gávea 22453-900, Rio de Janeiro, RJ, Brazil

Liposomes are small artificial vesicles of lipid bilayer, wich enclose and are surrounded by water. Morphological transformations in liposomes, starting from a spherical shape, due to changes in the osmotic pressure, have been described in the literature. The first transformation is into a circular biconcave form, afterwards the biconcave side view is maintained, while the front view reveals transformations into elliptical or regular polygonal forms, usually triangular, square or pentagonal. Finite elasticity and the theory of thin shells were used to analyse the behavior of the liposomes under decreasing volume. The biological membrane was considered as a two dimensional fluid layer, exhibiting solid properties to some extent, e.g., elasticity. The stability of the liposmes was studied by using the method of elastic perturbation to obtain the critical pressure for the biconcave transformation and the long liposome tubes. The transformations to elliptical and regular polygonal forms were studied using the linear stability equations of elasticity.

CONTENTS

INTRODUCTION

The mechanical properties and behavior of biological membranes has been studied since 1930. In particular, Evans and Skalak (1980) were engaged in the study of their mechanics and thermodynamics, while Jenkins (1977) and others studied the red blood cells and their equilibrium configurations.

Hotani (1984) has managed to observe the morphological behavior of the liposome by means of dark-field light microscopy. He verified that the change in osmotic pressure in initially spherical liposomes leads to a steady decrease of interior volume. The first transformation is into a cirvular biconcave shape, and then transformations through striking polygonal forms occur, until the liposomes reach the stable forms of thin filaments and small spheres.

In a previous paper Pamplona and Calladine (1993), describe a constitutive law for the lipid bilayer explaining the axially symmetric transformations, which are consistent with Hotani's observed morphological transformations.

The principal aim of this work is to study the changes of the liposomes in a variety of nonsymmetric configurations, and through Donnell's stability equations show that the number of lobes around the circumference, in a form which precedes the jump into two , three or four-armed configurations, would depend on the surface-strain elasticity.

HOTANI'S ESSAYS

Hotani (1984) made small bilayer vesicles of phospholipids with diameters between 7 and 8mm, which enclose and were surrounded by water.

Using dark-field light microscopy, whose lamp heat gradually evaporates the external water, he observed the liposomes transformations. Those transformations are due to the decrease in the interior volume of the vesicles. To some extent he observed that the transformations were reversible, when small amounts of water were added to the microscope slide.

The phospholipids which constitute the observed liposomes are molecules with a hydrophilic "head" which seeks water and a hydrophobic "tail" which shuns water. In an aqueous environment these hydrophobic effects drive the molecules to construct, by self-assembly, spherical bilayers of "heads". In the space of 5 nm between layers of "heads", the "tails" can be free of the contact with the water, Fig 1.

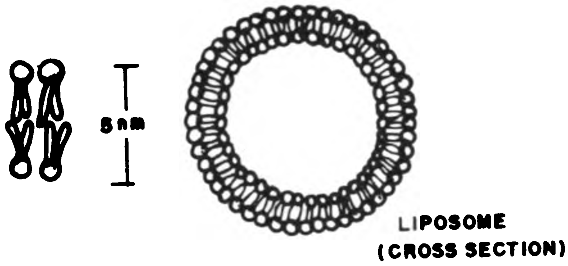

FIG 1 - Schematic representation of a liposome.

In Hotani's tests the original spherical shape first changed into a biconcave shape, after which the vesicle began to undulate in the equator until it suddenly jumped to a two, three, four or five pronged shape. As the reduction of interior volume continues, some of the arms could shrink, or eventually turn in a very long and thin tube, which could break up into a number of small spherical vesicles, as can be seen in Fig 2.

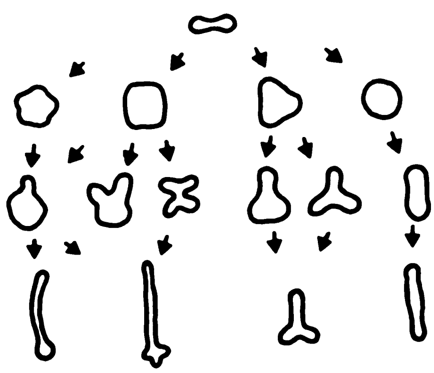

FIG 2 - Schematic of transformations of liposomes, Hotani (1984).

CONSTITUTIVE RELATIONS FOR THE BILAYER

A constitutive equation for the liposome membrane was extensively discussed by Pamplona and Calladine (1993). It is taken here as suggested in their paper.

In order to write the equations, we must consider the circumferential and meridional components of stretch λ_θ, λ_s and the curvatures k_θ^*, k_s^*. As observed by Hotani (1984), if the area of the membrane is assumed to be constant,

$$\lambda_s \lambda_\theta = 1 \,. \tag{1}$$

We assume that the constitutive relation for the stresses is

$$N_\theta^* = T^* + C^* F_1(\lambda) \tag{2}$$

$$N_s^* = T^* + C^* F_2(\lambda) \tag{3}$$

in which N_θ^* and N_s^* are the circumferential and meridional stresses, T^* is closely related to the mean of N_s^* and N_θ^*, and C^* is a constant that relates the stiffness against the change of area under equal bi-axial loading.

The bending constitutive equation is assumed such that:

$$M_s^* = M_\theta^* = B^* \left[k_s^* + k_\theta^* \right] \tag{4}$$

where,
M_s^* and M_θ^* are the meridional and circumferential bending moments and B^* is the "bending stiffness".

DIFFERENTIAL EQUATIONS OF THE PROBLEM AND BOUNDARY CONDITIONS

For the axisymmetric deformations of a liposome with an initial spherical shape of radius, a, the geometrical relations obtained from Fig 3 are

$$r = \sin s \tag{5}$$

$$z = 1 - \cos s \tag{6}$$

$$\frac{d\phi}{dS} = k \tag{7}$$

$$\frac{dR}{dS} = \cos\theta \tag{8}$$

$$\frac{dZ}{dS} = \sin\theta \tag{9}$$

By definition

$$\lambda_s = \frac{dS}{ds} \text{ and } \lambda_\theta = \frac{R}{r} = \frac{R}{\sin s},$$

The variables R, Z, r, k_s, k_θ have been made dimensionless dividing by the undeformed radius a. That is, $r = r^*/a$ etc ...

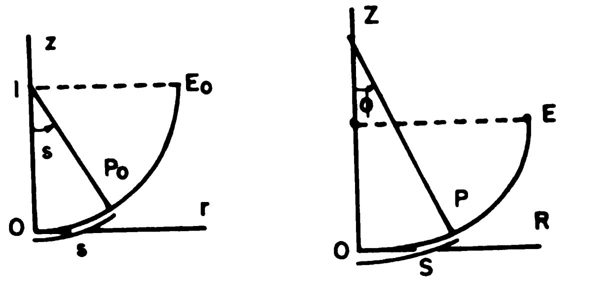
If, we consider the chain rule,

$$\frac{d()}{dS} = \frac{d()}{ds}\frac{ds}{dS} = \frac{d()}{dS}\lambda_\theta = \frac{d()}{ds}\frac{R}{\sin s} = ()' \frac{R}{\sin s} \,. \tag{10a}$$

Using Eq (1), and (10a)

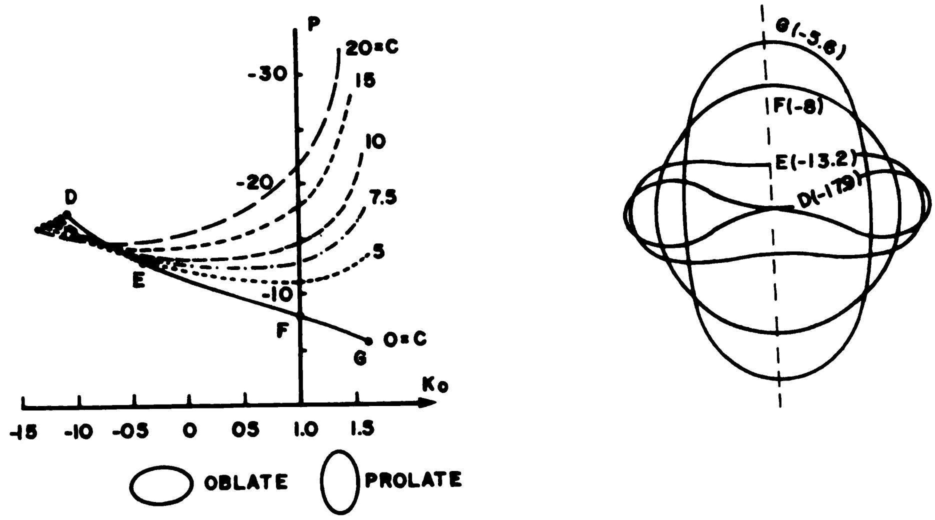
$$\frac{ds}{dS} = \frac{1}{\lambda_s} = \lambda_\theta = \frac{R}{\sin s} \,. \tag{10b}$$

Considering the equilibrium equations taken directly from Flugge (1962) or Calladine (1983), where the variables have been made dimensionless by multiplying by a^2/B (for example $N_s = N_s^* a^2/B$), after some manipulation and using the constitutive relations, we obtain



Und shape (Spherical) Def shape (Biconcave)

FIG 3 - Diagrams showing the meridians of a liposome.



(a) (b)

FIG 4 - Plots of equilibrium paths.

$$AQ = \left[p - (T + CF_1)k - (T + CF_2)\sin\phi/R - Q\cos\phi/R\right]$$
$$Q' = AQ \operatorname{sen} s/R \tag{11}$$

$$AT = -C\,dF_1/ds + \left[C(F_2 - F_1)\cos\phi/R + kQ\right]$$
$$T' = AT \operatorname{sen} s/R \tag{12}$$

$$k' = \left[-Q + \sin\phi\cos\phi/R^2 - k\cos\phi/R\right]\sin s/R \tag{13}$$

$$R' = \cos\phi\sin s/R \tag{14}$$

$$Z' = \sin\phi\ \sin s/R \tag{15}$$

$$\phi' = k\sin s/R \tag{16}$$

Equations (11) - (16) provide us with the 6 differential equations with the 6 unknowns R, Z, ϕ, k, Q and T. Equations (14) - (16) are Eqs (7) - (9) rewritten.

The equations were solved by a standard Runge-Kutta procedure of fourth order joined with a "shooting" method, used with unknown starting values of Q' and k at $s = 0$, until the appropriate conditions at the equator namely,

$$\phi\left(\frac{\pi}{2}\right) = \frac{\pi}{2} \text{ and } Q\left(\frac{\pi}{2}\right) = 0$$

are satisfied.

SOLUTIONS OF THE EQUATIONS

The equations of the previous item where solved for several different values of C, where

$$C = \frac{C^* a^2}{B^*}. \tag{17}$$

Since C^* and B^* are constants of the biological material, we will have a different C^* for each different initial size of the liposome. Some of these solutions are shown in Fig 4.

For every solution the meridional profile of the deformed liposome was generated and Fig 4(b) shows a selection of these cases with $C = 0$.

From observations of Fig 4(a), it is possible to notice that for each C the liposome will maintain the initial spherical form, $K_0 = 1$, until a critical pressure, P_{cr} is reached, when it can assume either the biconcave (prolate) or the peanut (oblate) forms.

The $C = 0$ case, although it seems strange since $a \neq 0$ always, represents the case when the deformations are not reversible anymore. It can be interpreted as the membrane having zero in-plane surface stiffness.

STABILITY: AXIALLY - SYMMETRIC BIFURCATION

As seen in last section, the liposome bifurcates in a prolate or oblate shape at a certain critical pressure.

Performing a first-order perturbation, $\phi^* = \phi^0 - A_0 \sin 2s = s - A_0 \sin 2s$, which involves a linearisation of the Eqs (11) - (16), it is possible to obtain an analytical expression for the critical pressure, namely

$$p_{cr} = -\left(8 + \frac{2}{3} C\right), \qquad (18)$$

what confirms the numerical result shown in Fig 5.

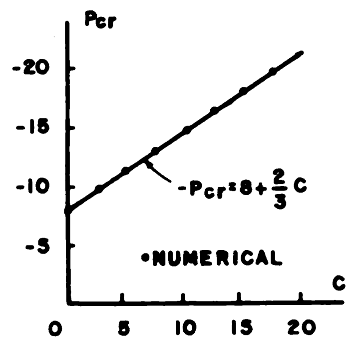


FIG 5 - Bifurcation pressures.

An extensive discussion of these results and comparison with other works done by Helfrich (1976) an Jenkins (1977) is given in Pamplona and Calladine (1993).

STABILITY: OTHER SHAPES

Lobed figures

After obtaining the path for the first bifurcation, which is when the spherical liposome buckles into a biconcave form, it is possible to observe *undulations* in the outer circumference of the deformed liposome. Eventually it formed, typically, a well-defined two-three-four or five lobed figure, Fig 6, and then rather suddenly, this figure would *jump* into a two four or five - pronged shape.

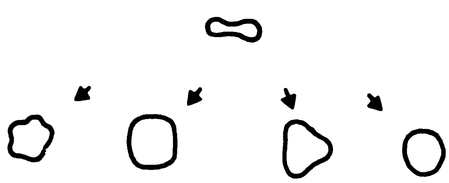

FIG 6 - Further transformations after the biconcave shape, Hotani (1984)

To study the stability at this stage, we choose to perturb the biconcave shape at several different external pressures. Donnell's stability equations, obtained by the second variation of the potential energy, in accordance with the Trefftz criterion, taken directly from Bruch and Almroth (1975), were choosed due to their simplicity. These are

$$(rN_\phi)_{,\phi} + r_\phi N_{\phi\theta,\theta} - r_\phi N_\theta \cos\phi - \qquad (19)$$

$$(rN_{\phi\theta})_{,\phi} + r_\phi N_{\theta,\theta} + r_\phi N_{\phi\theta} \cos \qquad (20)$$

$$\left[\frac{1}{r_\phi}(rM_\phi)_{,\phi}\right]_{,\phi} + 2\left[M_{\phi\theta,\phi\theta} + \frac{r_\phi}{r} M_{\phi\theta,\theta}\cos\phi\right] +$$

$$\left[\frac{r_\phi}{r} M_{\theta,\theta\theta} - (M_\theta \cos\phi)_{,\phi}\right]$$

$$-(rN_\phi + r_\phi N_\theta \sin\phi) = \left[(rN_\phi^0 \beta_\phi)_{,\phi} + (rN_\theta^0 \beta_\theta)_{,\theta}\right] \qquad (21)$$

(^{0}) are determined by the shape that is been perturbed, as the shell is not subjected to torsional loading, $N^0_{\phi\theta} = 0$.

Changing the variables, by introducing Eqs (7) - (8) into Eqs (19) - (21), gives

$$r\frac{\partial N_s}{\partial S} + \frac{\partial N_{s\theta}}{\partial \theta} + (N_s - N_\theta)\cos\phi = 0 \qquad (22)$$

$$r\frac{\partial N_\theta}{\partial S} + \frac{\partial N_{s\theta}}{\partial \theta} + 2\cos\phi\, N_{s\theta} = 0 \qquad (23)$$

$$r\frac{\partial^2 M_s}{\partial S^2} + 2\frac{\partial^2 M_\theta}{\partial\theta\partial S} + \frac{1}{2}\frac{\partial^2 M_\theta}{\partial\theta^2} + 2\cos\phi\frac{\partial M_s}{\partial S} -$$

$$\cos\phi\frac{\partial M_\phi}{\partial S} + 2\frac{\cos\phi}{r}\frac{\partial M_{S\theta}}{\partial\theta} +$$

$$+ \sin\phi\, K_s M_\theta - \sin\phi\, M_s K_s - N_{s\theta} K_s - N_\theta \sin\phi =$$

$$\cos\phi N_s^0 b_s + r\frac{\partial N_s^0}{\partial S}\beta_s + rN_s^0\frac{\partial\beta_s}{\partial S} + N_\theta^0\frac{\partial\beta_\theta}{\partial\theta} \qquad (24)$$

where

$$N_s = C\left[u_{,s} + \frac{w}{r_\phi} + \frac{\mu}{r}(v_{,\theta} + u\cos\phi + w\sin\phi)\right] \qquad (25)$$

$$N_\theta = C\left[\frac{1}{r}(v_{,\theta} + u\cos\phi + w\sin\phi) + \mu\left(u_{,s} + \frac{w}{r_\phi}\right)\right] \qquad (26)$$

$$N_{S\theta} = \frac{C(1-\mu)}{2}\left[v_{,s} - \frac{v\cos\phi}{r} + \frac{u_{,\theta}}{r}\right] \qquad (27)$$

$$M_s = -D\left[w_{,ss} + \frac{\mu}{r}\left(\frac{w_{,\theta\theta}}{r} + w_{,s}\cos\phi\right)\right] \qquad (28)$$

$$M_\theta = -D\left[\frac{1}{r}\left(\frac{w_{,\theta\theta}}{r} + w_{,s}\cos\phi\right) + \mu w_{,ss}\right] \qquad (29)$$

$$M_{S\theta} = -\frac{D(1-\mu)}{2}\left[\frac{w_{,s\theta}}{r} - w_{,\theta}\frac{\cos\phi}{r^2}\right] \qquad (30)$$

C, D are the extensional and bending stiffness parameters and μ is the Poisson's ratio. The quantities u, v and w are the incremental quantities of the middle-surface displacements components, u^*, v^* and w^*, in the meridional, circunferencial and transversal directions, namely

$$u^* = u^0 + u$$
$$v^* = v^0 + v \qquad (31)$$
$$w^* = w^0 + w .$$

The following increments, satisfying the boundary conditions, where choosen:

$$u = A_3 \sin 2\phi \sin n\theta$$
$$v = A_2 \sin \phi \cos n\theta \qquad (32)$$
$$w = A_1 \sin^2 \phi \sin n\theta$$

where n is the number of lobes in the equator.

To solve the differential problem, obtained when Eqs (25) - (30) are introduced in Eqs.(22) - (24), the Galerkin method was used. Since we are looking for non-vanishing values of A_1, A_2 and A_3, relations between the critical pressure p and the number of buckling lobes, n, can be achieved, as can be seen in Fig 7.

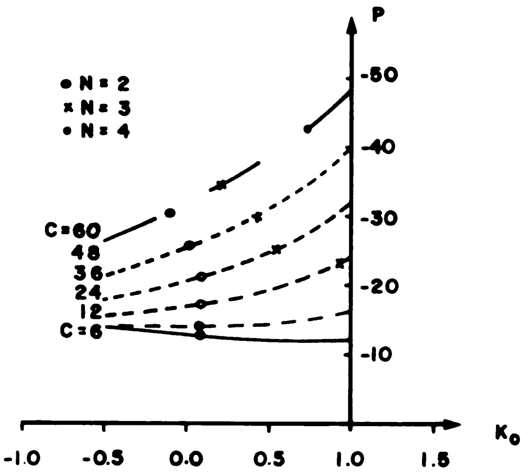

FIG 7 - Critical pressures on the plots of equilibrium paths.

As expected when Donnell's equations are used, for small values of n the critical pressure obtained is higher then it should be, as can be seem in Table 1, for the critical pressure of the liposome buckling from the spherical to the biconcave form.

C*	Numerical	Equation 18	Donnell
6	-12	-12	-15.00
12	-16	-16	-19.00
24	-24	-24	-27.15
36	-32	-32	-36.30
48	-40	-40	-43.45
60	-48	-48	-51.75

TABLE 1 - Critical pressure for the spherical liposome.

Although it is clear that the critical pressures obtained in this item are not the right ones, for the purpose of this work and for the sake of simplicity we accept the results. Since it was the intent to see if the number of lobes or undulations around the circumference, in a form which preceds the jump into a two, three or four-armed configurations, would depend on the surface - strain elasticity via constant C, it seems reasonable to us, to affirm it based in this study. For, if the value of C were to be confirmed effectively to zero, as in the studies done by Sekimura and Hotani (1989), there would be no feature on which the number of lobes could depend.

Long tubes

Performing a first-order perturbation, $\phi^* = \phi^0 + \phi = \pi/2 + A_4 \sin 2\pi x / b$, which involved the linearization of the various equilibrium equations for a cylindrical shell it was possible to observe that a long tube of liposome material, e.g.

$$M_\theta = M_s = B(k_\theta + k_s)$$

would spontaneously bifurcate. For b equal to the inital circumference of the tube, $2\pi a$, as can be seen in Fig 8.

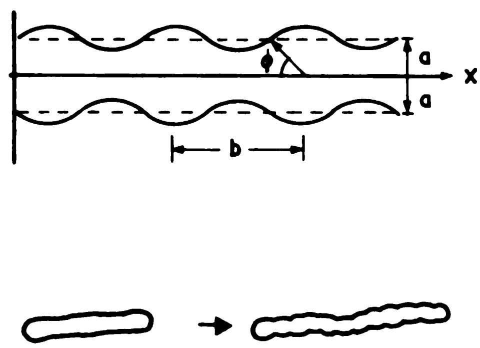

FIG 8 - Long tubes transformation.

In a subsequent paper we shall describe our studies on elongated axi-symmetric configurations of liposomes.

CONCLUSIONS

It seams desirable to develop a "physical" understanding of the shape-change of the vesicles made by lipid bilayers. In our first paper (Pamplona and Calladine, 1993) it was possible obtain a constitutive law for the lipid-bilayer and explain the axially symmetric transformations. In this paper it was possible to show that the number of lobes around the circumference, which precede the jump would depend on the surface-strain elasticity. It is concluded that if the surface strain were not considered, as has been done by other authors, the sphere would buckle in a prolate shape, not in a biconcave as it actually does. There then would be no feature on with the number of lobes would depend.

Although the cirtical pressures obtained throught Donnell's equations are higher then the correct ones, it seems reasonable to affirm a connection between the inital size of the liposome and the number of lobes of the transformation.

ACKNOWLEGMENT

The author wishes to express her appreciating to the Brazilian Government which, though the Brazilian Council for Scientific and Technical Development, provided financial support during the sabbatical leave when this work with Professor Calladine began. Expressing her gratitude for Professor Calladine, for the opportunity to work with him, which has been a very rewargidng professional experience.

The aeroelastic stability of helicopter rotors in hovering flight has been investigated by a set of generalized dynamic wake equations and hybrid equations of motion for an elastic blade cantilevered in bending and having a torsional root spring to model pitch-link flexibility. The generalized dynamic wake model employed is based on an induced flow distribution expanded in a set of harmonic and radial shape functions, including undetermined time dependent coefficients as aerodynamic states. The flow is described by a system of first-order, ordinary differential equations in time, for which the pressure distribution at the rotor disk is expressed as a summation of the discrete loadings on each blade, accounting simultaneously for a finite number of blades and overall rotor effects. The present methodology leads to a standard eigenanalysis for the associated dynamics, for which the partitioned coefficient matrices depend on the numerical solution of the blade equilibrium and inflow steady-state equations. Numerical results for a two-bladed, stiff-inplane hingeless rotor with torsionally soft blades show the importance of unsteady, three-dimensional aerodynamics in predicting associated generalized aerodynamic force mode shapes.

LIST OF SYMBOLS

a	lift curve slope (per radian)
a_n^m, b_n^m	induced flow expansion coefficients in the rotating frame, nondimensional
$\bar{a}_1^0$	steady uniform inflow (steady-state a_1^0)
$[\mathcal{DM}], [\mathcal{C}], [\mathcal{K}], [\mathcal{M}]$, and $[\mathcal{GF}]$	coefficient matrices of blade state-variables, Fig 7
$[am], [qs], [k]$	apparent mass, quasi-steady, and inflow stiffness matrices, Fig 7
B_{nl}^m	$= (-1)^{(n+l-2m-2)/2} \sqrt{\frac{K_n^m}{K_l^m}} \sqrt{(2n+1)(2l+1)} \cdot \sum_{q=m,m+2,\ldots}^{n-1} \frac{\pi}{2} K_q^m \frac{(2q-1)}{(l-q)(l+q+1)}$
K_n^m	$= \frac{2}{\pi} \frac{(n+m-1)!!\,(n-m-1)!!}{(n+m)!!\,(n-m)!!}$
m, n	harmonic and shape function numbers, respectively
N	number of modified orthogonal Duncan polynomials in blade modal expansions for each of the elastic torsion, flap bending, and lead-lag bending deflections
Q	number of rotor blades
R	rotor radius, m
$\bar{r}$	blade radial coordinate, $\bar{r} = r/R$
$\bar{t}$	nondimensional time, $\bar{t} = \Omega t$
U_∞	free-stream velocity component of the blade section, m/s
$\left[V_n^m\right]$	matrix of momentum theory flow parameters
y', z'	blade coordinates associated with the deformed blade reference frame, along unit vectors $\mathbf{j}', \mathbf{k}'$
α	local blade angle of attack
$\bar{\lambda}$	induced flow at the rotor disk due to shed wake, positive downwards, $\bar{\lambda} = \lambda/(\Omega R)$
$\phi_n^m(\bar{r})$	$= \sqrt{(2n+1)\frac{\pi}{2}K_n^m} \sum_{q=m,m+2,\ldots}^{n-1} \bar{r}^q \frac{(-1)^{(q-m)/2}(n+q)!!}{(q-m)!!\,(q+m)!!\,(n-q-1)!!}$
$\bar{\psi}$	azimuthal position on the rotor disk for induced inflow expansion in the rotating frame, *rad*
$\hat{\psi}_q$	relative position of q-th blade, $\hat{\psi}_q = \bar{t} + \frac{2\pi}{Q}(q-1)$
Ω	rotor rotational speed, *rad/s*
$\overset{*}{(\,)}$	$= d/d\bar{t}$

INTRODUCTION

The physical environment of helicopter rotor blades has been investigated for many years. At this time, it is well known that a continuous pumping of a substantial mass of air (inflow) through the rotor disk (due to the existence of a shed wake below the helicopter rotor) implies that its aerodynamic field, in hovering or forward flight, is very different and much more complicated than its fixed-wing counterpart. For performance predictions one can rely on average values of the wake geometry corresponding to a given configuration and operating condition. When dynamics is present though, as is the case of aeroelastic investigations, the task involves strong coupling of aerodynamic and structural dynamic loads. The advent of hingeless rotors with very flexible blades has made even stronger such inherent coupling of loads acting upon helicopter rotor blades. A realistic model for the aeroelastic behavior of the helicopter rotor can be summarized as shown in the flow-chart in Fig 1.

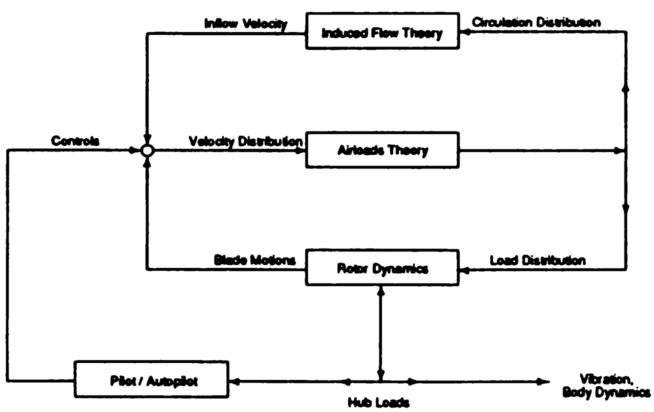

FIG 1. Aeroelastic environment of helicopter rotor.

At least three basic technology modules must be coupled within an aeroelastic analysis of the helicopter rotor (Peters and Su, 1991): 1) a structure dynamic model, 2) an induced flow model, and 3) an airloads model. The double feedback loop in Fig 1 emphasizes the important coupling between wake dynamics and rotor dynamics through the predicted airloads, that become the forcing functions for both the structure and induced flow.

In spite of this, classically, the induced flow model has often been treated with a two-dimensional, quasi-steady aerodynamics, including a uniform flow distribution (Hodges and Ormiston, 1976, and Hodges, 1976). That modeling lacks some physical information, such as three-dimensional tip relief and unsteady wake vortex alignment, which are very important in predicting aerodynamic damping. A much more realistic approach is three-dimensional vortex lattice unsteady aerodynamics, for which global effects and time history of circulation would be taken into account. These, however, are not amenable to eigenanalysis.

In the late 1980's, research work has attempted to bridge the critical gap between structural and aerodynamic operators used in aeroelastic applications such as those in Hodges and Ormiston (1976) and Hodges (1976). In Kwon (1988), and Kwon et al (1991), a panel code is formulated and coupled, respectively, with nonlinear blade models of Hodges and Ormiston (1976), and Hodges (1976), both based on the original Hodges and Dowell (1974) equations. This panel model is based on a piecewise constant distribution of sources and doublets, with a prescribed tip-vortex geometry and calculated inner wake. A Fourier analysis associated with a moving block technique is employed to obtain damping and frequency of the most lightly damping mode, which has the frequency near the fundamental lead-lag bending frequency of the rotating blade. The fact that a standard eigenanalysis is out of the question (meaning that only the damping and frequency of the most lightly damped mode can be obtained) and that excessive computer memory requirements are inevitable to accomplish convergence (since small time steps and many wake layers underneath the rotor must be suitably established) imposes innate limitations to the use of this method in aeroelastic stability investigations. Nevertheless, the method is useful, and results show the importance to the three-dimensional and unsteady effects in the prediction of lead-lag damping.

More recently, the generalized dynamic wake model developed by Peters and He (1987) and He (1989) has been coupled with Hodges (1976) nonlinear blade model. This blend is done in such a way that the aerodynamic forces and moments in the blade equations, as well as the pressure coefficients in the generalized dynamic inflow equations, are obtained as explicit nonlinear functions of the blade deformation and generalized dynamic inflow state variables, leading to standard eigenanalysis (de Andrade, 1992, and de Andrade and Peters, 1992). Consequently, reliable and computationally efficient results are expected, setting the generalized dynamic wake methodology as an appropriate alternative to use in rotor design and optimization.

As detailed in de Andrade (1992), the thick panel code (Kwon, 1988, and Kwon et al, 1991) requires large computing times and memory for coupling with Hodges-Dowell equations. This makes it difficult to perform any detailed study of the damping mechanisms with this code. On the other hand, the present state-space three-dimensional wake methodology applied to the Hodges-Dowell equations gives essentially identical answers for flap-lag-torsion damping as obtained with the panel code, but at 1/50th of the computing cost.

The generalized dynamic wake model has been extensively correlated with Kwon's thick panel aerodynamics (Kwon e al, 1991) and with the experimental results from Sharpe (1986). Complete details concerning the validation of the flap-lag-damping results obtained through this approach can be found in de Andrade and Peters (1992). Most recently, a deep investigation trying to explain the typical errors still present on both generalized dynamic wake model and panel aerodynamics flap-lag-torsion damping results with respect to experiments has been conducted (de Andrade and Peters, 1993). That research shows that correlations with experiments can be improved considerably when correct lift and drag coefficients

$$\begin{bmatrix} \ddots & & & \\ & [K_n^m] & & \\ & & \ddots & \\ & & & [K_n^m] \\ & & & & \ddots \end{bmatrix} \begin{Bmatrix} \vdots \\ \{a_n^m\} \\ \vdots \\ \cdots\cdots \\ \vdots \\ \{b_n^m\} \\ \vdots \end{Bmatrix}^{*} + \begin{bmatrix} \ddots & & \ddots & \\ [B_{nl}^m][V_n^m] & & -m[K_n^m] & \\ & \ddots & & \ddots \\ \ddots & & \ddots & \\ m[K_n^m] & & [B_{nl}^m][V_n^m] & \\ & \ddots & & \ddots \end{bmatrix} \begin{Bmatrix} \vdots \\ \{a_l^m\} \\ \vdots \\ \cdots\cdots \\ \vdots \\ \{b_l^m\} \\ \vdots \end{Bmatrix} = \frac{1}{2} \begin{Bmatrix} \vdots \\ \{\hat{\tau}_n^{mc}\} \\ \vdots \\ \cdots\cdots \\ \vdots \\ \{\hat{\tau}_n^{ms}\} \\ \vdots \end{Bmatrix}$$

FIG 2. Generalized dynamic wake equations in the rotating system.

based on the experimental Reynolds number are introduced, and when correction for recirculation in the test chamber is accounted for.

The purpose of this paper is to explore in detail the importance of unsteady three-dimensional aerodynamic effects in aeroelastic stability of helicopter rotors in hovering flight. With the present generalized dynamic wake model this task is naturally accomplished, since the solution approach leads directly to all eigenvalues and eigenvectors associated with a given rotor operating condition. Knowing the eigenvector associated with a given mode of interest, extraction of inflow distribution, blade displacements, and generalized aerodynamic force mode shapes, for example, is straighforward.

GENERALIZED DYNAMIC WAKE EQUATIONS IN THE ROTATING SYSTEM

The generalized dynamic wake equations formulated by Peters and He (1987, 1989) are derived from the basic potential flow conservation laws, where the spatial variation of pressure across the rotor is related to the variation of velocity at the disk (i.e., to the fluid flow momentum flux) and to the acceleration of the fluid flow through linear matrix operators. Particularized for hovering flight and written in the rotating system, they are given as in Fig 2.

Such a set of first-order differential equations is based on a nondimensional induced flow distribution at the rotor disk expanded in a entire set of harmonic and radial shape functions, including undetermined time dependent coefficients as aerodynamic states:

$$\bar{\lambda}(\bar{r}, \hat{\psi}, \bar{t}) = \sum_{m,n} \phi_n^m(\bar{r}) \left[a_n^m(\bar{t}) \cos(m\hat{\psi}) + b_n^m(\bar{t}) \sin(m\hat{\psi}) \right] \quad (1)$$

This induced flow representation not only offers a complete description of the flow, which is suitable to incorporate three-dimensional effects, but also handles higher harmonic dynamics, by the truncation at any harmonic of interest.

Within the first and second terms on the left-hand-side of Fig 2 one observes, respectively, the "apparent mass" and "quasi-steady" operators. The former is obtained in closed form and includes diagonal matrices as elements. In Fig 2, for the cosine part m assumes values 0, 1, 2,..., while for the sine part m has values 1, 2, 3,... The pressure distribution at the rotor disk, as seen on the right-hand-side of Fig 2, is modeled as a summation of the discrete loading on each blade, accounting simultaneously for a finite number of blades and overall rotor effects. For instance, the cosine part of the wake forcing functions has the form

$$\hat{\tau}_n^{mc} = \frac{1}{\pi} \sum_{q=1}^{Q} \left[\int_0^1 \phi_n^m(\bar{r})\, J_0(m\hat{b})\, \frac{L_S}{\rho_\infty \Omega^2 R^3}\, d\bar{r} \right] \cos(m\hat{\psi}_q) \qquad m \neq 0 \quad (2)$$

L_S is the total wake-generating circulatory lift at the blade section (Peters and Su, 1991; He, 1989, and de Andrade, 1992) which can be evaluated from a lift theory, and ρ_∞ is the air density (kg/m^3). The J_0 term arises from matching the present inflow model with Theodorsen lift theory (Peters and Su, 1991, and de Andrade, 1992). This is accomplished when a particular chordwise pressure distribution, which results in no induced flow on the airfoil due to bound vorticity, is applied with the inflow distribution defined in Peters' and He's model (1987, 1989). As discussed in Peters and Su (1991), when one deals with slender (high aspect-ratio) blades, it is reasonable to set J_0 to unity. This is equivalent to a lifting-line approximation for the lift and induced drag, with the inflow computed on the lifting-line. As a consequence, the nondimensional pressure expansion coefficients at the right-hand side of Fig 2 have their expressions simplified considerably. The present research is based on the above assumptions.

THE HINGELESS ROTOR BLADE MODEL AND THE BLADE EQUATIONS OF MOTION

Blade Configuration

The blade configuration adopted in this research is shown in Fig 3. The parameters of interest in this study are precone, β_{pc}, the inclination of the pitch bearing with respect to the plane of rotation (positive upwards); droop, β_d, the inclination (positive downwards at zero pitch angle) of the blade segment outboard of the pitch change bearing; and blade root offset, e_1, the distance between the center of rotation and the root of the blade. The blade is cantilevered in bending, and the kinematics of the pitch-link connection between the outboard segment of the blade and the swashplate control system is modeled by a torsional root spring.

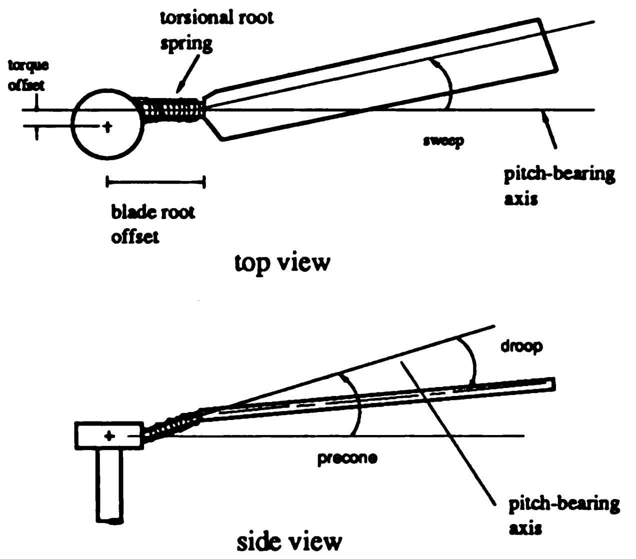

FIG 3. Rotor blade configuration.

The blade bending deflections v and w are defined parallel to and fixed to the sectional principal axes at the root end of the blade (along y and z axes), as sketched in Fig 4. This means that the lead-lag (v) and flap (w) deflections are literal inplane and out-of-plane displacements only at zero thrust condition, because they direction is established chordwise after the rigid body rotations, including collective pitch at the root (θ_0) and the pitch due to root spring deformation ($\Phi(t)$), are taken. The axial deflection u and the blade elastic torsion deformation ϕ are also shown in Fig 4.

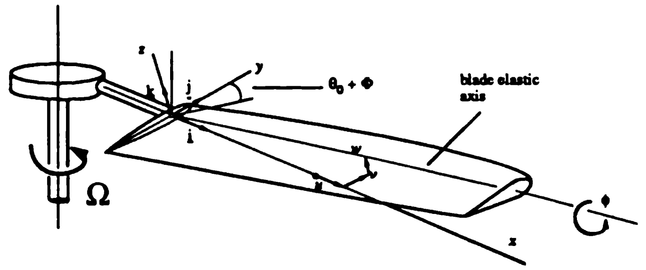

FIG 4. Orientation of blade elastic displacements.

Blade Equations of Motion

The rotor is treated in isolation; no couplings with the helicopter body degrees of freedom are accounted for. The blade equations of motion are derived from Hamilton's Principle. The cross section structural and inertial properties are assumed doubly symmetric with respect to the blade cross section principal axes and no strain energy from restrained torsional warping is considered. Furthermore, in this research, mass axis, tension axis, and aerodynamic center offsets from the elastic axis are all zero. The struc... and inertial operators are taken from Hodges and ... 1), and Hodges (1976), respectively. The aero... or is based on thin airfoil theory, in a way ... vs a time domain analysis, with a three... -induced flow governed by the generalized dynamic inflow model in Fig 2, according to the development presented in de Andrade (1992). The airfoil lift curve slope and the profile drag coefficients are assumed constant. The blade section is pivoted at an axis at its quarter-chord point (i.e., the x' axis normal to y' and z' axes in Figs 5-6; it coincides with the blade elastic axis intersection at the airfoil and is also the airfoil aerodynamic center in the context of thin airfoil theory). The deformed blade section is pitching at an angular speed $\dot{\varepsilon}$ about x' axis, as shown in those figures.

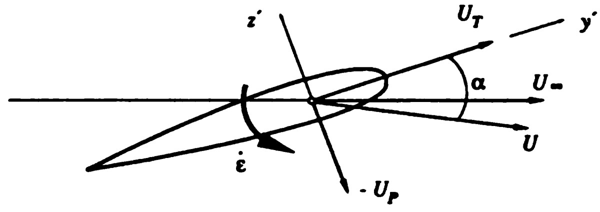

FIG 5. Unsteady motion of the blade section.

From Fig 5 it can be seen that the airfoil velocity components along the principal axes y' and z' (through the shear center of the section) are $U_T\,\underline{j}'$ and $U_P\,\underline{k}'$. α is the instantaneous angle of attack of the blade section and it is defined as the angle between the chordline and the resultant velocity at the cross section, $\underline{U} = U_T\,\underline{j}' + U_P\,\underline{k}'$. Also, the lift per unit of length (circulatory, L_C, and noncirculatory, L_{NC}) and pitching moment per unit of length (circulatory and noncirculatory) are expressed in terms of U_T, U_P and $\dot{\varepsilon}$. Since U_T, U_P and $\dot{\varepsilon}$ can be expressed in terms of the blade elastic displacements, v, w, and ϕ, the root pitch Φ, and the inflow expansion coefficients a_n^m and b_n^m, the generalized aerodynamic forces and moments, L_u, L_v, L_w, M_ϕ and the integral over the blade length of the moment due to the root spring, M_Φ, are expressed in terms of blade displacements and inflow expansion coefficients as well.

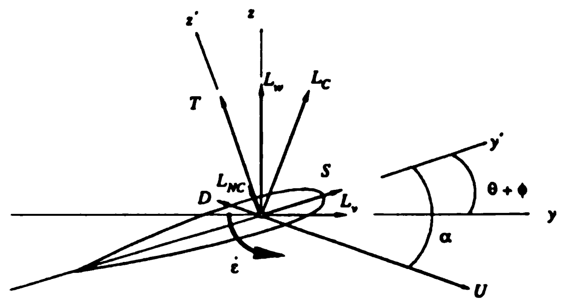

FIG 6. Orientation of aerodynamic loads.

In the derivation of the blade equations a ordering scheme is employed, based on a small parameter of the order of magnitude of the bending slopes. Resulting equations are simplified by integration of the variational equation for the blade radial displacement to obtain the blade tension and by an expression of tension and radial displacements in terms of remaining blade displacements and torsional root spring deformation. In summary, a set of nonlinear hybrid equations of motion, consisting of one integro-partial differential equation for the root pitch, and three integro-partial differential equations each for flapwise and chordwise bending and elastic torsion, is obtained.

Concerning the airloads-inflow coupling, three points should be mentioned: 1) under the assumptions of the thin airfoil theory ($U \approx U_\infty$), and up to the second order, the wake-generating circulatory lift is taken as the circulatory part of L_w in this research (rigorously, one should take the circulatory lift normal to the rotor disk, along the induced flow direction, for all operational conditions; 2) a lifting-line approximation is taken by setting J_0 to unity in the nondimensional pressure expansion coefficients (Fig 2 and Eq (2)); and 3) under thin airfoil theory, the lifting-line is placed at the blade quarter-chord, which, typically, has a constant azimuthal coordinate for a rectangular blade. Since $\widehat{\psi}_q$, the azimuthal position of the q-th blade, is defined at the blade midchord for the compatibilization with Theodorsen's lift theory (Peters and Su, 1991, and de Andrade, 1992), it would, rigorously, be a function of the radial coordinate $\bar{r}$. However, numerical results from Peters and Su (1991) show that this skewing (yawing) has a negligible effect on the inflow computation.

COUPLING INFLOW AND BLADE EQUATIONS OF MOTION - SOLUTION APPROACH

The first step towards solution is to simplify the blade nonlinear hybrid equations by the assumption of uniform mass and stiffness, and to obtain nonlinear ordinary differential equations in time by applying Galerkin's method. Before that, the blade nondimensional displacements in lead-lag, flap (both nondimensional on $(R - e_1)$), and torsion are expanded, respectively, as:

$$\left.\begin{aligned} \bar{v} &= \sum_{i=1}^{N} [V_{0i} + \Delta V_i(\bar{t})]\Psi_i(\bar{x}) \\ \bar{w} &= \sum_{i=1}^{N} [W_{0i} + \Delta W_i(\bar{t})]\Psi_i(\bar{x}) \\ \phi &= \sum_{i=1}^{N} [\Phi_{0i} + \Delta\,\Phi_i(\bar{t})]\Theta_i(\bar{x}) \end{aligned}\right\} \qquad (3)$$

Each expansion assumes small unsteady perturbation about steady equilibrium condition; the variables with "zero" indices are equilibrium generalized coordinates, and the ones with "delta" are perturbation coordinates. Modified orthogonal Duncan polynomials are taken as mode shapes ($\Psi_i(\bar{x})$ for lead-lag and flap bending and $\Theta_i(\bar{x})$ for torsion).

The pitch angle due to the root spring is expanded about the equilibrium condition as $\Phi = \Phi_0 + \Delta\,\Phi(\bar{t})$, with no dependence on the blade spanwise coordinate. Also, the inflow expansion coefficients are split into steady-state and perturbation part as:

$$a_n^m(\bar{t}) = \bar{a}_n^m + \tilde{a}_n^m(\bar{t}) \text{ and } b_n^m(\bar{t}) = \bar{b}_n^m + \tilde{b}_n^m(\bar{t}) \qquad (4)$$

Modal Equilibrium Equations

The steady-state part of the inflow equations can be expressed in the following short-hand notation:

$$\begin{bmatrix} [B_0][V_0] & -[K] \\ [K]^T & [B_1][V_1] \end{bmatrix} \begin{Bmatrix} \{\bar{a}_n^m\} \\ \{\bar{b}_n^m\} \end{Bmatrix} = \frac{1}{2} \begin{Bmatrix} \{\bar{\tau}_n^{mc}\} \\ \{\bar{\tau}_n^{ms}\} \end{Bmatrix} \qquad (5)$$

Since at steady-state the "antisymmetric" part of the pressure ($\bar{\tau}_n^{ms}$) is zero, the second row partition in Eq. (4) can be solved for the $\bar{b}$'s as:

$$\{\bar{b}_n^m\} = -[V_1]^{-1}[B_1]^{-1}[K]^T\{\bar{a}_n^m\} \qquad (6)$$

for $m = 0, Q, 2Q, 3Q, \ldots$

Then, substituting back in the first "row", a system of S nonlinear algebraic equations is obtained (S is the number of inflow steady-state expansion coefficients taken), that can be represented in the following form:

$$\bar{a}_n^m = \bar{a}_n^m(V_{0j}, W_{0j}, \Phi_{0j}, \Phi_0, \bar{a}_n^m) \qquad (7)$$

As observed in the above representation, the $\bar{a}$'s are nonlinear related to all blade equilibrium generalized coordinates, and to the $\bar{a}$'s themselves. This is a consequence of the use of the nonlinear version of the inflow equations (Peters and HaQuang, 1988), which defines the momentum theory flow parameters as function of the steady, uniform inflow as:

$$V_1^0 = V_T = \sqrt{3}\,\bar{a}_1^0; \qquad V_n^m = 2V_T = 2\sqrt{3}\,\bar{a}_1^0, \qquad (8)$$

$$(n,m) \neq (1,0)$$

Also, the steady-state lift, within the $\bar{\tau}_n^{mc}$ involves nonlinear relation between flap and lead-lag.

In the blade equations, by substituting only the equilibrium and steady-state quantities and dropping out all time derivative terms, a set of $(3N + 1)$ nonlinear equations for ($\delta V_{0i}, \delta W_{0i}, \delta\Phi_{0i}$, and $\delta\Phi_0$) is established.

Collecting altogether blade and inflow steady-state equations, a set of $((3N + 1) + S)$ nonlinear algebraic equations in terms of the equilibrium parts of the blade generalized coordinates and the inflow steady-state expansion coefficients $\bar{a}$'s is obtained.

$$\begin{Bmatrix} \{\Delta Z\} \\ \{\Delta Z^{*}\} \\ \begin{Bmatrix} \tilde{a}_n^m \\ \tilde{b}_n^m \end{Bmatrix} \end{Bmatrix}^{*} = \begin{bmatrix} 0 & I & 0 \\ -[\mathcal{M}]^{-1}[\mathcal{K}] & -[\mathcal{M}]^{-1}[\mathcal{C}] & -[\mathcal{M}]^{-1}[\mathcal{k}] \\ -[\mathfrak{am}]^{-1}[\mathfrak{QS}] & -[\mathfrak{am}]^{-1}[\mathfrak{AM}] & -[\mathfrak{am}]^{-1}[\mathfrak{qs}] \end{bmatrix} \begin{Bmatrix} \{\Delta Z\} \\ \{\Delta Z^{*}\} \\ \begin{Bmatrix} \tilde{a}_n^m \\ \tilde{b}_n^m \end{Bmatrix} \end{Bmatrix}$$

FIG 7. Linearized perturbation equations in state-variable form.

Eigenproblem for the Perturbation Variables

The perturbation equations are obtained by substituting the equilibrium (steady-state) and perturbation quantities, subtracting off the equilibrium (steady-state) equations, and discarding all nonlinear products of dynamic perturbation quantities. The coupled linearized perturbation equations can be set into a state-variable form as given in Fig 7. In that equation, the second row partition comes from the blade perturbation equations and the third row partition is from the unsteady inflow perturbation equations. At the right-hand-side of the equation, one can observe the stability matrix; its elements are constant partitioned coefficient matrices which depend on the solution of the equilibrium/steady-state equations (these matrices are defined in de Andrade (1992)). The column vector $\{\Delta Z\}$ contains the perturbation modal generalized coordinates from all blades. They are coupled through the inflow pressure functions, Eq (2), that involve summations over all the blades. The stability of small motions about the equilibrium operating condition is determined by the eigenvalues of the stability matrix. It is interesting to observe that by removing last partitioned row and partitioned column of the equations within Fig 7, one basically recovers the same stability problem obtained by Hodges and Ormiston (1976) in the 70's under a quasi-steady aerodynamic model.

Eigenproblem Solution Approach

To solve for the eigenproblem, a "harmonic-assumed approach" is adopted (de Andrade, 1992). Under this solution scheme, one takes advantage of multiblade coordinate transformation, and the equations of motion are written for a reference blade, with the blade modes of vibration (collective, differential, cyclic) assumed beforehand, by keeping selected harmonic numbers in the inflow expansion. This means that the effects of all blades are accounted automatically as the selected harmonic numbers in the inflow expansion are varied.

Taking, for example, a 2-bladed rotor, to obtain the dynamics associated with the collec[illegible]e, "even only" harmonic numbers are selected [illegible] expansion (p in the following expressions

$$\begin{Bmatrix} \tilde{a}_n^m \\ \tilde{b}_n^m \end{Bmatrix} = \left\lfloor \{\cdots(\tilde{a}_n^{2p})\cdots\},\ \{\cdots(\tilde{b}_n^{2p})\cdots\} \right\rfloor^T \tag{9}$$

and the vector of blade states takes the form

$$\{\Delta Z\} = \left\lfloor \frac{\Delta V_{j1}+\Delta V_{j2}}{2}, \frac{\Delta W_{j1}+\Delta W_{j2}}{2}, \frac{\Delta\Phi_{j1}+\Delta\Phi_{j2}}{2}, \frac{\Delta\Phi_1+\Delta\Phi_2}{2} \right\rfloor^T \tag{10}$$

$$j = 1, 2, 3, \ldots, N$$

Similarly, to obtain the dynamics of the differential (cyclic) mode, one assumes "odd only" harmonic numbers,

$$\begin{Bmatrix} \tilde{a}_n^m \\ \tilde{b}_n^m \end{Bmatrix} = \left\lfloor \{\cdots(\tilde{a}_n^{2p+1})\cdots\},\ \{\cdots(\tilde{b}_n^{2p+1})\cdots\} \right\rfloor^T \tag{11}$$

and the vector of blade states takes the form

$$\{\Delta Z\} = \left\lfloor \frac{\Delta V_{j1}-\Delta V_{j2}}{2}, \frac{\Delta W_{j1}-\Delta W_{j2}}{2}, \frac{\Delta\Phi_{j1}-\Delta\Phi_{j2}}{2}, \frac{\Delta\Phi_1-\Delta\Phi_2}{2} \right\rfloor^T \tag{12}$$

$$j = 1, 2, 3, \ldots, N$$

For a Q-bladed rotor, under the same solution method, the harmonic number varies as

$$\begin{array}{lll} \text{collective mode:} & m = j\,Q & \\ \text{differential mode:} & m = Q/2 + j\,Q & (Q \text{ even}) \\ p\text{-th cyclic mode:} & m = |\,p \pm j\,Q\,| & \end{array} \tag{13}$$

$$j = 0, 1, 2, 3, \ldots$$

RESULTS AND DISCUSSION

The rotor configuration and operational conditions for which the results are obtained in this research come from Sharpe's (1986) experimental investigations (a two-bladed, untwisted, stiff inplane, torsionally soft hingeless model rotor, including a blade root offset, tested at a nominal speed of 1,000 RPM). The hub was designed to allow variation in precone, blade droop, pitch control stiffness and blade pitch angle. Results from the present approach are denoted by GDWM (Generalized Dynamic Wake Model) in the following plots.

Values assumed for the harmonic numbers (m) are shown in the legends, where "(E)" means that "even only" harmonic numbers are taken within the inflow expansion. The total number of spatial modes (inflow states) in the inflow expansion is chosen as 15, 45, 66, and 91, leading to 6, 15, 21, and 28 expansion coefficients (S), respectively, in the steady-state (equilibrium) analysis. Such inflow expansion selections come from a mathematically consistent hierarchy presented in He (1989). The convergence of the present methodology is investigated in detail by de Andrade (1992) and de Andrade and Peters (1992). In this paper we present results for aerodynamic force mode shapes including steady-state and dynamics. All results include 5 mode shapes for each of elastic torsion, flap bending, and lead-lag bending deflections. Also, the aerodynamic loads to be presented in this section have been normalized by twice the product of the dynamic pressure at the blade tip and the blade length. It is important to mention that the theoretical approaches from which the numerical results are compared herein have the same structural, inertial, and airloads models (the first from Hodges and Dowell, 1974, and the last two from Hodges, 1976), so the differences are basically due to the differences in the inflow.

Numerical results for steady-state (equilibrium)

The effects of the present approach on general steady-state blade deflections and steady-state aerodynamic load mode shapes are presented in Fig 1-3. Results from the present methodology are correlated with two-dimensional, momentum/blade-element counterparts, which include uniform inflow distribution.

First, in Fig 8, one observes steady-state inflow distributions for rotor configurations including soft pitch flexures, zero precone and droop, for the blades at $\theta_0 = 8°$. The uniform momentum theory takes the inflow at the 3/4 blade span. It predicts too large induced flow at the root sections and to small values at the tip sections. The generalized dynamic inflow methodology shows nonuniform inflow distributions, and, as the number of expansion coefficients increases, the inflow begins to climb near the blade tip, meaning that they are converging to the Prandtl "exact" tip correction. Basically, this nonuniformity and implicit three-dimensional characteristics are the major ingredients responsible for the partial capture of the tip relief on both steady-state induced drag and lift distribution to be shown. On the other hand, since this finite-state inflow model is based on a cylindrical, undistorted wake, no upwash due tip-vortex is captured, what would happen if prescribed or free-wake models were used.

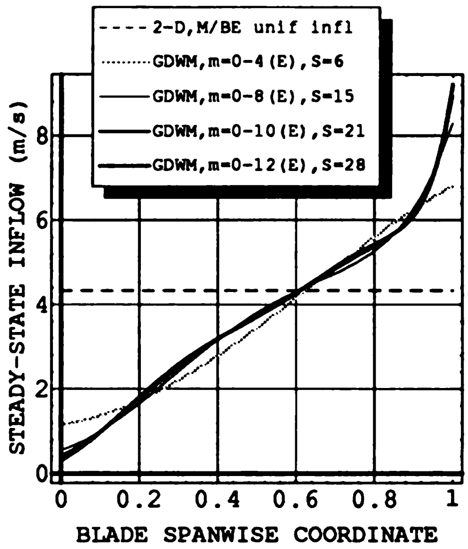

FIG 8. Spanwise steady-state inflow
SOFT PITCH FLEXURE, $\beta_{pc} = \beta_d = 0°$; $\theta_0 = 8°$

Figure 9 (a) show correlations for the steady-state induced drag. The finite-state results start capturing the three-dimensional tip-relief effects as the number of expansion coefficients increases, and show a maximum loading at 92% of the

blade length and quickly decreasing load towards the tip. Regarding the two-dimensional uniform momentum/blade-element results, too much induced drag is obtained at both the blade root and tip sections, which is basically responsible for different sectional bending moments leading to higher lead-lag equilibrium deflections, specially near the blade tip, as shown in Fig 10 (a).

Correlations for steady-state lift distributions are presented in Fig 9 (b). Here, the two-dimensional, uniform momentum/blade-element theory predicts too little lift at the root sections and too much lift at the tip sections. The GDWM results for lift have basically the same trend a those shown for the steady-state induced drag, showing more evident drop near the tip due to three-dimensional tip relief. The differences between the two approaches are ultimately responsible for the differences shown in the flap equilibrium deflections at the blade tip as shown in Fig 10 (b).

Figure 10 shows correlations for blade bending tip deflections in lead-lag and flap in terms of the collective pitch angle. Remarkable differences are observed in the lead-lag deflections from the two theoretical approaches as seen in Fig 10 (a). It is observed that a zero thrust the blade is lagging in the rotor plane, due to the profile drag. As the thrust gets higher, the blade assumes positive chordwise displacements (the transition occurs at 6° of collective pitch as predicted by the two-dimensional aerodynamics, and at 7° by the finite-state formulation). As commented before, such differences are essentially due to the differences in the induced drag predictions (shown in Fig 9 (a)), since ... oaches have the same profile drag (the same co... rag coefficient is assumed). Similarly, consi... s are obtained for the flap equilibrium de... ade tip, as observed in Fig 10 (b), which are basically due to the differences in the lift distribution between the respective approaches (Fig 9 (b)). Interpreting the bending equilibrium displacements results just shown, for instance, the values of lead-lag and flap at the blade tip at $\theta_0 = 12°$ and computing the inplane displacement, one finds that the blade tip is lagging 0.0052 *m* and is above the rotor disk about 0.048*m*.

As detailed in de Andrade (1992), relative small differences between the two approaches are obtained for the torsion equilibrium deflections at the blade tip. The role of the pitch flexure in the steady-state results was investigated as well. Aerodynamic loads and blade equilibrium deflections remain practically the same as the stiffness of the pitch flexure is largely varied.

Numerical results for dynamics (eigenanalysis)

The dynamics results from the present approach to be shown in this paper are obtained directly from an eigenanalysis. Recall that, with the finite-state wake model eigenvector information contains not only information on structural deflections and velocities, but also contains information on the inflow oscillations. Thus, one can construct the in-phase (real) and out-of-phase (imaginary) lift associated with any given mode. Here we are concerned with the generalized aerodynamic mode shapes which can be obtained directly from the eigenvectors associated with a given rotor operating condition. For this research, the rotor mode of interest is defined as the one with frequency nearest the fundamental lead-lag frequency of the rotating blade, which is known for being lightly damped (all results here are for the rotor mode with frequency around 1.5/*rev*). Unfortunately, no experimental data involving blade displacements or aerodynamic forces are

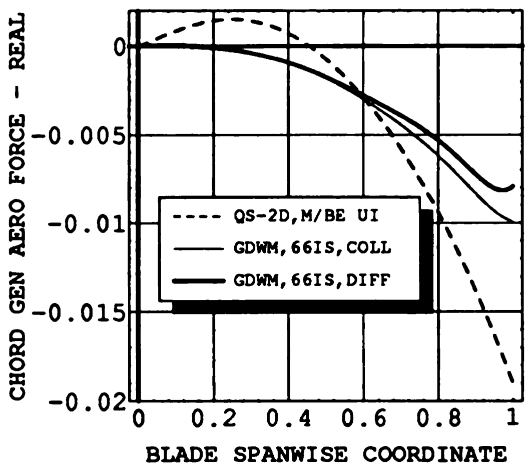

FIG 11. Spanwise distribution of chordwise generalized aerodynamic force (drag due to chordwise mode) - real part soft pitch flexure; $\theta_0 = 4°$; $\beta_{pc} = \beta_d = 0°$; diff vs. coll

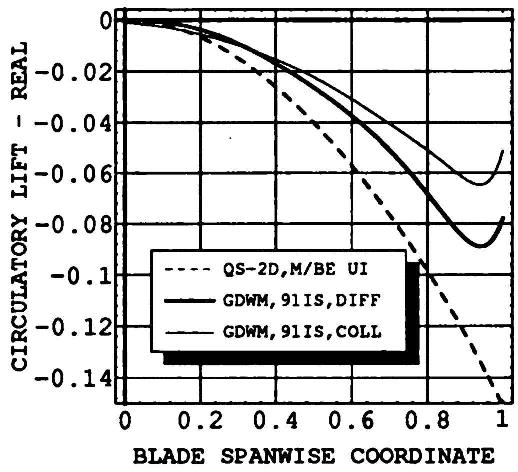

FIG 12. Spanwise distribution of circulatory lift (lift due to chordwise mode) - real part; $\beta_{pc} = \beta_d = 0°$ soft pitch flexure; $\theta_0 = 4°$; differential vs. collective

available at this point, so the correlations to be presented here include GDWM and quasi-steady two-dimensional aerodynamic techniques.

First, correlations are presented for eigenvectors associated with the "rotor mode of interest" at $\theta_0 = 4°$. With respect to the chordwise generalized aerodynamic force, the real part (which is the dominant contribution – the imaginary part is very small) is shown in Fig 11. GDWM results for the rotor differential and collective modes of vibration are presented along with the quasi-steady two-dimensional counterparts. First, we notice that the quasi-steady loads are even qualitatively correct due to assumption of uniform inflow and the neglect of unsteady induced inflow. Finite-state inflow chordwise generalized aerodynamic forces show a drop of about 50% with respect to the quasi-steady two-dimensional prediction. Due to the predominance of the first lead-lag at low values of collective pitch, a great part of that represents chordwise damping loss. This confirms the differences observed for the lead-lag damping between the two approaches (de Andrade and Peters, 1992 and 1993). Regarding the circulatory lift mode shapes, in Fig 12 the real part (in-phase) is presented (both real and imaginary parts have the same order of magnitude, due to close dependence on perturbational flap, for which real and imaginary parts have the same order of magnitude (de Andrade, 1992)). The higher level of circulatory lift associated with the differential mode (in comparison with the collective circulatory lift) is a direct consequence of the lower inflow resultant from this mode when compared to the inflow associated with the collective mode of vibration. Also, one observes a severe drop in the values for the incremental collective and differential circulatory lifts (which are the corresponding perturbation wake-generating circulatory lift, L_S, in Eq (2)) compared with the quasi-steady two-dimensional aerodynamic perturbational lift.

As the thrust increases, strong structural couplings are present. Figures 13 and 14 show generalized aerodynamic mode shapes for chordwise force and circulatory lift, respectively, for $\theta_0 = 8°$. Here the chordwise load goes along the real and imaginary part of the circulatory lift (flapwise loads) and coupled flap-lag-torsion motions to define the blade damping. The differences between generalized wake loads and the quasi-steady loads seen in Figs 13 and 14 account for the 50% improvement in damping as pointed out in de Andrade, 1992, and de Andrade and Peters (1992, 1993).

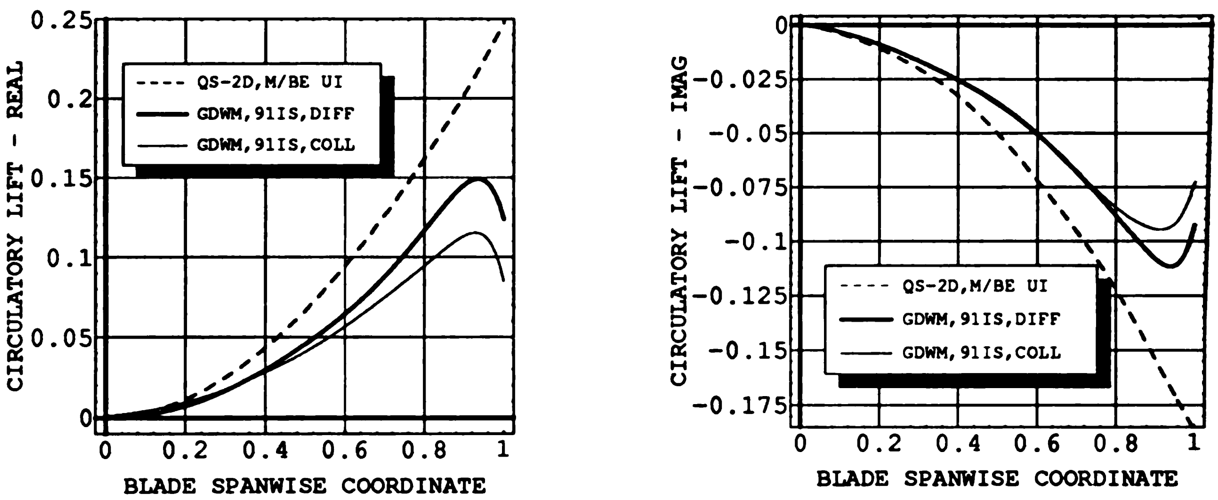
CONCLUSIONS

This research investigates the stability of helicopter rotors in hovering flight through a coupled set of generalized dynamic inflow equations and hybrid equations of motion for an elastic blade cantilevered in bending and having a torsional



(a) (b)

FIG 14. Spanwise distribution of circulatory lift - differential vs. collective soft pitch flexure; $\theta_0 = 8°$; $\beta_{pc} = \beta_d = 0°$; (a) real part; (b) imaginary part

root spring to model pitch-link flexibility. The present approach leads to a standard eigenanalysis for the dynamic part of the problem, for which the coefficient matrices depend on the numerical solution of blade equilibrium and inflow steady-states. Results presented in this paper are for a two-bladed, untwisted stiff inplane hingeless small scale (model) rotor with torsionally soft blades, including blade root offset, precone. They confirm the importance of three-dimensional, unsteady aerodynamics for aeroelastic investigations. The major conclusions associated with this application of the generalized dynamic wake model can be summarized as: 1) numerical results show that three-dimensional tip relief effects within the nonuniform steady-state inflow are significant to predict steady-state aerodynamic loads and blade deflections, and 2) eigenvector analysis correlations reinforced qualitative and quantitative shortcomings associated with quasi-steady two-dimensional aerodynamic theory for aeroelastic applications in hover.

The treatment of the aeroelastic stability through an eigenanalysis as formulated in this work is specially convenient when helicopter integrated dynamics are involved. The elimination of time-marching and moving block analyses, present current state-of-the-art approaches to the same problem, with essentially no essential loss of accuracy for the obtained results, constitutes the primary contributions of the present methodology. The efficiency of this makes rotor optimization with aeroelastic stability a practical endeavor.

Damping of vibrations of layered elastic-viscoelastic beams

Richard B Hetnarski, Ray A West[1] and Joseph S Torok

Rochester Institute of Technology, Rochester NY 14623

A five-layer cantilever beam consisting of an elastic core, two symmetric viscoelastic layers, and two elastic constraining layers is considered. The viscoelastic effects are incorporated in the Euler-Bernoulli beam theory. If the contraction and extension of the constraining layers is neglecterd a fourth order differential equation of motion is received. Inclusion of contraction and extension of the constraining layers results in a more accurate sixth order differential equation. Appropriate boundary conditions are derived. Laplace transforms are used extensively. Both the analytical solution and the numerical results are presented.

INTRODUCTION

For many years there has been a substantial interest among researchers and engineers in developing effective methods of damping of beam vibrations. One such method consists of bounding to the top and the bottom of an elastic beam symmetrical layers of viscoelastic material. These layers, due to internal shear during the motion of the beam, changes a part of the kinetic energy into heat, which then is distributed to the ambient atmosphere. In order to increase the effect of shear, additional two thin elastic layers are bounded to the viscoelastic layers. In this way, we deal with a five-layer beam shown in Fig. 1.

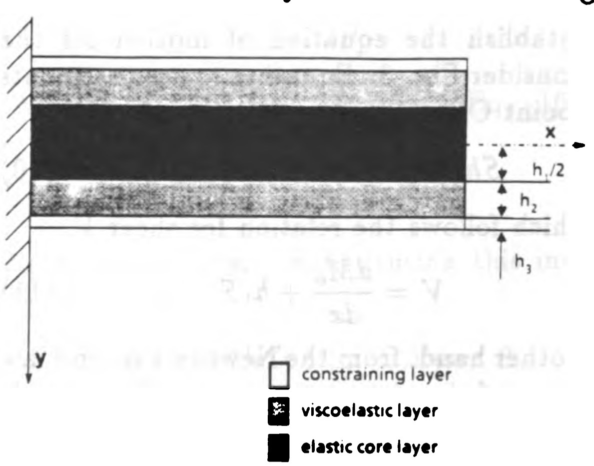

Fig. 1. Five-layer cantilever beam.

The analytical treatment of such or similar composite beams is difficult, see e.g., [1 - 4]. A short introduction to the method shown here has been presented in [5], and some other results are presented in [6] and [7].

The assumptions made in this analysis are: (1) Viscoelastic layers are characterized by a complex shear modulus $G = G^*(1 + \eta i)$. (2) The central structural element and the constraining layers and are assumed to remain in pure bending. (3) The neutral axes of the core and of the constraining layers have identical deflection lines during bending. In the next Section, it is also assumed that the lengths of constraining layers remain constant at all times during motion, and equal to the length of the central layer; this is equivalent to the assumption that the constraining layers are not stretched or shortened during bending. This assumption is waved in the subsequent Section where the sixth order differential equation of motion is derived.

FOURTH ORDER DIFFERENTIAL EQUATION OF MOTION

The analysis leading to the fourth-order equation of motion is based on the geometry of motion of the beam presented in Fig. 2 where the lower

[1] Present address: Xerox Corporation, Fairport, NY 14450.

half of the beam is shown. Segment AB lies on the line $a_1 - a_1$ normal to the deflection line of teh beam. Line segments AB' and C'D lie on a line $a_2 - a_2$ parallel to the y axis. Obviously, when the beam is not deflected, the lines $a_1 - a_1$ and $a_2 - a_2$ coinside. Segments AB' and C'D lie on the same line $a_2 - a_2$ if the constraining layer does not stretch and if deflections are small. It follows from $\triangle ABB'$ in Fig. 2 that

$$m \approx (h_1/2)y' \qquad (1)$$

where $y' = tan\angle BAB' \approx sin\angle BAB'$ for small deflections. Similarly, from $\triangle CC'D$, we have

$$n \approx -(h_3/2)y' \qquad (2)$$

It is seen, therefore, that the angle of shear $/\gamma$ in the viscoelastic layer is

$$\gamma = y' + (m-n)/2 \qquad (3)$$

or, after substitution,

$$\gamma = ay' \qquad (4)$$

where

$$a = 1 + (h_1 + h_3)/2h_2 \qquad (5)$$

A convention is used that γ is positive in the counter-clockwise direction if measured from the line $a_1 - a_1$. Therefore, the shear S acting on the surface of core per unit length of the beam and, in the opposite direction, on the surface of the constraining layer, is

$$S = \gamma G_1 b \qquad (6)$$

in units of force per units of length. Here b is the width of the beam.

In our case, the bending moment M in an arbitrary cross-section consists of two parts

$$M = M_o + M_1 \qquad (7)$$

where M_o is due to the stiffness of the beam

$$M_o = -EI\frac{\partial^2 y}{\partial x^2} \qquad (8)$$

while M_1 is due to shear S in the viscoelastic layers, see Fig. 3. Since the constr·ining layers are thin compared to the core, t[illegible] of inclusion of the bending stiffne[illegible] straining layers is very small. Ne[illegible] Eq. (8),

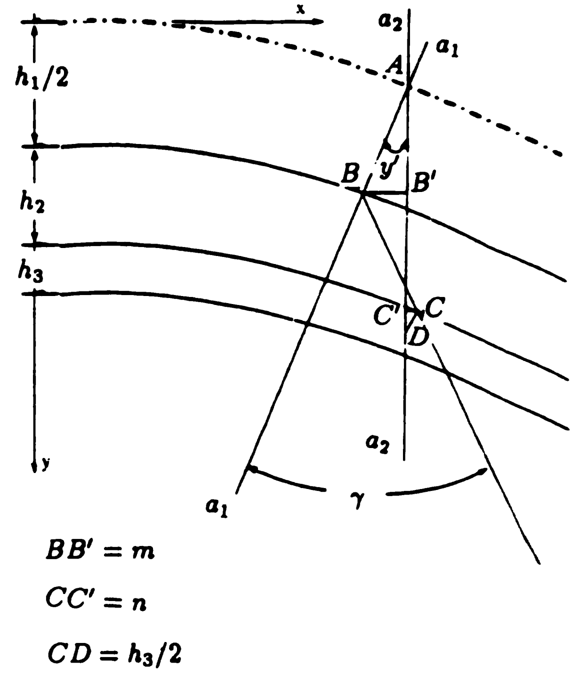

Fig. 2. Geometry of bending (fourth order eq.).

the stiffness EI of the layered beam is taken as a combination of the stiffnesses of the core and of the constraining layers:

$$EI = E_1 I_1 + 2E_3 I_3 \qquad (9)$$

It is assumed that the viscoelastic layers do not contribute to the stiffness of the beam.

To establish the equation of motion for the beam consider Fig. 3. Equating to zero moments about point O we receive

$$Sh_1 dx - Vdx + dM_o = 0 \qquad (10)$$

from which follows the relation for shear V

$$V = \frac{dM_o}{dx} + h_1 S \qquad (11)$$

On the other hand, from the Newton's second law the motion of the element in vertical direction is

$$(\rho dx)\ddot{y} = dV \qquad (12)$$

where $\rho = (\rho_1 h_1 + 2\rho_2 h_2 + 2\rho_3 h_3)b$ and ρ_i are mass densities of the materials of appropriate layers. Dividing by dx yields

$$\rho\ddot{y} = V' \qquad (13)$$

Differentiating V from Eq. (11) and substituting in Eq. (13) results in

$$\rho \ddot{y} = M_o'' + h_1 S' \qquad (14)$$

Substituting in Eq. (14) M_o from Eq. (8) and S from Eq. (6) with γ from Eq. (4) we arrive at the equation of motion

$$EIy^{IV} - abh_1 G y'' + \rho \ddot{y} = 0 \qquad (15)$$

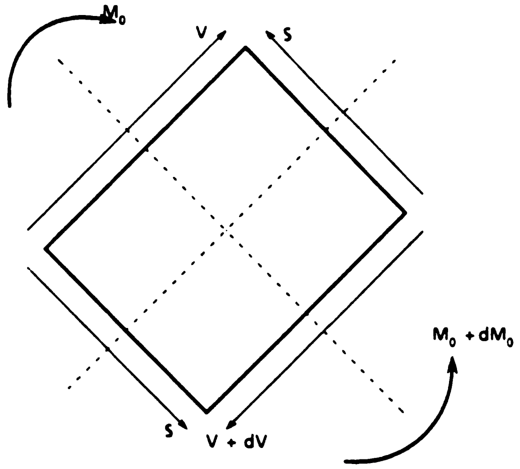

Fig. 3. Free body diagram for beam element.

or, in a simpler form,

$$y^{IV} - cGy'' + \frac{\rho}{EI}\ddot{y} = 0 \qquad (16)$$

where

$$c = \frac{abh_1}{EI} \qquad (17)$$

Assume that that the solution to Eq. (16) may be presented in the form

$$y(x,t) = w(x)e^{\omega t} \qquad (18)$$

where ω is complex. Substituting this into Eq. (16) results in

$$w^{IV} - cGw'' + (\omega/\omega_o)^2 w = 0 \qquad (19)$$

where

$$\omega_o = (EI/\rho)^{1/2} \qquad (20)$$

Applying the Laplace transform

$$\bar{w}(p) = \int_0^\infty w(x)e^{-px}dx \qquad (21)$$

to Eq. (19), we receive after simple transformation

$$\bar{w}(p) = \frac{1}{p^4 - rp^2 + s^2}(\alpha_1 p^3 + \alpha_2 p^2 + \alpha_3 p + \alpha_4) \qquad (22)$$

where $r = cG$, $s = \omega/\omega_o$, and

$$\alpha_1 = w(0), \quad \alpha_2 = w'(0)$$

$$\alpha_3 = w''(0) - cGw(0), \quad \alpha_4 = w'''(0) - cGw'(0) \qquad (23)$$

Writing the denominator in Eq. (22) in the form

$$p^4 - rp^2 + s^2 = (p^2 - u^2)(p^2 - v^2) \qquad (24)$$

we may observe that the appropriate inverse Laplace transforms are

$$L^{-1}\left\{\frac{p^3}{(p^2-u^2)(p^2-v^2)}\right\} = \frac{u^2 \cos ux - v^2 \cos vx}{u^2 - v^2} \equiv L_1 \qquad (25)$$

$$L^{-1}\left\{\frac{p^2}{(p^2-u^2)(p^2-v^2)}\right\} = \frac{u \,sh\, ux - v \,sh\, vx}{u^2 - v^2} \equiv L_2 \qquad (26)$$

$$L^{-1}\left\{\frac{p}{(p^2-u^2)(p^2-v^2)}\right\} = \frac{ch\, ux - ch\, vx}{u^2 - v^2} \equiv L_3 \qquad (27)$$

$$L^{-1}\left\{\frac{1}{(p^2-u^2)(p^2-v^2)}\right\} = \frac{v \,sh\, ux - u \,sh\, vx}{u^2 - v^2} \equiv L_4 \qquad (28)$$

Therefore,

$$w(x) = \alpha_1 L_1 + \alpha_2 L_2 + \alpha_3 L_3 + \alpha_4 L_4 \qquad (29)$$

The boundary conditions are determined from the energy approach. Utilizing the left-hand side of Eq. (19) calculate the integral

$$I = \int_0^l [w_i^{IV} - cGw_i'' + (\omega/\omega_o)^2 w_i]w_j dx \qquad (30)$$

where w_i and w_j are functions of x only, and subscripts i and j denote node numbers. Integrating Eq. (30) repeatedly by parts, the following result is obtained:

$$I = \int_0^l [w_j^{IV} - cGw_j'' + (\omega/\omega_o)^2 w_j] w_i dx$$
$$+ [w_i''' w_j - w_i'' w_j' + w_i' w_j''$$
$$- w_i w_j''' - cG(w_i' w_j - w_i w_j')]_0^l \qquad (31)$$

The boundary conditions are received when the expression in brackets in Eq. (31) is equal to zero both for $x = 0$ and for $x = l$. Observe first that $w_k(0) = w_k'(0) = 0$, $(k = i, j)$ are consistent with customary boundary conditions for a cantilever beam. Rearrange now the terms in brackets in Eq. (31) to arrive at the form

$$(w_i''' - cGw_i')w_j - (w_j''' - cGw_j')w_i - w_i'' w_j' + w_j'' w_i' \qquad (32)$$

This expression is zero when

$$w_k'''(l) - cGw_k'(l) = 0 \text{ and } w_k''(l) = 0, \quad (k = i, j) \qquad (33)$$

The first of these conditions is not intuitively obvious. A complete set of boundary conditions is then:

$$w = 0 \text{ and } w' = 0 \text{ for } x = 0 \qquad (34)$$

and

$$w''' - cGFw' = 0 \text{ and } w'' = 0 \text{ for } x = l \qquad (35)$$

SIXTH ORDER DIFFERENTIAL EQUATION OF MOTION

The results of the previous Section will lead to the derivation of a more accurate description of free vibrations of a beam. We will now assume that the extension and contraction of the constraining layers is not neglected.

Inasmuch as the angle of shear is $\gamma = ay'$ Eq. (15) is rewritten in the form

$$EIy^{IV} - bh_1G\gamma' + \rho\ddot{y} = 0 \qquad (36)$$

Because of the shear force exerted by the viscoelastic layers on the constraining layers, there exists a longitudinal deformation in the constraining layers in the form [illegible] sion and contraction. This deformati[illegible] magnitude of the angle of shear. I[illegible] olute value of the shear angle is a[illegible] n the absolute value of γ. As shown in Fig. 4, the resulting angle of shear is for a given moment of time t

$$\gamma + \delta = ay' = \frac{u(x)}{h_2} \qquad (37)$$

where $u(x)$ is the longitudinal displacement of the constraining layer on the positive side of the y-axis. Observe that u(x) in the situation shown in Fig. 4 is negative. This is consistent with the assumed convention for the sign of the angle; clock-wise direction of δ in Fig. 4 indicates a negative angle. Submitting $\gamma + \delta$ in place of γ in Eq. (36) yields

$$EIy^{IV} - bh_1G\frac{d}{dx}(\gamma + \delta) + \rho\ddot{y} = 0 \qquad (38)$$

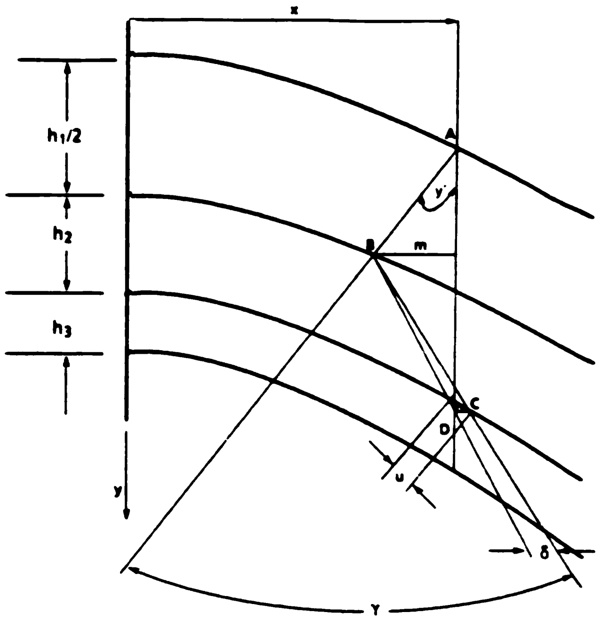

Fig. 4. Geometry of bending (sixth order eq.).

Introducing the value of $\gamma + \delta$ from Eq. (37) results in

$$EIy^{IV} - bh_1G(ay'' + u'/h_2) + \rho\ddot{y} = 0 \qquad (39)$$

The relation between the shear stress τ in the viscoelastic layer and the strain in the constraining layer at a position x is

$$E_3H_3u' = \int_x^l \tau dx \qquad (40)$$

in this relation the sign of τ is the same as the sign of u'. Differentiating Eq. (40) gives

$$E_3h_3u'' = -\tau(x) \tag{41}$$

On the other hand, the relation between τ and $\gamma+\delta$ is

$$\tau = -G(\gamma+\delta) \tag{42}$$

Combining Eqs. (41) and (42) results in

$$E_3h_3u'' - G(\gamma+\delta) = 0 \tag{43}$$

Differentiating Eq. (39) with respect to x and substituting u'' from Eq. (43) gives

$$EIy^{V} - bh_1G[ay''' + \frac{G}{h_2h_3E_3}(ay' + \frac{u}{h_2})] + \rho\ddot{y}' = 0. \tag{44}$$

Differentiating Eq. (44) with respect to x and substituting

$$\frac{u'}{h_2} = \frac{EI}{bh_1G}y^{IV} - ay'' + \frac{\rho}{bh_1G}\ddot{y} \tag{45}$$

which is obtained from Eq. (39), yields the sixth order differential equation of motion

$$y^{VI} - G(c + \frac{1}{h_2h_3E_3})y^{IV} + \frac{\rho}{EI}\ddot{y}'' - \frac{G}{h_2h_3E_3}\frac{\rho}{EI}\ddot{y} = 0 \tag{46}$$

This is the equation of motion in which the effect of the longitudinal deformation of constraining layers is included.

Assuming that

$$y(x,t) = y(x)e^{i\omega t} \tag{47}$$

we may present the equation of motion in the form

$$y^{VI} + a_4y^{IV} + a_2y'' + a_oy = 0 \tag{48}$$

where

$$a_0 = \frac{G}{h_2h_3E_3}\frac{\rho\omega^2}{EI}$$
$$a_2 = -\frac{\rho\omega^2}{EI}$$
$$a_4 = -G(c + \frac{1}{h_2h_3E_3}) \tag{49}$$

The six boundary conditions required for the solution fo the six-order equation are obtained by the variational approach (see [8])

$$\begin{aligned} y(0) &= 0 \\ y'(0) &= 0 \\ [y^{V} + a_4y''' + a_2y']_{x=l} &= 0 \\ [y^{IV} + a_4y'']_{x=l} &= 0 \\ y'''(0) &= 0 \\ y'''(l) &= 0 \end{aligned} \tag{50}$$

LENGTH CHANGES IN THE CONSTRAINING LAYERS

We present here a simple analysis in order to assess the magnitude of stretching and contraction of the constraining layers.

Observe that the longitudinal displacement in the constraining layer at any cross-section x is

$$u(x) = \int_0^x \frac{1}{E_3A_3}\int_\xi^l \tau(x)bd\zeta d\xi \tag{51}$$

where $\tau(x)$ is shear stress at the surface of the constraining layer due to shear force in the viscoelsatic layer. With $\tau = \gamma G$ and $\gamma = ay'$, this equation yields

$$u(x) = \frac{aG}{h_3E_3}[y(l)x - \int_0^x y(\xi)d\xi] \tag{52}$$

On the other hand, the displacement due to shear is $\gamma h_2 = ay'h_2$, and the ratio of u and γh_2 is therefore

$$\frac{u(x)}{\gamma h_2} = \frac{G}{h_2h_3E_3}\frac{y(l)x - \int_0^x y(\xi)d\xi}{y'(x)} \tag{53}$$

NUMERICAL ANALYSIS

The resultant sixth order differential equation is linear with constant coefficients. Such an equation admits exponential solutions. Subsequently, a general solution of the stated boundary value problem is a linear combination of six complex-valued exponential functions. Working through this approach leads to a rather complicated characteristic equation for the frequency parameter, see [8].

Again we turn to the Laplace transform method. From the transformed Eq. (46) follows:

$$L\{y(p)\}$$

$$= \frac{p^3 y''(0) + p[y^{IV}(0) + a_4 y''(0)] + y^{V}(0)}{p^6 + a_4 p^4 + a_2 p^2 + a_o} \tag{54}$$

The right-hand side of this equation is in the form

$$\frac{Ap^3 + Bp + C}{p^6 + a_4 p^4 + a_2 p^2 + a_o} \tag{55}$$

By means of partial fractions we can write

$$\frac{Ap^3 + Bp + C}{(p^2 - l^2)(p^2 - m^2)(p^2 - n^2)}$$

$$= \frac{d_1 p + d_2}{p^2 - l^2} + \frac{d_3 p + d_4}{p^2 - m^2} + \frac{d_5 p + d_6}{p^2 - n^2} \tag{56}$$

It follows that

$$d_1 = \frac{y''(0) l^2 + y^{IV}(0) + a_4 y''(0)}{(l^2 - m^2)(l^2 - n^2)} \tag{57}$$

$$d_2 = \frac{y^{V}(0)}{l(l^2 - m^2)(l^2 - n^2)} \tag{58}$$

$$d_3 = \frac{y''(0) m^2 + y^{IV}(0) + a_4 y''(0)}{(m^2 - l^2)(m^2 - n^2} \tag{59}$$

$$d_4 = \frac{y^{V}(0)}{m(m^2 - l^2)(m^2 - n^2)} \tag{60}$$

$$d_5 = \frac{y''(0) l^2 + y^{IV}(0) + a_4 y''(0)}{(n^2 - l^2)(n^2 - m^2)} \tag{61}$$

$$d_6 = \frac{y^5}{n(n^2 - l^2)(n^2 - m^2)} \tag{62}$$

CASE STUDY

Investigation to determine the effect of varying the damping of factor η on the system response was conducted. Some results are presented here, and more detailed analysis is contained in [8]. Five different values of η were selected: 0.06, 0.24, 0.36, 0.54, and 0.96. The thickness of the elastic core of the beam was taken as one inch and the thicknesses of the viscoelastic layers and the constraining layers were taken ... tenth inch and one-hundreth inch, resp... e length of the beam was taken as 2... tic core was considered steel. Th... naterial was considered rubber w... x modulus stated below together with other values:

$$c = 42.112 \times 10^{-6} 1/lb;\ E_3 = 30 \times 10^6 lb/in^2;$$

$$\rho/b = 7.4562 \times 10^{-4} lb\, sec^2/in^3;\ \Omega = 1;$$

$$G^* = 48.35(1 + i\eta);$$

$$EI/b = 2.5 \times 10^6 lb\, in;$$

$$\omega_o = [E(1 + i\eta)I/\rho]^{1/2};$$

$$\omega_j = \Omega[E(1 + i\eta)I/\rho]^{1/2}$$

Mathematica software was used to compute the various dynamic parameters, such as natural frequency. Graphical outputs depicting the real and the imaginary parts of the response functions were obtained. As the damping factor increased, the time for the response to be damped out was significantly reduced.

The parameters l, m, and n, the undamped natural frequency ω_o, and the damped natural frequency of the system ω_j, were computed for each value of the damping factor. Given the system's natural circular frequency and the parameters l, m, and n, the response of the system has been computed.

The reduction of time for the damping out of the system with the increase of the value of the damping factor is clear from the figures provided. For example, the absolute value of the amplitude of both the real and the imaginary curves shown for $\eta = 0.06$ is greater than 0.5 after 45 seconds. For $\eta = 0.36$ this is less than 0.5 after only 13 seconds, and for $\eta = 0.96$ this is less than 0.25 after only 9 seconds. Some results are shown in Figs. 5-8.

The thickness of the viscoelastic layers does not significantly affect the damping. However, its value appears in the eigenfunctions.

Evaluation of the structural health of mechanical cables

Patricio AA Laura

Institute of Applied Mechanics, (CONICET-SENID-ACCE), Universidad Nacional del Sur, 8000 - Bahia Blanca, Argentina

Mechanical cables have long been used for towing, for remote control or for the supplying of communication or other service links between two vehicles. They also constitute the basic structural element in suspended bridges. On the other hand they are used in biomedical engineering applications; to lower men underground as deep as 16,000 ft and they are considered in superconductivity applications. Obviously the problem of evaluating the "structural health" of cables or ropes by means of non-destructive test methods is of the utmost importance. This article is concerned with a survey of the available methods.

INTRODUCTION

A cable or rope is made of natural or man-made fibers and of metallic wires. They are used extensively from transmitting electrical or optical signals to hoisting, fishing, hauling, rigging and basic structural elements of the utmost importance whenever one encounters technological applications that demand lightweight, flexible, or easily deployable structural members or conductors. On top of these uses: they are employed in many life sustaining situations: suspended bridges, elevators, ski chairlifts and gondolas, etc.

As stated by Costello (1990), "... a list of the uses of wire rope is almost endless. Recent research into the possible use of wire strands as braces for teeth is one such example.

Wire rope is used to lower men underground as deep as 16,000 ft in the gold mines of South Africa... one such rope used in a shaft that runs over several sheaves is 9.3 miles long and weighs 110 tn.... Wire rope is also being considered in superconductivity applications". Certainly, ropes made out of synthetic materials (nylon, kevlar, etc.) have become increasingly popular in the last three decades (Goeller and Laura, 1971).

Obviously, methods of detecting imminent failure in cables could prevent the loss of valuable equipment, and more important, the possible loss of human life. The nondestructive test methods available are:

- thorough visual examination and measurement of the external diameter
- X-rays
- (induced) wave propagation
- electromagnetic field (EM)
- acoustic emission (AE)

In view of the fact that the electromagnetic field method and the acoustic emission technique have been reviewed recently (Laura, 1993) the present article will only present some basic concepts which are the foundations of both methodologies.

It is generally accepted that in order to perform a rational and careful inspection in the case of ropes used in mine hoists and, in general, in any type of elevators systems, it is necessary to combine the visual and the EM method (Weischedel, 1991).

On the other hand the AE method and the (induced) wave propagation approach are certainly valid techniques for the types of applications previously mentioned. Weischedel (1991) also feels that it is an inadequate, and probably dangerous, common practice in the North American mining practice to have in-house inspectors carry out the visual inspection while outside inspection companies perform EM inspections as a service. According to Geller *et al* (1989), sole reliance on inspection results obtained by outside inspection services is probably to be blamed for many rope failures in the mining industry.

Weischedel feels (1991) that both visual and EM inspections should be performed or, at least, supervised by knowledgeable in-house personnel.

Obviously, the method of visual inspection of the rope is very simple and does not require expensive instrumentation. It requires experienced personnel to carry it out and only surface flaws can be detected. Visual inspection must be used as a supplement to other test procedures.

The extremely valuable X-ray method yields detailed information on the cable at a defined location. Once a trouble zone in the cable has been found, the X-ray approach will allow for the determination of broken inner wires, degree of damage suffered by the core, etc. This

part of "MECHANICS PAN-AMERICA 1993" edited by MRM Crespo da Silva and CEN Mazzilli
ASME Reprint No AMR134

technique can be used as a supplement to other test procedures.

INDUCED WAVE PROPAGATION METHOD

Vanderveldt and Gilheany (1970) are probably among the first researchers who have studied the propagation of a longitudinal pulse in wire ropes subjected to axial loads with the goal of generating a failure detection method.

Kwun and Burkhardt (1988 and 1990) have developed a nondestructive evaluation method based on the analysis of wave motion in a rope. The technique involves:

1. applying a transverse, impulsive force to a cable
2. detecting the resulting motion of the propagating impulse wave
3. analyzing the detected signal.

Their approach allows for the measurement of tension in the rope and detection of defects such as broken strands and damage caused by corrosion. They emphasize the fact that the propagation motion of the impulse wave, although generally following the well known classical description of the wave motion on a flexible string, is rather complicated (Kwun and Burkhardt, 1992).

This complicated behavior is caused, mainly, by wave dispersion.

The governing partial differential equation, in the case of small amplitude transverse vibrations and when a stiff string is considered, is:

$$\frac{\partial u^2}{\partial x^2} - B\frac{\partial u^4}{\partial x^4} = m\frac{\partial u^2}{\partial t^2} \tag{1}$$

where

u (x, t): transverse displacement
T: tension in the string
B: πr^4 E/4 (flexural rigidity of the string)
E: Young's modulus
r: radius of the string
m: $\rho\pi r^2$ (mass per unit length of the string)
ρ: density.

Since the stiffness term is present, a wave will propagate at a speed which is a function of its frequency. The dispersion relation is:

$$k^2 = -\frac{T}{2B} + \left[\left(\frac{T}{2B}\right)^2 + \frac{m\omega^2}{B}\right]^{1/2} \tag{2}$$

where:
k: wavenumber
ω: angular wave frequency.

When $\omega \to 0$, the phase velocity $V = \omega/k \to \left[\frac{T}{m}\right]^{1/2}$ which is the phase velocity in a flexible string. If the frequency is very high, V approaches $\left(\pi^2 E r^2 f^2 / \rho\right)^{1/4}$ which is the phase velocity in a circular bar of radius r. The dispersive effect is greater with increasing radius in view of the fact that the stiffness is proportional to the fourth power of the radius.

In the case of wire rope each strand and wire can bend individually. Hence, the stiffness of a rope having radius r is smaller than the stiffness of a rod having the same radius (Kwun and Burkhardt, 1992). These authors have shown that the dispersion relation determined experimentally agrees well with the theoretical one derived for a stiff string when proper adjustment is made in the bending stiffness for the rope and which takes into account the relative ease of movement between the individual wires or strands.

THE ELECTROMAGNETIC (EM) INSPECTION METHOD

Two approaches have been developed:

- localized fault inspection (LF)
- loss of metallic cross sectional inspection (LMA).

The first practical LF instruments (developed early in the 30's) used DC magnetization of the rope. They measure the magnetic flux leakage surrounding the rope and saturate magnetically a section of the steel rope in the longitudinal direction by strong permanent or electric magnets. In the case of a broken wire or core, corrosion or abrasion, the magnetic flux is distorted and leaks from the rope. Sense coils or Hall generators, close to the rope, sense the leakage of flux. these transducers sense only *changes* of the magnetic flux.

The LMA AC instruments were developed early in the present century (Wait, 1979).

They are based on AC magnetization of the rope which serves as a ferrous core of a coil or transformer. A variation of the cross sectional area of the rope is tranduced into a change of the impedance of the system and in turn, this change is a measure of the alteration of the cross sectional area. the modern rope evaluation equipment by the electromagnetic approach allows for a simultaneous LMA/LF determination.

Extremely thorough studies on the EM method are available in the open literature (Weischedel, 1985, 1991). In the case of mooring ropes *in-situ* inspection is now possible since a waterproof sensor head has been recently developed (Bavins, 1988)

Clearly the EM inspection method is not applicable in the case of cables made out of synthetic materials.

THE ACOUSTIC EMISSION (AE) METHOD

Acoustic emission is defined as the high frequency stress waves generated by the rapid release of strain energy that occurs within a solid. Sources of acoustic emission are: initiation and propagation of cracks, twin[illegible] [illegible]lip, sudden reorientation of grain boundaries, bubble formation during boiling or martensitic phase transformations (Liptai and Tatro, 1976).

The words "acoustic emission" mean nowadays not only the phenomenon but also a rather complex and sophisticated technology of methods and applications in many fields of engineering: nuclear reactors, structures, space vehicles, materials research, etc (Matthews and Black, 1981).

Earlier studies which made use of acoustic emission for monitoring the "state of health" of ropes employed very simple reasoning: "... in the case of continuous media when a stress wave is emitted due to the propagation of a small flaw or a crack, motion can be detected using a standard accelerometer. It seems reasonable, then, to use a similar detection system which basically consist of tightly woven strands while, in turn, each strand is made up of tightly wound wires" (Laura *et al*, 1969, 1970). Accordingly, if an increasing tensile load is applied, the individual wires fail first and strands later. Preliminary investigations showed that clearly audible stress waves were emitted at approximately 95% of the maximum load allowing then enough time to terminate any further loading of the wire rope. On the other hand, significant stress wave emissions were obtained as a loading to failure was applied to the wire rope.

The experimental investigation previously described was extended by Harris and Dunegan (1974) who employed more sophisticated and sensitive instrumentation and obtained acoustic emissions when performing tensile, fatigue and fatigue with periodic overload tests.

Extremely thorough and successful investigations have been performed at the Defense Research Establishment Pacific late in the 70's (Matthews and Black, 1981) on acoustic emission phenomena of a variable depth sonar tow cable while in operation.

The monitoring system, calibrated by having a cable system crack and fail in service while towing a concrete block, measures the peak amplitude of the transient signals and counts those which exceed IV (indication of general fatigue cracking) and 10V (gives an estimate of broken strands). There is also a unit which provides an audible sound from the acoustic emission signals. Vanderveldt and Tran (1971) were the first researchers to apply the stress wave emission monitoring method to the study of synthetic ropes. These researchers showed that an increase of at least an order of magnitude in the slope of the curve of the number of stress wave emissions vs the applied load is a good indicator of impeding catastrophic failure. No significant differences in stress wave emission characteristics were observed for the types of synthetic ropes considered.

Acoustic emissions of synthetic ropes subjected to loading have been studied by other researchers. Important results were obtained by Williams and Lee (1982). Recently the NDE technique of acoustic-ultrasonic testing has been applied to nylon ropes. (Williams *et al*, 1984)

CONCLUDING REMARKS

Cables, ropes, or yarns are among the oldest tools that man has developed and used in order to improve his living conditions. An eloquent proof of the importance of the subject matter is given by recent publications which deal with the following problems:

- stress analysis in power conductors predicting low cycle fatigue life and static overload conditions under handling and installation conditions (Owen *et al*, 1992)
- bending of spiral strands in the case of large radii of curvature analyzing bending stiffness and overall hysteresis, both being amplitude dependent (Raoof and Huang, 1992)
- prediction of cable damping under cyclic bending (Raoof and Huang, 1991).

Performing tests of the integrity of such ropes without in any way impairing their function is certainly of the utmost importance.

This paper has presented a brief survey of the methods which allow for the evaluation of the "structural health" of mechanical cables.

The obvious question is: Which is the best method? As in many other situations in engineering, there is not a unique answer. In the case of off-shore applications, a suspended bridge and similar structural situations, the EM method is more convenient. If monitoring the "state of health" of a tow cable while in operation is needed, it is necessary to make use of AE techniques. Furthermore, the EM inspection method is not applicable in the case of synthetic ropes while the AE technique gives satisfactory answers.

It appears at this point that the wave propagation approach (Kwun and Burkhard, 1992) exhibits highly promising features but additional research on the methodology is needed. On the other hand, if on adopts the philosophy of monitoring the state of structural health of a cable during its entire operation, one finds that the AE technique is the most convenient one. Obviously, the location of the transducing devices must be chosen very carefully in order to optimize the cost of the monitoring operation. It is important to point out that Malyshev and Chentsov (1989) have proposed an acoustic emission method of determining the actual bending resistance of cables. The method is potentially useful for the inspection of the quality of products and the development of new cable grades.

Green's functions in generalized micropolar thermoelasticity

Ranjit S Dhaliwal and Jun Wang

Department of Mathematics and Statistics
University of Calgary, Calgary, Alberta T2N 1N4

General solution of the generalized micropolar thermoelastic equations has been obtained for arbitrary distribution of the body couples, body forces, and heat sources in an infinite body. Short time solutions have been obtained for the cases of impulsive body force and heat source acting at a point. Numerical values of the short time solutions have been displayed graphically.

INTRODUCTION

In recent years the so-called "second sound" effect in solids has been given increasing attention. This effect arises from the possible transport of heat by a wave propagation process rather than diffusion. Lord and Shulman (1967), Green and Lindsay (1972), Lebon (1982), developed various generalized theories of thermoelasticity based on different approaches to thermodynamics. Boschi and Iesan (1972), Dost and Tabarrok (1978), Chandrasekharaiah (1986) derived various generalized theories of micropolar thermoelasticity. Owing to the newness of these theories, only few problems have been studied by Dhaliwal and Sherief (1981), Sherief (1986; 1992), Ignaczak and Mrowka-Matejewska (1989), Oncu and Moodie (1992) and Wang and Dhaliwal (1993).

In this paper, we study the problem of determining the displacements, rotations, and temperature in an infinite micropolar thermoelastic medium under the action of time dependent body forces, body couples, and heat sources. In section 2, we summarize the basic equations of the generalized micropolar thermoelasticity derived by Chandrasekharaiah (1986). In section 3, we derive the general solution of these equations by using the Fourier-Laplace transforms for any arbitrary distribution of body forces, body couples, and heat sources in an infinite medium. In sections 4 and 5, respectively, we derive solutions for an impulsively applied point body force and heat source. Exact inversions have been obtained in the space domain and Laplace inversions have been obtained only for small time approximations.

PRELIMINARIES

Consider a homogeneous isotropic elastic solid occupying an infinite space. The governing equations of generalized micropolar thermoelasticity are given Chandrasekharaiah (1986) [we have changed the notations of variables in order to compare our results with that for coupled theory derived by Shanker and Dhaliwal (1975)] as

$$(\lambda + \mu - \alpha)u_{j,ji} + (\mu + \alpha)\ddot{u}_{j,ji} + 2\alpha\varepsilon_{ijk}w_{k,j} - \nu\theta_{,i} + \rho X_i = \rho\ddot{u}_i, \tag{2.1}$$

$$(\gamma + \varepsilon)w_{i,jj} + (\beta + \gamma - \varepsilon)w_{i,ji} + 2\alpha\varepsilon_{ijk}u_{k,j} - 4\alpha w_i + JY_i = J\ddot{w}_i, \tag{2.2}$$

$$k\theta_{,ii} = \dot{\theta} + \tau\ddot{\theta} + \eta_{\circ}(\dot{u}_{i,i} + \tau\ddot{u}_{i,i}) - Q - \tau\dot{Q}, \tag{2.3}$$

where

- u_i = the components of the displacement vector
- θ = the temperature deviation above the initial temperature $\theta_{\circ}$
- w_i = the components the microrotation vector
- X_i = the components of body force
- Y_i = the components of body couple
- Q = the strength of internal heat source
- k = the coefficient of heat conduction
- ρ = mass density
- τ = the relaxation time
- J = the rotational inertia
- $\eta_{\circ}$ = $\rho\nu\theta_{\circ}/C_e$
- C_e = the specific heat at constant deformation
- ε_{ijk} = the unit anti-symmetric tensor

and λ, μ, ν, α, β, γ, and ε are material constants.

In above equations, the notation of Cartesian tensor is employed, superposed dots denote the time derivatives and a comma followed by the idex i denotes the partial derivative with respect to x_i.

The basic equations (2.1)-2.3) may be rewritten in vector form as

part of "MECHANICS PAN-AMERICA 1993" edited by M and CEN Mazzilli — ASME Reprint No AMR134
Appl Mech Rev vol 46, no 11, part 2, November 1993

$$(\lambda + 2\mu)\nabla\nabla \cdot \mathbf{u} - (\mu + \alpha)\nabla \times \nabla$$
$$+ 2\alpha\nabla \times \mathbf{w} - \nu\nabla\theta + \rho X = \rho\ddot{\mathbf{u}}, \tag{2.4}$$

$$(\beta + 2\gamma)\nabla\nabla \cdot \mathbf{w} - (\gamma + \varepsilon)\nabla \times \nabla \times \mathbf{w}$$
$$+ 2\alpha\nabla \times \mathbf{u} - 4\alpha\mathbf{w} + JY = J\ddot{\mathbf{w}}, \tag{2.5}$$

$$k\nabla^2\theta = \dot{\theta} + \tau\ddot{\theta} + \eta_o(\nabla\dot{\mathbf{u}} + \tau\nabla\ddot{\mathbf{u}}) - Q - \tau\dot{Q}. \tag{2.6}$$

THE GENERAL SOLUTION OF THE BASIC EQUATIONS

In this section we shall find the displacement vector $\mathbf{u}(x_1, x_2, x_3, t)$, microrotation vector $\mathbf{w}(x_1, x_2, x_3, t)$, and temperature field $\theta(x_1, x_2, x_3, t)$, in an infinite thermoelastic body under the action of time dependent body forces **X**, body couples **Y**, and heat sources Q, ie, we shall find the solution of equations given by (2.4)-(2.6) for $-\infty < x_1, x_2, x_3 < \infty$, $t > 0$, under prescribed body forces, body couples and heat sources, with the initial conditions

$$\mathbf{u}(x_1, x_2, x_3, 0) = \dot{u}(x_1, x_2, x_3, 0) = 0,$$

$$\theta(x_1, x_2, x_3, 0) = \dot{\theta}(x_1, x_2, x_3, 0) = 0,$$

$$\mathbf{w}(x_1, x_2, x_3, 0) = \dot{\mathbf{w}}(x_1, x_2, x_3, 0) = 0,$$

and the regularity conditions

$$\mathbf{u} \to 0,\ \mathbf{w} \to 0,\ \theta \to 0 \text{ as } (x_1, x_2, x_3) \to \pm\infty.$$

To solve the equations (2.4)-(2.6), we shall first reduce them to a simpler form by decomposing the vectors **u, w, X** and **Y** into their potential and solenoidal parts, ie.

$$\mathbf{u} = \nabla\varphi + \nabla \times \Psi, \quad \mathrm{div}\Psi = 0, \tag{3.1}$$

$$\mathbf{w} = \nabla\Sigma + \nabla \times \mathbf{H}, \quad \mathrm{div}\mathbf{H} = 0, \tag{3.2}$$

$$X = \nabla\upsilon + \nabla \times \psi, \quad \mathrm{div}\psi = 0, \tag{3.3}$$

$$Y = \nabla\phi + \nabla \times \eta, \quad \mathrm{div}\eta = 0. \tag{3.4}$$

Substitution of equations (3.1)-(3.4) into the basic equations (2.4)-(2.6), yields

$$[\square_1 D - \omega_1\nabla^2\frac{\partial}{\partial t}(1 + \tau\frac{\partial}{\partial t})]\varphi = -\rho D\upsilon - \frac{q}{p}\nu Q \tag{3.5}$$

$$(\square_2\square_4 + 4\alpha^2\nabla^2)\Psi = 2\alpha J\nabla \times \eta - \rho\square_4\psi, \tag{3.6}$$

$$(\square_2\square_4 + 4\alpha^2\nabla^2)\mathbf{H} = 2\alpha\rho\nabla \times \psi - J\square_2\eta, \tag{3.7}$$

$$\square_3\Sigma + J\phi = 0, \tag{3.8}$$

$$[\square_1 D - \omega_1\nabla^2\frac{\partial}{\partial t}(1 + \tau\frac{\partial}{\partial t})]\theta$$
$$= -\rho\eta_o\nabla^2\frac{\partial}{\partial t}(1 + \tau\frac{\partial}{\partial t})\upsilon - \frac{q}{p}\square_1 Q, \tag{3.9}$$

where

$$D = \nabla^2 - \frac{1}{k}\frac{\partial}{\partial t}(1 + \tau\frac{\partial}{\partial t}), \quad \omega_1 = \eta_o\nu/k,$$

$$\square_1 = (\lambda + 2\mu)\nabla^2 - \rho\frac{\partial^2}{\partial t^2}, \quad \square_2 = (\mu + \alpha)\nabla^2 - \rho\frac{\partial^2}{\partial t^2},$$

$$\square_3 = (\beta + 2\gamma)\nabla^2 - 4\alpha - J\frac{\partial^2}{\partial t^2},$$

$$\square_4 = (\gamma + \varepsilon)\nabla^2 - 4\alpha - J\frac{\partial^2}{\partial t^2}$$

To solve these wave equations, we introduce the Laplace transform $\bar{f}(x_1, x_2, x_3, p)$ of the function $f(x_1, x_2, x_3, t)$ by the relation

$$\bar{f}(x_1, x_2, x_3, p)$$
$$= \int_0^\infty f(x_1, x_2, x_3, t)\exp\{-pt\}dt, \quad \mathrm{Re}(p) > 0, \tag{3.10}$$

and also the Fourier-Laplace transform $\hat{f}(\xi_1, \xi_2, \xi_3, p)$ of the function $f(x_1, x_2, x_3, t)$ by the relation

$$\hat{f}(\xi_1, \xi_2, \xi_3, p)$$
$$= (2\pi)^{-3/2}\int_\Omega \bar{f}(x_1, x_2, x_3, p)\exp\{ix_k\xi_k\}d\Omega \tag{3.11}$$

where $d\Omega = dx_1dx_2dx_3$ and Ω is the x_1, x_2, x_3, - space

Application of (3.10) and (3.11) to equations (3.5)-(3.9) yields the following system of algebraic equations

$$[(\xi^2 + \beta_1^2)(\xi^2 + q) + \omega q\xi^2]\hat{\varphi}$$
$$= \frac{1}{c_1^2}(\xi^2 + q)\hat{\upsilon} - \frac{\nu q}{\rho c_1^2 p}\hat{Q}, \tag{3.12}$$

$$[(\xi^2 + \beta_2^2)(\xi^2 + 2s^* + \beta_4^2) - r^*s^*\xi^2]\hat{\Psi}_i$$
$$= -i\frac{r^*}{c_4^2}\xi_j\varepsilon_{ijk}\hat{\eta}_k + \frac{1}{c_2^2}(\xi^2 + 2s^* + \beta_4^2)\hat{\psi}_i, \tag{3.13}$$

$$[(\xi^2 + \beta_2^2)(\xi^2 + 2s^* + \beta_4^2) - r^*s^*\xi^2]\hat{\mathbf{H}}_i$$
$$= -i\frac{s^*}{c_2^2}\xi_j\varepsilon_{ijk}\hat{\psi}_k + \frac{1}{c_4^2}(\xi^2 + \beta_2^2)\hat{\eta}_i, \tag{3.14}$$

$$(\xi^2+\beta_3^2)\hat{\Sigma} = \frac{1}{c_3^2}\hat{\phi}, \tag{3.15}$$

$$[(\xi^2+\beta_1^2)(\xi^2+q)+\omega q\xi^2]\hat{\theta}$$

$$= \frac{1}{c_1^2}\eta_o k q\hat{\upsilon} + \frac{q}{p}(\xi^2+\beta_1^2)\hat{Q}, \tag{3.16}$$

where

$$c_1^2 = \frac{\lambda+2\mu}{\rho}, \quad c_2^2 = \frac{\mu+\alpha}{\rho},$$

$$c_3^2 = \frac{\beta+2\gamma}{J}, \quad c_4^2 = \frac{\gamma+\epsilon}{J},$$

$$\beta_1 = \frac{p}{c_1}, \quad \beta_2 = \frac{p}{c_2},$$

$$\beta_3 = \left[\frac{p^2+4\alpha/J}{c_3}\right], \quad \beta_4 = \frac{p}{c_4},$$

$$\omega = \frac{k}{\lambda+2\mu}\omega_1 = \frac{\nu\eta_\circ}{\lambda+2\mu}, \quad q = \frac{1}{k}p(1+\tau p),$$

$$r^* = \frac{2\alpha}{\rho c_2^2}, \quad s^* = \frac{2\alpha}{Jc_4^2}.$$

and $\xi^2 = \xi_1^2+\xi_2^2+\xi_3^2$

Taking the Fourier-Laplace transform of (3.1)-(3.4), we find that

$$\hat{u}_i = -i\xi_i\hat{\varphi} - i\xi_j\epsilon_{ijk}\hat{\Psi}_k, \tag{3.17}$$

$$\hat{w}_i = -i\xi_i\hat{\Sigma} - i\xi_j\epsilon_{ijk}\hat{H}_k, \tag{3.18}$$

$$\hat{X}_i = -i\xi_i\hat{\upsilon} - i\xi_j\epsilon_{ijk}\hat{\psi}_k, \tag{3.19}$$

$$\hat{Y}_i = -i\xi_i\hat{\phi} - i\xi_j\epsilon_{ijk}\hat{\eta}_k. \tag{3.20}$$

Substituting for $\hat{\varphi}$, $\hat{\Psi}_k$, $\hat{\Sigma}$, $\hat{H}_k$ from equations (3.17)-(3.20) into equations (3.12)-(3.15) and taking into account the relation

$$\epsilon_{ijk}\epsilon_{kmn} = \delta_{jn}\delta_{mi} - \delta_{jm}\delta_{in}$$

along with the conditions div$\psi = 0$, div$\eta = 0$, where δ_{ij} is the Kronecker delta function, we obtain

$$\hat{u}_i = i\frac{\nu q\xi_i}{\rho c_1^2 p\Delta_1}\hat{Q} - i\frac{\xi^2+q}{c_1^2\Delta_1}\xi_i\hat{\upsilon} + \frac{r^*\xi^2}{c_4^2\Delta_2}\hat{\eta}_i$$
$$- i\frac{\xi_j\epsilon_{ijk}}{c_4^2\Delta_2}(\xi^2+2s^*+\beta_4^2)\hat{\psi}_k, \tag{3.21}$$

$$\hat{w}_i = -\frac{i}{c_3^2(\xi^2+\beta_3^2)}\xi_i\hat{\phi} + \frac{s^*\xi^2}{c_2^2\Delta_2}\hat{\psi}_i$$
$$- i\frac{\xi_j\epsilon_{ijk}}{c_4^2\Delta_2}(\xi^2+\beta_2^2)\hat{\eta}_k, \tag{3.22}$$

where

$$\Delta_1 = (\xi^2+\beta_1^2)(\xi^2+q)+\omega q\xi^2$$
$$= (\xi^2-\lambda_1^2)(\xi^2-\lambda_2^2), \tag{3.23}$$

$$\Delta_2 = (\xi^2+\beta_2^2)(\xi^2+2s^*+\beta_4^2) - r^*s^*\xi^2$$
$$= (\xi^2-\mu_1^2)(\xi^2-\mu_2^2), \tag{3.24}$$

and $\lambda_{1,2}^2$ and $\mu_{1,2}^2$ are the roots of the equations $\Delta_1(\xi^2) = 0$, $\Delta_2(\xi^2) = 0$, respectively. From equation (3.16), we obtain

$$\hat{\theta} = \frac{kq}{c_1^2\Delta_1}\eta_o\hat{\upsilon} + \frac{q}{p\Delta_1}(\xi^2+\beta_1^2)\hat{Q}. \tag{3.25}$$

From equation (3.19) and (3.20), we find that

$$\hat{\upsilon} = i\frac{1}{\xi^2}\xi_k\hat{X}_k, \qquad \hat{\psi}_i = -\frac{i}{\xi^2}\epsilon_{ijk}\xi_j\hat{X}_k, \tag{3.26}$$

$$\hat{\phi} = i\frac{1}{\xi^2}\xi_k\hat{Y}_k, \qquad \hat{\eta}_i = -\frac{i}{\xi^2}\epsilon_{ijk}\xi_j\hat{Y}_k. \tag{3.27}$$

Substituting from equations (3.26) and (3.27) into equations (3.21), (3.22) and (3.25), we obtain

$$\hat{u}_i = i\frac{\nu q\xi_i}{\rho c_1^2 p\Delta_1}\hat{Q} + \frac{\xi^2+q}{c_1^2\Delta_1\xi^2}\xi_i\xi_k\hat{X}_k - \frac{ir^*}{c_4^2\Delta_2}\epsilon_{ijk}\xi_j\hat{Y}_k$$
$$+ \frac{\xi^2+2s^*+\beta_4^2}{c_2^2\Delta_2\xi^2}(\xi^2\hat{X}_i - \xi_i\xi_j\hat{X}_j), \tag{3.28}$$

$$\hat{w}_i = \frac{1}{c_3^2(\xi^2+\beta_3^2)\xi^2}\xi_i\xi_k\hat{Y}_k - \frac{s^*i}{c_2^2\Delta_2}\xi_j\epsilon_{ijk}\hat{X}_k$$
$$+ \frac{\xi^2+\beta_2^2}{c_4^2\Delta_2\xi^2}(\xi^2\hat{Y}_i - \xi_i\xi_k\hat{Y}_k), \tag{3.29}$$

$$\hat{\theta} = \frac{(\xi^2+\beta_1^2)q}{p\Delta_1}\hat{Q} + \frac{\eta_\circ kq}{c_1^2\Delta_1}i\xi_k\hat{X}_k. \tag{3.30}$$

The above system of equations (3.28)-(3.30) give rise to the general solution for the determination of displacement, microrotation, and temperature field for any given body forces, body couples, and heat sources applied in the infinite medium by first inverting the Fourier transform and then inverting the Laplace transform.

If we let $\tau \to 0$, then $q \to p/k$ and the equations (3.28)-(3.30) reduce to the corresponding ones derived by Shanker and Dhaliwal (1975) for the coupled theory. If we let $\alpha \to 0$, then equations (3.28) and (3.29) give rise to the following solution for generalized thermoelasticity

$$\hat{u}_i = i\frac{\nu q\xi_i}{\rho c_1^2 p\Delta_1}\hat{Q} + \frac{\xi^2+q}{c_1^2\Delta_1\xi^2}\xi_i\xi_k\hat{X}_k$$
$$+ \frac{\xi^2\hat{X}_i - \xi_i\xi_j\hat{X}_j}{c_2^2(\xi^2+\beta_2^2)\xi^2}, \tag{3.31}$$

$$\hat{\theta} = \frac{(\xi^2 + \beta_1^2)q}{\Delta_1 p}\hat{Q} + \frac{\eta.\,kq}{c_1^2\Delta_1}i\xi_k\hat{X}_k, \tag{3.32}$$

which agree with the previous results obtained by Wang and Dhaliwal (1993), where dimensionless variables have been used.

THE EFFECT OF AN IMPULSIVELY APPLIED BODY FORCE

In this section we consider the case when a body force is applied impulsively at the origin of an infinite elastic space. For such a body force we may write

$$X = \frac{1}{\rho}\delta(x)\delta(y)\delta(z)\delta(t)\{0,\ 0,\ F\},\ Y = 0,\ Q = 0, \tag{4.1}$$

where $\delta(\cdot)$ is the Dirac delta function, F is a constant, and, for the sake of convenience, we have written (x, y, z) for (x_1, x_2, x_3).

The Fourier-Laplace transform of equation (4.1) gives

$$\hat{X} = \frac{F}{(2\pi)^{3/2}\rho}\{0,\ 0,\ 1\},\quad ,\ \hat{Y} = 0,\quad \hat{Q} = 0. \tag{4.2}$$

Substitution from equation (4.2) into equations (3.28)-(3.30) yields

$$\hat{u}_1(\xi_1,\xi_2,\xi_3,p) = \frac{F}{(2\pi)^{3/2}\rho}\Big[\frac{\xi^2 + q}{c_1^2\Delta_1\xi^2} - \frac{\xi^2 + 2s^* + \beta_4^2}{c_2^2\Delta_2\xi^2}\Big]\xi_1\xi_3, \tag{4.3}$$

$$\hat{u}_2(\xi_1,\xi_2,\xi_3,p) = \frac{F}{(2\pi)^{3/2}\rho}\Big[\frac{\xi^2 + q}{c_1^2\Delta_1\xi^2} - \frac{\xi^2 + 2s^* + \beta_4^2}{c_2^2\Delta_2\xi^2}\Big]\xi_2\xi_3, \tag{4.4}$$

$$\hat{u}_3(\xi_1,\xi_2,\xi_3,p) = \frac{F}{(2\pi)^{3/2}\rho}\Big[\frac{\xi^2 + q}{c_1^2\Delta_1\xi^2}\xi_3^2 + \frac{\xi^2 + 2s^* + \beta_4^2}{c_2^2\Delta_2} - \frac{\xi^2 + 2s^* + \beta_4^2}{c_2^2\Delta_2\xi^2}\xi_3^2\Big], \tag{4.5}$$

$$\hat{w}_1(\xi_1,\xi_2,\xi_3,p) = -\frac{s^*F}{(2\pi)^{3/2}\rho c_2^2\Delta_2}i\xi_2, \tag{4.6}$$

$$\hat{w}_2(\xi_1,\xi_2,\xi_3,p) = \frac{s^*F}{(2\pi)^{3/2}\rho c_2^2\Delta_2}i\xi_3, \tag{4.7}$$

$$\hat{w}_3(\xi_1,\xi_2,\xi_3,p) = 0, \tag{4.8}$$

$$\hat{\theta}(\xi_1,\xi_2,\xi_3,p) = \frac{\eta.\,kFq}{(2\pi)^{3/2}\rho c_1^2\Delta_1}i\xi_3. \tag{4.9}$$

On inverting the Fourier transform with respect to ξ_1, ξ_2, and ξ_3, in equations (4.3)-(4.9), we obtain

$$\bar{u}_1(x,y,z,p) = \frac{iF}{(2\pi)^3\rho}\frac{\partial}{\partial x}\Big(\frac{1}{c_1^2}I_1 - \frac{1}{c_2^2}I_2\Big), \tag{4.10}$$

$$\bar{u}_2(x,y,z,p) = \frac{iF}{(2\pi)^3\rho}\frac{\partial}{\partial y}\Big(\frac{1}{c_1^2}I_1 - \frac{1}{c_2^2}I_2\Big), \tag{4.11}$$

$$\bar{u}_3(x,y,z,p) = \frac{F}{(2\pi)^3\rho}\Big[i\frac{\partial}{\partial z}\Big(\frac{1}{c_1^2}I_1 - \frac{1}{c_2^2}I_2\Big) + \frac{1}{c_2^2}I_3\Big], \tag{4.12}$$

$$\bar{w}_1(x,y,z,p) = \frac{s^*F}{(2\pi)^3\rho c_2^2}\frac{\partial}{\partial y}I_4, \tag{4.13}$$

$$\bar{w}_2(x,y,z,p) = -\frac{s^*F}{(2\pi)^3\rho c_2^2}\frac{\partial}{\partial x}I_4, \tag{4.14}$$

$$\bar{w}_3(x,y,z,p) = 0, \tag{4.15}$$

$$\bar{\theta}(x,y,z,p) = -\frac{\eta.\,kFq}{(2\pi)^3\rho c_1^2}\frac{\partial}{\partial z}I_5, \tag{4.16}$$

where

$$I_1 = \iiint_{-\infty}^{\infty}\frac{(\xi^2 + q)\xi_3}{\xi^2(\xi^2 - \lambda_1^2)(\xi^2 - \lambda_2^2)}\exp\{-i(\xi_1 x + \xi_2 y + \xi_3 z)\}d\xi_1 d\xi_2 d\xi_3, \tag{4.17}$$

$$I_2 = \iiint_{-\infty}^{\infty}\frac{(\xi^2 + 2s^* + \beta_4^2)\xi_3}{\xi^2(\xi^2 - \mu_1^2)(\xi^2 - \mu_2^2)}\exp\{-i(\xi_1 x + \xi_2 y + \xi_3 z)\}d\xi_1 d\xi_2 d\xi_3, \tag{4.18}$$

$$I_3 = \iiint_{-\infty}^{\infty}\frac{\xi^2 + 2s^* + \beta_4^2}{(\xi^2 - \mu_1^2)(\xi^2 - \mu_2^2)}\exp\{-i(\xi_1 x + \xi_2 y + \xi_3 z)\}d\xi_1 d\xi_2 d\xi_3, \tag{4.19}$$

$$I_4 = \iiint_{-\infty}^{\infty}\frac{1}{(\xi^2 - \mu_1^2)(\xi^2 - \mu_2^2)}\exp\{-i(\xi_1 x + \xi_2 y + \xi_3 z)\}d\xi_1 d\xi_2 d\xi_3, \tag{4.20}$$

$$I_5 = \iiint_{-\infty}^{\infty}\frac{1}{(\xi^2 - \lambda_1^2)(\xi^2 - \lambda_2^2)}\exp\{-i(\xi_1 x + \xi_2 y + \xi_3 z)\}d\xi_1 d\xi_2 d\xi_3. \tag{4.21}$$

Using polar coordinates

$$\xi_1 = r_1\cos\theta_1,\ \xi_2 = r_1\sin\theta_1,\ x = r\cos\theta_2,\ y = Y\sin\theta_2,$$

we have found that

$$I_1 = \int_{-\infty}^{\infty} \xi_3 e^{-i\xi_3 z}\int_0^{\infty}\int_0^{2\pi} \frac{(\xi_3^2+r_1^2+q)\exp\{-ir_1r\cos(\theta_1-\theta_2)\}}{(\xi_3^2+r_1^2)(\xi_3^2+r_1^2-\lambda_1^2)(\xi_3^2+r_1^2-\lambda_2^2)} r_1 dr_1 d\theta_1 d\xi_3. \quad (4.22)$$

Evaluating the θ_1 integration, we get

$$I_1 = 2\pi\int_0^{\infty} r_1 J_0(r_1 r)dr_1 \int_{-\infty}^{\infty} \frac{(\xi_3^2 + r_1^2 + q)\xi_3\exp\{-i\xi_3 z\}d\xi_3}{(\xi_3^2 + r_1^2)(\xi_3^2 + r_1^2 - \lambda_1^2)(\xi_3^2 + r_1^2 - \lambda_2^2)}, \quad (4.23)$$

where $J_n(z)$ is the Bessel function of the first kind and of order n. Evaluating ξ_3 integration we find that

$$I_1 = -2\pi i\int_0^{\infty}\Big[\frac{\pi q}{\lambda_1^2\lambda_2^2}\exp\{-|z|r_1\} + \frac{\pi(\lambda_1^2 - q)}{\lambda_1^2(\lambda_1^2-\lambda_2^2)}\exp\{-|z|(r_1^2-\lambda_1^2)^{1/2}\} - \frac{\pi(\lambda_2^2 - q)}{\lambda_2^2(\lambda_1^2-\lambda_2^2)}\exp\{-|z|(r_1^2-\lambda_2^2)^{1/2}\}\Big] r_1 J_0(r_1 r)dr_1. \quad (4.24)$$

Using the known integral (Watson, 1958; p 514), we find that

$$I_1 = -2\pi^2 i\Big[\frac{2q\Gamma(3/2)}{\lambda_1^2\lambda_2^2\sqrt{\pi}}\frac{|z|r}{(z^2+r^2)^{3/2}} + \frac{\lambda_1^2 + q}{\lambda_1^2(\lambda_1^2-\lambda_2^2)}\sqrt{\frac{2}{\pi}}\frac{|z|(i\lambda_1)^{3/2}}{(z^2+r^2)^{3/4}}K_{3/2}[i\lambda_1(z^2+r^2)^{1/2}] + \frac{\lambda_2^2 + q}{\lambda_2^2(\lambda_2^2-\lambda_1^2)}\sqrt{\frac{2}{\pi}}\frac{|z|(i\lambda_2)^{3/2}}{(z^2+r^2)^{3/4}}K_{3/2}[i\lambda_2(z^2+r^2)^{1/2}]\Big], \quad (4.25)$$

where $K_n[Z]$ is the modified Bessel function of the third kind and of order n. Replacing $\lambda_{1,2}$ by $\mu_{1,2}$ and by $2s^* + \beta_4^2$ in equation (4.25), we find that

$$I_2 = -2\pi^2 i\Big[\frac{4s^*\Gamma(3/2)}{\mu_1^2\mu_2^2\sqrt{\pi}}\frac{|z|r}{(z^2+r^2)^{3/2}} + \frac{\mu_2^2+2s^*+\beta_4^2}{\mu_2^2(\mu^2-\mu_1^2)}\sqrt{\frac{2}{\pi}}\frac{|z|(i\mu_2)^{3/2}}{(z^2+r^2)^{3/4}}K_{3/2}[i\mu_2(z^2+r^2)^{1/2}]\Big], + \frac{\mu_1^2+2s^*+\beta_4^2}{\mu_1^2(\mu_1^2-\mu_2^2)}\sqrt{\frac{2}{\pi}}\frac{|z|(i\mu_1)^{3/2}}{(z^2+r^2)^{3/4}}K_{3/2}[i\mu_1(z^2+r^2)^{1/2}] \quad (4.26)$$

Adopting the above procedure, we find that

$$I_3 = (2\pi)^{3/2}(i\mu_1)^{1/2}(z^2 + r^2)^{-1/4}K_{1/2}[i\mu_1(z^2 + r^2)^{1/2}]. \quad)$$

$$I_4 = -\frac{(2\pi)^{3/2}}{\mu_1^2-\mu_2^2}\Big[(i\mu_1)^{1/2}(z^2 + r^2)^{-1/4}K_{1/2}[i\mu_1(z^2 + r^2)^{1/2}] - (i\mu_2)^{1/2}(z^2 + r^2)^{-1/4}K_{1/2}[i\mu_2(z^2 + r^2)^{1/2}]\Big]. \quad (4.28)$$

Replacing $\mu_{1,2}$ by $\lambda_{1,2}$ in equation (4.28), we find that

$$I_5 = -\frac{(2\pi)^{3/2}}{\lambda_1^2-\lambda_2^2}\Big[(i\lambda_1)^{1/2}(z^2 + r^2)^{-1/4}K_{1/2}[i\lambda_1(z^2 + r^2)^{1/2}] - (i\lambda_2)^{1/2}(z^2 + r^2)^{-1/4}K_{1/2}[i\lambda_2(z^2 + r^2)^{1/2}]\Big]. \quad (4.29)$$

It is a formidable task to find the inverse Laplace transform of the equations (4.25)-(4.29). For this reason we have resorted to the case of small time approximations. First, we note that

$$2\lambda_{1,2}^2 = -[\frac{p^2}{c_1^2} + \frac{p}{k}(1+\omega)(1+\tau p)] \pm \sqrt{[\frac{1}{c_1^2}p^2 + \frac{p}{k}(1+\omega)(1+\tau p)]^2 - \frac{4}{c_1^2}\frac{1}{k}p^3(1+\tau p)}, \quad (4.30)$$

$$2\mu_{1,2}^2 = -[(\frac{1}{c_2^2} + \frac{1}{c_4^2})p^2 + (2-\tau^*)s^*] \pm \sqrt{[(\frac{1}{c_2^2} + \frac{1}{c_4^2})p^2 + (2-\tau^*)s^*]^2 - 4p^2(p^2/c_4^2 + 2s^*)/c_2^2}. \quad (4.31)$$

Expanding the above equations binomially and retaining only the necessary terms, we obtain

$$\lambda_1 \approx -a_1 i - m_1 pi, \qquad \lambda_2 \approx -a_2 i - m_2 pi, \quad (4.32)$$

$$\mu_1 \approx n_2 pi, \qquad \mu_1 \approx n_2 pi, \quad (4.33)$$

where

$$m_{1,2} = \frac{\sqrt{2}}{2}\Big[\frac{1}{c_1^2} + \frac{\tau}{k} + \frac{\tau}{k}\omega \mp [(\frac{1}{c_1^2} + \frac{\tau}{k} + \frac{\tau}{k}\omega)^2 - 4\tau/(c_1^2 k)]^{1/2}\Big]^{1/2}, \quad (4.34)$$

$$a_{1,2} = \frac{1}{4m_1}\Big[-\frac{1+\omega}{k} \pm [(\frac{1}{c_1^2} + \frac{\tau}{k} + \frac{\tau}{k}\omega)\frac{1+\omega}{k} - 2/(c_1^2 k)]/[(\frac{1}{c_1^2} + \frac{\tau}{k} + \frac{\tau}{k}\omega)^2 - 4\tau/(c_1^2 k)]\Big], \quad (4.35)$$

$$n_{1,2} = \frac{\sqrt{2}}{2}\Big[\frac{1}{c_2^2} + \frac{1}{c_4^2} \mp [(\frac{1}{c_2^2} + \frac{1}{c_4^2})^2 - 4/(c_2^2 c_4^2)]^{1/2}\Big]^{1/2}, \quad (4.36)$$

Substituting for λ_1, λ_2, μ_1, and μ_2 from equations (4.32) and (4.33) into equations (4.25)-(4.29) and expanding the right hand sides of these equations in inverse powers of p by making use of the relation (Watson, 1958):

$$K_{n+\frac{1}{2}}(z) = \left(\frac{\pi}{2z}\right)^{1/2} e^{-z} \sum_{k=0}^{n} \frac{(n+k)!}{k!(n-k)!} \frac{1}{(2z)^k}, \tag{4.37}$$

we obtain the following expressions for I_i ($i = 1, 2, 3, 4, 5$):

$$\begin{aligned} I_1 \approx 2\pi^2 i\Big[&\frac{|z|}{R^2}e^{-(a_1+m_1 p)R}\left(r_1\frac{1}{p} + s_1\frac{1}{p^2}\right) \\ &+ \frac{|z|}{R^3}e^{-(a_1+m_1 p)R}\, r_1\frac{1}{m_1}\frac{1}{p^2} \\ &+ \frac{|z|}{R^2}e^{-(a_2+m_2 p)R}\left(r_2\frac{1}{p} + s_2\frac{1}{p^2}\right) \\ &+ \frac{|z|}{R^3}e^{-(a_2+m_2 p)R}\, r_2\frac{1}{m_2}\frac{1}{p^2}\Big], \end{aligned} \tag{4.38}$$

$$\begin{aligned} I_2 \approx 2\pi^2 i\Big[&\frac{|z|}{R^2}e^{-n_1 pR}\left(b_1\frac{1}{p} + d_1\frac{1}{p^2}\right) \\ &+ \frac{|z|}{R^3}e^{-n_1 pR}\, b_1\frac{1}{n_1}\frac{1}{p^2} \\ &+ \frac{|z|}{R^2}e^{-n_2 pR}\left(b_2\frac{1}{p} + d_2\frac{1}{p^2}\right) \\ &+ \frac{|z|}{R^3}e^{-n_2 pR}\, b_2\frac{1}{n_2}\frac{1}{p^2}\Big], \end{aligned} \tag{4.39}$$

$$I_3 = 2\pi^2 \frac{1}{R}e^{-n_1 Rp}, \tag{4.40}$$

$$I_4 = \frac{2\pi^2}{n_1^2 - n_2^2}\left[\frac{1}{R}e^{-n_1 Rp} - \frac{1}{R}e^{-n_2 Rp}\right]\frac{1}{p^2}, \tag{4.41}$$

$$I_5 = \frac{2\pi^2}{m_1^2 - m_2^2}\left[\frac{1}{R}e^{-n_1 Rp} - \frac{1}{R}e^{-n_2 Rp}\right]\frac{1}{p^2}, \tag{4.42}$$

where $R = (x^2 + y^2 + z^2)^{1/2}$ and

$$r_1 = \frac{\tau - m_1 k}{k m_1 (m_2^2 - m_1^2)}, \qquad r_2 = \frac{\tau - m_2 k}{k m_2 (m_1^2 - m_2^2)}, \tag{4.43}$$

$$s_1 = \frac{(1-a_1 k)m_1(m_2^2 - m_1^2) - (\tau - m_1 k)\left[a_1(m_2^2 - m_1^2) + 2m_1(m_2 a_2 - m_1 a_1)\right]}{k m_2^2 (m_1^2 - m_2^2)^2}, \tag{4.44}$$

$$s_2 = \frac{(1-a_2 k)m_2(m_1^2 - m_2^2) - (\tau - m_2 k)\left[a_2(m_1^2 - m_2^2) + 2m_2(m_1 a_1 - m_2 a_2)\right]}{k m_1^2 (m_2^2 - m_1^2)^2}, \tag{4.45}$$

$$b_1 = \frac{1 - n_1 c_4^2}{c_4^2 n_1 (n_2 - n_1)}, \qquad b_2 = \frac{1 - n_2 c_4^2}{c_4^2 n_2 (n_1 - n_2)}, \tag{4.46}$$

$$d_1 = \frac{2s^*}{n_1^2 (n_2 - n_1)}, \qquad d_2 = \frac{2s^*}{n_2^2 (n_1 - n_2)}. \tag{4.47}$$

Substituting the above values I_1, I_2, I_3, I_4 and I_5 into equations (4.10)-(4.16), we find that

$$\begin{aligned} \bar{u}_1(x,y,z,p)\frac{4\pi\rho}{F} \approx \frac{|z|x}{c_1^2 R^3}\Big[&\frac{1}{R}m_1 e^{-a_1 R}e^{-m_1 Rp} \\ &+ \left(a_1 r_1 + m_1 s_1 + 3\frac{1}{R}r_1\right)e^{-a_1 R}e^{-m_1 Rp}\frac{1}{p} \\ &+ \left(a_1 s_1 + \frac{2s_1 m_1 + a_1 r_1}{m_1 R} + \frac{3r_1}{m_1 R^2}\right)e^{-a_1 R}e^{-m_1 Rp}\frac{1}{p^2} \\ &+ \frac{1}{R}m_2 e^{-a_2 R}e^{-m_2 Rp} \\ &+ \left(a_2 r_2 + m_2 s_2 + 3\frac{1}{R}r_2\right)e^{-a_2 R}e^{-m_2 Rp}\frac{1}{p} \\ &+ \left(a_2 s_2 + \frac{2s_2 m_2 + a_2 r_2}{m_2 R} + \frac{3r_2}{m_2 R^2}\right)e^{-a_2 R}e^{-m_2 Rp}\frac{1}{p^2}\Big] - \frac{|z|x}{c_2^2 R^3}\Big[\frac{1}{R}n_1 e^{-n_1 Rp} \\ &+ \left(n_1 d_1 + 3\frac{1}{R}b_1\right)e^{-n_1 Rp}\frac{1}{p} \\ &+ \left[\frac{2}{R}d_1 + 3b_1/(n_1 R^2)\right]e^{-n_1 Rp}\frac{1}{p^2} + \frac{1}{R}n_2 e^{-n_2 Rp} \\ &+ \left(n_2 d_2 + \frac{3}{R}b_2\right)e^{-n_2 Rp}\frac{1}{p} \\ &+ \left[\frac{2}{R}d_2 + 3b_2/(n_2 R^2)\right]e^{-n_2 Rp}\frac{1}{p^2}\Big], \end{aligned} \tag{4.48}$$

$$\bar{u}_2(x,y,z,p) = \frac{y}{x}\bar{u}_1(x,y,z,p) \tag{4.49}$$

$$
\begin{aligned}

\end{aligned}
\tag{4.58}
$$

$$w_2(x,y,z,t) = -w_1(y,x,z,t), \tag{4.59}$$

$$w_3(x,y,z,t) = 0, \tag{4.60}$$

$$\theta(x,y,z,t)\frac{4\pi\rho}{\eta.F} \approx \frac{z}{c_1^2(m_1^2-m_2^2)R^2}\Big[m_1H(t-m_1R) + \frac{1}{R}A(t-m_1R) - m_2H(t-m_2R) - \frac{1}{R}A(t-m_2R)\Big]. \tag{4.61}$$

where

$$A(t-a) = \begin{cases} 0 & \text{for } 0 < t < a, \\ t-a & \text{for } t > a, \end{cases} \tag{4.62}$$

$H(t)$ is the Heaviside step function and $\delta(t)$ is the Dirac delta function.

From equations (4.55)-(4.61), we note that the displacement components have four inifinite discontinuities at $t = m_1 R$, $t = m_2 R$, $t = n_1 R$ and $t = n_2 R$, due to the presence of Dirac delta functions. The microrotation components w_1 and w_2 have only two finite discontinuities at $t = n_1R$ and $t = n R$, with the respective jumps of the magnitudes

$$\frac{F}{4\pi\rho}\frac{s^*\zeta}{c_2^2(n_2^2-n_1^2)R^2}n_1 \quad \text{and} \quad \frac{F}{4\pi\rho}\frac{s^*\zeta}{c_2^2(n_1^2-n_2^2)R^2}n_2,$$

where $\zeta = y$ for w_1 and $\zeta = x$ for w_2. The third microrotation component w_3 vanishes identically when the applied body force is in the z-direction. The temperature field has only two finite discontinuities at $t = m_1 R$ and $t = m_2 R$, with jumps of magnitudes

$$\frac{F}{4\pi\rho}\frac{\eta.zm_1}{c_1^2(m_1^2-m_2^2)R^2} \quad \text{and} \quad \frac{F}{4\pi\rho}\frac{\eta.zm_2}{c_1^2(m_2^2-m_1^2)R^2}$$

respectively. These jumps diminish with the increase of the distance of the disturbance from the origin.

THE EFFECT OF IMPULSIVELY APPLIED HEAT SOURCE

Consider when a heat source of constant strength S is applied impulsively at the origin. Then we may take

$$Q(x,y,z,t) = S\delta(x)\delta(y)\delta(z)\delta(t), \quad X = 0, \quad Y = 0. \tag{5.1}$$

In our transform notation this can be written as

$$\hat{Q}(\xi_1,\xi_2,\xi_3,p) = \frac{S}{(2\pi)^{3/2}}, \quad \hat{X} = 0, \quad \hat{Y} = 0. \tag{5.2}$$

Substituting from equation (5.2) in equations (3.28)-(3.30), we find that

$$(\hat{u}_1,\hat{u}_2\ \hat{u}_3) = \frac{\nu Sq}{(2\pi)^{3/2}\rho c_1^2 p}\frac{i}{\Delta_1}(\xi_1,\xi_2,\xi_3), \tag{5.3}$$

$$\hat{\theta}(\xi_1,\xi_2,\xi_3,p) = \frac{Sq}{(2\pi)^{3/2}p}\frac{\xi^2+\beta_1^2}{\Delta_1}, \tag{5.4}$$

$$\hat{w}_i(\xi_1,\xi_2,\xi_3,p) \equiv 0, \quad i = 1,2,3. \tag{5.5}$$

Inverting the Fourier transform with respect to ξ_1, ξ_2 and ξ_3 in the above equations, we obtain

$$(\bar{u}_1,\bar{u}_2,\bar{u}_3) = \frac{-\nu Sq}{(2\pi)^3\rho c_1^2 p}\Big(\frac{\partial}{\partial x},\frac{\partial}{\partial y},\frac{\partial}{\partial z}\Big)I_5, \tag{5.6}$$

$$\bar{\theta}(x,y,z,p) = \frac{Sq}{(2\pi)^3 p}I_6, \tag{5.7}$$

where I_5 is defined in equation (4.29) and

$$I_6 = \iiint_{-\infty}^{\infty}\frac{\xi^2+\beta^2}{(\xi^2-\lambda_1^2)(\xi^2-\lambda_2^2)}\exp\{-i(\xi_1 x + \xi_2 y + \xi_3 z)\}d\xi_1 d\xi_2 d\xi_3. \tag{5.8}$$

Integrating equation (5.8), we obtain

$$I_6 = 2\pi^2\sqrt{\frac{2}{\pi}}\Big[\frac{\lambda_1^2+\beta_1^2}{\lambda_1^2-\lambda_2^2}\frac{(i\lambda_1)^{1/2}}{R^{1/2}}K_{1/2}(i\lambda_1 R) - \frac{\lambda_2^2+\beta_1^2}{\lambda_1^2-\lambda_2^2}\frac{(i\lambda_2)^{1/2}}{R^{1/2}}K_{1/2}(i\lambda_2 R)\Big]. \tag{5.9}$$

It may be noticed that this is a spherically symmetric case and we will find the radial displacement u_R instead of u_1, u_2 and u_3. From equation (5.6), we see that

$$\bar{u}_R(R,t) = \frac{-\nu Sq}{(2\pi)^3\rho c_1^2 p}\frac{\partial}{\partial R}I_5. \tag{5.10}$$

Using equation (4.42), we find that

$$\bar{u}_R(R,p)\frac{4\pi\rho k}{\nu S} = \frac{1}{c_1^2 R}\Big[\tau n_1 e^{-n_1 R p} - \tau n_2 e^{-n_2 R p} + (n_1 + \frac{\tau}{R})e^{-n_1 R p}\frac{1}{p} - (n_2 + \frac{\tau}{R})e^{-n_2 R p}\frac{1}{p} + \frac{1}{R}e^{-n_1 R p}\frac{1}{p^2} - \frac{1}{R}e^{-n_2 R p}\frac{1}{p^2}\Big]. \quad (5.11)$$

Expanding the right hand terms of equation (5.9) in the ascending powers of $\frac{1}{p}$ and retaining only the necessary terms, we obtain

$$I_6 = 2\pi^2\frac{1}{R}\Big[(h_1 + h_2\frac{1}{p} + h_3\frac{1}{p^2})e^{-(a_1+m_1 p)R} + (l_1 + l_2\frac{1}{p} + l_3\frac{1}{p^2})e^{-(a_2+m_2 p)R}\Big], \quad (5.12)$$

where

$$h_1 = \frac{1 - m_1^2 c_1^2}{c_1^2(m_2^2 - m_1^2)}, \quad (5.13)$$

$$h_2 = 2\,\frac{a_1 m_1 c_1^2(m_1^2 - m_2^2) + (a_1 m_1 - a_2 m_2)(1 - m_1^2 c_1^2)}{c_1^2(m_2^2 - m_1^2)^2}, \quad (5.14)$$

$$h_3 = 2\,\frac{a_1^2(m_1^2 - m_2^2)c_1^2 + (a_1^2 - a_2^2)(1 - m_1^2 c_1^2)}{c_1^2(m_2^2 - m_1^2)^2} + \frac{4(a_1 m_1 - a_2 m_2)h_2}{m_2^2 - m_1^2}, \quad (5.15)$$

$$l_1 = \frac{1 - m_2^2 c_1^2}{c_1^2(m_1^2 - m_2^2)}, \quad (5.16)$$

$$l_2 = 2\,\frac{a_2 m_2 c_1^2(m_2^2 - m_1^2) + (a_2 m_2 - a_1 m_1)(1 - m_2^2 c_1^2)}{c_1^2(m_1^2 - m_2^2)^2}, \quad (5.17)$$

$$l_3 = 2\,\frac{a_2^2(m_2^2 - m_1^2)c_1^2 + (a_2^2 - a_1^2)(1 - m_2^2 c_1^2)}{c_1^2(m_1^2 - m_2^2)^2} + \frac{4(a_2 m_2 - a_1 m_1)l_2}{m_1^2 - m_2^2}. \quad (5.18)$$

Substituting from equation (5.12) into equation (5.7), we find that

$$\bar{\theta}(R, p)\frac{4\pi k}{S} = \frac{1}{R}\Big[\tau h_1 p + h_1 + \tau h_2 + (h_2 + \tau h_3)\frac{1}{p} + h_3\frac{1}{p^2}\Big]e^{-a_1 R}e^{-m_1 R p} + \frac{1}{R}\Big[\tau l_1 p + l_1 + \tau l_2 + (l_2 + \tau l_3)\frac{1}{p} + l_3\frac{1}{p^2}\Big]e^{-a_2 R}e^{-m_2 R p}. \quad (5.19)$$

On inverting the Laplace transform in equations (5.11) and (5.19), we obtain the displacement and temperature field for the case of impulsively applied heat source as

$$u_R(R,t)\frac{4\pi\rho k}{\nu S} = \frac{1}{c_1^2 R}\Big[\tau n_1\delta(t - n_1 R) - \tau n_2\delta(t - n_2 R) + (n_1 + \frac{\tau}{R})H(t - n_1 R) - (n_2 + \frac{\tau}{R})H(t - n_2 R) + \frac{1}{R}A(t - n_1 R) - \frac{1}{R}A(t - n_2 R)\Big]. \quad (5.20)$$

$$\theta(R, t)\frac{4\pi k}{S} = \Big[\tau h_1\delta'(t - m_1 R) + (h_1 + \tau h_2)\delta(t - m_1 R) + (h_2 + \tau h_3)H(t - m_1 R) + h_3 A(t - m_1 R)\Big]\frac{1}{R}e^{-a_1 R} + \Big[\tau l_1\delta'(t - m_2 R) + (l_1 + \tau l_2)\delta(t - m_2 R) + (l_2 + \tau l_3)H(t - m_2 R) + l_3 A(t - m_2 R)\Big]\frac{1}{R}e^{-a_2 R}. \quad (5.21)$$

From equations (5.20) and (5.21), we note that the radial displacement u_R and temperature field θ have two infinite discontinuities each at $t = n_1 R$, $t = n_2 R$ and $t = m_1 R$, $t = m_2 R$ respectively while in this case the microrotation vector is identically equal to zero.

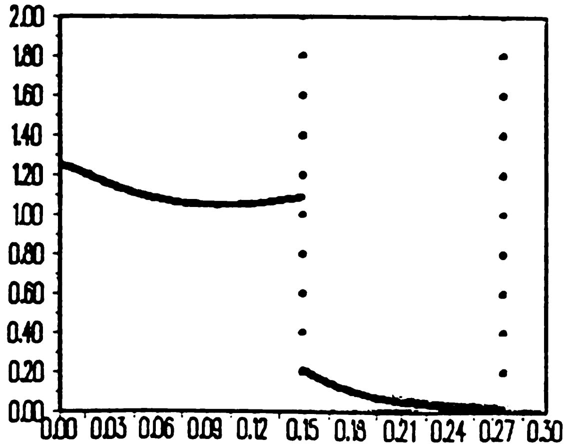

Fig 6. Numerical values of $T = \dfrac{4\pi k}{S} \theta \times 10^{-5}$ *vs* R for the case of impulsively applied heat source.

NUMERICAL RESULTS AND CONCLUSIONS

From equations (4.55)-(4.61) and equations (5.20)-(5.21), it is apparent that for the generalized problems, the displacement, microrotation and temperature fields vanish identically for $R > t/M$, where $M = \max\{m_1, m_2, n_1, n_2\}$, due to the finite supports of functions $H(t\text{-}MR)$ and $A(t\text{-}MR)$ for fixed t and constant M; hence the effect of the body force or heat source is confined to a bounded but time-dependent region of space surrounding the point where the external load is applied. This means that we have a signal propagating with a finite speed.

We have calculated the numerical values of the displacement, microrotation, and temperature field for the cases of impulsively applied body force and heat source. To obtain these numerical values, we have taken, as in Shanker and Dhaliwal (1975), $c_1 = 5.2$, $c_2 = 3.8$, $c_3 = 3.45$, $c_4 = 1.5$, $\omega = 0.0729$, $k = 1$, $\tau = 0.1$ and $t = 0.05$.

For the case of an impulsive body force, the numerical values have been calculated at a plane $z = 0.01$ along the r axis, in the cylindrical polar coordinates, and have been displayed in Figs 1-4, in which the dotted vertical lines denote the infinite discontinuities. In this case, displacements have infinite discontinuities, at r = 0.074137, 0.149528, 0.189498, and 0.273741.

The microrotation component w_r has only two finite discontinuities at r = 0.074137 and 0.189498 with jumps of magnitude 1.597888 and 0.257279, respectively. While the component w_z is identically zero.

The temperature also has two finite discontinuities at r = 0.149528 and 0.273741 with jumps of magnitude 0.699699 and 0.116881, respectively.

For the case of impulsively applied heat source, the numerical results are calculated along R axis and have been shown in Figs 5 and 6. the radial displacement, in this case, has two infinite discontinuities at R = 0.074808 and 0.189762 while the temperature has two infinite discontinuities at R = 0.149862 and 0.273924. The components of microrotation vector are identically zero.

Principles and the uncertainty principles of the probabilistic strength of materials and their applications to seismology

P Kittl, G Díaz and V Martínez

Departamento de Ingeniería de los Materiales, IDIEM, Facultad de Ciencias Físicas y Matemáticas, Universidad de Chile, Casilla 1420, Santiago, Chile.

The principles of Fracture-Statistics Mechanics are presented using two functional equations, namely one for the cumulative probability of fracture, and another for the local probability of fracture. These two functional equations are independent and they become compatible only when the volume considered is very small. The determination of the specific-risk function can be made by means of integral equations, without having to specify the analytical expression for this function. This two principles give two principles of uncertainty. Some applications to seismology are given where it is shown that the possibilities of predicting the instant of occurrence and the magnitude of an earthquake are null. Only the probability of occurrence of an earthquake of a given magnitude in a given place can be known. The instant of occurrence, the magnitude and the location are aleatory.

INTRODUCTION

In any discipline, it is important to know which are the hypothesis employed for its development. Thus, it is obtained a hypothetic-deductive system that, when it does not result in its applications, permits to check rapidly the hypothesis or models in order to produce a new model or a new theory that corresponds to the events occurred. In the present work, it is attempted to do this. One of the unavoidable consequences of the present theory is the impossibility of predicting that one is going to occur, which is expressed by means of the uncertainty principles. Let suppose that we have a set of fractures (earthquakes), from where we choose some of them (the earthquakes already occurred), and that we also require to know the stress (magnitude of the earthquake) and in what place of the next sample (earthquake epicenter) will occur the fracture (earthquake). In such a case, the uncertainty principles indicate that this is impossible. In the following, the above ideas anticipated will be developed.

PRINCIPLES OF THE PROBABILISTIC STRENGTH OF MATERIALS

The cumulative probability of fracture in an isotropic brittle body subjected to a constant stress field σ can be determined [1,2] using the following functional equation:

$$\tilde{F}_{12}(V = V_1 + V_2, \sigma) = \tilde{F}_1(V_1, \sigma)\tilde{F}_2(V_2, \sigma), \qquad (1)$$

where V_1 and V_2 are the volumes resulting from an arbitrary disjointed division of the body of volume V. $\tilde{F}_{12}$ is the cumulative probability of nonfracture of the whole volume V, and $\tilde{F}_1$ and $\tilde{F}_2$ are the cumulative probabilities of nonfracture of volumes V_1 and V_2, respectively. The boundary condition $\tilde{F}_{12}(0,\sigma) = \tilde{F}_1(0, \sigma) = \tilde{F}_2(0,\sigma) = 1$ yields easily $\tilde{F}_{12} = \tilde{F}_1 = \tilde{F}_2 = F$ and then functional Eq 1 has a solution already indicated by Euler:

$$F(V,\sigma) = 1 - \tilde{F}(V,\sigma) = 1 - \exp\left\{-\frac{V}{V_0}\phi_1(\sigma)\right\}, \qquad (2)$$

where V_0 is the unit volume and $\phi_1(\sigma)$ is the specific-risk-of-fracture function. This formula given by Weibull can be easily generalized for uniaxial variable-stress fields:

$$1-F(V,\sigma) = \lim_{N\to\infty}\prod_{i=1}^{N}\left[1-F(V_i,\sigma_i)\right] = \lim_{N\to\infty}\prod_{i=1}^{N}\exp\left[-\frac{V_i}{V_o}\phi_1(\sigma_i)\right] = \lim_{N\to\infty}\exp\left[-\sum_{i=1}^{N}\frac{V_i}{V_o}\phi_1(\sigma_i)\right]$$

$$\Rightarrow F(V,\sigma) = 1 - \exp\left\{-\frac{1}{V_o}\int_V \phi_1[\sigma(r)]dV\right\}, \tag{3}$$

where r is the position vector, $\sigma(r) \le \sigma$ is the stress field, and the volume is determined by the condition $\sigma(r) \ge 0$. When $F(V,\sigma)$ is experimentally known and $\sigma(r)$ is obtained from the Theory of Elasticity then integral Eq 3 can be solved in particular cases.

As regards the local probability of fracture F_L, *ie* the percentage of fractures starting in a given region of the body subjected to some stress, the proofs known so far [3,4] as obtained by a passage to the limit. The following discussion shows that it cannot be otherwise and it supplies an expression for ascertaining this percentage.

Since $F_L(V_1,\sigma) = n_1/N$ and $F_L(V_2,\sigma) = n_2/N$ where n_1 and n_2 are the numbers of the fractures that are started in V_1 and V_2, respectively, and N is the total number of test — with $n_1/n_2 = V_1/V_2$ — then the local probability of fracture is given by the following functional equation:

$$F_L(V_1,\sigma)V_2 - F_L(V_2,\sigma)V_1 = 0 \tag{4}$$

Putting $V_1 = V$ and $V_2 = V + \Delta V$, $\Delta V \longrightarrow 0$, yields:

$$F_L(V,\sigma) = F_L'(V,\sigma)V, \tag{5}$$

whose solution is:

$$0 \le F_L(V,\sigma) = \frac{V}{V_o}\phi_2(\sigma) \le 1, \tag{6}$$

in which $\phi_2(\sigma)$ must be determined.

Thus the principles of Fracture-Statistics Mechanics are represented by functional Eqs 1 and 4 (whose solutions are 2 and 6) that are independent and incompatible except in the region where $(V/V_0)\phi_1(\sigma)$ and $(V/V_0)\phi_2(\sigma)$ tend towards zero. In order that the functions become equal in that boundary then $\phi_1 = \phi_2$ and accordingly

$$F(V,\sigma) = F_L(V,\sigma) = \frac{V}{V_o}\phi(\sigma)$$
$$\frac{V}{V_o}\phi(\sigma) \to 0. \tag{7}$$

The foregoing means that the local probability of fracture can be determined only by a passage to the limit in a very small region of the total body. Hence Eq 7 becomes:

$$\frac{dn}{N} = \frac{\phi[\sigma(r)]}{V_o}dV, \tag{8}$$

where dn is the number of the fractures started in dV. The integration of Eq 8 produces:

$$\frac{n}{N} = \frac{1}{V_o}\int_V \phi[\sigma(r)]dV;\ r \in V[\sigma(r) \ge 0], \tag{9}$$

and the elimination of N from Eqs 8 and 9 yields:

$$\frac{dn}{n} = \frac{\phi[\sigma(r)]dV}{\int_{rev[\sigma(r)\ge 0]}\phi[\sigma(r)]dV}. \tag{10}$$

From Eq 10, where $\sigma(r) = \sigma$ = constant, it is easy to reobtain $n_1/n_2 = V_1/V_2$.

If the percentage of fractures in some volume $V_1 \le V$ is to be ascertained, then Eq 10 must be integrated in this volume, assuming that $\phi(\sigma)$ is known. If $dn/ndV = 1/g(r,\sigma)$ is already known then Eq 10 is converted into an integral equation allowing to obtain $\phi(\sigma)$:

$$\int_{rev[\sigma(r)\ge 0]}\phi[\sigma(r)]dV = g(r,\sigma)\phi[\sigma(r)]. \tag{11}$$

Integral equation 11 is a particular instance of integral equation 3 and it allows to obtain $\phi(\sigma)$ excepting a constant factor. Integral equation (11) becomes trivial solely when $\sigma(r) = \sigma$, *ie* when the stress field is uniform; hence the particular instances of the solutions will be dealt with in other works. As $\sigma(r) = \sigma f(r)$, where $|f(r)| \le 1$, the expression of dn/ndV tends towards a finite limit when σ tends to infinite. In the stress space the integral equation 11 is transformed into

$$\int_0^\sigma \phi(\Sigma)dV(\Sigma,\sigma) = g(\sigma)\phi(\sigma). \tag{12}$$

A great number of works supports the mentioned theories and $\phi(\sigma)$ can be expressed in the following form of Weibull:

$$\phi(\sigma)=\begin{Bmatrix}\left(\dfrac{\sigma-\sigma_L}{\sigma_0}\right)^m & \sigma\geq\sigma_L \\ 0 & \sigma<\sigma_L\end{Bmatrix} \tag{13}$$

and Kies-Kittl:

$$\phi(\sigma)=\begin{Bmatrix}K\left(\dfrac{\sigma-\sigma_L}{\sigma_S-\sigma}\right)^m & \sigma_L\leq\sigma\leq\sigma_S \\ 0 & 0\leq\sigma\leq\sigma_L \\ \infty & \sigma>\sigma_S\end{Bmatrix} \tag{14}$$

Equation 10 coincides with that one previously obtained by Kittl and Camilo [4]. It is equivalent to the one obtained by Oh and Finnie [3] solely when $\phi(\sigma)=(\sigma/\sigma_0)^m$ where σ_0 and m are real numbers greater than zero.

THE UNCERTAINTY PRINCIPLES OF PROBABILISTIC STRENGTH OF MATERIALS

In Probabilistic Strength of Materials [2], when $\phi(\sigma)$ has the expression given by formula (3), the following relationships are well known:

$$\bar{\sigma}=\int_0^\infty \sigma\frac{dF}{d\sigma}d\sigma=\sigma_0\left(\frac{V}{V_0}\right)^{-1/m}\Gamma\left(1+\frac{1}{m}\right)+\sigma_L \tag{15}$$

$$\Delta\sigma=\int_0^\infty(\sigma-\bar{\sigma})^2\frac{dF}{d\sigma}d\sigma=\sigma_0\left(\frac{V}{V_0}\right)^{-1/m}$$

$$\times\left\{\Gamma\left(1+\frac{2}{m}\right)-\Gamma^2\left(1+\frac{1}{m}\right)\right\}^{1/2} \tag{16}$$

By means of simple transformations it is obtained:

$$V\left(\frac{\bar{\sigma}}{\sigma_0}\right)^m=V_0K_1;\quad V\left(\frac{\Delta\sigma}{\sigma_0}\right)^m=V_0K_2, \tag{17}$$

where K_1 and K_2 are constant. Hence, it may be guessed that the following relationships would be valid:

$$\frac{V}{V_0}\bar{\phi}=K_1\ ;\ \frac{V}{V_0}\Delta\phi=K_2 \tag{18}$$

where $\phi(\sigma)$ is the specific risk of fracture function of Weibull without any definite analytical form and with the unique condition that it is positive. $\bar{\phi}$ and $\Delta\phi$ are the mean value and the dispersion of $\phi(\sigma)$, respectively.

The relations defined in equation 18 would constitute the uncertainty principle of probabilistic strength of materials. This principle, for the case of uniform stress field, was already enunciated previously [5,6]. In the following paragraphs it will be intended to extend this principle to the case of variable stress field.

The formulas (18) can be easily proved. In accord with equation 2 the function of frequency is:

$$\frac{dF(v,\sigma)}{d\sigma}=\frac{v}{v_0}\exp\left\{-\frac{v}{v_0}\phi(\sigma)\right\}\phi'(\sigma). \tag{19}$$

The mean value of ϕ is calculated as follows:

$$\begin{aligned}\bar{\phi}&=\int_0^\infty\phi\frac{v}{v_0}\exp\left\{-\frac{v}{v_0}\phi(\sigma)\right\}\phi'(\sigma)d\sigma\\&=\frac{v_0}{v}\int_0^\infty\xi e^{-\xi}d\xi=\frac{v_0}{v},\end{aligned} \tag{20}$$

Calculating $\overline{\phi^2}$ it is obtained:

$$\begin{aligned}\overline{\phi^2}&=\int_0^\infty\phi^2\exp\left\{-\frac{v}{v_0}\phi(\sigma)\right\}\frac{v}{v_0}\phi'(\sigma)d\sigma\\&=\left(\frac{v_0}{v}\right)^2\int_0^\infty\xi^2e^{-\xi}d\xi=2\left(\frac{v_0}{v}\right)^2,\end{aligned} \tag{21}$$

and finally the dispersion of ϕ is determined as follows:

$$\begin{aligned}\overline{\Delta\phi^2}&=\overline{\phi^2}-\bar{\phi}^2=2\left(\frac{v_0}{v}\right)^2-\left(\frac{v_0}{v}\right)^2=\left(\frac{v_0}{v}\right)^2\\\Delta\phi&=\sqrt{\overline{\Delta\phi^2}}=\frac{v_0}{v}.\end{aligned} \tag{22}$$

So the relationships guessed (18) give now exactly:

$$\bar{\phi}\frac{V}{V_0}=1\ ;\ \Delta\phi\frac{V}{V_0}=1, \tag{23}$$

where ϕ has no any analytical prefixed form. In the case when the function of cumulative probability of fracture or yielding has the following expression:

$$F(V,\sigma) = 1 - \exp\left\{ -\frac{V}{V_0} K\phi(\sigma) \right\}, \tag{24}$$

where K is a constant, it is easy to see that the expressions of equation 18 are transformed in the following ones:

$$\bar{\phi}\frac{V}{V_0} = K \; ; \; \Delta\phi\frac{V}{V_0} = K. \tag{25}$$

When the stress-field space is variable the space can be divided by means of isotensional surfaces [2] and the cumulative probability of fracture or yielding is given by the following expression:

$$F(\sigma) = 1 - \exp\left\{ -\frac{1}{V_0}\int_0^{\infty} \phi(\Sigma)\,dV(\Sigma,\sigma) \right\}. \tag{26}$$

Adopting as a new variable

$$0 \le \xi(\sigma) = \frac{1}{V_0}\int_0^{\sigma} \phi(\Sigma)\,dV(\Sigma,\sigma) < \infty, \tag{27}$$

where $dV(\Sigma,\sigma)$ depends upon the geometry of the material subjected to the variable stress field. Hence the functions of cumulative probability and frequency can be expressed in a simplified manner:

$$F(\xi) = 1 - e^{-\xi} \qquad \frac{dF}{d\xi} = e^{-\xi} \tag{28}$$

Hence, with a great simplicity the mean value and the mean square dispersion of ξ can be obtained:

$$\bar{\xi} = \int_0^{\infty} \xi e^{-\xi} d\xi = 1 \; ; \; \overline{\xi^2} = \int_0^{\infty} \xi^2 e^{-\xi} d\xi = 2. \tag{29}$$

Therefore, the dispersion of ξ is:

$$\Delta\xi = \sqrt{\overline{\xi^2} - \bar{\xi}^2} = \sqrt{2 - 1.} = 1. \tag{30}$$

So if in a variable stress field ξ is adopted as the independent variable then the uncertainty relationships have a particular simple form. Therefore, upper limits can be obtained for the equations 27 and the first of equations 29 and also a limit for the equation 30

$$\xi \le \frac{V}{V_0}\phi ; 1 = \bar{\xi} \le \frac{V}{V_0}\bar{\phi} ; \begin{cases} \frac{V}{V_0}\Delta\phi \rightarrow 1 = \Delta\xi \\ V \longrightarrow 0 \end{cases} \tag{31}$$

The relationships (Eq 31) are true relationships of uncertainty because the first relation shows that for the place of fracture or yielding to be exactly located then V-->0, since $\bar{\phi}V \ge V_0$ according to the second relation, the stress will increase indefinitely, $\bar{\phi} - - > \infty$, then the piece will not break or will not yield and σ-->∞. However, according to the last relationship, $1 = (V/V_0)\Delta\phi$, $\Delta\phi$-->∞ and then the uncertainty in the determination of the stress at which the failure occurs becomes indefinitely great. Therefore, there is a contradiction and it can be seen that the problem of the exact determination of the place and the stress wherever the fracture occurs has an impossible solution. It can be remembered that $\phi(\sigma)$ is a crescent and monotonous function [1]. These considerations can also be made from the equations 23 corresponding to uniform stress field taking a small portion of a variable stress field where the same can be considered as uniform.

For the special case when the function of Weibull takes the potential form $\phi(\sigma) = (\sigma/\sigma_0)^m$ the constants K_1 and K_2 can be calculated in an exact and simple form and the relations of uncertainty are valid for the body subjected to a variable stress field as a whole. Hence, with $\xi(\sigma)$ defined into the stress-field space, the following expression into the real space [2] is obtained:

$$\xi(\sigma) = \frac{1}{V_0}\int_V \phi[\sigma f(r)]dV = \frac{\phi(\sigma)}{V_o}\int_V f^m(r)\,dV = \frac{\phi(\sigma)KV}{V_0}, \tag{32}$$

where r is the position vector and f is a function obtained from the elasticity theory. Thus,

$$\bar{\phi} = \int_0^{\infty} \phi(\sigma) e^{-\xi(\sigma)} \frac{d\xi(\sigma)}{d\sigma} d\sigma, \tag{33}$$

therefore

$$\bar{\phi} = \int_0^\infty \frac{VK}{V_0}\phi(\sigma)e^{-\frac{V}{V_0}K\phi(\sigma)}\phi'(\sigma)d\sigma = \frac{V_0}{VK}\int_0^\infty \xi e^{-\xi}d\xi = \frac{V_0}{VK}, \tag{34}$$

and finally

$$\frac{V}{V_0}\bar{\phi} = K_1 = \frac{1}{K} = \frac{1}{\frac{\sigma_0^m}{V}\int_V \phi[f(r)]dV} = \frac{1}{\frac{1}{V}\int_V f^m(r)dV} \tag{35}$$

Likewise it is obtained:

$$\frac{V}{V_0}\Delta\phi = K_1 = K_2 \tag{36}$$

It can be seen without any difficulty that the volume is proportional to the dispersion in the position. The function of frequency of the position can be expressed in the following manner:

$$f(r) = \frac{1}{V} \quad r \in V; f(r) = 0 \quad r \notin V; \int_V f(r)dV = 1. \tag{37}$$

The mean value and the dispersion are calculated in the following form:

$$\begin{aligned} \bar{r} &= \int_V r f(r)dV \\ \overline{\Delta r^2} &= \overline{r^2} - \bar{r}^2 = \int_V r^2 f(r)dV - \bar{r}^2 \\ \Delta r &= \sqrt{\overline{\Delta r^2}}. \end{aligned} \tag{38}$$

In the case of a volume included into a parallelepiped of coordinates $(b_1-a_1, b_2-a_2, b_3-a_3)$ and considering a system of cartesian coordinates (x,y,z) the calculations give the following results:

$$\begin{aligned} \bar{x} &= \int_{a_1}^{b_1} dx \int_{a_2}^{b_2} dy \int_{a_3}^{b_3} \frac{x dz}{(b_1-a_1)(b_2-a_2)(b_3-a_3)} = \frac{b_1+a_1}{12} \\ \overline{\Delta x^2} &= \int_{a_1}^{b_1} dx \int_{a_2}^{b_2} dy \int_{a_3}^{b_3} \frac{(x-\bar{x})^2 dz}{(b_1-a_1)(b_2-a_2)(b_3-a_3)} = \frac{(b_1-a_1)^2}{12} \\ \Delta x &= (b_1-a_1)/2\sqrt{3}. \end{aligned} \tag{39}$$

Analogous results are obtained for $\bar{y}$, $\bar{z}$, Δy, Δz. Thus:

$$\Delta x \Delta y \Delta z = \frac{(b_1-a_1)(b_2-a_2)(b_3-a_3)}{24\sqrt{3}} = \frac{V}{24\sqrt{3}}, \tag{40}$$

Therefore, the equation $\Delta\phi V = 1$ is transformed into:

$$\Delta x \Delta y \Delta z \Delta\phi = \frac{V_0}{24\sqrt{3}}, \tag{41}$$

and for the case of a global rectangular body:

$$\Delta x \Delta y \Delta z \Delta\phi = \frac{V_0 K_2}{24\sqrt{3}}. \tag{42}$$

As to the local probability of fracture, the dispersion of the number of fractures n_1 starting in volume V_1 is obtained through the following group of relationships, as it is well-known from the elemental theory of Statistics:

$$\begin{aligned} n_1 &= N\frac{V_1}{V} \\ \Delta n_1 &= \sqrt{n_1} = \sqrt{N}\sqrt{\frac{V_1}{V}} \\ \frac{\Delta n_1}{n_1} &= \frac{1}{\sqrt{N}}\sqrt{\frac{V}{V_1}} = \frac{1}{\sqrt{n_1}} \end{aligned} \tag{43}$$

This group of relationships (43) represents the second principle of uncertainty of Probabilistic Strength of Materials. None of the two principles of uncertainty, relationships (31) and (43), depends on constants of the material.

APPLICATIONS TO SEISMOLOGY

An immediate application to Seismology can be made wherein probabilistic [7] or implicitly probabilistic [8] models have been introduced. The Seismic phenomenon is equivalent to a brittle fracture by a slowly gradual stress and if in a definite volume we have a definite number n of earthquakes of magnitude equal or greater than a given one, then fluctuations of order $\sqrt{n}$ may be expected, and if the mean time between earthquakes is $\bar{t}$ then stretchs of time of order $\bar{t}\sqrt{n}$ may be expected. For instance, in the closenesses of Valparaíso city (Chile, latitude 33°S) five strong earthquakes have had since 1575 with an approximate average interval of 82 years which makes possible to expect the existance of intervals of order of 200 years without earthquakes. However, another analysis can be made. If the Seismological phenomenon in front of Valparaíso Coasts consists of a constant increasing in the time of the mean space stress σ and later the fracture, then $\sigma \alpha$ t; $\Delta\sigma \alpha \Delta t$; $\bar{\sigma} \alpha \bar{t}$ t wherein $\bar{\sigma}$ is the time medium stress. If the material that is fracturing at the seism moment is of the Weibullian type, with $\phi(\sigma) = (\sigma/\sigma_0)^m$ (σ,m>0), then the equations 15 and 16 are valid.

In the case of the surrounding of Valparaíso $\bar{t}$ = 82 years, Δt = 6 years and, therefore, $\Delta t/\bar{t} = \sigma/\bar{\sigma}$ = 0.073 which implies, according to Eqs 15 and 16, m ~ 20. This last value belongs to a rock of impossible material properties. In consequence, this hypothesis of the average intervals of 82 years cannot be accepted and it must be revised. In all probability, the epicenters of old earthquakes were equivocally determined. In the case of earthquakes on the surrounding of Santiago city (Chile, latitude 33° 27'S) $\bar{t} \sim \Delta t$ = 28 years which gives us m ~ 1 and, hence, this hypothesis cannot be accepted too because the rocks have m ~ 6. Therefore the most probable hypothesis is that one of the variable volumen $V = \lambda t$ with σ = constant which was developed by Kittl and Díaz [7].

The growth of fissures that finally originate the fracture can be basically attributed to some of the following situations. The first of them implies an increasing of tension until the critical tension is reached which activates the crack causing the fracture. The second case is referred to a fatigue phenomenons, static as much as dynamic, and here is required an aggressive atmosphere in static fatigue, for example corrosion by water in ceramic materials, or in the case of metals when they are in presence of any acid in processes of static and/or dynamic fatigue. In the seismological ambit and particularly in the central coast of Chile, in front of Valparaíso, the said aggressive environments do not exist, neither aqueous nor gaseous, to the deepnesses in which the contact between the Nazca and Continental plates is verified. The creep does not exist too because if it existed then the great seisms registered would not produce there. In relation to the dynamic fatigue this does not exist in any way because of it needs approximately 10^4 cycles to be noted.

The theory of fracture of Weibull has, in the present time, a wide variety of applications because of which the simile of the chain, the most weak link, has been exceeded and the statistic is not necessary referred to bodies in which an only crack propagating activates the mechanism of fracture [2]. It is a mistake the idea concerning that since Weibull statistics is valid in an unidimensional body then it is not valid in three dimensions. This last because a body of three dimensions, where the probability of fracture is given by formula (3), can be constructed with unidimensional bars. In seismology, it deals with the fracture of a rocky material for which, in the case of granite, the Weibull function has been applied [9] where the growth of a certain number of cracks was required to fracture the material. Whichever the activation of the fracture, friction between plates, roughness [10] and so on, all of them must undergo a Weibull statistics. In the case of concrete in which the mechanism of fracture is by coalescence of cracks [11], the Weibull function even is valid there too. In a tectonic process, the failure is simply by slip at high velocity. Once the tension is annuled, since the earthquake has occurred, a new growth in the tension is initiated. When this last is verified, we are in presence of a new sample because the surrounding of the last failure is similar to that where the next one will produce. It is also worthwhile to note that this zone – where the phenomenon is produced – displaces.

It is necessary to emphasize the importance of the local probability of fracture, because in seismology a big relevance is given to the place where the earthquake occurs. Therefore, the local probability is very useful. By means of it, we may determine whether a certain number of events occurred in a determined zone correspond at the same statistical serie or not. This last may lead to decide whether events considered as concurrent in a same place, have been or not.

In the present time, the concept of seismic gap is the most widely criterion used for prediction of earthquakes [12-16]. However, according with the scarce number of events considered, such predictions fall out of the ambit of statistics, that is to say very few samples for a population evidently greater.

As a consequence of the uncertainty principles we can say that nor the place, nor the time, nor the magnitude of an earthquake can be predicted, but its probability.

FOURTH PAN AMERICAN CONGRESS OF APPLIED MECHANICS

PACAM IV

January 3-6, 1995, Universidad del Salvador, Buenos Aires, Argentina

CALL FOR PAPERS

The **Fourth Pan American Congress of Applied Mechanics** will be held in **Buenos Aires, Argentina** on the campus of the **Universidad del Salvador** during **January 3-6, 1995.** The Congress is sponsored by the **American Academy of Mechanics** and the **Asociación Argentina de Mecánica Computacional,** and is open to participants from all over the world.

The purpose of PACAM IV is (1) to expose mature engineers and scientists as well as advanced graduate students to new findings, techniques, and problems, and (2) to provide opportunities for personal interactions through formal lectures and informal conversations.

Papers in all areas of applied mechanics, including computational mechanics, are solicited by the Organizing Committee, which consists of the following persons:

Patricio A.A. Laura, Bahia Blanca, Argentina, *Chairman*
Sergio R. Idelsohn, Santa Fe, Argentina and **Dean T. Mook,** Blacksburg, Virginia, USA, *Vice Chairmen*
Luis A. Godoy, Córdoba, Argentina, *Chairman of the Editorial Committee*
Gustavo Sanchez Sarmiento, Buenos Aires, Argentina, *Chairman of the Local Arrangements Committee*

P. Bainum (Washington, D.C., USA)
F. Basombrio (Bariloche, Argentina)
P. Ballesteros (Mexico City, Mexico)
M. Crespo da Silva (Troy, New York, USA)
G. Dulikravich (Univ. Park, Pennsylvania, USA)
E. Dvorkin (Buenos Aires, Argentina)
R. Feijoo (Rio de Janeiro, Brazil)
J. Geer (Binghamton, New York, USA)
P. Glockner (Calgary, Canada)
P. Hajela (Troy, New York, USA)
J. Kelly (Berkeley, California, USA)
P. Kittl (Santiago, Chile)
A. Leissa (Columbus, Ohio, USA)
H. Liebowitz (Washington, D.C., USA)
O. Manero (Mexico City, Mexico)
C. Mazzilli (Sao Paulo, Brazil)
A. Müller (Caracas, Venezuela)
E. Oñate (Barcelona, Spain)
M. Paidoussis (Montreal, Canada)
M. Pazini Brandão (São Jose dos Campos, Brazil)
J. Reddy (College Station, Texas, USA)
J. Schetz (Blacksburg, Virginia, USA)
H. Sosa (Philadelphia, Pennsylvania, USA)
M. Souza (Rio de Janeiro, Brazil)
L. Suarez (Mayagüez, Puerto Rico)
E. Taroco (Rio de Janeiro, Brazil)
G. Treviño (Houghton, Michigan, USA)
R. Villaverde (Irvine, California, USA)

Accepted four-page manuscripts will appear in the Proceedings, which will be distributed at the Congress. After the Congress, selected participants will be invited to prepare full-length articles for a special issue of **Applied Mechanics Reviews** entitled **Mechanics Pan America.**

A packet with more information about PACAM IV and the typing requirements for manuscripts to be published in the Congress Proceedings can be obtained by writing to one of the following persons:

Prof. Sergio R. Idelsohn
Grupo de Tecnologia Mecánica de INTEC
Guemes 3450
3000 Santa Fe
ARGENTINA
Tel 54-42-559181
FAX 54-42-550944/E-MAIL rnsergio@arcride.edu.ar

Prof. Dean T. Mook
Virginia Polytechnic Institute and State University
Department of Engineering Science and Mechanics
Blacksburg, Virginia 24061-0219
USA
Tel 1-703-231-6841
FAX 1-703-231-4574/E-MAIL Sally@vtvm1.cc.vt.edu

The deadline for receipt of papers for the Congress is April 30, 1994. The languages for the Congress are English, Spanish, and Portuguese; nevertheless, authors are encouraged to write and present their papers in English.
