## **Sound intensity feedback during running reduces loading rates and impact peak**

**Financial Disclosure and Conflict of Interest:** The authors of this manuscript affirm that we have no financial affiliation (including research funding) or involvement with any commercial organization that has a direct financial interest in any matter included in this manuscript, except as disclosed in an attachment and cited in the manuscript. Any other conflict of interest (ie, personal associations or involvement as a director, officer, or expert witness) is also disclosed in an attachment.

1 **ABSTRACT**

2 **Study design:** Controlled laboratory study, within session design

3 **Background:** Gait retraining has been proposed as an effective intervention to reduce  
4 impact loading in runners at risk of stress fractures. Interventions that can be easily  
5 implemented in the clinic are needed.

6 **Objective:** To assess the immediate effects of sound intensity feedback related to  
7 impact during running on vertical impact peak (VIP), peak vertical instantaneous loading  
8 rate (VILR), and vertical average loading rate (VALR).

9 **Methods:** Fourteen healthy, college-aged runners who ran at least 9.7 km per week  
10 participated (4 males, 10 females; age,  $23.7 \pm 2.0$  years; height,  $1.67 \pm 0.08$  m; mass,  
11  $60.9 \pm 8.7$  kg). A decibel meter provided real-time sound intensity feedback of treadmill  
12 running via an iPad application. Participants were asked to reduce the sound intensity  
13 of running while receiving continuous feedback for 15 minutes while running at their  
14 self-selected preferred speed. Baseline and follow up ground reaction force data were  
15 collected during overground running at their self-selected preferred running speed.

16 **Results:** Dependent t-tests indicated a statistically significant reduction in VIP (1.56 BW  
17 to 1.13 BW,  $P < .0001$ ), VILR (95.48 BW/s to 62.79 BW/s,  $P = .001$ ), and VALR (69.09  
18 BW/s to 43.91 BW/s,  $P < .001$ ) after gait retraining compared to baseline.

19 **Conclusion:** The results of the current study support the use of sound intensity  
20 feedback during treadmill running to immediately reduce loading rate and impact force.  
21 Within session reductions in impact peak and loading rates transferred to over ground

22 running were demonstrated. Decreases in loading were of comparable magnitude to  
23 other gait retraining methods.

24 **Key words:** running, feedback, rehabilitation.

25

26

27           The association between lower-extremity stress fractures and impact loading  
28 variables, such as increases in vertical impact peak (VIP) and vertical average loading  
29 rate (VALR), has been well established in the literature.<sup>8, 9</sup> A recent prospective study  
30 has also demonstrated that female runners who received a medical diagnosis of injury  
31 compared to runners with no history of injury had higher impact variables.<sup>5</sup> The linking  
32 of VIP and VALR to running injuries has led to the creation of gait retraining programs  
33 aimed at reducing impact loading.<sup>3, 11</sup> In a recent systematic review on the effects of  
34 gait retraining using augmented feedback, Agresta and Brown<sup>1</sup> concluded that real-time  
35 feedback using augmented feedback was effective in reducing variables related to  
36 impact loading. The authors suggested that gait retraining should be considered as a  
37 treatment option for both injured runners and healthy runners who display potentially  
38 injurious running mechanics.

39           The sound intensity (ie, decibels) of a runner's initial contact with the ground may  
40 be a useful form of feedback when attempting to reduce impact loading. Feedback with  
41 an external focus of attention (directed at the movement effect) has been shown to  
42 enhance motor learning.<sup>13</sup> and sound intensity provides a more external focus for  
43 biofeedback than focusing on specific body movement. A recent study by Wernli et al<sup>10</sup>  
44 demonstrated that landing sound intensity explained 42% of the variability in the  
45 magnitude of the vertical ground reaction force during single leg drop landings. Running  
46 can be considered a series of landings from the flight phase. Thus, the sound intensity  
47 related to a runner's impact may also be closely related to ground reaction force  
48 variables. Feedback based on subjective clinician interpretation of the sound intensity of  
49 a runner's impact has been compared to real-time visual feedback of tibial acceleration

50 during running.<sup>2</sup> Results demonstrated that both forms of feedback led to significant  
51 reductions in peak tibial acceleration. With recent advances in technology mobile  
52 devices are now capable of providing accurate external feedback related to the sound  
53 intensity of a runner's impact.<sup>7</sup> It remains unknown if gait retraining involving the sound  
54 intensity of a runner's impact at footstrike provided visually in real-time visual could  
55 result in a meaningful reduction in impact forces during running.

56 The aim of this study was to determine if objective real-time sound intensity  
57 feedback during a single 15 minute session of treadmill running would transfer to  
58 reductions in impact loading during over-ground running. It was hypothesized that  
59 impact sound intensity feedback would result in immediate decreases in VIP, peak  
60 vertical instantaneous loading rate (VILR), and VALR during over-ground running.

## 61 **METHODS**

### 62 **Participants**

63 Participants were recruited from the student body in the department of physical  
64 therapy and by word of mouth. Each participant met the following criteria: 1) currently  
65 running at least 9.7 km/week; 2) ran at least 30 minutes continuously at least once per  
66 week; 3) familiar with treadmill running; 4) no known hearing problems; and 5) free of  
67 any current lower extremity injuries. The study was approved by the University of  
68 Tennessee at Chattanooga's IRB and informed consent was obtained from each  
69 participant. An a priori power analysis ( $\alpha=0.05$ ;  $\beta=.80$ ) indicated that a total of 12  
70 participants was needed to detect a change (effect size 0.8) in impact loading variables  
71 from baseline to post gait retraining (G\*Power 3.1.5).<sup>6</sup>

### 72 **Baseline Data Collection**

73 Each participant wore their own shorts, t-shirt, and usual running shoes.  
74 Participants first performed a 5-minute run on a treadmill (Precor World, Woodinville,  
75 WA) to serve as a warm-up and to establish their self-selected preferred running speed.  
76 Baseline data were then collected for over-ground running immediately following the  
77 warm-up. Participants ran along a 10m runway landing with the right foot contacting a  
78 40 X 60cm force plate (Bertec, Columbus, OH) sampling at 1200Hz and centered in the  
79 runway. A timing device system (Brower Timing Systems, Draper, UT) was centered  
80 around the force plate, 4m apart, to determine running speed. Ample practice was  
81 allowed to insure that each participant was able to maintain his or her self-selected  
82 speed ( $\pm 5\%$ ) while making contact with the middle of the force plate without altering  
83 their stride. Any trials in which participants targeted or missed the force plate were  
84 discarded. Each participant performed 5 acceptable trials.

### 85 **Gait Retraining**

86 **Immediately** after baseline data collection, participants underwent gait retraining  
87 via impact sound intensity feedback on the treadmill while running at the self-selected  
88 speed. While running for 15 minutes, participants continuously received real-time visual  
89 feedback regarding their sound intensity in decibels using a sound meter application  
90 (SPLnFFT Noise (Sound) Meter version 5.2; (Fabian Lefebvre)) provided visually via an  
91 iPad 2 tablet (Apple Inc, Cupertino, CA). The SPLnFFT Noise (Sound) Meter  
92 application is capable of providing accurate measurements of sound intensity (ie,  
93 decibels).<sup>7</sup> The iPad was placed on the treadmill's console with the device's  
94 microphone oriented to the right to keep it from being muffled by the console.

95 Participants were instructed to decrease the decibel level as much as possible by trying  
96 to run as quietly as possible.

### 97 **Immediate Retention and Transfer Test**

98 After gait retraining, participants immediately performed 5 more acceptable trials  
99 of over-ground running at the self-selected speed using the same methods that were  
100 used during baseline data collection. Participants were reminded prior to data collection  
101 to use the running strategy developed during gait retraining.

### 102 **Data Analysis**

103 Initial data reduction was performed using Visual 3D (C-Motion, Inc, Germanton,  
104 MD). Data were filtered at 50 Hz using a Butterworth recursive low pass filter. A  
105 threshold of 20 N in the vertical ground reaction force was used to determine stance  
106 phase. VIP, VILR, and VALR were calculated using a custom LabVIEW program  
107 (National Instruments, Austin, TX) following established procedures (Figure 1) and  
108 normalized to body weight.<sup>8</sup> Briefly, the VALR was the slope between 20% and 80% of  
109 the peak magnitude during the initial loading period (ie, footstrike to VIP) and the VILR  
110 was the maximum slope between adjacent data points in the same period. In the  
111 absence of a VIP during baseline, 13% of stance phase was used to indicate the end of  
112 the initial loading period for determination of the dependent variables<sup>12</sup> In the absence  
113 of a VIP following gait retraining, the same percent of stance that indicated the end of  
114 the initial loading during baseline was used. Each dependent variable was calculated  
115 for each trial and then averaged across the 5 trials per participant at baseline and during  
116 the retention test prior to statistical analysis. A dependent t-test ( $p < .05$ ) was used to

117 identify any significant differences in these variables following gait retraining. Percent  
118 change and effect size were also calculated for each variable.

## 119 **RESULTS**

120 Fourteen participants were included (4 males, 10 females). The average age,  
121 height, mass, kilometers per week, and preferred running speed were as follows: 23.7  
122  $\pm 2.0$  years; 1.67  $\pm 0.08$  m; 60.9  $\pm 8.7$  kg; 18.7  $\pm 13.8$  km; and 2.96  $\pm 0.24$  m/s.

123 Statistically significant reductions in VIP, VILR, and VALR were observed after gait  
124 retraining (TABLE). Review of individual data indicated that 11 of 14 (79%) participants  
125 reduced their VIP, VILR and VALR by 20% or more, while 3 participants (#6, 12, and  
126 14) were unable to achieve similar reductions. Additionally, 11 of 14 (79%) participants  
127 demonstrated a VIP prior to gait retraining. In 6 of these 11 participants the VIP was no  
128 longer present following gait retraining (FIGURES 2a and 2b).

## 129 **DISCUSSION**

130 The purpose of this study was to determine the effects of sound intensity  
131 feedback on impact loading variables in runners. The majority (79%) of our participants  
132 were able to reduce each impact variable by at least 20%, indicating that impact  
133 variables associated with running injuries can be reduced with a single session of sound  
134 intensity feedback. The results of this proof of concept study support further exploration  
135 of this approach as a clinically applicable method of reducing loading variables during  
136 running.

137 Our feedback paradigm is an advancement of Creaby and Smith's<sup>2</sup> work in which  
138 they provided verbal feedback based on the clinician's subjective interpretation of the  
139 sound intensity of impact. Our approach uses an objective measure of sound intensity

140 via a decibel meter and provides real-time visual feedback independent of the clinician.  
141 Our approach may provide more consistent feedback to the runner than clinician-based  
142 subjective feedback. Unfortunately, the results of our study cannot be directly  
143 compared to those of Creaby and Smith<sup>2</sup> due to different outcome variables. In their  
144 study, peak tibial acceleration was the main outcome variable and reductions of 24-28%  
145 were achieved within session. In our study, we demonstrated slightly higher reductions  
146 of 28-36% in VIP, VILR, and VALR.

147         The immediate reductions in impact loading variables reported here are  
148 comparable to those achieved using more advanced equipment. A 2-week gait  
149 retraining program focused on reducing peak tibial acceleration led to reductions in VIP  
150 of 19% and in VILR and VALR of 34% and 32%, respectively.<sup>3</sup> Our approach led to a  
151 larger reduction of 28% in VIP and similar reductions of 34% and 36% in VILR and  
152 VALR. Our method does not require specialized equipment and, therefore, may be  
153 more clinically applicable than the methods of Crowell et al.<sup>4</sup> Our method would also  
154 allow runners with access to a treadmill to self-manage their retraining after an initial  
155 orientation to the protocol.

156         Sound intensity feedback may enable runners to experiment with different  
157 running mechanics (eg, footstrike pattern, lower extremity compliance, etc) in efforts to  
158 decrease the sound intensity of their impact. Other gait retraining methods have  
159 specifically aimed their methods at increasing cadence. Willy et al<sup>11</sup> studied the effects  
160 of increasing cadence 7.5% in efforts to lead to gait modifications that would lessen  
161 loading rates. Following a 2-week gait retraining program, VILR and VALR were  
162 reduced by 19% and 18%, respectively. While not tested over an extended period, our

163 method produced greater initial percent changes and may allow the runner freedom to  
164 select a gait modification that best suited them.

165 As is typical in the initial reporting of new approaches, this proof of concept study  
166 was limited to immediate responses to feedback during a single session. Following the  
167 immediate reductions demonstrated in this study, future work is needed to determine  
168 whether the changes can be retained long term with additional training. Future studies  
169 should include a comparison group that received the same verbal instructions, without  
170 sound intensity feedback, to determine the effects of verbal instruction alone. This  
171 design would determine the additional benefit of augmented feedback over and above  
172 simple verbal instruction. Kinematic and spatiotemporal analyses would also indicate  
173 how participants augmented their running gait to achieve these reductions. Additionally,  
174 a true control group would indicate whether fatigue contributed to the reductions seen in  
175 our study. However, running for 15 minutes during gait retraining and short overground  
176 trials with frequent breaks, minimized the risk of fatigue. While reductions in loading  
177 variables were noted, the short 10m runway may have impacted the runner's ability to  
178 achieve a steady state prior to contact with the force plate. Replication of this study with  
179 a longer bout of overground running would confirm that the reductions in loading remain  
180 during steady state running. The current application of this gait retraining method is also  
181 limited to healthy runners. It is unknown if runners who are experiencing pain or  
182 recently returning to running after injury could achieve similar reductions. It should be  
183 noted that our participants' average VILR was 95.48 BW/s at baseline and 11 out of 14  
184 participants' VILR was above the 85 BW/s threshold that has been used by previous  
185 investigators to denote high-impact runners.<sup>11</sup> Therefore, the majority of our

186 participants could be considered candidates for gait retraining to reduce impact loading.  
187 Finally, our participants represent recreational runners in terms of running speed and  
188 volume of training. Therefore, caution should be exercised in applying these results to  
189 those who run faster or have higher training volumes.

## 190 **CONCLUSIONS**

191 VIP, VILR, and VALR were reduced significantly following 15 minutes of objective  
192 real-time sound intensity feedback related to footstrike using a decibel meter during  
193 treadmill running. About 80% of runners were able to achieve an immediate reduction of  
194 20% or more in all 3 variables. Thus, objective decibel meter feedback of sound  
195 intensity provided via personal portable devices may provide clinicians with a simple  
196 way to provide gait retraining to runners. In particular, those at risk of tibial stress  
197 fracture due to high impact loading may benefit. Further work is needed to determine  
198 the long-term effects of this approach in return to following injury or as a preventative  
199 measure in runners that exhibit high impact loading rates.
