# CHAPTER 21

---

## Teaching Physics

**Reinders Duit**

*Leibniz-Institute for Science Education, Germany*

**Hans Niedderer and Horst Schecker**

*University of Bremen, Germany*

A deliberate subject-specific view is employed in the present chapter. We attempt to provide an overview of research on teaching and learning physics—in particular from the perspective of what is special in this domain as compared with biology, chemistry, and earth science. We would like to point to two issues where physics education appears to be “special” already.

First, according to the bibliography on constructivist-oriented research on teaching and learning science by Duit (2005), about 64% of the studies documented are carried out in the domain of physics, 21% in the domain of biology, and 15% in the domain of chemistry. There are various reasons for this dominance of physics in the research on teaching and learning. The major reason appears to be that physics learning includes difficulties that are due to the particular nature of physics. We just mention the abstract and highly idealized kind of physics (mathematical) modeling. Research on students’ conceptions has shown that most pre-instructional (“everyday”) ideas students bring to physics instruction are in stark contrast to the physics concepts and principles to be achieved—from kindergarten to the tertiary level. Quite often students’ ideas are incompatible with physics views (Wandersee, Mintzes, & Novak, 1994). This also holds true for students’ more general patterns of thinking and reasoning (Arons, 1984).

Secondly, physics clearly is the domain that is greeted with the lowest interest by students among the sciences. This is true in particular for girls (Parker, Rennie, & Fraser, 1996). It appears also that the nature of physics mentioned is at least partly responsible for these findings. Students, especially girls, perceive physics not only as very abstract, complicated, and difficult, but also as counterintuitive and incomprehensible.

The review presented draws on European views of science education, more precisely, continental European views—with German views somewhat predominant. On the one hand, the issue of scientific literacy is discussed from a position includ-

ing the German idea of *Bildung*, with its emphasis on issues that are beyond functional scientific literacy (Bybee, 1997). On the other hand, European ideas of *Didaktik* (Westbury, Hopmann, & Riquarts, 2000) are used to analyze the particular role of designing the content structure of physics instruction in such a way that it meets students' perspectives (e.g., pre-instructional conceptions and interests) and the aims of instruction.

## THE INTERDISCIPLINARY NATURE OF PHYSICS EDUCATION AS A RESEARCH DOMAIN

As illustrated in Fig. 21.1, physics education research is interdisciplinary in nature. There are several "reference domains" that are needed to meet the challenges of investigating and analyzing the key issues of teaching and learning physics. Philosophy and history of physics provide frameworks that make it possible to identify what is usually called the "nature of physics" in the literature (McComas, 1998). Hence, these domains play a major role in discussing what is special in physics and therefore also what is special in teaching and learning physics. But also social sciences, especially pedagogy and psychology, are essential reference domains. Research and development that aims at improving practice has to address issues of physics as a specific way of knowing as well as general issues of learning. This is the underlying position of the present review.

### CHARACTERISTICS OF PHYSICS EDUCATION RESEARCH

Dahncke et al. (2001) argued that there is a split in the science education community. On the one side the major focus is on science—here physics. This group usually is at home in organizations that are close to the "mother" discipline, like physical societies. Research work in this group is in most cases restricted to issues of subject matter structure or presentation techniques, more or less neglecting the way in which the ideas developed may be learned by students. On the other hand, there are science educators who try to find a balance between the mother discipline and educational issues. The latter position is the background of Fig. 21.1.

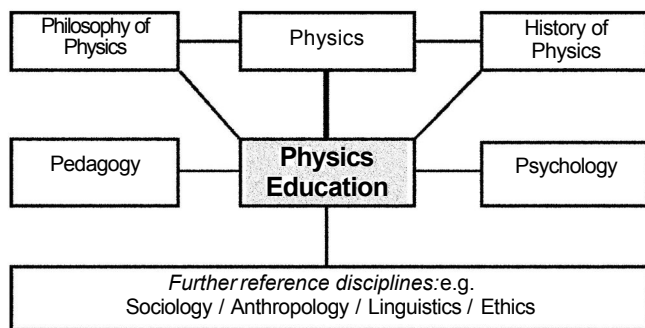

FIGURE 21–1. Reference disciplines of physics education.

Jenkins (2001) provided another distinction of research in science education, namely *pedagogical* versus *empirical*. The pedagogical tradition aims at improving practice. Research and development are intimately linked. Research is usually carried out in actual classrooms or at least in settings that are close to a classroom situation. The major concern of the empirical tradition is acquiring “objective data” that are needed to understand and influence educational practice. This distinction has much in common with the differentiation between “applied” and “basic” research. It has been argued in science education (Wright, 1993) as well as in research on teaching and learning in general (Kaestle, 1993) that basic research in education is viewed as irrelevant by practitioners and hence is in danger of widening the gap between research findings and practice. Therefore, a fine-tuned balance between the two positions is needed in research that aims to improve practice.

## The German *Didaktik* Tradition

The meaning of the German term *Didaktik* should not be associated with the Anglo-Saxon meaning of *didactical*. Whereas the latter primarily denotes issues of educational technology, *Didaktik* stands for a multifaceted view of planning and performing instruction that is based on the German concept of *Bildung*. *Bildung* shares certain features of scientific literacy but also includes particular views of aims of schooling and instruction (Westbury, Hopmann, & Riquarts, 2000).

A literal translation of *Bildung* is “formation.” In fact, *Bildung* is viewed as a process. Here appears to be a first significant difference to scientific literacy, which primarily denotes certain competencies, that is, outcomes of a process. *Bildung* stands for the formation of the learner as a whole person, that is, for the development of the personality of the learner. *Bildung* hence includes not only the achievement of domain-specific knowledge, but also the formation of what may be called “cross-curricular competencies” (including competencies allowing rational thinking and various social competencies). There is an emphasis on these cross-curricular competencies, which stand for a well-educated personality.

The meaning of *Didaktik* is based on the above conception of *Bildung*. It concerns the analytical process of transposing (or transforming) human knowledge (the cultural heritage) like domain-specific knowledge into knowledge for schooling, which contributes to the above formation (*Bildung*) of young people. Fensham (2001) claims that many recent attempts to improve science teaching and learning (e.g., based on constructivist perspectives) put a strong emphasis on improving the way science is taught (i.e., focus on the improvement of teaching methods and media). He thinks that science content should also be seen as problematic, that the neglected content structure for instruction should also be given attention. He is of the opinion that the *Didaktik* tradition allows such an improvement of instruction by developing a content structure for instruction that addresses students’ learning needs and capabilities as well as the aims of instruction.

Briefly put, the content structure of a certain domain (e.g., physics) has to be transformed into a content structure *for* instruction. The two structures are substantially different. The physics content structure for a certain topic (like the force concept) may not be directly transferred into the content structure for instruction. It has not only to be simplified (in order to make it accessible for students), but also

enriched by putting it into contexts that make sense to the learners. Two phases of this process may be differentiated. The first may be called *elementarization*. It leads to a set of “elementary” ideas comprising the key features of the content in question. For the energy concept the following elementary ideas may result: conservation, transformation, transfer, and degradation. On the basis of this set of elementary ideas the content structure for instruction is constructed. It is a key claim of the *Didaktik* tradition that both processes, “elementarization” and “construction of the content structure for instruction,” are intimately interrelated to decisions on the aims of teaching the content and the students’ affective and cognitive perspectives. Kattmann, Duit, Gropengießer, and Komorek (1995) have called the whole process “educational reconstruction” (for an example of the use of the model, see Duit, Komorek, & Wilbers, 1997).

The essence of the content analysis outlined in Fig. 21.2 may be well illustrated by a set of questions comprising the *Didaktische Analyse* proposed by the German educator Klafki (1969; see also Fensham, 2001):

1. What is the more general idea which is represented by the content of interest? What basic phenomena or basic principles, what general laws, criteria, methods, techniques or attitudes may be addressed in an exemplary way by dealing with the content?
2. What is the significance of the content for students’ actual and future life?
3. What is the structure of the content if viewed from the pedagogical perspectives outlined in questions 1 and 2?
4. What are particular cases, phenomena, situations, experiments that allow the teacher to make the structure of the referring content interesting, worth questioning, accessible, and understandable for the students?

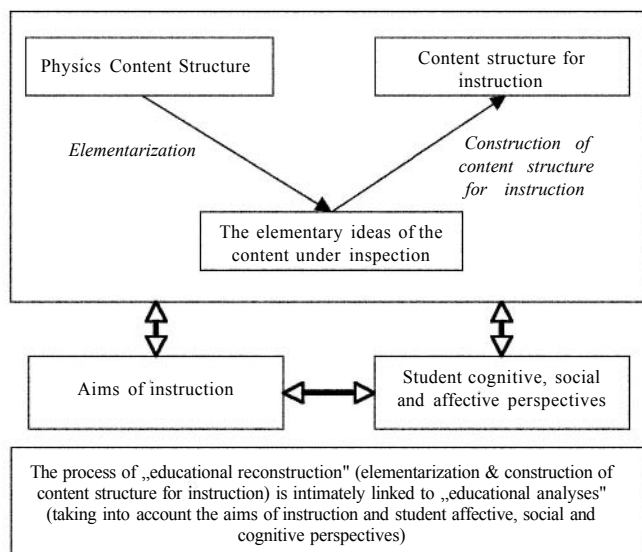

FIGURE 21–2. Educational reconstruction of physics content structure.

The concept of educational reconstruction outlined in Fig. 21.2 adds to Klafki's set of questions the idea of a fundamental interplay of all variables of instruction, namely, the *Aims*, the *Content*, the *Teaching and Learning Methods* and the *Media*, which is also a key figure of thought in the German *Didaktik* tradition (Heimann, Otto, & Schulz, 1969). In the process of instructional planning this fundamental interplay has to be taken into account. Students' perspectives must also be taken into consideration as a key point of reference for construction of the content structure for instruction and for developing the phases of instruction, the methods, and the materials and media used.

In a nutshell, the German *Didaktik* tradition as well as similar traditions in other European countries critically take the content issue into account. It is a key assumption that a content structure has to be developed which addresses students' pre-instructional perspectives and that the learning environment has to be designed in such a way that students may achieve the content in question. Improving instruction includes both critical analysis and reconstruction of content and development of supportive learning environments.

Clearly, major ideas of Shulman's (1987) approach of content specific pedagogical knowledge are in accordance with the European *Didaktik* tradition. However, whereas Shulman puts the main emphasis on teacher competencies, the *Didaktik* tradition has also developed strategies for taking the content issue seriously in instructional planning.

## OVERVIEW OF THE CHAPTER

In the following chapter we first discuss major fields of research on teaching physics. The emphasis is on issues that are special for physics teaching. In the subsequent section, research on three content domains, the force concept, the electric circuit, and atomic physics, is reviewed. These three topics allow us to discuss major learning difficulties and major attempts to improve learning that are particularly relevant for physics instruction. Finally, we want to summarize major concerns and desiderata of physics education research.

## TEACHING PHYSICS: MAJOR FIELDS OF RESEARCH

As detailed below, we provide a brief overview of major fields of research. We draw on the perspective of the above *Didaktik* tradition where normative research on the aims of instruction, analytical research on subject matter clarification and elementarization, as well as empirical research on teaching and learning processes are closely linked.

### Aims of Instruction

The international science achievement studies TIMSS (Third International Mathematics and Science Study) and PISA (Programme for International Student Assessment) have had a strong impact on the discussion about the proper aims of instruction, in

particular for lower secondary education (cf. the discussion on scientific literacy in Chapter 26). Science is seen as a major factor influencing the daily lives of individuals as well as economic progress in technology-based societies (e.g., Beaton et al., 1996, p. 7). Physics forms the basis of information technology, transport, and energy production. In order to make sensible use of technological means, to find a place in a technology-based economy, and to participate in political processes about technology-related decisions, citizens need a certain amount of physics knowledge. The PISA consortium has agreed on a notion of scientific literacy that consists of understanding basic scientific concepts, familiarity with scientific thinking and processes, and the ability to apply this knowledge in concrete situations (cf. OECD, 1999). Students should be able to identify issues that can be understood by the application of scientific knowledge, to draw conclusions from scientific investigations, and to assess the scope of scientific findings. As these competencies apply for all citizens, they have to be targeted during the obligatory phase of science education. Important physics concepts are energy, conservation/devaluation, particle/matter, and interaction.

From a European perspective, in the *upper secondary* level physics education has to contribute to three major goals of higher education: further general education (*Bildung*), scientific thinking, and providing a foundation for learning at the tertiary level. In this voluntary phase scientific literacy has to be broadened in these aspects (cf. Schecker, Fischer, & Wiesner, 2004):

- Insights into modern physics world views (basic ideas of quantum physics, relativity, nonlinear physics)
- A systematic view of the cultural and social consequences of physics and technology (e.g., in energy production and consumption)
- Awareness of the specific physics conception of the world, aiming at a small set of general and universally applicable concepts and laws
- Sustainable knowledge of standard physics procedures (e.g., using lab instruments, formal problem solving) as a basis for university studies and vocational training in science and technology

Competencies of applying physics concepts and processes have to be embedded in a proper understanding of the nature of science (NOS; cf. McComas, 1998). Standards for curriculum development based on Scientific Literacy and the NOS can be found in AAAS (1993) and in NRC (1996).

Compared with the American tradition with its pragmatic and optimistic view of science as a means for social progress, the European view as outlined above puts more weight on the contribution of scientific knowledge to the formation of students' personalities. Students have to decide the extent to which they integrate scientific thinking into their world views. This belongs to the process of *Bildung*. It includes the critical reflection on problematic outcomes of the scientific enterprise.

## Science Processes and Views of the Nature of Science

Learning about science processes and the nature of science (NOS) has to be an integral part of physics education. There is a wide consensus about this thesis among

science educators (see Chapter 29). Some central elements of a proper understanding of the NOS are (cf. McComas, 1998; AAAS, 1993) the following:

- Scientific knowledge has a tentative character. Scientific concepts and theories are the result of a historical genetic process.
- Observation, experimental evidence, rational arguments, and skepticism play an important role in generating scientific knowledge.
- Observations are theory-laden. There is no direct path from an experiment to a theory.

Physics is distinguished from other sciences by its extremely high level of abstraction and idealization. Complexity is strongly reduced in order to make quantitative predictions possible. For this purpose physics produces its own prototypical phenomena in lab settings. From the physics point of view the true order of nature lies beyond the “touch and show reality.” The book of nature is written in the language of mathematical models. Theories should contain a very limited set of laws that are all-applicable. Before an everyday world phenomenon with its complexity of influences and parameters qualifies for a physics analysis, it has to be “cleaned.” It is nearly impossible to calculate the path of a leaf falling from a tree; but it is easy to predict precisely the motion of a feather in an evacuated tube. Physics thinking does not originate from the minute observation of the world around us but from the reconstruction of this world under the assumption of theoretical principles. This shift of perspectives (cf. the following section on conceptual change) is a major factor that makes it so difficult for students to learn physics.

There are good reasons to take account of epistemological and concept-genetic aspects in physics teaching (cf. McComas, 1998). They range from a better understanding of physics concepts (e.g., Galili & Hazan, 2000) enabling students to make rational decisions in a democratic society (Driver et al., 1996).

Still, there is often a gap between the strategic aims formulated in the preambles of science curricula and the actual content of textbooks and teaching (cf. Kircher, Girwidz, & Häußler, 2000, p. 38). The NOS is seldom taught explicitly (Duit, Müller, Tesch, & Widodo, 2004). NOS items are hardly included in physics exams. Teachers do not feel competent in this domain (cf. Abd-EI-Khalick, Bell, & Lederman, 1998). Empirical studies reveal widespread misunderstandings of the NOS. Students’ epistemological beliefs can be characterized as naive-empiristic: scientific theories are seen as everlasting truths, derived from precise observations and theory-free experiments. Creative speculation and theory-laden construction are not taken into account (cf. the analyses of data from TIMSS, population 3, in Köller, Baumert, & Neubrandt, 2000).

Abd-EI-Khalick, Bell, and Lederman (1998) thus strongly argue for including more NOS elements in teacher training and teaching (see also Schecker, Fischer, & Wiesner, 2004). McComas’s book (1998) gives examples of how to introduce students and teachers into epistemological issues. Matthews (1994) stresses the historical perspective in teaching science. Meyling (1997) provides empirical evidence for how an explicitly epistemology-based physics course can change students’ ideas toward a proper understanding of the NOS.

## Conceptual Change

The dominating perspectives of research on teaching and learning science have been constructivist views of conceptual change since the 1980s (Mintzes, Wandersee, & Novak, 1997; Duit & Treagust, 2003). A problem-solving perspective on teaching and learning physics that addresses slightly different facets is provided by Maloney (1994). Both research perspectives have been rather influential in developing new teaching and learning approaches that deliberately take students' preinstructional views, beliefs, and conceptions into account (for proposals on teaching and learning physics see the following volumes: Viennot, 2001, 2003; Redish, 2003; Arons, 1997).

As mentioned above, physics is the domain in which most research studies on investigating students' conceptions and on conceptual change have been carried out. Table 21.1 presents the number of studies documented in the bibliography by Duit (2006). It becomes obvious that there is a particular emphasis on mechanics and electricity. In both domains there is a strong focus on the force concept or the (simple) electric circuit, respectively. Clearly, these subdomains are somewhat over-researched. Other domains, especially the domains of modern physics, need further attention. More details on research findings in the domains of mechanics, electricity, and atomic physics are given below. General findings of research on conceptual change are reported elsewhere. The particular difficulty of conceptual change in the process of learning physics appears to be that usually students' preinstructional conceptions about phenomena are deeply rooted in everyday experiences and are therefore in stark contrast to physics conceptions. Radical idealization and decontextualization, the reduction to pure phenomena accompanied by particular mathematical modeling, seems to be a major hurdle for students to understand physics concepts and principles. Furthermore, in quantum physics and relativity the physics

**TABLE 21.1**  
**Number of Publications on Students' Ideas in the Bibliography by Duit (2005)**

Biology—total	748
Chemistry—total	548
Physics—total	2,274
Mechanics (force)*	792
Electricity (electrical circuit)	444
Optics	234
Particle model	226
Thermal physics (heat/temp.)	192
Energy	176
Astronomy (Earth in space)	121
Quantum physics	77
Non linear systems (chaos)	35
Sound	28
Magnetism	25
Relativity	8

\*Predominant concept in brackets.

view is incomprehensible in principle from everyday world perspectives. Interestingly, this also holds for the “classical” particle view, which is usually introduced in early school grades. Also here the world of the particles is fundamentally different from the world of our everyday experiences.

Viewed from the perspective of scientific literacy (Bybee, 1997), understanding physics includes understanding physics concepts and principles on the one hand and physics processes as well as views of the nature of physics on the other. As argued in the previous section, these views *about* physics are not only essential features of scientific literacy, but are also essential in understanding physics concepts and principles. Looking at teaching and learning physics from a conceptual change perspective should therefore include conceptual changes on the level of concepts and principles and on the level of processes and views of the nature of physics as well. Research has shown that students’ ideas of processes (like modeling) or views of the nature of physics are “naive” in the same sense as their views of phenomena and concepts (Treagust, Chittleborough, & Mamiala, 2002). A multiple conceptual change view has to be employed (Duit & Treagust, 2003).

## Students’ Interests and Gender Issues

Research has shown that emotional factors play an essential role in learning science. Conceptual change, for instance, is not successful if it is based merely on “cold cognition” (Pintrich, Marx, & Boyle, 1992). A recent study on introductory electricity teaching (Laukenmann et al., 2003) has shown the significance of emotional factors. It became obvious again that positive emotions promote achievement. Interestingly, this is especially the case during the first phase of learning the new topic, where students need to be convinced that it is worthwhile to achieve the understanding intended. Kroh and Thomsen (2005) point out the significance of attitudes toward physics and students’ self-concepts for learning physics. They argue that teaching and learning methods that take students’ cognitive and affective variables into account and provide them with significant responsibility for their own learning will develop more positive attitudes and self-concepts and hence will result in more pleasing outcomes of instruction.

The issue of emotional factors (like interests, motivation, attitudes, and self-concept) in learning science and gender differences are more fully discussed elsewhere in the present *Handbook* (Chapters 5 and 11). Here only a few issues are added that are characteristic of physics instruction.

International comparison studies reveal that girls’ achievements and interests in physics are substantially lower than those of boys (Keeves & Kotte, 1996). However, there are significant differences between the countries concerning the gap between the genders. Nevertheless, physics is usually the science domain that is greeted with the lowest interest in particular by girls. It appears that students’ views of physics play a certain role. Science in general but physics in particular is seen as a male domain (Baker, 1998; Harding, 1996). Stadler, Benke, and Duit (2000) argue that girls and boys hold different (tacit) notions of what it means to understand physics. Briefly put, girls do not think that they understand a concept until

they can put it into a broader (nonscientific) context. They try to understand the relations of the system of physics to the world seen as a whole. Boys, in contrast, seem to be more "pragmatic." They tend to regard physics as valuable in itself. They appear to be pleased with the internal coherence of the system of physics itself. It appears that boys' views of physics and their notions on understanding physics are somewhat nearer to the above-mentioned characteristic of radical idealization and decontextualization in physics than girls' views.

In order to improve the situation, several studies have been carried out to embed physics in contexts that make sense especially to girls, that is, to address their particular notion of understanding physics. Briefly, such studies have shown that instructional materials addressing girls' interests, such as the human body and issues of social relevance, significantly enhance girls' interests and achievement (Baker, 1998; Häußler & Hoffmann, 2002; Reid & Skryabina, 2003) and have also proved successful for boys. Research has also revealed that the way physics is taught is another major factor. Teaching strategies that enhance the self-confidence of girls, like collaborative work in single-sex groups, have also improved interests and achievement for girls and boys alike (Baker, 1998; Häußler & Hoffmann, 2002).

## **Labwork and Multimedia**

Student work with real apparatus in the physics lab and student work with computer-based tools can be regarded as two ways of active engagement with physics phenomena. In modern teaching strategies the two modes are gradually integrated (cf. Goldberg & Bendall, 1995; Laws, 1997; Schecker, 1998). Redish (2003) describes the relevant teaching methods together with available resources.

## **Labwork**

The experiment plays a major role in science classes. In physics instruction most of the teaching time appears to be oriented in some way toward experiments with a certain emphasis on teacher demonstrations (Duit et al., 2004). Learning with hands on in laboratory work or from demonstrations has a particular meaning for physics instruction with respect to the nature of physics. Leach (2002) has formulated empirically supported hypotheses about how students' actions during lab work are based on their image of the nature of science, thus setting up a basis for analyzing learning processes in the lab with respect to students' epistemological beliefs. It is further argued that a limited practice in which straightforward demonstration experiments dominate leads to rather limited views about the nature of science. The tension between theory with its general and sharply defined concepts and practice setting up a context with many aspects of everyday life language is a specific issue (Woolnough, 1991; Hodson 1993). In a large Delphi-type study, teachers from universities and high schools gave the following objectives high priority (Welzel et al., 1998):

For students:

- A. to link theory to practice,
- B. to learn experimental skills,

- C. to get to know the methods of scientific thinking,
- D. to foster motivation, personal development, and social competence.

For teachers:

- E. to evaluate the knowledge of the students.

Especially with respect to objective (A), a lot of empirical work has been done. Lunetta (1998) summarized some of the findings: "To many students, a 'lab' means manipulating equipment but not manipulating ideas." He consequently speaks of a "mismatch between goals, behavior and learning outcomes." Niedderer et al. (2002) have developed a "category-based analysis of videotapes from labwork" to analyze the amount of students' talking physics during lab work. Results show that students often use lab sheets like recipes without thinking and talking physics.

## Multimedia

Multimedia tools for physics instruction can be divided in six categories:

- *Micro-based labs (MBL)*: probes, interfaces, and software for on-line data acquisition, evaluation, and graphing (cf. Tinker, 1996).
- *Content-specific simulation programs*: Learners vary the parameters and explore the behavior of physical systems on the basis of a given mathematical model; numerous packages are available for all domains of physics.
- *Microworlds*: Learners can set up their own simulation settings interactively by combining given object-like building blocks, such as lenses and screens on a virtual optics bench (e.g., Goldberg & Bendall, 1995; Interactive Physics, 2004).
- *Model building systems (MBS)*: Students generate a quantitative model describing the behavior of a system (e.g., the motion of bodies) either by putting in a set of equations or by constructing a computer-based concept map, while the software generates the equations (cf. Schecker, 1998).
- *General tools*: For example, spreadsheets with tables and graphs.
- *Targeted tools*: For example, tools for analyzing digitized motion videos (e.g., Beichner, 1996).

Multimedia packages integrate tools from several of these categories. The tools can be bound together with nonlinear interactive multimedia hypertext to so-called hypermedia systems.

The effectiveness of multimedia tools in physics education has become a major field of empirical research. Redish, Saul, and Steinberg (1996) found significant positive effects of MBL-based tutorials in teaching mechanics. Schecker (1998) reports that the use of MBS has a positive effect on semiquantitative reasoning about force and motion. A review of the literature on teaching and learning with the computer (Urhahne et al., 2000) draws a positive picture for science. There is a general agreement that the learning effects of multimedia in science education crucially depend on the instructional approach in which the materials are embedded (e.g., Linn et al., 1993).

## TEACHING PHYSICS: PEDAGOGICAL CONTENT KNOWLEDGE IN THREE DOMAINS

In this section we want to outline characteristics of teaching and learning physics by reviewing the literature in three domains, ranging from a rather basic topic—simple electric circuits—to modern physics.

### Teaching Electricity

Electricity is one of the physics domains where a huge number of research studies are available (Table 21.1). Particular emphasis lies on simple electric circuits. It becomes rather obvious that simple electric circuits are neither simple for students in the early grades of school nor for those at the tertiary level as well (Duit & v. Rhöneck, 1998).

### Physics Concepts

The simplest circuit of all is presented in Fig. 21.3. A bulb is connected to a battery. The same geometrical (better: topological) structure holds for all kinds of “sources” and “consumers”.

There are several levels of theoretical frames to allow predictions of whether the circuit will properly work or not.

(1) *Level of connecting conditions.* “Source” and “consumer” have two connection points each; they have to be connected by *conductors* in such a way that the two connecting wires do not have direct contact (no *short circuit*). The *voltages* printed on source and consumer need to be (nearly) the same, otherwise the consumer will not work or will be destroyed. Note that voltage is simply a connecting condition. All the students need to know here is: the higher the voltage, the stronger the effect, and that voltages above 20 V are dangerous for humans.

(2) *Level of current flow.* Usually the *current* view as indicated by the two arrows in Fig. 21.3 is also seen as an essential part of theoretically framing the electric circuit

FIGURE 21–3. The simple electric circuit.

from the outset. There is a closed current flow, that is, a flow of electrically charged particles. The intensity of current is the same all over the circuit. In introductory physics instruction the particular nature of charges is usually not further discussed. There are good reasons for that because it depends on the source, the consumer, and the wires which kind of particles compose the charge flow. There is another essential feature of the current flow that needs attention in instruction. The charged flowing particles may not be viewed as moving independently from one another. Rather, the whole current flow forms a strongly coupled system—which can be compared to a bicycle chain. Whenever the current flow is changed at a certain spot the current all over the circuit is also changed.

(3) *Level of simultaneous current and energy flows.* It is important to enrich the above current flow view with the view of energy flow. If a current is flowing in the circuit of Fig. 21.3, the bulb glows. Hence energy is transported from the battery to the bulb. Therefore, every current flow is accompanied by an energy flow. Whereas the current flow is easy to locate, namely in the wire, this is more complicated for the energy flow. It seems that two different views are possible, namely energy flow in the electromagnetic field *around* the wires or *within* the wires. In any case, energy flow and current flow are fundamentally different in two regards. First, the energy flow is fast (nearly the speed of light), whereas the speed of charges (like electrons) is less than a few millimeters a second. Furthermore, the current flow is closed, the energy flow is not. Either on the path to the consumer or on the way back, energy and current flow in opposite directions.

The sketch of different levels of theoretical framing of the simple electric circuit presented above has revealed that the simple electric circuit is not so simple and easy to conceptualize also from the physics point of view. The issue of Educational Reconstruction discussed earlier (Fig. 21.2) comes into play here. The “elementary ideas” of the simple electric circuit may appear simple, but research on students’ conceptions and on learning processes presented in the following show that too simple ideas may deeply mislead students in their attempts to understand the function of the electric circuit.

## Students’ Ideas

The following overview draws to a certain extent on the review by Duit and von Rhöneck (1998).

(1) *Everyday meanings of current.* Everyday talk about electricity is markedly different from physics talk. The meanings of words for current, for instance, are, at least in English and most major European languages, closer to the meaning of energy than to current as used in physics. Misunderstandings in class are likely if these differences are not taken into consideration.

(2) *Consumption of current.* Already students at the elementary level establish a causal connection between the battery and the bulb and explain that there is an agent moving from the battery to the bulb. The agent may be called electricity or electric current. It may be stored in the battery and is consumed within the bulb. Hence, there is no idea of conservation of electricity or current among children. A number of children think that one wire between battery and bulb suffices and that the second

wire simply serves to bring more current to the bulb. Some students believe that two different kinds of currents, called "plus" and "minus" current, travel from both sides of the battery to the bulb. In the bulb then there is a clash of the two currents producing the light ("clashing current"; Osborne, 1983) or a sort of chemical reaction. The idea of consumption of current is commonly held also by students beyond elementary level. Research has shown that it is very difficult to change this idea; it does not vanish through formal science education. It appears that the above way of talking about current is at least partly responsible for this dominance of the consumption conception.

(3) *Local and sequential reasoning.* Many students focus their attention upon one point of the circuit and ignore what is happening elsewhere. A "system" view of the current flow as described above is usually missing. An example of such local reasoning is the view that the battery delivers a constant current, independent of the circuit that is connected to the battery. Another variant of local reasoning may be called sequential reasoning. A number of students analyze a circuit in terms of "before" and "after" current passes a certain place. If, for instance, in the simple circuit of Fig. 21.3 a resistor is put into the connection leading from the battery to the bulb, students are correctly of the opinion that the bulb shines less brightly. But if the resistor is put into the other connection leading back to the battery, many students think that in this case the bulb shines as bright as before, because only the current leading back is influenced by the additional resistor.

(4) *Current and voltage.* Voltage has proved to be particularly difficult concept for students across different age levels. Before instruction voltage is usually related to the "strength of the battery" (or another source) or is viewed as the intensity of force or current. Usually there is not much progress after instruction. Many students still have severe difficulties in differentiating the two concepts.

(5) *Learning processes.* Many studies (e.g., Shipstone et al., 1988) have shown that the success of physics instruction in developing students' ideas about the electric circuit toward the physics view is rather limited. Most of these data draw on pre-post-test designs. However, there are also studies that follow the learning processes in detail. It becomes obvious that the learning pathways students follow are very complicated. There are forward and backward movements, there are parallel developments, and there are dead-end streets. In a study by Niedderer and Goldberg (1995), for instance, a group of three college students approaching the physics ideas of the electric circuit in a guided inquiry approach was involved. These students started with typical, alternative conceptions. On the *level of connecting conditions* they had many difficulties connecting a bulb to a battery in the correct way. On the *level of current flow* they viewed current as a kind of fuel that flows from the battery to the bulb and is consumed there. They further referred to previous knowledge taught in their science class on positive and negative charge. They merged these two concepts (the consumption idea and the notion of plus and minus current) in such a way that they constructed a new intermediate conception, similar to the well-known clashing currents concept which provided them with fruitful explanations. It was their own cognitive construction, which was not intended and not even realized by the teacher. During their further learning process these students developed more intermediate concepts: "Electron current" helped them to see current as moving electrons. The "electron gas pressure" idea provided a first understanding of the difference between the concepts of current and voltage. At the end of the whole teaching

sequence, however, these students still had difficulties seeing voltage as analogous to pressure *difference*, not merely to pressure.

A case study by Clement and Steinberg (2002) provided evidence that a student can start from an analogical source such as air pressure and flow and follow a learning pathway that builds a dynamically imaginable model of electric potential differences that cause current flow. There the learning pathway consisted of a series of partial models generated by dissonance-driven evaluations and revisions of the student's original model, and the student was able to apply the final model to a transfer problem. However, they still found intermittent difficulties with the distinction between potential and current.

## Teaching Approaches

A substantial number of studies have been carried out investigating possibilities to guide students from their ideas to the physics concepts of the electric circuit. Basically, the same kinds of approaches as used in other science domains have also been employed here. There have been attempts to support conceptual change by specially designed multimedia learning environments and by a number of constructivist-oriented teaching and learning settings. It appears that such attempts usually (but not always) have proved superior to more "traditional" kinds of physics instruction. Still, the success is often disappointingly limited. There is, however, one exception. Almost all students, after appropriate experiences with electric circuits, are convinced that two wires are necessary to make the consumer work.

Students' pre-instructional conceptions of the electric circuit are—as outlined—in stark contrast to the referring physics concepts. Often new teaching and learning strategies start with the elicitation of students' ideas and with establishing their experiences in question. Students carry out experiments (e.g., with batteries and bulbs) and develop and exchange their views of the phenomena investigated. From such a basis the teacher tries to guide students toward the physics view. Challenging students' ideas is often a crucial period; that is cognitive conflicts play a certain role. Cognitive conflict strategies, though successful in a number of cases, bear one of several difficulties. The most important is that it is often difficult for students to experience the conflict. It may also happen that elicitation and long discussions of students' pre-instructional views may strengthen just this view. Therefore, also in the domain of electricity, various approaches have been developed that attempt to avoid cognitive conflicts. These approaches usually start from students' ideas that are mainly in accordance with the physics view and try to guide students from this kernel of conformity to the physics view via a continuous pathway. One such strategy Grayson (1996) calls "concept substitution." Instead of challenging students' views of current consumption, she provides the following reinterpretation: The view that something is consumed is not wrong at all—if seen in terms of energy as outlined above: energy is actually flowing from the battery to the bulb while current is flowing. Energy is "consumed," that is, transformed into heat and light.

Briefly summarized, understanding the simple electric circuit has proved rather difficult for students both in school and at the tertiary level. It appears that these difficulties are due at least partly to the fact that students' ideas are deeply rooted in certain everyday experiences (predominantly everyday speech about electricity, cur-

rent, and electric circuits) and that these conceptions are not adequately addressed in instruction. The case of teaching and learning about electric circuits also shows that instruction may support “false” ideas. In general, the somewhat limited success of conceptual change approaches points to the issue that the content structure for instruction has to be carefully developed in a process called educational reconstruction above (Fig. 21.2). Also seemingly simple topics need substantially deep understanding of the physics “behind” that simple topic.

## Teaching Mechanics

Within the domains of school physics, mechanics has the most substantial body of empirical research on students’ conceptions (Table 21.1). There are various proposals for teaching approaches and a variety of multimedia tools. Nevertheless, mechanics remains one of the most difficult domains to teach and to learn. “Force” and “velocity” are subsumed by everyday interpretations of motion phenomena that differ substantially from physics concepts.

## Physics Concepts

The concepts of classical mechanics—kinematics and dynamics—are *displacement, velocity, acceleration, force, and momentum*. *Mechanical energy (kinetic and potential energy, work)* belongs to the intersection between mechanics and thermodynamics. Mechanics is canonized by Newton’s three laws. A trivialized version still found in many classrooms goes along the following lines:

1. If there are no forces acting on a body, it remains in its state of motion—at rest or with uniform velocity (“inertia”).
2. The (resultant) force acting on a body is proportional to the body’s mass and acceleration ( $\mathbf{F} = m \cdot \mathbf{a}$ ).
3. To each force exerted on a body (“action”) there is an equal but opposite force (“reaction”).

Many students reproduce Newton’s laws in similar phrases without understanding their conceptual content.  $\mathbf{F} = m \cdot \mathbf{a}$  is probably the best known and least understood equation of physics. A sound way of expressing Newton’s ideas is:

- (1\*) The motion of a body can only be changed by forces acting from outside. If there is no change, then there are either no forces at all or the vector sum of the single forces ( $\mathbf{F}_R = \sum \mathbf{F}_i$ ; the resultant force) is zero.
- (2\*) The state of motion of a body is described by its momentum ( $\mathbf{p} = m \cdot \mathbf{v}$ ). In order to change momentum, a resultant force has to be exerted over a certain time interval ( $\Delta \mathbf{p} = \mathbf{F}_R \cdot \Delta t$ ).
- (3\*) Forces result from the interaction of bodies. Whenever a body A exerts a force on another body B, then B simultaneously exerts an equal but opposite force on A ( $\mathbf{F}_{A \rightarrow B} = -\mathbf{F}_{B \rightarrow A}$ ).

Although the problems of teaching and learning mechanics cannot be solved simply by the use of proper formulations, the second set of laws helps to work out the conceptual core of mechanics. Law 1\* opposes a widespread misunderstanding that inertia is only true in the absence of *any* force. Law 2\* stresses the aspect of a *time process* of changing motion by forces. Law 3\* underlines that interaction forces act on different bodies. An important aspect of conceptualizing mechanics is to distinguish clearly between the resultant force and single forces. Although the equations  $\mathbf{F} = m \cdot \mathbf{a}$  (Newton's resultant force that changes the motion of a body) and  $\mathbf{F} = m \cdot \mathbf{g}$  (for the single force of gravity) look very similar, the meanings of the "Fs" are completely different.

## Students' Ideas

Driver et al. (1994, p. 149) summarize the empirical findings about students' ideas on force and motion in these statements:

- if there is motion, there is a force acting;
- if there is no motion, there is no force acting;
- there cannot be a force without motion;
- when an object is moving, there is a force in the direction of its motion;
- a moving object stops when its force is used up;
- a moving object has an own force within it which keeps it going;
- motion is proportional to the force acting;
- a constant speed results from a constant force.

One can add:

- friction is no "real" force but a resistance to motion;
- objects at rest or non-active objects (like tables or roads) do not exert forces;
- objects in circular motion "sense" a centrifugal force (independent of the system of reference).

These findings have been confirmed in empirical studies all over the world. They form the body of intuitive mechanics.

Research on students' ideas in mechanics was stimulated by Warren's book *Understanding Force* (1979). From a physicist's perspective Warren worked out the inherent difficulties and the conceptual stepping stones—sometimes caused by imprecise instruction. Warren developed a set of test items for university beginners that were also used in many follow-up studies with younger students (see Fig. 21.4 for an example). He showed that many students failed to solve seemingly "simple" problems.

Students are asked to mark the forces acting on the ball at points *P* and *Q* and to indicate their probable relative magnitudes (Warren, 1979, p. 34). Most students see a "force" in the direction of motion instead of a (resultant) force in the direction of the *change* of motion (in *P* vertically downward).

FIGURE 21-4. Diagram from a tutorial test on student ideas of forces.

Viennot (1979) expanded on the question of how students conceptualize mechanics alternatively. She claimed that students' "spontaneous reasoning" was consistent and could be formed into an intuitive law of force in which "force" depends on velocity  $v$  (instead of acceleration  $a$ ). Viennot found a coexistence between the idea of "force" as an interaction force impressed on a body and a "supply of force" stored in a body.

McCloskey (1983) drew parallels between students' "intuitive physics" and medieval "impetus theory", based on the idea that force impressed on an object can be stored in the body and is later used up in its motion. Students' impetus reasoning is very resistant to instruction. It leads to wrong predictions of the path of moving objects, like a cannon ball traveling in a straight line before the impetus is used up, so that it falls down vertically. Students even use impetus ideas when they are asked to drop a ball on a target on the ground while they are running.

Jung, Wiesner, and Engelhard (1981) worked out that "inertia" is conceptualized by students as a sort of "lameness"—a resistance to motion that has to be overcome by force. It is often associated with static friction. For students "force" has a polyvalent meaning that integrates facets of the physics concepts of energy, momentum, and Newtonian force. This is comparable to the ambivalent meaning of "force" in physics up to the mid-1850s. Students organize their mechanics knowledge in episodes (cases of force and motion) rather than in generalized principles.

There are a great number of further details on student difficulties, misunderstandings, and alternative concepts in mechanics:

- the problem of distinguishing between points of time and time intervals, which makes it difficult to understand the concepts of momentary velocity and acceleration: "If the velocity is zero, there can be no acceleration" (see, e.g., Trowbridge & McDermott, 1981).
- the misunderstanding that "action" and "reaction" refer to the same body (thus students believe that in order to cause motion, "action" must be stronger than "reaction" (see, e.g., Viennot, 1979).

A controversial issue is whether students' intuitive physics forms a systematic and coherent scheme—a sort of "alternative theory" (e.g., Viennot, 1979). diSessa (1988) strongly opposes this notion. He argues that students' knowledge consists of single loosely connected phenomenological primitives like "force as mover" or "more effort begs more result." According to diSessa, the transition to scientific understand-

ing involves a major structural change toward systematization. In contrast, Vosniadou (2002) has argued on the basis of patterns in student responses that students construct their own narrow but coherent explanatory frameworks in mechanics. Chi, Slotta, and de Leeuw (1994) propose to organize students' thinking along ontological categories: In students' minds "force" belongs to the category "matter" (something that can be stored), while it should be re-assigned to the "constrained-based interaction" category. Jung, Wiesner, and Engelhard (1981) claim that it is more effective to address students' general categories of reasoning than to address specific alternative conceptions. Such categories are:

- functional descriptions of motion—in contrast to seeking the "cause" of motion
- relationships and *interactions* between bodies—in contrast to the *properties* of bodies

Research on students' understanding of mechanics culminated in the 1980s and has since reached a high degree of consensus. There are standardized instruments to assess students' reasoning:

- Force Concept Inventory (FCI; Hestenes, Wells, & Swackhamer, 1992)
- Force and Motion Conceptual Evaluation (FMCE; Thornton & Sokoloff, 1998)
- Test of Understanding Graphs in Kinematics (TUGK; Beichner, 1994)

## Teaching Approaches

Under subject matter aspects Warren (1979, p. 13) points out that the Newtonian system of mechanics should be fully developed in terms of "real" forces. A "real" force can be attributed to a concrete body in a definable interaction which is subject to a recognizable law, such as gravitational forces caused by a planet or elastic forces caused by a deformed ball. Imaginary forces ("pseudo" forces) like centrifugal force only confuse students. Herrmann (1998) builds a mechanics curriculum around the concept of "momentum" that can be stored, shared between bodies, or flow from one body to another.

Minstrell (1992) reports on positive effects of high school mechanics courses where students are explicitly asked to express their intuitive ideas about force and motion. The students' ideas are then juxtaposed with the physics concepts. A similar strategy is presented by Schecker and Niedderer (1996) under the term "contrastive teaching." After introducing Newton's laws, the teacher poses an open-ended problem like "investigate forces in collisions." Students often make statements like "a force is transferred from body A to body B"—even though they nominally know the Newtonian definition of "force." This elicitation of students' own ideas (cf. Driver & Oldham, 1986) helps to contrast their intuitive views with the scientific notion of "force". Clement (1993) shows how students' intuitive ideas can be used as starting points ("anchors") for teaching sequences that lead to a proper understanding of related Newtonian concepts by way of "bridging analogies." Camp and Clement (1994) present a series of student activities that help them to overcome known learning obstacles.

Hake (1998) carried out a meta-analysis of studies done with the Force Concept Inventory-FCI (6,000 students involved). He found that so-called “interactive-engagement courses” score higher than “traditional” teacher-centered methods. Interactive engagement can be effectively assisted by multimedia. Laws (1997) and Thornton and Sokoloff (1990) have developed activity-based mechanics curricula that center around microcomputer-based labs with a range of new sensors, interfaces, and software. In a collaborative learning environment where students investigate “real” motion phenomena the approach leads to a considerable increase in the understanding of kinematics (Thornton, 1992). Motion in sports (like high jumping) can be analyzed by digital video tools like Videograph (cf. Beichner, 1996). The active construction of virtual microworlds from a given set of building blocks (bodies, springs, ropes, etc.) is another means of prompting students to explore mechanics phenomena (leading software package: Interactive Physics, 2004).

## Teaching Atomic Physics

Teaching atomic physics concerns the introduction to various views of the “micro-world” ranging from somewhat “simple” particle models to quantum mechanical views. Many research studies are available on students’ views and the conceptual change processes concerning the particle model. Also, a substantial number of studies on quantum views have been carried out (Table 21.1). For both domains it turns out that students’ everyday conceptions are in stark contrast to the science views. This is already true for the simple particle model which is part of every introductory science course. The microworld of particles is totally different from the world of objects in life-world dimensions. Attempts to make the microworld understandable by introducing analogies to everyday world features usually lead to major student misunderstandings. Students, for instance, tend to view the particles as if they were objects of the life world and hence attach life-world features like color or temperature to them (Duit, 1992; Scott, 1992).

The clash between everyday world views and physics concepts is even more fundamental for quantum views of the microworld. A number of quantum features in principle appear to be inconceivable by everyday world thinking. Examples are particle/wave dualism (Bohr’s idea of complementarity) and Heisenberg’s uncertainty principle, leading, for instance, to the consequence that it is not possible to know both the speed and location of a particle with unlimited precision.

Concerning models of the atom, students tend to have naïve realistic views. The majority see models more or less as copies of the reality (Harrison & Treagust, 1996; Treagust, Chittleborough, & Mamiala, 2002). It appears that there is not much development of such views toward awareness of the model character of atoms in lower secondary science teaching (Knote, 1975). In upper secondary physics instruction of the German Gymnasium, Bethge (1992) found that many students differentiated between a model (of an atom) and reality. However, it has to be taken into account that the German Gymnasium caters only to the top level of students and that physics instruction at this level usually includes modern physics and considerations on the philosophy of physics. This is not the case in many other countries. Briefly summarized, the domains under inspection firstly provide further examples of science views fundamentally different from students’ everyday world

views. Secondly, it becomes obvious that learning science concepts and principles should include the development of views about the nature of science. Here, proper understanding of particle models and models of the atom only develop if views about models develop accordingly.

## Models of the Atom in Physics and Students' Ideas

The interplay between two different views—the particle view and the continuum view—characterizes scientific ideas of substance and atoms. Already the Greek philosophers (Sambursky, 1975, p. 38) held both views about the constitution of matter. Matter was either seen as consisting of tiny particles called atoms, or as a continuous “something” that fills space and is indefinitely divisible. The basic particle view was further elaborated in the eighteenth and nineteenth centuries, culminating in statistical mechanics. After 1900, various atomic models were developed, proposed different structures of positive and negative charges with respect to particle and continuum. Scientific views of the atom have grown over centuries. Certain stages of this process parallel the models constructed by students.

(1) *Atom as a ball.* In 1808, Dalton published his book *A New System of Chemical Philosophy*, in which he viewed atoms as tiny balls (Fig. 21.5). Each element had its own kind of atoms. This hypothesis was suitable to explain fundamental empirical laws about weights in chemical reactions. Later in the nineteenth century Boltzmann's theory of statistical mechanics was also based on atoms as balls. However, in this case the atoms were merely conceptualized as mass points without any other features.

(2) *Atom as a plum pudding.* In Thomson's “plum pudding” model of the atom (published 1904) the positive charge is spread out across the whole atom continuously, whereas the negative charge sits in the form of particles (electrons) in this positive charge like plums in a dough (Fig. 21.6).

A discussion of atomic models with respect to their texture, using analogies with and without a nucleus, can be valuable. Discussing fruits as analogies *with* (cherry) and *without* (kiwi) a nucleus may help students to clarify their thinking. In this respect it is interesting that Harrison and Treagust (1996) found that 76% of their students preferred space-filling models.

(3) *Atom as a nucleus with a shell.* This model was developed by Rutherford in 1911. A heavy positive nucleus is surrounded by electrons as a shell (Fig. 21.7).

Often this model is presented in science instruction. Harrison and Treagust (1996) found that 38% of lower secondary students view atoms as something with a hard center, and 50% are aware of some sort of electron clouds.

(4) *The planetary model of the atom.* A most influential model was developed by Bohr (Fig. 21.8) in analogy of the system of planets revolving around the sun.

FIGURE 21-5. Four atoms of Dalton's ball model of atoms.

FIGURE 21-6. The first three atoms of the J.J. Thomson plum pudding model.

This model is still taught in science instruction, and often it is the only model of so-called modern atomic physics students learn. About half of the students in lower secondary as well as the majority in upper secondary and in university actually see the atom as a planetary system with a nucleus being surrounded by moving electrons (Knote, 1975; Harrison & Treagust, 1996; Fischler & Lichtfeldt, 1992). As the model provides a powerful mental model by drawing an analogy to the planetary system, it has proved to be very resistant against the teaching of more advanced models (Bethge, 1992; Fischler & Lichtfeldt, 1992; Mashhadi, 1995; Taber, 2001; Müller & Wiesner, 2002).

(5) *Intermediate conceptions of the quantum atomic models.* At least in the United Kingdom and in Germany there is a certain tradition to teach quantum atomic physics beyond the Bohr model in upper secondary school. In these teaching approaches, students typically construct intermediate concepts of a quantum atomic model (Bethge, 1992; Mashhadi, 1995; Petri & Niedderer, 1998). One of these models conceptualizes smeared orbits (Fig. 21.9). A number of students at university level appear to hold such models (Müller & Wiesner, 2002).

(6) *The probability density conception of the atom.* This model is based on Born's interpretation of the Schrödinger equation (Fig. 21.10).

In this conception the Schrödinger term  $\psi^2$  is interpreted as the probability of finding the electron at a certain distance from the nucleus: the larger the distance, the smaller is the probability. Studies have shown that students have difficulty understanding this view (Bethge, 1992; Mashhadi, 1995).

(7) *The electron cloud model of the atom.* This model consists of a nucleus as a particle and an electron cloud as a charge cloud surrounding the nucleus. Its density is calculated by the Schrödinger  $\psi$ -function (Fig. 21.11).

The charge density in this model decreases when the distance from the nucleus increases. This may be seen analogously to the distribution of the air around the

FIGURE 21-7. The Rutherford model.

FIGURE 21-8. Bohr's planetary model of the atom.

FIGURE 21-9. Smearred orbits model (Petri & Niedderer, 1998).

FIGURE 21-10. Visualization of an atom according to Born.

FIGURE 21-11. Visualization of an atom according to Schrödinger.

earth. This model of a charge cloud is called “electronium” in an approach by Herrmann (1995, 1998). Studies (Niedderer & Deylitz, 1999; Budde et al., 2002) show that the electron cloud model (electronium Fig. 21.11) is easier to learn than the Born model in Fig. 21.10. If both models are offered, students prefer the electronium model, and about 90% of them use it in the final test and in interviews.

## Teaching Approaches

Various approaches of teaching and learning quantum mechanics have been developed and evaluated. *Gedankenexperimente* (thought experiments) or computer simulations to introduce the concepts of quantum physics, such as the “preparation” of samples of equal particles or the new view of “measurement”, play a significant role in many approaches. In the following a brief overview of different emphases is presented.

Fischler’s (1999) approach does not begin with the quantum nature of photons which is the starting point in most other courses. Right from the beginning electron diffraction experiments are carried out and interpreted. Surprising results of the experiments catch students’ attention, and mechanistic interpretations of electrons are avoided. In a treatment-control-group design Fischler and Lichtfeldt (1992) found that about 20% of the students in the experimental group developed satisfactory concepts about quantum principles, whereas in the control group (starting from photons) no student reached that level. Also Müller (2003) found positive effects on understanding by introducing a more modern quantum model of the atom and by abandoning the planetary model.

In a number of approaches, major emphasis is put on explaining basic phenomena and interesting technical applications of quantum physics. Niedderer’s approach (Niedderer & Deylitz, 1999) aims at understanding the size and spectra of atoms, chemical bonding, and the spectra of solids. An evaluation study (Niedderer & Deylitz, 1999) showed that—apart from problems with understanding the mathematics of Schrödinger’s equation—most goals of conceptual understanding could be reached with reasonable success. As mentioned, a majority of the students preferred the “electron cloud” model to the “probability density” model.

Zollman et al. (2002) analyze objects like LEDs and gas lamps, fluorescent and phosphorescent materials, as well as the tunneling microscope. Potential energy diagrams are used to explain these materials. In the “Visual Quantum Mechanics” approach, the emphasis is on conceptual understanding and visualization as opposed to of mathematical formalisms. In an evaluation study, Rebello and Zollman (1999) observed that hands-on activities, computer visualization programs, and constructivist pedagogy enabled their students to build mental models that allowed them to explain their observations. The preliminary study also provided information about difficulties in helping students to learn abstract concepts by the approach used.

Briefly summarized, research has shown that students’ understanding of particle models and quantum models of the atom may be substantially improved by approaches that are oriented toward constructivist conceptual change views of teaching and learning. However, the success rate is still somewhat limited. Much more research-based development is necessary for both domains. It appears that the above views of the German *Didaktik* tradition (see the idea of educational reconstruction in Fig. 21.2) may help in further improving the existing approaches. The content structure for instruction—seen from that perspective—has to be developed by taking into account (a) physics views of particles and atoms, (b) physics views of the nature of particles and atoms, (c) students’ views of particles and atoms and of the nature of the models provided, and (d) the aims of teaching particles and atoms. From a scientific literacy perspective it appears that through adoption of the *Didaktik* tradition the purpose of teaching and learning particle views and especially quantum physics views of the atoms may also be further clarified.

## OUTLOOK: DESIDERATA FOR PHYSICS EDUCATION RESEARCH

In order to improve physics teaching and learning in school as well as in other institutions, various changes in the present state of practice are necessary. Most changes are not specific to physics instruction. However, they have to be specifically designed for the particular content and content specific pedagogical issues of physics. Other necessary changes are specific for physics instruction, in particular those concerning emphases of the content taught. In the following, major concerns are briefly outlined.

### General Concerns

*Teachers’ thinking about instruction and their teaching practices.* Teachers, of course, are the key players in education reforms (Anderson & Helms, 2001). Research has shown that (a) many teachers are not (well) informed about research findings on teaching and learning, (b) their views about “good” physics instruction are rather topic dominated, modeling of student learning is deficient, and (c) in educational practice there still appears to be a dominance of teacher-centered instruction. It is essential that teachers’ thinking about instruction includes all the facets addressed in the European *Didaktik* tradition as outlined above (Fig. 21.2). In terms of Shulman’s (1987) perspective, there should be a balance between content *and*

content-specific pedagogical issues in teacher thinking. Instructional planning should include considerations on content issues as well as on issues of how students may be able to learn the content.

More research is needed, especially concerning the following two issues (see Chapter 39 on teacher professional development for more details):

- To investigate how teachers may be made familiar with research findings and how their views about teaching and learning physics may be improved and whether instructional practice improves accordingly. Here issues of conceptual change discussed above come into play. Changing deeply rooted views (here teachers' views) has proved to be a long-lasting process.
- In order to be able to design more efficient instructional approaches it is necessary to be familiar with the actual practice of physics instruction. So far only a few studies that allow deep insight into actual practice (e.g., by analyzing videos) are available (Duit et al., 2004). More studies on the normal practice of physics instruction are needed.

*Aims and standards.* The present discussion on scientific literacy is focused on the use of physics knowledge for understanding daily life concerns and participation as citizens in decisions on science and technology. The above concept of *Bildung* adds the idea of forming the learners' personalities. It appears to be necessary to further analyze whether the actual concepts of scientific literacy are sound and can be put into practice, that is, are not just visions. A broad spectrum of research methods has to be employed, ranging from historical and hermeneutical studies on various views of scientific literacy in different areas and countries, empirical studies on the actual need of physics knowledge to understand daily life issues and to participate in society, as well as empirical studies on students' capabilities to achieve the envisioned facets of scientific literacy.

Standards have been a key concern for a number of countries since the 1990s (e.g., in the United States and Canada); in other countries (like Germany) this is a more recent issue. Standards usually attempt to make the more general concepts of scientific literacy explicit. This serves two related functions: to provide a frame for setting key issues of scientific literacy into practice and for facilitating construction of test measures that make it possible to determine the extent to which the various competencies stated are put into practice.

Standards are based on implicit or explicit models of the structure and development of competence. More research is needed:

- To design models of students' competency structures, drawing on data from achievement tests, favorably in a longitudinal perspective
- To design psychometric methods to prove the competency levels achieved

*Content, processes, and views about the nature of science.* As more fully outlined above, processes and views about the nature of science are given only rather limited attention in physics teaching. Research appears to be needed to investigate

the interplay of understanding content on the one hand and processes as well as views of the nature of science on the other.

**Holistic approaches.** Research has shown that the outcomes of instruction (e.g., the development of achievement and affective variables) are not due simply to a single factor of the instructional arrangement but to an intimate interplay of many factors (Baumert & Köller, 2000; Oser & Baeriswyl, 2001). In other words, it does not make sense to change just one factor to improve physics instruction (e.g., introducing multimedia learning environments, new exciting experiments, or innovative teaching methods). The above idea of educational reconstruction (Fig. 21.2), which is based on the European *Didaktik* tradition, may provide a frame for designing approaches that take into account the essential interplay of the many factors determining instructional outcomes.

### Physics-Specific Concerns

Physics instruction in school includes a certain canon of content that is quite similar all over the world. Interestingly, most topics of this canon concern rather “old” physics, namely physics of the nineteenth century. So-called modern physics plays a certain role only in the upper secondary levels. Most teaching approaches for quantum physics and relativity (Table 21.1) are suited only for rather gifted students. Attempts to make more recent thinking about matter, space, and time accessible to younger or less gifted students as part of their scientific literacy are rare. There is a certain irony in this situation when schools appear to be reluctant to address this issue, while popular science books on modern physics are booming. Serious attempts are needed to make key basic ideas of modern physics accessible to “normal” students. Some studies in the field of nonlinear systems have shown that this is possible (Duit, Komorek, & Wilbers, 1997).

### ACKNOWLEDGMENTS

Many thanks to John Clement (University of Massachusetts) and Ron Good (Louisiana State of University), who reviewed this chapter.

# CHAPTER 22

---

## Teaching and Learning the Many Faces of Chemistry

**Onno De Jong**

*Utrecht University, the Netherlands*

**Keith S. Taber**

*Cambridge University, United Kingdom*

The goal of this chapter is to review research on teaching and learning science that focuses on the specific domain of chemistry, with particular emphasis on the high school level. Many chemistry topics can be either viewed or taught from three potential perspectives that are mutually related (Fig. 22.1). First, the macroscopic perspective, focusing on substances and phenomena that can be observed with the naked eye. Second, the submicroscopic perspective, focusing on molecules, atoms, ions, and so on. Third, the symbolic perspective, focusing on formulas, equations, ionic drawings, and the like. The use of this three-cornered relationship (Johnstone, 1991) is not exclusive to the chemical domain, but it plays a more dominant role here than in the domains of the other natural sciences. Many students experience difficulties in understanding the macro/submicro/symbolic triangle and, in particular, in appreciating how and when to make the transitions between the three perspectives. Teachers do not always realize the importance of modeling the relationships here, by being explicit about the perspective being used, and the transitions being made, and helping students to overcome their difficulties.

The present chapter includes a review of studies that highlight two difficult chemical topics at the high school level. Part 1 of the chapter deals with a key topic in junior high schools: chemical reactions. Part 2 of the chapter concerns a core topic in senior high schools: atomic structure and chemical bonding. For each topic, students' main conceptual difficulties are presented. They are explained concisely by the use of another triangle: the related perspectives of teaching, chemistry content, and learning. Studies of courses designed to help students respond to their difficulties are also presented and discussed. Special attention is given to courses based on

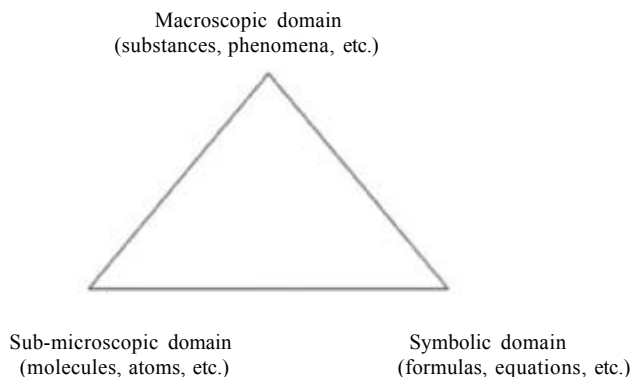

FIGURE 22-1. The triangle of meanings.

modern perspectives on teaching and learning, such as context-based teaching strategies and approaches incorporating a constructivist view of learning. Suggestions for priority areas for further research and curriculum development are given at several places. Finally, part 3 of the chapter presents a look to the near future of chemical education.

## INTRODUCING MULTIPLE MEANINGS OF CHEMICAL REACTIONS

### Multiple Meanings

In introductory chemical education, the central core content deals with chemical reactions. In elementary schools, if chemical reactions are introduced, students only have to learn the macroscopic meaning in terms of conversions of substances. High school students should also learn the submicroscopic meaning in terms of the rearrangement of particles (molecules, atoms, ions) and the symbolic meaning in terms of chemical equations (words, iconic drawings, formulas). These students also should become able to switch mentally between these meanings in an adequate and flexible way.

This section addresses studies of students' conceptual difficulties, related to reactions that can be considered to proceed to completion, taking place in one direction. Difficulties in understanding more complex chemical reaction types can be found elsewhere, such as problems with understanding equilibrium reactions (Van Driel & Graeber, 2002) and redox reactions (De Jong & Treagust, 2002). The present section also offers some explanatory perspectives on students' difficulties. Studies of efforts to prevent and to respond to their difficulties are discussed. Suggestions for further research and course development are also given.

### Students' Conceptual Difficulties

In the last two decades, numerous articles on students' difficulties in understanding the multiple meanings of chemical reactions have been published. From stud-

## Vignette

In a junior high school class, a chemistry teacher puts a burning piece of wood in a glass with water. The burning stops.

The teacher asks: *How is that possible?*

Student #1 answers: *We do not understand, burning should go on because there is oxygen in the water, as we know because fish live in water.*

The teacher responds: *But there is not enough oxygen in the water.*

Student #2 argues: *We know that water is  $H_2O$ , so, one-third of water is oxygen, whereas it consists of oxygen for one-fifth only . . . so, teacher, how is that possible?*

In this vignette, student #2 compares water and air as providers of oxygen for a burning process. However, the student interprets the formula of water in an additive rather than from an interactive way:  $H_2O$  is seen as  $H_2$  and  $O$ . This way of reasoning demonstrated a common difficulty in understanding symbolic representations.

ies and reviews, written by Ahtee and Varjola (1998), Andersson (1986), Fensham (1994), Gabel and Bunce, (1994), Johnson (2000), and Krnel, Watson, and Glazar (1998), a list of 12 of the most recurrent difficulties has been compiled and is presented below.

Regarding *the macroscopic meaning*, recurrent difficulties are the following:

- Students may fail to recognize a process as a chemical change, through lack of sufficient knowledge of substance identity. For instance, students may interpret the product of a chemical change as a mixture where the original substances still persist.
- Students may believe that during chemical changes substances are displaced without any change of their properties. This is illustrated by students who think that parts of burning wood are driven off as smoke.
- Students tend to interpret chemical reactions as a process of modification, that is, chemical changes are seen as physical changes, and properties of substances are seen as changing, whereas the substances themselves remain the same. For instance, students may believe that the black coating formed on a piece of copper metal during heating represents black or burned copper.
- Students may interpret chemical changes as a transmutation of a given substance into another substance or into energy. This is demonstrated by students who believe that burned steel wool has been turned into carbon.
- Students sometimes seem to be unaware of the interactive role of "invisible" (gaseous) reactants or products. For instance, students may believe that the mass of a rusty nail is the same as that of the nail before rusting.
- Students tend to treat properties of substances as some kind of extra substance. This can be seen in students who believe that sugar disappears when it is dissolved in water, but the sweetness remains.

Regarding *the submicroscopic meaning*, recurrent difficulties are the following:

- Students often attribute macroscopic features to molecules or atoms and attribute submicroscopic features to substances. Typical examples are: students think that a molecule of water means a small drop of the liquid and may use expressions like “substances exchange outer electrons between them.”
- Students may fail to invoke atoms and molecules as explanatory constructs of chemical reactions, although they have knowledge of atoms and molecules.
- Students’ ability to give a submicroscopic explanation of chemical reactions in terms of a dynamic process is often limited. For instance, students may not refer to the rearrangement of atoms, that is, breaking of bonds and formation of new bonds.

Regarding *the symbolic meaning*, recurrent difficulties are as follows:

- Students tend to perceive a formula as representing one unit of a substance rather than a collection of particles, and they tend to interpret the formulas of compounds in an additive rather than from an interactive way. This is shown by students who interpret the formula  $\text{H}_2\text{O}$  as  $\text{H}_2$  and  $\text{O}$ .
- Students may have difficulties in understanding the meaning of formula subscripts and equation coefficients. For instance, students tend to change the subscripts while balancing reaction equations.
- Students may consider balancing chemical reactions as mainly mathematical manipulation of symbols without much insight into the chemical meaning. A typical example: students may consider  $3\text{H}_2$  as six linked atoms.

The reported difficulties can be explained from several perspectives. Three perspectives offering particular insight are:

- (i) The *teaching perspective*, especially the influence of the traditional chemistry curriculum structure and textbook context, and the usual teaching practice. In many chemistry courses, chemical reactions are considered predominantly at the submicroscopic and symbolic levels, without much attention to students’ everyday conceptions of chemical phenomena. This situation promotes the tendency among students to consider chemical reactions as very formal processes and chemical equations as algebraic expressions. In chemistry classrooms, teachers tend to use language that may evoke confusions among students, such as using the expression “copper is formed,” without indicating explicitly if this statement refers to the substance copper, the type of atoms, or the type of ions (De Jong, Acampo, & Verdonk, 1995).
- (ii) The *science content perspective*, especially the abstract character of many chemistry concepts. Understanding such concepts requires formal reasoning and knowledge of models as representations of phenomena. This is not easy for many students, who are tending to see, for instance, molecules and atoms as *minima naturalia* (the Aristotelian concept of small particles) instead of theoretical model concepts (De Vos & Verdonk, 1985).

- (iii) The *learning perspective*, especially the role of the initial knowledge of students, based on daily life experiences and expressed in everyday language. Many of the students' authentic perceptions and interpretations of phenomena are often not very fruitful in a chemistry context, such as the idea that milk that has become sour is still milk (Stavidrou & Solomonidou, 1998).

## Courses Developed from Modern Teaching and Learning Perspectives

The reported students' conceptual difficulties have been found among students taught quite traditional chemistry courses. Efforts to prevent and to respond to their difficulties have led to a series of chemistry courses developed from modern teaching and learning perspectives. Studies of five exemplars are given below.

- A course that included three phases of the *learning cycle*, namely explication, concept introduction, and concept application, was investigated by Cavallo, McNeely, and Marek (2003). They reported on the development of understanding among 60 junior high-school students with respect to the three levels of meaning of chemical reactions. Findings indicate significant positive shifts in understanding. A minority (about 20%) of the students, however, showed persistent conceptual difficulties, especially regarding the difference between chemical change and physical change, and the relationship between atoms and substances.
- A course that introduced a teaching strategy based on the *conceptual change perspective*, that is, confronting students with "chemical events" that evoke cognitive conflicts because of existing everyday conceptions, was investigated by Nieswandt (2001). She reported on the development of understanding among 81 junior high school students with respect to macroscopic features of substances and chemical reactions (with particular emphasis on combustion). Results show a significant "erosion" of students' everyday conceptions in favor of scientific concepts. A minority (about 25%) of the students, however, only developed "mixed" concepts, consisting of everyday concepts and chemistry explanations.
- A course that incorporated a *context-based* teaching approach by presenting chemistry concepts within the context of everyday events was investigated by Barker and Millar (1999). They reported on the development of understanding among 250 senior high school students with respect to the conservation of mass in closed- and open-system chemical reactions. Data indicate that students' reasoning improved steadily as the course progressed. Nevertheless, a minority of the students retained misunderstandings about the conservation of mass in closed systems (23%) and open systems (29%), especially for reactions including gases.
- A course that included a *constructivist view* on learning by taking students' own conceptions into account was investigated by Laverty and McGarvey (1991). They reported on the development of understanding among two classes of junior high school students with respect to macro, submicro, and symbolic

meanings of chemical reactions. Results reveal good learning gains, although about 30% of the students were not able to identify particle diagrams correctly.

- A course designed from a *mix of perspectives*, namely conceptual change, context-led, and constructivist, was investigated by Solomonidou and Stavridou (2000). They reported on the development of understanding among 168 junior high school students with respect to macroscopic features of substances and various chemical reactions. Results show significant positive shifts in understanding. A minority (percentage not given) of the students, however, did not change their “concrete substance” idea toward the “unknown substance plus properties” scheme, and the “inert mixture” concept toward the “interaction between substances” concept.

Some of the reported studies cover only macroscopic features of chemical reactions (Barker & Millar, 1999; Nieswandt, 2001; Solomonidou & Stavridou, 2000), whereas others also cover submicroscopic and symbolic features (Cavallo et al., 2003; Lavery & McGarvey, 1991). All studies report a positive development of students’ understanding, but all of them also indicate conceptual difficulties, despite the use of modern course designs and teaching strategies. This raises the question: what causes the persistency of the reported difficulties in these courses?

To answer this question, knowledge of the teaching-learning processes in the classroom could be helpful. Unfortunately, four of the studies only focused on learning outcomes, by using written questionnaires, sometimes combined with some interviews, in the context of pre-test/(repeated) post-test designs. As a consequence, they are not able to report on learning processes. Fortunately, in the fifth study, not only were a pre-test/post-test design and questionnaires used, but so were other instruments, such as audio records of lessons and classroom observations (Lavery & McGarvey, 1991). This study offers a better insight into students’ struggle for understanding. The researchers report how students design their own diagrammatic representations for the effect of heat on copper carbonate, why some of them mistake this decomposition for burning in air, and how they argue to find the best representation for the decomposition. In an older but still influential study of another constructivist course, De Vos and Verdonk (1985) also analyzed audiotaped classroom discussions. They found that junior high school students were able to develop primitive particle models of matter in the context of a chemical reaction, for example, for explaining the appearance of the brilliant yellow line, consisting of glittering tiny crystals in a continuous motion, when lead nitrate and potassium iodide are placed in opposite positions in a Petri dish filled with water.

In conclusion, more in-depth and longitudinal studies are needed to get a better “ecologically” valid insight into the factors and conditions that hinder or facilitate the development of students’ conceptions of the multiple meanings of chemical reactions.

## The Dilemma of the Course Content Structure

The five reported studies deal with courses where the choice for a particular general teaching strategy is reported, but where the course content structure is hardly indicated, especially the issue of developing the idea of chemical reactions from a

macroscopic level to a submicroscopic level by an early or late introduction of the particle theory. This issue is the subject of an old but ongoing debate in chemical education.

Several scholars have proposed a delayed introduction of molecules and atoms (e.g., Ahtee & Varjola, 1998; Fensham, 1994), but others have shown that students do not naturally have a concept of substance identity that allows them to recognize chemical change in a proper way (e.g., Johnson, 2000; Stavidrou & Solomonidou, 1998). For instance, although many courses introduce the burning of substances in an early stage, students experience a lot of difficulties in recognizing and understanding this event as a chemical reaction (Watson, Prieto, & Dillon, 1997). Johnson (2002) even found that students began to accept the idea of substances changing into other substances only after a teaching unit in which atoms had been introduced. The model of atoms and changes in bonding was not the explanation for the idea of chemical change, but the means by which chemical change was acknowledged. On the other hand, it is clear that premature introduction of the concepts of molecules and atoms is not indicated, because this approach will not enable students to consider particles as a fruitful concept for explaining chemical reactions, and may induce many difficulties at the submicroscopic level, as reported before. This raises the question: how should we escape from this content-related teaching approach dilemma?

A promising way out could be the development of context-led constructivist courses that use the students' initial conceptions of substances and particles (most students have at least heard about atoms), although their conceptions are inevitably rather primitive and unscientific, to promote the development of knowledge of the multiple meanings of chemical reactions in a coherent and simultaneous way (see, e.g., Nakleh, Samarapungavan, & Saglam, 2005).

In conclusion, further research is required to get a deeper insight into the most effective course content structure for meaningful student learning of chemical reactions.

## INTRODUCING MULTIPLE MEANINGS OF ATOMIC STRUCTURE AND CHEMICAL BONDING

### Introduction

In chemical education at the senior high school level, one of the key concepts is chemical bonding, because knowledge of this concept allows students to make predictions, and give explanations, about physical and chemical properties of substances. For a good understanding of the bonding concept, knowledge of the structure of the atom is a prerequisite. Students who progress to learn chemistry from the high school level to the university level will meet multiple models of both concepts. Regarding atomic structure, students usually have to learn initially the shell model in terms of a positive central nucleus surrounded by shells of negative electrons. Later on, they have to learn the orbital model in terms of subshells, orbitals, and electron density patterns. Regarding chemical bonding, students usually learn first about covalent bonding (initially described as electron sharing) and ionic bonding (often implied to be equivalent to electron transfer; see below). If metallic bonding is introduced it is often presented in terms of a sea-of-electrons model. Progression toward

## Vignette

In a senior high school class, a chemistry teacher shows a sheet including the equation for the reaction starting  $\text{H}_2(\text{g}) + \text{F}_2(\text{g}) \dots$  (indicating that the reactants were in the form of molecules).

The teacher asks: *In your own words, explain why you think hydrogen reacts with fluorine?*

A student answers: *Because both atoms need one extra electron in their outside shell to have a noble gas structure, so by sharing two electrons (one from each atom) in a covalent bond, hydrogen fluoride becomes a very stable molecule . . .*

In this vignette, the student response demonstrates a confident reply, yet one that contradicts the information in the teacher's question. This is a common student response that exemplifies how students find the curriculum models of atomic structure and bonding problematic (Taber, 2002).

a more sophisticated understanding of these bonds types is expected later, as is knowledge of hydrogen bonding, van der Waals forces, and so forth.

This section addresses studies of students' difficulties in understanding these multiple models and offers some explanations of how these difficulties arise and ideas to prevent and to respond to them. Suggestions for further research and course development are also given.

## Teaching and Learning about Atomic Structure

***Students' recurrent conceptual difficulties.*** In the last decade, the interest in students' difficulties in understanding the concept of atomic structure has been growing. Typical examples of recurrent difficulties are reported below (see also Justi & Gilbert, 2000). Usually, at the senior high school level, teaching about atomic structure starts with the shell model of this concept. One of the main strengths of this model is that it can act as a major explanatory device linking atomic structure to chemical behavior in terms of the periodic table. Electronic configurations expressed in symbols, such as 2.7, 2.8.2, etc., may be readily related to the period and group of the element, which in turn link to patterns of chemical behavior. Indeed the periodic table as often currently presented in chemical education is described as a table of the elements (i.e., of substances), but often presents data about atoms, sometimes juxtaposed with macroscopic properties such as melting temperature (Schmidt, Baumgärtner, & Eybe, 2003).

The shell concept is often problematic for students. First of all, the idea that the atom has a certain structure may seem to be inconsistent with prior learning. Students at the junior high school level have learned that atoms are the fundamental components of matter. However, Harrison and Treagust (1996) found that students still often appreciate this concept in only a vague way, and tend to consider these constituent particles as solid spheres. A second area of difficulties relates to learning about the construction of the atom. For instance, Harrison and Treagust (1996) reported that some students believed that an electron shell is some form of protective

coating on the atom. A third area of difficulty is in appreciating the nature of interactions within the atom. For instance, Taber (1998a) showed that many high school students feel that the positively charged nucleus gives rise to a certain amount of attraction that is shared out among the electrons present. Students also tend to use alternative notions when explaining the stability of the nucleus, for example suggesting that nuclear stability is due to a force from the electrons pushing the protons together. A common alternative explanation is the conception that neutrons neutralize the charge on the protons in some way so that the protons may be collected together in the nucleus (Schmidt, Baumgärtner, & Eybe, 2003).

In a second stage of teaching about atomic structure, the shell model is replaced (or at least supplemented) by the more subtle and complex orbital model, to provide more explanatory power. Many students experience this transition as difficult to understand. As Harrison and Treagust (2000) indicated, they often initially adopt the new terminology, but still largely think in terms of shells of orbiting electrons. Even chemistry undergraduates have been found to think largely in terms of simple Bohr-type models of the atom (Cros et al., 1986). Not surprisingly, concepts such as orbital hybridization have been found to be difficult for both high school students (Taber, 2004) and undergraduates (Nakiboglu, 2003) to master.

Students' conceptual difficulties can be explained from the same three perspectives as mentioned in the previous section:

- (i) The *teaching perspective*. Teachers may be hindered by their own familiarity with ideas about atomic structure from understanding why the model presented to students is unclear for them and is often inconsistent with students' familiar notions. Furthermore, teachers often do not pay sufficient attention to the historical background and model characteristics of the shell and orbital versions of atomic structure met in the curriculum.
- (ii) The *science content perspective*. The nature of the atom is very abstract. A key idea is the electrostatic interactions between the charged particles present (the electrons and the nucleus), but although necessary, this is not sufficient to understand atomic structure. Not only is quantum theory needed to appreciate why electrons should occur in shells, but the stability of the nucleus requires a completely different type of force—something that is often ignored at this level.
- (iii) The *learning perspective*. Students have to learn counterintuitive ideas about the nature of atomic structure. Moreover, they have learned about electric forces and energy, but the application of these concepts to understanding the shell and orbital meaning of atoms leads to cognitive conflicts, as mentioned above.

***Courses developed from modern perspectives.*** Several studies have been reported about approaches to preventing and responding to students' difficulties in this area. Many conventional courses introduce atomic structure by comparison with the solar system, which is assumed to be more familiar to students. This type of teaching by analogy is very powerful when done well, but needs to focus students on both similarities and differences between the two systems. However, in practice, as Taber (2002) found, students may not have a sound appreciation of the forces at work in either the solar or atomic systems.

In a study of teaching at the junior high school level, Moran and Vaughan (2000) reported on a course, developed from a *conceptual change perspective*, that included the use of model building to make atomic structure seem more concrete for students, and that set up discussion about potential cognitive conflicts. These features seem worthy; however, the cognitive conflicts involved spotting errors in fake students' work, rather than engineering situations where the students' own ideas could be challenged by evidence. Although the authors imply that the approach was successful, they offer no evaluation of the learning outcomes.

In a study related to teaching at the high school level, Petri and Niedderer (1998) reported on a computer-assisted instruction (CAI) approach to teaching about atomic structure based around the concepts of state and orbital, and the standing wave analogy for electrons in atoms. This approach, which included a *constructivist view* on learning, uses computers to allow students to undertake mathematical modeling—yet focuses on the models produced, not the mathematics. Their case study of student learning showed that although initial, relatively limited, models of the atom continued to be used by the student, these were augmented by more sophisticated models that were closer to the target knowledge. These findings are consistent with the study of Harrison and Treagust (2000).

Understandably, there is a real debate about when and how quantum ideas ought to be taught in schools and universities. Some authors have argued that orbital concepts should be avoided completely for a longer time (e.g., Tsaparlis, 1997). Gillespie (1996) has argued that a conceptualization of atomic and molecular structure in terms of electron pair domains should be the preferred approach at the senior high school and introductory university levels.

In conclusion, the research highlights many of the difficulties students face in studying atomic structure. Unfortunately, the research does not provide clear advice to the teacher about how to proceed. In many cases, suggestions to delay the study of material may not be consistent with the prescribed curriculum. This underlines the need for further research, especially with respect to course designs that provide sufficient time for students to consolidate new ideas before being expected to develop them further.

## Teaching and Learning about Chemical Bonding

*Students' recurrent conceptual difficulties.* Research interest is growing in the area of students' difficulties in understanding chemical bonding. Exemplars of recurrent difficulties are reported below. At the senior high school level, students commonly develop notions of two basic types of bonding that they take forward to more advanced levels of study: covalent and ionic. The covalent bond is often defined as electron-sharing; the ionic bond is often identified with the process of electron transfer between a metal atom and a nonmetal atom. These associations may be inappropriate as students often think that the notion of electron sharing is sufficient to explain the covalent bond, and that the ionic bond is an electron-transfer event, rather than the force holding ions together.

Regarding the understanding of the *covalent bond*, Barker and Millar (2000) showed that students may think that covalent bonds are weak, because many substances of which the constituent particles are considered to be covalently bound have low

melting points. Other research indicated that students might think that covalent bonds break when a piece of material is reshaped, and may assume that high viscosity is due to covalent bonds (Peterson, Treagust, & Garnett, 1989). Tan and Treagust (1999) found that some students think that substances that actually have giant molecular structures contain discrete molecules with strong intermolecular forces.

Regarding the understanding of the *ionic bond*, research has shown that students tend to think that ionic substances consist of molecules, or ion-pair units that act like molecules, even if the actual term is not used (Taber, 1997; Barker & Millar, 2000). So, for the NaCl structure (which tends to be the archetypal teaching example, and is commonly quoted by learners) students would expect each ion to be involved in two types of interaction: with the one counter-ion within the same “molecule”/ion pair, and with the five other counter-ions that are not conceptualized as part of the same structural unit (Butts & Smith, 1987). A UK survey of over 300 students showed that a “molecular” model of ionic bonding was applied—to at least some extent—by most of the students, at both the junior high and senior high levels (Taber, 1997). Some students may believe that that the “molecules” assumed to be present in NaCl break up to give ions when the salt dissolves, but others consider the molecules/ion pairs to be the solvated species (Butts & Smith, 1987).

When students have to learn about *polar bonds*, they often tend to see these as a subclass of covalent bonds (Peterson et al., 1989). So, students may suggest that substances such as HCl exist as dissolved molecules in aqueous solutions (Barker & Millar, 2000).

Students often have a quite limited understanding of the *metallic bond*. Many expect molecules or ions to be present in metallic structures and, for that reason, think that the constituent particles are linked by covalent or ionic bonds (Taber, 2003).

Students’ conceptual difficulties can be examined from the same three perspectives applied earlier:

- (i) The *teaching perspective*. Scientific explanations for chemical bonding are usually considered too complex for students and are therefore not discussed with them. To fill this explanatory vacuum that exists in school chemistry, the octet framework is adopted (Taber, 1998b). This framework is based around a key explanatory principle that atoms actively seek to fill their electron shells or obtain octets of electrons, and is often described in anthropomorphic terms as what atoms want or need. Student understanding of ionic bonding provides a clear illustration of how the octet rule pervades thinking about bonding. Rather than see the ionic bond as the electrostatic attraction between any adjacent counter-ions, it is common for students to conceptualize two types of interactions. So, in NaCl, students will suggest that each sodium ion is ionically bonded only to the one chloride ion it donated an electron to (in order for the sodium and chloride atoms to obtain octet structures), and it will be attracted to other counter-ions “just by forces.”
- (ii) The *science content perspective*. The multiple models of chemical bonding are very abstract, especially because they include a number of abstract subconcepts, such as force, energy, electrostatic interaction, and atomic structure. Moreover, these subconcepts are related to each other in a very complex way.
- (iii) The *learning perspective*. From previous lessons, students are more familiar with molecules than with ions, and the covalent bond is commonly taught be-

fore the ionic bond. For that reason, students may tend to construct their mental models of the ionic bond by analogy with the covalent case. This implies that (i) an ion is considered to be only bonded to a counter-ion with which it had exchanged an electron (in the way that in the simple covalent model atoms are only bonded when sharing electrons) and (ii) that the number of bonds formed was seen as limited by electrovalency (as in covalency, where the valency of the atom determines the number of other atoms it could be directly bonded to).

*Developing research-based approaches.* There are several studies that report courses informed by research into student learning difficulties in this area. In a study of teaching at the senior high school level, Barker and Millar (2000) reported on a *context-based* teaching approach that presents information about chemical bonding (and other theoretical notions) through a story line. The story line provides the context in which to introduce the concept as and when needed. Although the researchers found that the course seemed successful at teaching chemical bonding, they also found similar alternative conceptions about bonding among the students taking the course, as has been reported in the other studies discussed here.

Taber (1998b) reported a longitudinal study of teaching chemical bonding to senior high school students. He found that students often started their course with the idea that chemical bonding was always either covalent (= electron sharing) or ionic (= electron transfer). This finding can be related to research into the levels of intellectual development of students when they are introduced to these abstract concepts (e.g., Finster, 1991). They often had considerable difficulty adjusting their thinking to allow intermediate forms of bonding (i.e., polar) or accepting new categories of bond (e.g., hydrogen bonds). Unless a type of bond could be understood as a variation on the ionic or covalent case, it was often excluded from being considered a real bond and was seen as “just a force.” The study also reported on the progression through the course as involving a gradual process of coming to conceptualize chemical reactions and bonding in physical terms, rather than being about atoms trying to obtain octets of electrons. The results showed that this was a difficult succession that often required more time for learning than the course allowed, so that—at best—students were left with partly developed “multiple frameworks” for chemical bonding (Taber, 2001). This result is consistent with a study of Coll and Taylor (2002), who found that undergraduates and even post-graduate chemists may still often think in terms of the limited models acquired in school.

In conclusion, there has been a good deal of research on aspects of learning about chemical bonding, although much of this simply reports findings related to the alternative conceptions of rather disparate students. Although such research can inform teaching, it often fails to suggest how fundamental improvements in teaching strategies can occur. More detailed studies, exploring individual learners over time, can provide greater insights. The studies considered here led to recommendations for teaching strategy and course content structure that may be fruitful:

- Discuss bonding in physical terms (i.e., in terms of forces) rather than octets.
- Avoid anthropomorphic or animistic language when explaining why reactions occur or bonds form.

- Present discussions of bonding in an order of increasing complexity: metals, then ionic compounds (added complication, two types of ion present), then giant covalent structures (added complication—number of bonds determined by atomic structure), then simple covalent (added complication—two types of bond present).

However, more research is needed to find out if following such recommendations can actually improve student outcomes in practice.

As new learning is only meaningful and secure when it is constructed upon suitable foundations; then there needs to be a suitable period of time before any newly acquired concepts are suitable to be relied upon as prerequisite learning for new learning. This period of consolidation may be many months (e.g., Harrison & Treagust, 2000), and yet in chemistry teaching the curriculum often requires teachers to introduce such interdependent material in a much shorter time scale. As suggested above, this is another area where more research is indicated, as it is quite possibly a major factor in many of the difficulties that students face in learning about atomic structure and chemical bonding.

## A LOOK TO THE NEAR FUTURE OF CHEMICAL EDUCATION

Chemical education reform is under way in many countries. An important reason for this reform is the growing dissatisfaction with the position of many chemistry curricula: quite isolated from students' personal interest, society and technology issues, and modern chemistry. As a consequence, there is a growing interest in new issues, such as relevant and meaningful contexts (Bennett & Holman, 2002); multimedia tools, including computer software (Ardac & Akaygun, 2004); and multiple meanings of models (Justi & Gilbert, 2002). The new issues are not very specific to chemical education, but are also found in the curriculum reform of the other sciences. Most of them are elaborated in other parts of this book. Although the three exemplar issues—contexts, multimedia, and models—are already mentioned at several places in the previous sections, we will elaborate them more within the limited space available in the present chapter. First, we relate the issue of meaningful contexts and the issue of multimedia tools to the topic of chemical change. Second, we relate the issue of models to the topic of atomic structure and chemical bonding. At the end of the chapter, we briefly pay attention to the preparation of chemistry teachers for teaching multiple meanings, and, as a final note, we point out the need for a more coherent innovation of chemical education.

### Teaching Multiple Meanings through Contexts

One of the most promising contributions to abolishing current curriculum isolation is the use of relevant and meaningful contexts for teaching chemistry topics (Bennett & Holman, 2002). Contexts are often considered as situations in which chemistry or other science concepts, rules, and so on, can help communicate meaning to students. They can come from several domains, such as students' personal life, social

FIGURE 22-2. The tetrahedron of meanings.

life, and scientific life. Mahaffy (2004) even proposes to extend the triangle of meanings into a tetrahedron by adding the context issue (Fig. 22.2).

Usually contexts are presented to students as illustrations of topics already presented as "theory," but interest in another function of contexts is growing, namely contexts as a rationale or starting point for teaching topics. However, it would be naive to expect context-based chemistry courses to provide the solutions to all problems. These courses do not seem to help all students improve their reasoning about chemical reactions (see, e.g., Barker & Millar, 1999). Studies that compare the effects of context-based chemistry teaching with more traditional teaching are quite rare. Ramsden (1997) executed such a comparative study for introductory chemistry teaching at high schools. She found that there is little difference in understanding chemical change, but there appear to be some benefits associated with the context-based approach in terms of stimulating students' interest in chemistry. Although this result may be somewhat disappointing from a cognitive development point of view, it is positive from an affective development point of view. The use of context-based approaches may not solve all of the reported problems with cognitive learning for several reasons. For instance, the contexts might have been too complex or quite unfamiliar to students, and the relation between a context and the intended accompanying concepts might not have been very meaningful to students. What is clear is that the results of existing studies suggest a need for further research in context-based chemistry teaching, especially in terms of the factors that contribute to cognitive learning outcomes.

### Teaching Multiple Meanings Through Multimedia Tools

Within chemical education, there are a fast-growing number of articles on the use of multimedia tools, especially computer software with supplementary handouts. We will not review this literature, but only consider some experiences with teaching and learning the multiple meanings of chemical reactions.

Dynamic sequences of atomic and molecular interactions can be provided by computer-generated graphic representations. For instance, Garnett and Hackling (1999) reported on a short instructional intervention using a CD-ROM on balancing and interpreting chemical equations for high school students. The interactive program was designed to make extensive use of video illustrations of chemical

reactions, followed by animations using dynamic graphics to show particle behavior and balancing chemical equations. Results indicate a growth of students' understanding of chemical formulas and equations as well as in their skills in balancing these equations. Although these results are interesting, the value of the study is limited because it is unknown whether this intervention offers outcomes in excess of those that can be obtained by regular instruction. A comparison between both instructional conditions is made in a study of Ardac and Akaygun (2004) of a multimedia instructional unit that relates the multiple meanings of chemical reactions. They investigated the immediate and long-term (15 months) effects of high school students using this unit and found, for both time periods, that students from the experimental group showed a higher performance level than students who received regular instruction.

Despite success stories about the use of computerized learning environments, disappointing results are also reported. For instance, Wainwright (1989) evaluated a software package as a supplement to traditional instruction in balancing and interpreting chemical equations for high school students. The experimental group received reinforcement via the computer program, while the control group used parallel worksheets for concept reinforcement. After the intervention period, the control group performed significantly higher than the intervention group.

In conclusion, although the effectiveness of multimedia tools varies, they have the potential for enhancing students' understanding of chemical reactions. They can improve students' understanding of more complex reaction types, as studies have shown for acid-base reactions (Nakleh & Krajcik, 1994), redox reactions (Williamson & Abraham, 1995), and equilibrium reactions (Russell et al., 1997). In all cases, these tools require a very careful design and should be properly embedded in an overall teaching approach. More research is required to get a good insight into their use, especially concerning the factors that explain their effectiveness.

## Teaching Multiple Meanings Through Models

In chemistry, it is very common to use models to represent molecular-level structures and processes. That these models are to some extent models of models—as any molecular level description of matter is, strictly, theoretical—complicates learning for students. Much has been written about the various types of models used in science and science education (Harrison & Treagust, 1996), and “model confusion” has been identified as a particular problem for learners in chemistry (Carr, 1984).

Indeed, it has been suggested that it is useful to distinguish between at least three different types of models that are important for chemistry education: scientific, curriculum, and teaching models (Justi & Gilbert, 2000). *Scientific models* are used extensively by chemists—for example to help visualization, theory development, and problem solving. *Curriculum models* are the (often simplified) versions that are set out in syllabuses as acceptable (or even desirable) target knowledge suitable for a particular age group. The level of simplification here may reflect considerations about the learners' overall levels of cognitive development (e.g., the extent to which they are judged to be capable of formal abstract thinking), but also about their limited existing knowledge of a topic. *Teaching models* are constructed for or by teachers to help them communicate the curriculum models to students—

such as a model to help students write Lewis structures when they are learning to understand acid-base reactions at a higher school level (Quilez Pardo, 1989).

The students themselves may not even realize that the target knowledge is a model, as research shows that many students do not appreciate the meanings and roles of models and theories in science (Driver, Leach, Millar, & Scott, 1996). Indeed, studies even suggest that teachers themselves show widely varying sophistication in appreciating the importance and nature of the models they teach about and with (De Jong, Van Driel, & Verloop, 2005; Justi & Gilbert, 2002). In the present chapter, many difficulties are reviewed regarding junior high-school students' understanding of the submicroscopic meaning of chemical reactions, especially how to relate this model to the macroscopic meaning of chemical reactions. At the senior high school level, students use submicroscopic models to explain substance properties and behavior, though these are often alternative models. Indeed, it is very common for the chemical explanations produced at this level to be animistic or even anthropomorphic. Not only does research suggest that junior high school students may think that atoms are alive and grow (Harrison & Treagust, 1996), but even senior high school students may tend to believe that atoms are alive (Griffiths & Preston, 1992). Students seem to use psychological and sociological metaphors to produce explanations of chemical properties and behavior. Atoms are said to *need* and *want* full shells and to be happy once they obtain them (Taber & Watts, 1996).

Given these considerations—the centrality of models and modeling in chemistry, yet the unsophisticated understanding of models shown by students—it seems especially important that curriculum models (which will be presented to students as target knowledge, and often accordingly imbued with a high status by students) should be carefully chosen. Now it is suggested here that there are three clear criteria for any suitable curriculum model:

- (i) It must be presented at a level of complexity and abstraction that fits the developmental levels of the learners concerned.
- (ii) It must build upon conceptual foundations that are already familiar—that is, the prerequisite learning must already be in place. (This suggests that careful conceptual analysis of topics, diagnostic assessment of the range of current learning in a class, and individualized remedial instruction will be important in the effective teaching of these models.)
- (iii) It must form part of a suitable progression of models that facilitates learners' subsequent learning of more advanced models.

We believe that the research that is available suggests that the curriculum models used in high school and undergraduate chemistry education often fail to meet these criteria. For example, the research of Coll and Taylor (2002) suggests that in many teaching institutions the octet explanation for bonding (found by these authors to be commonly used by undergraduate and post-graduate chemists) has such currency in the curriculum that it should be considered as a curriculum model. So, the notion of ionic bond formation as electron transfer between isolated atoms has become a standard curriculum model (see, for example, the curriculum benchmarks recommended in the United States, AAAS, 1993). This model is not only inaccurate, but closely tied to common misconceptions of the ionic bond discussed above—for example, that each sodium atom can only form a bond to one chlorine atom.

We believe that the use of the octet rule as the basis of an explanatory scheme should not be part of any curriculum model. Chemical reactions and bond formation are not explained in chemistry in terms of atoms filling their shells, and this is not a suitable simplification of actual (current) scientific thinking. Moreover, the octet framework seems to act as an impediment to learning more chemically valid models, rather than a suitable intermediate. This suggests that it does not make an appropriate curriculum model.

It might seem odd that such dubious chemical models should be presented as target knowledge in the curriculum. However, a number of studies are now suggesting that many curriculum models reflect ideas that once had scientific currency, but which have fallen into disuse (Justi & Gilbert, 2000; Tsaparlis, 1997). Some of the problems could be overcome if it was ensured that scientific models (those that may no longer be current in chemistry, but still have currency as curriculum models) are presented in their historical perspective, for instance, models of atomic structure (Justi & Gilbert, 2000), or the historical significance of the octet rule in the development of ideas about affinity and valency. Research into other chemistry topics where less attention has so far been paid to curriculum models could be very valuable. In view of the difficulties so many students have understanding the models of chemistry, as revealed in the literature reviewed in this chapter, more research into the status of the prescribed curriculum models, and how learners can be encouraged to appreciate them as models, is needed to inform both curriculum change and the teaching of chemistry itself.

## **Preparation of Chemistry Teachers for Teaching Multiple Meanings**

Teaching chemical topics through modern student-centred courses looks attractive, but it requires teachers to have a very good insight into the topic, because these courses, especially the courses that include a constructivist view on learning, often require students to address questions where the answers are not given in the textbook. This raises the question: are prospective teachers sufficiently prepared for answering authentic questions from students about chemical topics? This question will be considered in the context of teaching the topic of chemical reactions.

At the elementary school level, prospective teachers often show conceptual difficulties, especially when they have no high school background or incomplete high school background in chemistry, as many have. For instance, prospective elementary school teachers tend to believe that mass is not conserved when a piece of paper is burned in a closed system (Ryan, Jiminez, & De Torre, 1989). They may also ignore the conservation of particles when drawing diagrammatic representations of chemical change (Gabel, Samuel, & Hunn, 1987). In more recent studies, Kokkotas, Vlachos, and Kouladis (1998) indicated that prospective elementary school teachers may attribute macroscopic properties to particles, and Del Pozzo (2001) found that they may have difficulty in interrelating macro- and submicroscopic concepts describing the composition of matter in a proper way.

At the secondary school level, prospective chemistry teachers also show conceptual difficulties, although not so many as elementary school teachers. Nevertheless, prospective chemistry teachers may show good understanding of balancing

chemical equations but lack the ability to apply the concepts of conservation of mass and the same number and kind of atoms (Haidar, 1997). They may be able to draw diagrams depicting chemical reactions in terms of particles, but tend to ignore the creation of intermediate products, and to draw loosely packed representations of particles in solid ionic substances (Lee, 1999). Finally, De Jong, Ahtee, Goodwin, Hatzinikita, and Kouladis (1999) found that prospective chemistry teachers are not very familiar with current students' difficulties in understanding combustion at a macroscopic level.

Studies of courses focusing on helping prospective teachers to understand the multiple meanings of chemical reactions and to teach them are rather scarce. Kokkotas, Vlachos, and Kouladis (1998) examined a training course for prospective elementary teachers. The participants were confronted with students' authentic ideas as they are expressed when the students answer questions about the macro- and submicroscopic meaning of the composition of matter and change. Results indicate that the participants show improvement in terms of scientific understanding and knowledge of students' conceptual difficulties. In a study of a teacher training course for prospective chemistry teachers, De Jong and Van Driel (2004) reported that the participants became aware of the need to show students the relations among the multiple meanings in a much more explicit way than they initially tended to do and to ignore their own dominant orientation toward submicroscopic meanings. Moreover, they noticed the importance of the careful and consistent use of symbolic representations, for example, not using the formulas  $\text{NaCl(s)}$  and  $\text{Na}^+\text{Cl}^-(\text{s})$  in the same context.

In conclusion, the reported studies show the importance of courses for teachers that pay attention to improving prospective teachers' knowledge of multiple meanings of chemical topics, and how to teach them. However, *how* prospective teachers link their "course" knowledge with their classroom practice is still not very clear. This is a general problem and requires further research.

## LOOKING FORWARD

Innovations in chemical education should be carried out in a more coherent way than is currently the case. This requires the fine-tuning of at least the following components of innovations:

- (i) The development and implementation of experimental instructional materials and student courses based on new insights into teaching and learning chemical topics, especially with respect to a substantiated content structure for introducing the multiple meanings of many chemical concepts
- (ii) The development and implementation of courses for chemistry teachers, to help them to acquire sufficient knowledge of new topics and appropriate competence to teach in ways that are congruent with the new approaches
- (iii) The design and execution of in-depth and longitudinal studies. The purpose of this research can be twofold:
  - From a theoretical point of view: to develop a better understanding of teaching and learning processes and outcomes with respect to particular chemistry.

- From a practical point of view: to develop guidelines for school and college courses and courses of teacher preparation in chemical education that are informed by research.

The integration of these three innovative steps implies an important challenge for the near future of chemical education.

## ACKNOWLEDGMENTS

# CHAPTER 23

---

## Learning Earth Sciences

**Nir Orion**

*Weizmann Institute of Science, Israel*

**Charles R. Ault, Jr.**

*Lewis & Clark College*

Great news! I've just been accepted into graduate school in geology with the opportunity to work on a terrific project. The professor I'll work with would like someone to do a photographic survey of the Lower Colorado River along the same route as traversed by an expedition of 150 years ago and documented in journals and watercolor paintings. The aim is to compare habitats and channels of today with those from the past within the context of reconstructing climate trends in western North America. The work would be very similar to what I did in Argentina on my fellowship last year, where I visited Charles Darwin's fossil collecting locales and compared his journal entries as well as sketches of landscapes made by the *Beagle's* artist with present-day photographs. I am very excited about getting started, and I can't believe that there is a project in geology so similar to what I have dreamed about doing.

—Message from a twenty-first century graduate student

This young graduate student's excitement echoes the themes and claims developed in this chapter. The message offers a glimpse into the nature of earth science inquiry. The proposed research crosses several disciplines, though housed in the geosciences, and has importance to understanding climate change on different scales in time and space. The data include works of art found in historical literature. The reconstruction of past habitats and the extrapolation of future ones will guide human actions in response to environmental change. The project has intrinsic appeal to some, social value to many. At the dawn of the twenty-first century, earth scientists are doing multidisciplinary and interdisciplinary research serving the public good.

The image of an optimistic student captures several characteristics proposed in this chapter as representative of the earth sciences. Section 1, "Distinctive characteristics," introduces these features, arguing that they are crucial for guiding teaching and learning earth sciences. There follows a profile of earth science education worldwide, including trends evident over the past 25 years. This profile focuses

on significant reforms in geosciences education undertaken at the very end of the twentieth century: the trend away from disciplinary-based science education toward an integrative, environmentally based, earth systems approach, in part a consequence of profound expectations for the science K–12 curriculum stemming from the “Science for All” movement (American Association for the Advancement of Science [AAAS], 1990).

“Learning earth sciences,” Section 2 of this chapter, continues with careful attention to the empirical record of learning earth sciences in schools. Section 2 identifies the main characteristics of earth science education in the schools, such as the integration of subjects within earth sciences and between earth sciences and environmental education. Section 2 then proceeds to examine the cognitive aspects of learning earth sciences: misconceptions, spatial visualization, temporal thinking, and systems thinking. This section ends with a discussion of learning environments for the earth sciences (outdoor and indoor classrooms; the earth science laboratory) and the prospect for cultivating environmental attitudes and insights from learning earth sciences.

Today’s ambitious reform agenda, guided by the principle of “science for all,” scaffolds Section 3. Here the concern becomes how well, or how poorly, teachers have adapted to calls for changing their philosophies of teaching. Section 3 deals with the difficulties of reforming earth science education for science teachers who have limited content knowledge and who may lack the motivation to deal with new priorities among subjects, unfamiliar learning environments, and changes in teaching strategies.

The chapter concludes by challenging researchers to study teaching and learning in the earth sciences not only as historically practiced as a discipline-based curriculum, but also as increasingly practiced as integrated study. The conclusion acknowledges that, from a research perspective, we know very little about teaching and learning earth sciences when they have been thoroughly contextualized: for example, in the context of inquiry about changes in the climate of western North America. Such contexts value knowledge for the sake of making public policy, not only theory-building and model-testing within the earth sciences. Such contexts find promising data not only in records of sediments, but also in historical photography, journals, and art. The chapter ends, in effect, with the challenge to the next generation of researchers to embrace the implications of science for all: ambitious integration and social contextualization. At the same time, the next generation of curriculum designers must preserve distinctive characteristics of the earth sciences when setting objectives for student learning.

## DISTINCTIVE CHARACTERISTICS

Every subject has something important to offer science for all. The challenge is one of establishing priorities. Essential features of what to teach ought to

1. Encompass an “intellectually honest” (Bruner, 1960, p. 33) portrait of what scientists do (e.g., date rocks radiometrically).
2. Emphasize ideas with high conceptual worth or value (Toulmin, 1972), ideas proved to advance thinking and solve problems (e.g., the law of superposition).

The host of individual fields that comprise the earth sciences, the need to integrate these subjects within schools, and the goal of contributing to science for all make characterizing distinctive features imperative. In effect, we are asking, What are the earth sciences about? and What's so important to learn from earth science? The earth sciences are simply about everything beneath our feet and above our heads, with concern for how our collective actions interact with these realms. To learn about the earth sciences is to learn about complex systems on many scales in time and space, about the interactions of these systems with each other and us with them. Learning earth sciences often means learning to think about processes linking the earth's oceans, atmosphere, land, interior, and orbit from a systems perspective. By classifying the learning concepts from the concrete to the abstract, topics from the earth sciences can be presented appropriately to students of all levels of ability, achievement, and age, from kindergarten to high school.

Let us emphasize the notion of "distinctiveness" on four levels: disciplinary, psychological, pedagogical, and sociohistorical. Characterization of the crucial features of a subject begins with attention to phenomena of interest (history of the earth, for example) that are distinctive to the discipline, then turns to cognitively distinctive challenges for learning these phenomena (psychological misconceptions about geologic time, for example). Approaches to pedagogy must demonstrate their responsiveness to such distinctive cognitive challenges (making use of outdoor learning or field study, for example). The endpoint for characterization of a subject's distinctive potential is consideration of its social and historical context: how knowing about climate change and its scale may matter in the personal and social lives of citizens, for example. Derived most explicitly from the geosciences, the use of the label *earth sciences* encompasses a host of fields and subfields in geology, hydrology, oceanography, meteorology, climatology, and even astronomy. Clearly, a definitive characterization of the crucial features of the earth sciences remains well beyond the scope of this (and perhaps any other) chapter. Nevertheless, there are heuristically useful questions to pose in the search for distinctive features of the earth sciences. These features, to repeat, are ones useful to curriculum design, framing the scope of research about teaching and learning earth sciences, and promoting science for all. For example, presumably, from learning earth sciences students acquire an intellectually honest understanding of change through earth's history across many scales. Developing a sense of scale is a distinctive feature of learning earth sciences. The concept of scale functions both psychologically and epistemologically. Psychologically, scale may present obstacles to perception and insight. Epistemologically, extrapolation of earth processes in time and space is a goal of explanation. The geologic time scale encompasses durations and changes vastly beyond the scale of human lifetimes; forecasts of global climate change must wrestle with problems of sampling and modeling on various scales. Such inquiry in the earth sciences has distinctive features; our synthesis highlights six:

1. The *historical approach*, pioneered by Charles Lyell and Charles Darwin, to scientific inquiry (e.g., Darwin's account of the reefs around coral atolls of the Pacific: the islands as a sampling distribution across space and through time of what happens to a volcanic island as it rises and subsides over immense, unwitnessed durations).

2. The concern for *complex systems* acting over the Earth as whole (e.g., the several “spheres”: *hydro, geo, atmo*, and their interaction with the biosphere) as well as analysis of their subsystems on more regional and local scales.
3. The conceptualization of very *large-scale phenomena* through time and across space (e.g., “deep time” and the construction of the geologic time scale).
4. The need for *visual representation* as well as high demand upon spatial reasoning (e.g., the role of geologic maps, contour maps, and the modeling of structures and dynamic processes, such as ocean currents and storms, in three dimensions).
5. The *integration across scales* of solutions to problems (e.g., the validation of meteor impact hypotheses with evidence gathered across scales from mineral crystal to regional topography).
6. The uniqueness of *retrospective scientific thinking*. To unravel processes that took place millions of years ago, geologists have developed a distinctive way of thinking that involves retrospection. Geological inquiry applies knowledge of present-day processes in order to draw conclusions about the conditions of materials, processes, and environments of the past.

The earth sciences are both similar to and distinct from other fields of science. To the extent that earth sciences serve as concrete contexts for better understanding of basic concepts from physics, chemistry, and biology, they inherit many common challenges, for example, using operational definitions, thinking in terms of direct and inverse proportions, and overcoming pervasive misconceptions about energy, motion, particulate matter, inheritance, and adaptation (Driver, Squires, Rushworth, & Wood-Robinson, 1994; Driver, Guesne, & Tiberghien, 1985; Wandersee, Mintzes, & Novak, 1994). The readily accessible contexts for learning earth sciences may introduce young adolescents to features of scientific reasoning such as observing, hypothesizing, and drawing conclusions from evidence. At the same time, learning about the earth sciences presents distinctive challenges and opportunities.

The history and philosophy of science, when turned toward the examination of geological explanations and the concept of geologic time, reveal features of thought characteristic of the earth sciences (Ault, 1998; Brandon, 1994; Cleland, 2002; Gould, 1986; Kitts, 1977; LeGrand, 1988; Schumm, 1991). So, too, does the psychology of learning earth science concepts unveil what is cognitively distinctive about this field (Ault, 1994; Schoon, 1989; Trend, 1998, 2001b).

A strategy of compare and contrast has proved essential to forming understandings of earth's features and systems that have resulted from long and complex histories. Indeed, Gould has characterized approaches to problem solving in geology, paleontology, and evolution, from Lyell and Darwin forward, as a distinctive historical style of argument and explanation in science (Gould, 1986). The objects of explanation—such as mountain building, ice age onset, seafloor topography, storm generation, magma distillation, planetary coalescence, and earthquake frequency—have unique histories. As a consequence of individual history, each example of a basic category has, at some level of resolution, features distinct from other examples of the category (e.g., the Nile River delta is similar to, yet distinct from, other examples of deltas due to similar, though not identical histories of formation).

This insight into the nature of categorization of rocks, volcanoes, river deltas, clouds, moons, and other objects of interest to the earth (and space) sciences con-

trasts with the situation easily noted in chemistry and physics, where fundamental entities come in categories whose members are quite often utterly indistinguishable from each other (Hanson, 1965): protons, atoms of carbon, electromagnetic fields. At an important level, disciplines depart from each other in how they categorize and represent what is most salient about reality, with important consequences for learning from a constructivist standpoint (Driver, Asoko, Leach, Mortimer, & Scott, 1994).

Quite obviously, most subjects are hybrids of theorizing and categorization, and the distinction between fundamental entities that have complex and distinguishing histories (for example, solar bodies) and those basic aspects of reality that differ from each other in well-determined, rule-governed ways (for example, solar energies) refers more properly to endpoints of a continuum, rather than to incommensurable opposites.

In conclusion, the distinctive features of the earth sciences stem from the centrality of historical methods of inquiry pioneered at the dawn of geology. In addition, investigating the earth depends heavily upon spatial reasoning and visual representation. The concept of scale permeates historical methods and visualization tasks, both as an obstacle to cognitive insight (phenomena happening on vast scales, well beyond the purview of human experience) and an arbiter of convincing explanation (solutions to problems on different scales must cohere). When geologic scale and historical complexity are combined with basic ideas from physical and life sciences, earth systems thinking emerges, with attention to dynamism on global scales of interest and the realization that human action affects earth systems on global scales. In brief, people acting collectively have become geologic agents, and their societies can change climates across local, regional, and global scales. Human communities consume earth resources and depend upon earth systems for the disposal of wastes. Too obviously, degradation, scarcity, and pollution reach levels that threaten human communities or interfere with vital “ecosystem services” that undergird agricultural productivity, maintain habitat and biological diversity, clean both air and water, and ameliorate climatic variation. Hence, there would appear to be no clear or useful demarcation between learning earth sciences and learning environmental sciences.

The general themes of interdisciplinary study, multidisciplinary study, environmental issues, and relationship to social responsibility invariably lie close to the surface when learning earth sciences. “Holistic” properly describes this situation. Learning earth sciences offers holistic perspectives to science for all, and this holism entails a shift from traditional science teaching.

## Shifting Profiles

The stature and role of learning earth sciences in keeping with the goal of science for all has shifted in recent decades. Examples of this shift exist worldwide, and these examples answer questions such as:

1. What status does and should earth science occupy in school science?
2. How has the profile of earth science education changed in recent decades?
3. What does learning earth sciences, when linked to environmental education, offer as part of science education for all?

At the level where distinctions between earth and environmental sciences melt away, there arises another general theme of extraordinary importance: the conduct and understanding of sciences in social contexts. Citizens with knowledge of earth sciences clearly have some capacity to choose (or hold leaders accountable for choosing) policies in light of their consequences for earth systems and for society to exist in profitable harmony with earth resources.

Increased multidisciplinary and interdisciplinary research within the sciences and across other fields has had a conspicuous impact on the earth sciences. For decades a new field has grown rapidly: environmental geology. This field embraces most of the topics traditionally addressed in the earth sciences from the perspective of human interaction with natural systems (Tank, 1983; Pickering & Owen, 1994).

The time has come for science education to situate itself squarely within the educational conversation about social justice, poverty, wealth, sustainability, and the human condition. The National Science Education Standards (NSES) for the United States invite science educators to do so in the standard *Science in Personal and Social Perspective* (National Research Council, 1996). This conversation is at the same time about the nature of democratic institutions for governing the use of earth resources and affecting earth systems. The features distinctive of the earth sciences clearly align with these aims. Systems thinking, hierarchy theory, holistic explanation, and attention to scale and complexity bind learning earth sciences to environmental topics. Indeed, the environmental imperative and the role of learning earth sciences in order to achieve environmental insight has achieved a central position in the field of earth science education (Mayer & Armstrong, 1990; Brody, 1994; Mayer, 1995; Orion, 1996).

In many respects education in earth sciences has, in fact, converged upon environmental education in nations around the globe. In addition, changes in curriculum have often treated the subject more from the perspective of integration and systems (holism) rather than from the perspectives of separate disciplines (reductionism). Whether from the point of view of integrating multiple disciplines, from the acknowledgement that the phenomena of interest are complex, interacting systems, or simply in response to the imperative of educating citizens for making environmentally responsible decisions, the profile of learning earth science has changed in recent decades. It will continue to change in the direction of holism, in the sense of the multidisciplinary study of complex systems and from the standpoint of environmental concerns.

Reductionist philosophy has historically constrained the introduction of earth sciences within school science curricula by prioritizing physics, chemistry, and biology. Reduction of science literacy to competence within these three fields has allowed relatively limited time for learning earth sciences. The reductionist paradigm works quite well in keeping with the goal of science education as a preparation of a nation's new generation of scientists. From the perspective of science for all, it has serious limitations.

The shift toward a science for all paradigm places the earth sciences in a better position. The new paradigm sets the goal for science education as preparation for citizenship. Science for All Americans (AAAS, 1990) defines minimal levels of scientific literacy. The Benchmarks for Science Literacy (AAAS, 1993), which followed Science for All Americans, advocates balancing scientific knowledge, the processes

of science, and the development of personal-social goals (Bybee & Deboer, 1994). The United Kingdom has adopted a similar approach in the National Curriculum for England and Wales (Department of Education and Science [DES], 1989). In the United States, the National Science Education Standards (NSES; National Research Council, 1996) encompass eight categories of content. Four are traditional categories (physical, life, earth and space, science and technology); two incorporate holistic conceptions of science (unifying concepts and processes, science as inquiry) and two examine science within wider contexts (science in personal and social lives, history and nature of science). Reform topics have equal billing with traditional subjects in the NSES.

The shift from direct instruction toward constructivist pedagogy also has influenced the profile of science education (Mintzes & Wandersee, 1998; Driver et al., 1994; Driver et al., 1985; Osborne & Wittrock, 1985; Bezzi, 1995). The constructivist approach acknowledges that individuals must construct new understandings in light of personal experience and private meanings. Constructivists recognize, in addition, the importance representations of reality (models, diagrams, equations, and category systems) play within the epistemology of a subject (Driver et al., 1994). Learners must assume personal responsibility to construct these representations and compare their thinking with that of others when in pursuit of "shared meaning" (Gowin, 1981). A constructivist might ask, "Is the concept adequate to the purpose it serves?" rather than "Is the idea true?" From a constructivist standpoint, pedagogy ought to engage students in learning meaning through the use of concepts rather than expecting them to learn ideas simply from listening to lectures and studying texts.

Conceptual change theory (Posner, Strike, Hewson, & Gertzog, 1982; Smith, 1991) has also exerted a strong influence over science teaching. Conceptual change theory recognizes that beliefs about knowledge shape student efforts to learn science. Conceptual change theory, using historical examples of major shifts in scientific conceptualizations, focuses on the adequacy of ideas. Ideas that are adequate resolve anomalies in plausible ways. In addition, they are intelligible in terms of current understanding and fruitful in the creation of new knowledge. Smith has elaborated upon conceptual change theory by describing the understanding it fosters as "usefulness in a social context" (Smith, 1991).

The concept of sea floor spreading, for instance, resolved anomalies in the pattern of magnetic fields recorded on ocean bottom rocks (a pattern detected incidentally and puzzlingly during attempts to detect enemy submarines during World War II; see LeGrand, 1988). Sea floor spreading made plausible the notion of drifting continents; the concept has proved enormously fruitful as a component (and precursor) of plate tectonic theory. Now, understandings of geologic hazards due to seismic and volcanic activity depend upon knowledge of plate tectonic theory. Public policy, from building codes to tsunami alerts, has made this knowledge useful in a social context.

Problems, projects, and issues often provide a proper context for promoting meaningful learning. No doubt many students are exposed in their daily lives or through the mass media to earthquakes, volcanoes, global atmospheric changes, journeys to Mars, ocean pollution, fresh water shortages, energy conservation, floods, hurricanes, landslides and avalanches, etc. These topics are contextual goldmines

from a constructivist standpoint: opportunities to engage students in the construction of meaning through the use of concepts in personally relevant contexts.

Constructivism and holism have influenced the profile of learning earth sciences in another and very fundamental way: the growing interest in earth systems education. At least 15 countries have undertaken to reform science teaching by placing greater emphasis on the dynamic systems of the Earth (Mayer, 2002).

## **Earth Systems Science and Education**

Earth science education worldwide has undergone a process of revival during the past decade. Since 1993 four international conferences on geoscience education have been conducted in Europe, the United States, Australia, and Canada (Stow & McCall, 1996; IGEO, 1997, 2000, 2003). At the first international conference in England participants widely supported the proposal to reinforce the environmental aspect of learning earth sciences (Carpenter, 1996; Orion, 1996; Mayer, 1996). In 1997 in Hawaii earth science educators convened again for an international conference, this time titled "Learning about the Earth as a System" (IGEO, 1997). Now, at the beginning of the twenty-first century, earth science educators accept that the purpose of earth science education for ages 5–19 is both to educate for citizenship and to prepare students to become professional geoscientists.

Orion and Fortner (2003) have argued that the earth systems approach is ideal as a holistic framework for science curricula. The starting point is the four earth systems: geosphere, hydrosphere, atmosphere, and biosphere. The study of cycles organizes earth systems education: the rock cycle, the water cycle, the food chain, and the carbon cycle. The study of these cycles emphasizes relationships among subsystems through the transfer of matter and energy based on the laws of conservation. Such natural cycles should be discussed within the context of their influence on people's daily lives, rather than being isolated to scientific disciplines. The earth systems approach also connects the natural world and technology: technology transforms raw materials that originate from earth systems.

Through the elaboration of cycles, the approach underscores that society is a natural part of the systems of the Earth and that manipulation of one part of this complex system might adversely affect people. In contrast with traditional approaches for teaching science, the earth systems approach does not sequence the curriculum using topics from physics or chemistry. Instead, this approach organizes study in terms of systems and cycles as experienced in peoples' lives. It does utilize physics and chemistry as tools for understanding science at a deeper and more abstract level within this context. However, the main educational goal is the development of environmental insight in two senses. First, we live in a cycling world that is built upon a series of subsystems (geosphere, hydrosphere, biosphere, and atmosphere) that interact through an exchange of energy and materials. Second, people are a part of nature and thus must act in harmony with its laws of cycling.

Ten years after introducing the earth systems approach, Mayer introduced Global Science Literacy (GSL; Mayer, 1997, 2002, 2003). GSL expands the argument for new science curricula for secondary schools. Instead of presenting major disciplines, Mayer argued the importance of organizing curricula with the "Earth System" concept. This approach includes teaching the methodology of system sciences and capitalizing on the cross-cultural characteristics of science.

The Earth System concept embraces holism and extends learning earth sciences into environmental, social, and political debate. However, do scientists practice holistic science? Yes; holism exists as a basic goal of research within the earth and space sciences community, as the following example illustrates.

The year 2003 witnessed in the United States the inauguration of an unprecedented multidisciplinary, earth and space science program of research: EarthScope. The National Science Foundation (NSF), the United States Geological Society (USGS), and the National Aeronautics and Space Administration (NASA) together with a number of prestigious research universities have combined resources to advance knowledge about North America's

three-dimensional structure, and changes in that structure, through time. By integrating scientific information derived from geology, seismology, geodesy, and remote sensing, EarthScope will yield a comprehensive, time-dependent picture of the continent beyond that which any single discipline can achieve. Cutting-edge land- and space-based technologies will make it possible for the first time to resolve Earth structure and measure deformation in real-time at continental scales. These measurements will permit us to relate processes in Earth's interior to their surface expressions, including faults and volcanoes. (EarthScope Project Plan 2001, pp. 1–2)

EarthScope organizers fully expect to affect school and museum science in substantial ways, as an example of integrated science and a resource for real-world data. EarthScope is the preeminent example of "holistic" work in earth and space science. Its education and outreach components are as essential as its primary investigations because among its fundamental goals is achieving understandings of volcanoes and earthquakes needed to promote public safety, commerce, and engineering.

The profile of learning earth sciences continues to shift, as does the practice of earth and space science: from isolated, disciplinary agendas, to integrated research with outcomes of interest to the public; from separate concern for earth history and systems, to convergence upon themes essential to environmental science and education; from less reductionism to more holism; from direct instruction based upon text materials to constructivist pedagogy with access to real-world data.

## LEARNING EARTH SCIENCES

### Cognitive Aspects of Learning Earth Sciences

The following section describes several traditions of research about learning earth sciences. Collectively, these studies inform those whose aims are to fulfill the educational potential of learning earth sciences as part of science for all. We have grouped studies of cognitive learning in earth sciences as examples of alternative frameworks research, studies of spatial visualization, examination of temporal thinking, and investigations of systems thinking.

### Alternative Frameworks of Learners Concerning Earth Sciences Concepts

The constructivist paradigm has dominated the field of science education in recent decades, producing studies of misconceptions, preconceptions, naive ideas, and al-

ternative frameworks. Although there are relatively few published studies of students' alternative frameworks in earth sciences education, findings and patterns have emerged in four areas (see Ault, 1994, for an earlier review of this literature and related studies of "expert and novice" styles of solving earth science problems):

1. Students' conceptions of processes and mechanisms of geospheric change, including plate tectonics, the rock cycle, earthquakes, and erosion (Ault, 1984; Happs, 1985; Ross & Shuell, 1993; Bezzi & Happs, 1994; Lillo, 1994; Marques & Thompson, 1997a,b; Schoon, 1989; Gobert & Clement, 1998; Stofflett, 1994; Dove, 1997, 1999; Gobert, 2000; Kali, Orion, & Elon, 2003; Libarkin et al., 2005).
2. Students' and teachers' understanding and conceptions of the Earth's interior (DeLaughter, Stein, Stein, & Bain, 1998; Gobert & Clement, 1998; Marques & Thompson, 1997a,b; Lilio, 1994; Nottis & Ketter, 1999; King, 2000; Beilfuss, Dickerson, Boone, & Libarkin, 2004).
3. Students' and teachers' perceptions of geological deep time (Happs, 1982a,b; Marques, 1988; Oversby, 1996; Schoon, 1989; Marques Thompson, 1997a; Noonan-Pulling & Good, 1999; Trend, 1997, 1998, 2000; Dodick & Orion, 2003a, 2003b).
4. Students' and teachers' conceptions of hydrospheric processes and the water cycle (Meyer, 1987; Fetherstonhaugh & Bezzi, 1992; Brody, 1994; Taiwo, Ray, Motswiri, & Masene, 1999; Agelidou, Balafoutas, & Gialamas, 2001; Dickerson, 2003; Ben-zvi-Assaraf & Orion, 2005; Beilfuss et al., 2004).

Review of the above studies indicates that children, adolescents, and adults hold alternative frameworks in relation to almost every topic in the earth sciences. These alternative frameworks are seen across nations, cultures, and ages. Some of these frameworks emerge as students encounter difficult abstractions about the Earth in conflict with the scale of their everyday perceptions. For example, students overestimate the effect of external forces of the Earth observed directly at its surface and fail to appreciate the importance of the internal forces shaping structures. They struggle with their perceptions of geological time and spatial phenomena. Finally, they often misconceive the interior of the Earth and the state of matter within the interior of the Earth.

Review of these studies leads to another striking conclusion: the same preconceptions appear across grade levels, from kindergarten to college. These studies indicate that schooling all over the world has influenced only in a limited way the ability of students to construct scientifically sound conceptions of the Earth, congruent rather than in conflict with knowledge from the earth sciences.

Sadly, the literature suggests that many teachers hold the same alternative frameworks as their students and that even text materials foster misconceptions. Thus, it seems that earth science education in many countries is trapped in a cycle of ineffective instruction and inadequate learning—with preconceptions and misconceptions dominating learning earth sciences. Research studies about earth science education have the potential to break this nonproductive cycle.

## Visualization and Spatial Reasoning

Teaching and learning earth sciences at all levels relies upon spatial reasoning. The phenomena of interest sometimes have simple geometries, though on grand scales: spiral structures of galaxies, gyres in ocean circulation, axes of synclinal folds. Sometimes the geometries are confusing: the intersection of complex topography with complicated stratigraphy, for example. Sometimes the surfaces of interest are mapped indirectly: gravitational anomalies and magnetic fields. And most confusingly, the geometries change with time.

Often earth science phenomena have challenging geometries. As a result, earth scientists use visual representations to record and study them. These representations place demand upon spatial reasoning as well. There are contour maps of a host of phenomena to master, from topography to pressure gradients, from glacial thickness to stress fields. Geologic maps contour time. Maps are two-dimensional representations yet often include data about three-dimensional structures. Seeing “through the surface” to visualize three-dimensional structure is indeed challenging. Sometimes, visualization requires skill at projecting structures from three dimensions onto two. Consider also that visual patterns among sedimentary rocks record in three dimensions events through time. In geology, visual pattern is the key to unlocking temporal puzzles.

Although the basic dependence of geoscientists on spatial abilities has long been recognized (Chadwick, 1978), the geoscience education community has only begun to explore the array of spatial reasoning abilities for learning earth sciences (McAuliffe, Hall-Wallace, Piburn, Reynolds, & Leedy, 2000). These spatial reasoning abilities may, in fact, be quite distinct from those commonly associated with tasks in learning chemistry (Dori & Barak, 2001; Pribyl & Bodner, 1987), physics (Pallrand & Seeber, 1984), and engineering (Hsi, Linn, & Bell, 1997).

The spatial objects that are studied in the geological sciences are usually large enough to walk in physically (the field learning environment). Block models can also readily represent them, as can more sophisticated renderings in a virtual setting. In the earth sciences, these blocks are visualized, but rotated, inspected, and modified to reflect temporal changes.

An understanding of deep geologic time also is associated with spatial cognition (Dodick & Orion, 2003a, 2003b). There is additional evidence that the outdoor field learning environment enhances the ability to construct a coherent narrative for layers of sedimentary rocks as experienced in the field (Orion, Ben-Chaim, & Kali, 1997; Riggs & Tretinjak, 2003).

Kali and Orion (1996) characterized the specific spatial abilities required for the study of basic structural geology. To do this they developed a geologic spatial ability test (GeoSAT), in which students were required to draw two-dimensional cross sections of geological structures that were represented as block diagrams. Their outcomes indicate that the problem solving involved in GeoSAT requires a special type of spatial visualization, which they named VPA (Visual Penetration Ability). Spatial visualization is defined as the ability to create a mental image from a “pictorially presented object” and to operate different mental manipulations on those images. The manipulations usually referred to are mental rotation and mental translation. In contrast, the manipulations involved in VPA are to visually penetrate into a three-dimensional mental image in order to envision two-dimensional cross sections.

Based on their findings about VPA, Kali and Orion developed Geo3D, a software package designed to assist high school students in developing their VPA and in acquiring the skills needed for understanding basic structural geology (Kali & Orion, 1997). Using four case studies, they showed that even with a short-term interaction with the software, students significantly improved their ability to solve the problems involved in GeoSAT. Hsi, Linn, and Bell (1997) have also demonstrated the advantage of virtual worlds and computer tools in improving learners' capability to solve problems that require spatial skills. They found that students acquired spatial skills in relatively short time with the use of technological tools.

The NSF-funded Hidden Earth Project (Reynolds et al., 2002) successfully investigated the role of spatial visualization in an introductory geology course. This project developed web-based versions of three standard visualization tests (Cube Rotation, Spatial Visualization, and Hidden Figures) and a geospatial test, containing items of the more visual aspects of geology, such as visualization of topography from contour maps. Reynolds and others developed innovative instructional modules for (1) Visualizing Topography and (2) Interactive 3D Geologic Blocks. An experimental group used these modules, and the control group did not. Although all subjects profited from both the control and the experimental conditions, the effectiveness of the treatment experienced by the experimental group was confirmed by Analysis of Variance and a comparison of normalized gain scores. Very powerful gender effects have also been demonstrated, with the experiment equalizing the performance of males and females in a case where the performance of males was initially superior to that of females. The experiment also was very effective at improving scores and lowering times to completion on the spatial visualization test.

As part of the Hidden Earth Curriculum Project, Reynolds, Piburn, and Clark (2004) conducted a detailed investigation of college student's pre-instructional knowledge, skills, and misconceptions about visualizing topography from contour maps. Students completed pre-tests and post-tests, and selected students were interviewed to assess what their initial skills and strategies were. These interviews exposed several previously unrecognized misconceptions about topographic maps, and a Topographic Visualization Instrument was developed to see how prevalent these misconceptions were in a broader sample of students.

Spatial cognition in a geoscientific problem-solving context must address more than two-dimensional representations of three-dimensional objects. In a geoscientific problem, students inspect three-dimensional objects and infer temporal histories from spatial features.

Studies in geoscience education for Native American students show that students from certain cultural backgrounds more readily learn geoscience in a field setting than do others (Riggs, 2003; Riggs & Semken, 2001). There is probably some robust connection between place-based, indigenous cultures and their success in field-based learning spatial reasoning. Clearly, experience plays an essential role in developing spatial reasoning ability.

## Temporal Thinking

In the history of geology two discoveries, plate tectonics and geological time, have determined how geologists view the Earth. Geological time means the understanding (aptly referred to by John McPhee in 1980 as "deep time") that the universe has

existed for countless millennia, and that humanity's earthly dominion is confined to the last milliseconds of a metaphorical geological clock.

The understanding of geological time has shaped numerous disciplines, especially geology, cosmology, and evolutionary biology (Dodick & Orion, 2003c). Roseman (1992) noted in a review of the literature of science education that there "was next to nothing about . . . how kids' understanding of notions of systems, scale or models develop over time" (p. 218). Since that time, there have been several large-scale studies of how students understand this concept. They divide roughly into two groups: "event-based studies" and "logic-based studies."

Event-based studies include all research that surveys student understanding of the vast duration of "deep time" (that is, time beginning with the formation of the Earth or the universe). In such studies, the general task is sequencing a series of events (for example, the first appearance of life on Earth) absolutely, along a time line, or relatively, using picture-sorting tasks. Often the subject is asked to justify his or her reasons for the proposed temporal order. Such studies include: Noonan-Pulling and Good's (1999) research on the understanding of the origins of Earth and life among junior high students; a similar study by Marques and Thompson (1997a) with Portuguese students; and Trend's studies on the conception of geological time among 10–11-year-old children (Trend, 1997, 1998), 17-year-old students (Trend, 2001b), and primary teacher trainees (Trend 2000, 2001a).

Qualitative research (structured interviews) with small sample groups dominates the literature. There has never been a large-scale, quantitative study of older students' (junior high to senior high) understanding of geological time.

In logic-based studies, the researcher is interested in the cognitive processes undergone by students when they are confronted with problems of geologic time. It might be added that such studies are more concerned with probing the subject's logical processes rather than his or her knowledge of earth science.

This approach is seen in the work of Ault (1981, 1982) and Dodick and Orion (2003a, 2003b). Ault interviewed a group of 40 students from grades kindergarten, two, four, and six, using a series of puzzles that tested how they understood (and could reconstruct) a series of geological strata. Based on Zwart's (1976) suggestion that the development of people's temporal understanding lies in the before and after relationship, Ault (1981) theorized that children organize geological time relationally.

Based on his findings, Ault (1981, 1982) claimed that young (grade 2–6) children's concept of conventional time in a logical sense (reasoning about before and after) was no impediment to their understanding of geologic events. Many of the children in his test group were successful at solving puzzles involving skills necessary to understanding the logic, though not the extent, of geological time. Nonetheless, in the field, these same children had difficulties in solving similar types of problems, indicating that there was little transfer from classroom problems to authentic geological settings. Children believed rock layers in the field to be old, based upon their being dark or crumbly—not based upon their position in a series of strata.

Piaget's (1969) work on time cognition influenced and restricted Ault's (1981) research design. According to Piaget, a young child's understanding of time is tightly bound to his or her concept of motion; thus, the research problems he used were taken from physics. However, geological science builds its knowledge of time

through visual interpretation of *static* entities (formations, fossils; Frodeman, 1995, 1996). Indeed, there is no reason to suggest that an understanding of the (logical) relationships among strata should necessarily allow one to both conceptualize and internalize the entirety of geological time.

Dodick and Orion (2003a, 2003b) conducted a large-scale study with junior high and high school students using validated, reliable quantitative tools. In this study, geological time was divided into two different concepts:

1. A (passive) temporal framework in which large-scale geological events occur. Such understanding depends upon building connections between events and time. In the cognitive literature this is comparable to Friedman's (1982) associative networks, a system of temporal processing used for storing information on points in time. By this reasoning, an understanding of geological time should be mitigated by a person's knowledge of such events.
2. A logical understanding of geological time used to reconstruct past environments and organisms based on a series of scientific principles. This is similar to the work done in logic-based studies, noted above. Based on this definition, it might seem that students unfamiliar with geology might be unable to reconstruct a depositional system; however, in structure, geo-logic is comparable to Montagnero's (1992, 1996) model of "diachronic thinking." He defines diachronic thinking as the capacity to represent transformations over time; such thinking is activated, for example, when a child attempts to reconstruct the growth (and decay) cycle of a tree.

Montagnero (1996) argues that there are four schemes, which are activated when one attempts to reconstruct transformational sequences. Dodick and Orion translated three of these schemes into the logical skills needed to solve temporal problems about geological strata:

1. *Transformation*: This scheme defines a principle of change, whether qualitative or quantitative. In geology it is understood through the principle of actualism (i.e., the present as key to the past).
2. *Temporal Organization*: This scheme defines the sequential order of stages in a transformational process. In geology, principles based on the three-dimensional relationship among strata (ex: superposition) are used in determining temporal organization.
3. *Interstage Linkage*: The connections between the successive stages of transformational phenomena. In geology such stages are reconstructed via the combination of actualism and causal reasoning.

For the purposes of this research, Montagnero designed a specialized (validated) instrument, the GeoTAT, consisting of a series of open puzzles that tested the subject's understanding of diachronic schemes as applied to geological settings.

In addition, two other questionnaires were distributed to subunits of this population to answer questions that arose through the use of the GeoTAT: (a) a Time-Spatial Test (or TST), which tested the possibility that spatial thinking influences temporal thinking and (b) a Stratigraphic Factors Test (SFT), which tested the influence of (geological strata) dimensions on students' temporal understanding. In ad-

dition, researchers pursued qualitative research in the classroom and field by studying and interviewing students who were studying geology and paleontology as part of their matriculation studies.

From this study Montagnero constructed a model of temporal thinking. This model identified abilities needed to reconstruct geological features in time:

1. The transformation scheme, which influences the other two diachronic schemes.
2. Knowledge, most importantly empirical knowledge (such as the relationship between environment and rock type) and organizational knowledge (i.e., dimensional change).
3. Extracognitive factors, such as spatial-visual ability, that influence how a subject temporally organizes three-dimensional structures such as geological strata.

Among students who were not taking geology as part of their school program, it was seen that there was a significant difference between samples composed of high school and ninth-grade students (on the one hand) and seventh-grade students (on the other) in their ability to understand geological phenomena with the use of diachronic thinking. This suggests that somewhere between grades 7 and 8 it should be possible to start teaching some of the logical principles permitting one to reconstruct geological structures. These include complex superposition (consisting of tilted strata) and correlation (two outcrop problems), which rely on the use of isolated diachronic schemes, as well the integrated use of all the diachronic schemes to solve complex problems of deposition.

Moreover, this research shows that the ability to think diachronically can be improved if practiced in the context of learning earth sciences. A comparison of high school (grade 11–12) geology and non-geology majors indicated that the former group held a significant advantage over the latter in solving problems involving diachronic thinking. This relationship was especially strengthened by the second year of geological study (grade 12), with the key factor in this improvement (probably) being exposure to fieldwork. Fieldwork both improved students' ability to understand the three-dimensional factors influencing temporal organization and provided them with experience in learning about the types of evidence that are critical in reconstructing a transformational sequence.

The work of Riggs and Tretinjak (2003) supports this finding. Riggs and Tretinjak studied a non-majors course in earth science for pre-service elementary school teachers. They were able to show that integrated field investigations enhance higher-order content knowledge in geoscience, specifically the understanding of environmental change through time as read from the sedimentary rock record. Prior to the field trip students could identify past environments from sedimentary rock, but only after completing the fieldwork unit were they able to understand these rocks as a dynamic temporal/historical record. This is consistent with the findings of Dodick and Orion (2003a, 2003b), who found a correlation between the understanding of geologic time and spatial ability, which in turn implies that well-designed geologic fieldwork will enhance both, even for non-majors. There currently is no comparable data of this nature for geoscience majors, nor do we fully understand the reasons for this correlation among temporal/spatial/and field abilities.

In addition to the studies mentioned above, one might add the small body of research that catalogues general misconceptions in geology and includes within its parameters problems related to geological time (Happs, 1982a,b; Marques, 1988; Oversby, 1996; Schoon, 1989). Finally, one might note those works that have focused on the practical elements of teaching the scale of time (Everitt, Good, & Pankiewicz, 1996; Hume, 1978; Metzger, 1992; Ritger & Cummins, 1991; Rowland, 1983; Spencer-Cervato & Day, 2000). Unfortunately, these teaching models have never been critically evaluated, so they are of untested value to the pedagogic literature.

## Systems Thinking

Current earth science education is characterized by a shift toward a systems approach to teaching and curriculum development (Mayer, 2002). Earth science educators call for reexamination of the teaching and learning of traditional earth science in the context of the many environmental and social issues facing the planet (IGEO, 1997). Orion (1998, 2002) claimed that since the natural environment is a system of interacting natural subsystems, students should understand that any manipulation in one part of this complex system might cause an effect in another part, sometimes in ways that are quite unexpected.

Systems thinking is regarded as a type of higher order thinking required in scientific, technological, and everyday domains. Therefore, researchers in many fields have studied systems thinking extensively, for example, in the social sciences (e.g., Senge, 1998), in medicine (e.g., Faughnan & Elson, 1998), in psychology (e.g., Emery, 1992), in decision making (e.g., Graczyk, 1993), in project management (e.g., Lewis, 1998), in engineering (e.g., Fordyce, 1988), and in mathematics (e.g., Osimitz, 2000). However, little is known about systems thinking in the context of science education.

During the late 1990s and the beginning of this decade three studies were conducted at the Weizmann Institute of Science in relation to system thinking as part of the field of learning earth sciences. Gudovitch and Orion (2001) studied systems thinking in high school students and developed a system-oriented curriculum in the context of the carbon cycle. Kali, Orion, and Elon (2003) studied the effect of a knowledge integration activity on junior high school students' systems thinking, characterizing students' conceptions of the rock cycle as an example of systems thinking. Ben-zvi-Assaraf and Orion (2004) explored the development of system thinking skills at the junior high school level in the context of the hydro (water) cycle.

Gudovitch (1997) examined students' prior knowledge and perceptions concerning global environmental problems in general and the role of people among natural systems in particular. Importantly, the curriculum in this study provided a means of stimulating students to explore the carbon cycle system. Gudovitch found that students' progress with systems thinking consisted of four stages:

1. The first stage includes an acquaintance with the different Earth systems and an awareness of the material transformation between these systems.
2. The second stage includes an understanding of specific processes causing this material transformation.

3. The third stage includes an understanding of the reciprocal relationships between the systems.
4. The fourth stage includes a perception of the system as a whole.

Ault (1998) referred to drawing conclusions about past events as “retrodiction” (a term drawn from Kitts, 1977) as opposed to prediction. Often retrodictions follow from observations of phenomena in present time presumed to sample what has happened through time. The challenge is “to hypothesize an arrangement by stages for what is observed” (p. 196). Stages stand for periods of time; retrodiction and stage inference go hand in hand. Coral atolls, arc volcanoes, and river basins are often explained as developing through stages over time. Examples of a volcano, coral atoll, or river basin at any stage of development exist in the present. Hence, place substitutes for time in order to make retrodictions; one example is another’s future.

Kali, Orion, and Elon (2003) claimed that understanding the rock cycle is exactly such a challenge and that such a challenge requires systems thinking. They studied seventh-grade students who participated in learning a 40-hour unit. The main challenge was to assist students in understanding the rock cycle as a system, rather than a set of facts about the Earth’s crust.

Kali, Orion, and Elon (2003) reported that while answering an open-ended questionnaire about the rock cycle, students expressed a systems-thinking continuum, ranging from a completely static view of the system to an understanding of the system’s cyclic nature. They suggested placing dynamic thinking (which is a critical aspect of systems thinking) on a continuum, in which one side represents a static view and the opposite side represents a highly dynamic view of the system. On top of this continuum they superimposed a dimension of interconnectedness. In the case of the rock cycle, they based higher, more dynamic understanding upon making connections between parts of the system. At the low end of this continuum they located students who expressed a lack of connectedness between parts of the system, indicated poor dynamic thinking, and represented a completely static view of the rock cycle system. At the opposite end of the continuum there were the students who thought dynamically about material transformation within the rock cycle and therefore demonstrated a rich understanding of the interconnectedness between parts of the system. With such a view students were able to grasp the holistic idea that any material in a system can be a product of any other material and apply this insight to novel situations.

It is important to note that students’ alternative incorrect models of the rock cycle described above were not interpreted as misconceptions, or naive theories, about the Earth’s crust. Rather, placing these models on a continuum reflects the view that such models can serve as the basis for developing more sophisticated models, until the highest level of understanding the cyclic nature of the system is reached.

Ben-zvi-Assaraf and Orion (2005) used a large battery of qualitative and quantitative research tools in order to explore the development of systems-thinking skills of junior high school students who studied the water cycle as part of the “Blue Planet” program. The pre-test findings indicated that most of the students sampled experienced substantial difficulties in all aspects of systems thinking. They even struggled to identify basic system components. They entered the eighth grade holding an incomplete and naive perception of the water cycle and were only acquainted

with the atmospheric component of the cycle (i.e., evaporation, condensation, and rainfall). They ignored the groundwater, biospheric, and environmental components. Moreover, they lacked the dynamic and cyclic perceptions of the system and the ability to create a meaningful relationship among the system components as stages linked through processes. Ben-zvi-Assaraf and Orion (2005) found the same phenomenon of disconnected "islands of knowledge" that Kali, Orion, and Elon (2003) reported in reference to how students conceived of the rock cycle. Most of the students were not able to link the various components of the water cycle together into a coherent network of processes and stages. Some of them demonstrated an ability to create a relationship between several components, but even those students were not able to draw a complete network of relationships.

The post-test findings indicated that most of the students shifted from a fragmented conception of the water cycle toward a more holistic view. About 70% of the students who initially grasped only the atmospheric component of the water cycle significantly increased their familiarity with the other stages and processes of the water cycle. For about half of the students, this knowledge improved their ability to identify relationships among the stages and processes of the water cycle. The classification of students' achievements indicated that the development of systems thinking in the context of the earth systems consists of several sequential stages arranged in a hierarchical pyramid structure. The findings of a hierarchical notion and the interrelationships between dynamic perception and cyclic perception are in accordance with the studies of Kali, Orion, and Elon (2003) and Gudovitch (1997). Thus, it suggested that these findings might be generalized to the study of the earth systems. In light of the findings and conclusions of the above studies, it is suggested that the following aspects might contribute to improvement of students' abilities to develop systems thinking:

1. Focusing on inquiry-based learning.
2. Using the outdoor learning environment for the construction of a concrete model of a natural system.
3. Using knowledge integration activities throughout the learning process.

There are interesting connections among the several cognitive studies mentioned above. For example, Dodick and Orion (1993a) reported an interrelationship between temporal thinking ability and spatial thinking ability. Orion, Ben-Chaim, and Kali (1997) and Riggs and Tretinjak (2003) determined that geological outdoor experiences tended to increase students' spatial thinking abilities. Ben-zvi-Assaraf and Orion (1994) found systems thinking about the Earth to be related to temporal thinking (retrospective thinking) and spatial perception (the ability to perceive the hidden parts of a system). Here again, the outdoor learning environment turned out to be a very effective tool for developing a concrete, realistic perception of nature serving as a cognitive bridge for the development of abstract thought: temporal, spatial, and systems thinking. Moreover, all of the above studies acknowledged the significance of alternative frameworks and experiences that most students bring to earth science classes (no matter what age), thus indicating the need to respond to preconceptions and misconceptions with appropriate instruction, whether in the laboratory, the outdoors, or the classroom, or when working with computers.

Despite the limited amount of research about learning earth sciences, a holistic framework has emerged to guide teachers who work within an earth systems approach. Holism in this sense refers not only to the systems approach, but also to the interconnectedness of spatial reasoning and temporal thinking and the cultivation of environmental insight.

## The Integration of Learning Environments within the Earth Sciences

An important characteristic of earth science education (and other sciences as well) is the potential to conduct formal teaching in a variety of learning environments: the classroom, the laboratory, the outdoors (field site, museum, or industrial site), and the virtual worlds of computers.

*The outdoor learning environment.* Review of the proceedings of the three International Geosciences Education Organization international conferences on geoscience education (IGEO, 1997, 2000, 2003) indicates worldwide agreement on the central place of the outdoor learning environment within earth science education.

Orion (1993a) suggested a holistic model that connects the outdoor and the indoor learning environments. The guiding principle of this model is a gradual progression from the concrete levels of the curriculum toward its more abstract components. This model can be used for designing a whole curriculum, a course, or a small set of learning activities (Orion, 1986, 1991).

Orion's holistic model combines indoor and outdoor environments. In this model the learning process begins with a "meaning construction" session. In this session, students converse, with guidance by the teacher, to discover what interests them about a particular subject. Depending on the subject and the school's location, this stage takes place in a relevant outdoor environment or in a versatile indoor space.

According to Orion (1993), the main role of an outdoor learning activity in the learning process is to offer direct experience with concrete phenomena and materials. Familiarity with properties and possibilities is the principal outcome—the raw material for forming concepts and posing questions. Kempa and Orion (1996) add that the outdoor learning environment may introduce the methodology of field research from disciplines such as biology, ecology, and geology. Thus, the goal of the outdoor learning environment includes two main objectives: (a) learning basic concrete concepts through direct interaction with the environment and (b) learning field investigation methodology.

One point is most crucial to understand: the outdoor learning environment addresses phenomena and processes that *cannot be cultivated indoors*. The outdoors, however, is a very complicated learning environment and includes a large number of stimuli that can easily distract students from meaningful learning.

Consider a location where students find that an outcrop reveals an anticline. They begin to infer geological processes that might have produced this structure. Are they ready to approach this task? Or is the challenge too novel? Many of the concepts useful to drawing conclusions about the anticlinal structure (sedimentation, superposition, and initial horizontality) can be better explained through lab observations and simulations. Following the understanding of these concepts, stu-

dents who arrive at this specific outcrop can conclude that the layers are not located in their original setting. Then, through a field observation they might decipher the anticline structure. From this point, a better understanding of the three-dimensional nature of a folded structure as well as the folding mechanism can be effectively achieved through the use of computer software and hand-held models (Kali & Orion, 1997).

The main aim of the initial indoor phase is to prepare the students for their outdoor learning activities. This preparation reduces what Orion and Hofstein (1994) term the “novelty space” of an outdoor setting (Fig. 23.1). Novelty space consists of three factors: cognitive, geographical, and psychological. The cognitive novelty depends on the concepts and skills that students are asked to deal with throughout the outdoor learning experience. The geographical novelty reflects the acquaintance of the students with the outdoor physical area. The psychological novelty is the gap between the students’ expectations and the reality that they face during the outdoor learning event.

The novelty space concept has a very clear implication for planning and conducting outdoor learning experiences. It defines the scope of preparation required for an educational field trip. Preparation that considers the three novelty factors reduces the novelty space to a minimum, thus facilitating meaningful learning during the field trip. Working with the materials that the students will meet in the field and conducting simulations of geological processes through laboratory experiments directly reduces cognitive novelty. To reduce the geographic and psychological novelty of the outdoor learning experience, teachers may turn first to slides, films, and maps, and second to detailed information about the event. Students should know the purpose of outdoor learning, the learning method, the number of learning sta-

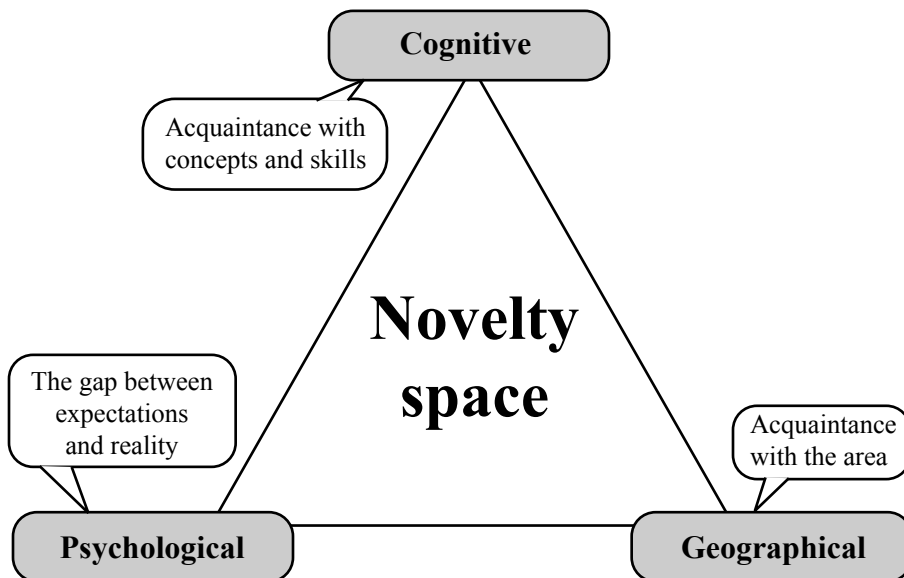

FIGURE 23–1. The three dimensions, which identify the novelty space of an outdoor learning activity.

tions, the length of time, the expected weather conditions, the expected difficulties along the route, etc. Safety briefing is a must as well.

The next phase in this cycle is the outdoor learning activity. The curriculum materials for the outdoor learning experience should lead students to interact directly with the phenomenon and only secondarily, if at all, with the teacher. The teacher's role is to act as a mediator between the students and the concrete phenomena. Some of the students' questions can be answered on the spot, but only those that might be answered according to the evidence uncovered at the specific outdoor site. Otherwise time and resources, including the students' attention, are wasted on activities that might be done elsewhere. Lectures, discussions, and long summaries should be postponed until the next phase, which is better conducted in an indoor environment.

Marques, Paria, and Kempa (2003) explored Orion's model within the Portuguese earth sciences curriculum. Their study supported the importance of preparation for the outdoor learning experience. Furthermore, they found a positive influence of this learning environment on students' learning. However, their study also highlighted the difficulties teachers faced in adapting to the novel, outdoor learning environment.

Geo3D software (Kali & Orion, 1996) clearly illustrates an example of the indoor-outdoor cycle. The design of this software fosters the development of spatial visualization skill. Most geological outcrops hide elements of the three-dimensional configuration of geological structure. Even having observed a structure such as an anticline in the field, most students have difficulty perceiving its three-dimensional form. Thus, the outdoors is not as suitable a learning environment as a computer simulation for the development of spatial visualization (Kali & Orion, 1996). However, without previous concrete outdoors experience with geological structures, such software loses much of its relevance for many students.

*Integrating inquiry and the laboratory learning environment.* Although there are many laboratory-based earth science units for various age levels all over the world, little has been published concerning the role of the laboratory learning environment within earth science education.

A review of many such lab-based units indicates that the main role of the laboratory is to demonstrate or simulate the Earth's processes. However, little has been published concerning the influence of simulations on the development of misconceptions among school students.

The earth science laboratory environment has great potential to contribute to the development of the skills of scientific inquiry reasoning. Inquiry in the geosciences has a unique characteristic: its "experiments" in the grandest sense have already been conducted by nature. They are unrepeatable and unreplicable. No one can send glacial ice across a continent or carve a Grand Canyon. Consequently, many geological inquiries are of a retrospective type—trying to unravel what happened in the past, using "fingerprints" left on the Earth.

Frodeman (1995) describes geology as an interpretive and historical science that "embodies distinctive methodology within the sciences." He further argues that "the geologist picks up on the clues of past events and processes in a way analogous to how the physician interprets the signs of illness or the detective builds a circumstantial case against a defendant" (p. 963). Edelson, Gordin, and Pea (1999) describe the geosciences as "observational sciences" that emphasize comparisons and

contrasts among features of the Earth in different times and places. Inference based upon comparison and contrast, especially when considered across different scales in time and place, differs from inference based upon the results of experimentation (Ault, 1998). Both approaches are empirical, quantitative, and subject to scrutiny by rules of logic. They offer different milieus for illustrating the meaning of some of the most basic constructs of scientific thinking: for example, observations, hypotheses, and conclusions.

A traditional method for categorizing inquiry curricula is to analyze the degree of structure or openness of the activities they include (Schwab, 1962; Herron, 1971; German et al., 1996). With such methods, inquiry-based curricula can be placed anywhere on a continuum extending from completely structured curricula on one side to completely open curricula on the other.

Those who advocate inquiry in the science curricula for all accept that the educational system ought to enable students to design, conduct, and analyze their own investigations, then communicate their findings. However, the appropriate stages for engaging students in open inquiry are not clear, nor are the means for bringing students to a stage in which they will be able autonomously to design and conduct their own experiments. While some researchers suggest designing a variety of activities to suit a diversity of cognitive developmental stages in a classroom (e.g., Germann, 1989), others suggest preparing students for open inquiry by engaging them with well-structured investigations (e.g., Edelson et al., 1999).

One of the rarely asked questions regarding inquiry learning concerns the cognitive prerequisites necessary for using open inquiry methods. Elshout and Veenman (1992) claim that "In unguided-discovery learning, one expects high metacognitive skill and intellectual ability to be essential requisites to keep the learning process going" (p. 135). It is therefore reasonable to claim that students should understand the meaning of some of the most basic concepts used in scientific methodologies before they can begin an independent inquiry process. Such understanding provides the means for making hypotheses, designing experiments, collecting and analyzing data, and reporting their findings. Unfortunately, evidence exists indicating that students in junior and senior high schools have severe difficulties in understanding the essence of the scientific method. They have, in effect, failed to learn scientific method as a content with its own concepts and principles. Zohar (1998) reported that junior high school students had difficulties in understanding the difference between their experimental results and their conclusions. Solomon, Duvveen, and Hall (1994) reported that high school students had difficulties in distinguishing between descriptions and causal explanations. Tamir (1989) claims that "Students do not understand the concepts that underlie the processes of scientific investigations. These concepts (e.g., hypothesis, control) are not easy to understand" (p. 61).

Learning earth sciences has a role to play in remedying this situation. Orion and Kali (2005) suggest that earth sciences education has the potential to provide students, at beginning stages of their science education, with basic inquiry skills that are required for further open-ended inquiry endeavors. They developed a 34-hour lab-based curriculum unit for junior high school students, focusing on geological processes that transform the materials within the crust of the Earth—"The Rock Cycle"—and organized this curriculum into nine structured inquiry modules. To foster students' awareness of the different inquiry routes embedded in the inquiry

modules, each of the modules was followed by a MIR (Metacognitive Inquiry Reconstruction) assignment. In these activities linguistic terms were used as organizing schemes. Students examined their investigation with “scientific inquiry spectacles” and categorized different stages of the inquiry with terms such as *observations*, *hypotheses*, and *conclusions*.

Orion and Kali (2005) tested the influence of learning an inquiry-based “Rock Cycle” curriculum and its accompanying MIR activities on student ability to distinguish between observations, hypotheses, and conclusions on a sample of 582 students in seventh and eighth grade from 21 classes sharing 14 teachers at 8 junior high schools in Israel. The schools represented urban, suburban, and rural societies. The study used a large battery of qualitative and quantitative research tools in a pre-test/post-test structure.

The pre-test outcomes indicated that the seventh- and eighth-grade students included in this study had considerable difficulty in understanding concepts underlying the scientific method. The large and significant pre-post differences found in many of the classes indicated the high potential for an inquiry-based “Rock Cycle” program to develop and distinguish among three basic elements of scientific thinking (observations, hypotheses, conclusions).

The large improvement in students’ scientific thinking skills, found in many of the classes, might have been a result of students’ engagement with the unique inquiry methods of geoscience. Students focused their tangible observations on materials of the Earth. They drew conclusions from “experiments” that were conducted by nature in the past and did not design their own investigations.

However, Orion and Kali also found no improvement among classes taught by teachers who did not properly adopt the inquiry-based teaching strategy. These teachers taught the “Rock Cycle” unit in their traditional manner. Appropriate curriculum materials are not sufficient in themselves for inducing cognitive development among students. Sometimes teachers are the limiting factor in students’ ability to exploit the potential of “The Rock Cycle” in developing scientific thinking skills.

## **Research and the Development of Curriculum Materials**

The main goal of earth science education is to improve the way students learn about and understand our planet. In this section we report in detail about a curriculum for teaching the water cycle from an earth systems and environmental insight perspective. The curriculum “The Blue Planet” emerged from a “design research” effort.

Edelson, Gordin, and Pea (2004) advocate for “design research” as a powerful model for the development of effective learning tools. They used this model to develop inquiry-based software for the study of climatology through visualization. In design research, the study of learning takes place in the context of designing and revising curriculum materials based upon careful study of student response to these materials.

Orion’s (2002) helical model of research, curriculum development, and implementation is similar. In this model, each curriculum development effort starts with a pre-development study to identify misconceptions, preconceptions, and learning

difficulties associated with the specific subject. The findings from this stage serve as a basis for the first curriculum development phase. An implementation phase follows curriculum development. The implementation phase involves in-service training for a small number of teachers who will teach the curriculum to their classes.

An evaluation study follows the implementation stage. The results of the evaluation inform the second iteration of curriculum development. In turn, this phase is followed by a wider implementation cycle.

### **Pre-development of “The Blue Planet” Curriculum**

Based upon Orion’s helical model, research preceded and followed development for eighth-grade students of an earth systems unit on the hydrosphere, “The Blue Planet.” In order to examine students’ prior knowledge and understanding in relation to the water cycle, a “zoom-in” analysis was conducted. Quantitative research tools were used with a large sample in order to obtain a general picture of students’ knowledge and perceptions. Later, qualitative research tools were used with a smaller, randomly selected sample in order to gain insight into student misconceptions and to validate the quantitative tools.

Review of the literature concerning the predevelopment phase revealed that in spite of the crucial importance of water from the environmental perspective, most of the studies that have been conducted in this area have concentrated on students’ perceptions of the physical aspects of the water cycle, namely, changes in the water state (Bar, 1989; Bar & Travis, 1991). An ERIC search in 2002 revealed only a few published studies that focused on children’s perceptions of the water cycle in the environmental context of the Earth. Agelidou, Balafoutas, and Gialamas (2001) reported that students do not perceive how human activities are related to water problems and their consequences. Specifically, they do not recognize the principal factors responsible for these problems. Fetherstonhaugh and Bezzi (1992) reported that after 11 years of schooling, students could only present simplistic and naïve conceptions of the water cycle. Moreover, the students showed a poor and inadequate scientific understanding of groundwater as a part of the water cycle.

Brody (1994) conducted a meta-analysis study of about 30 articles published between 1983 and 1992 that dealt with difficulties of middle and high-school students in understanding different subjects connected with water. Only a few of those articles dealt with the environmental aspects of water, whereas at least 80% of them focused on the following three areas of difficulty:

1. Understanding chemical and physical processes such as condensation, evaporation, and the molecular structure of water.
2. Understanding the significance of water for processes that take place in living organisms.
3. Understanding interdisciplinary subjects such as water resources, and the social and scientific linkages of these topics.

Taiwo, Ray, Motswiri, and Masene (1999) confirmed that students’ perceptions of the water cycle were influenced by their cultural beliefs and to a large extent by their pseudoscientific knowledge about cloud formation and rainfall. Barker (1998)

reported that in spite of the fact that about 90% of the water absorbed by the roots is lost by evaporation, mainly through the leaves, 50% of the students in his study claimed that plants retain all the water that they absorb.

Transcription and qualitative analysis of the questionnaires from the predevelopment study for the Blue Planet curriculum indicated that most of the students demonstrated an incomplete picture of the water cycle and held many misconceptions about it. Children who drew the water cycle usually represented the upper part of the water cycle (evaporation, condensation, and rainfall) and ignored the groundwater system. More than 50% of the students could not identify components of the groundwater system even when they were familiar with the associated terminology. In their mind, underground water was a static, subsurface lake. Furthermore, they imagined that water chemistry was constant throughout the entire water cycle (no purification by evaporation). Presumably, environmental insight regarding water pollution and water conservation requires connecting the stages of the water cycle to the processes that modify water quality and abundance. The water cycle alternative frameworks held by more than 50% of the students do not bode well for learning environmental insights.

Cyclic thinking correlated significantly with drawing the water cycle to include its groundwater component. A student who drew the underground water system held the following concept about the cyclic nature of the water cycle: "I absolutely disagree. There is no starting point and no end point in the water cycle. It is a continuous process."

## **Development and Evaluation of the "The Blue Planet" Curriculum**

The findings of the pre-development study served as a basis for the development of an interdisciplinary program named "The Blue Planet." This program focused on the water cycle as an example of the relationships seen among the various earth systems. Students were asked to create concept maps at the beginning and end of the learning process. Comparison of the number and type of items between the concept maps served as a measure of changes in students' knowledge and understanding of processes. The number of connections within the concept map served as an indication of students' understanding of the relationship between the components of the water cycle (Edmondson, 1999). In addition, regular observations were conducted in the classes.

Observations indicated that teachers concentrated primarily on scientific principles and only very little on the cognitive aspects of the connections between the water cycle and other earth systems, or between the water cycle and environmental case studies. In addition, most teachers tended to ignore the constructivist activities developed in light of the findings of the pre-development study. These were activities intended to correct students' misconceptions and to develop a broader, more coherent conception of the water cycle within an earth systems context.

A significant improvement was found in the student's level of knowledge, namely acquaintance with the components of the water cycle. A significant improvement was found in relation to students' understanding of the evaporation process. However, in relation to all the other processes, only a minor improvement was found.

The analysis of the cyclic and systemic thinking questionnaires showed some improvements in students' understanding of interrelationship among earth systems. However, even after completing The Blue Planet program, poor understanding of the systemic nature of the water cycle dominated student thinking. Most of the students demonstrated a fragmented conception of the water cycle and made no connections between the atmospheric stages of the water cycle and the geospheric (underground) stages of the water cycle.

These findings indicate that improvement in knowledge falls short of the development of environmental insight. For environmental insight, students must develop cyclic and systemic thinking about what happens to water in the air, on the Earth's surface, and underground. Teachers should not overlook activities developed directly for this purpose. Although such activities were provided, teachers tended to ignore them. They need to understand that simply gaining knowledge about the components of the water cycle does not contribute to progress in the development of environmental insight.

### **PEDAGOGICAL INERTIA AND THE STRUGGLE FOR PARADIGM SHIFT**

The science for all paradigm holds promise around the globe. However, its implementation will take decades—perhaps until the return of Haley's Comet in 2061. For learning earth sciences, science for all means cultivating environmental insight through the study of earth systems.

For teachers to move from traditional science teaching to proper earth systems teaching, they must change their goals for student learning, the contents of their curricula, and their approaches to instruction. Clearly, this shift constitutes a major change in philosophy, from reductionism and disciplinary-driven schooling toward holism and attention to educating students for lives of social responsibility within democratic societies. The shift demands something more: that properly trained teachers actually teach earth science subjects, an area in which many science teachers in many countries have little or no scientific background (King, 2003; Orion, 2003b). Furthermore, students learn these subjects best—and often can only learn field methodologies of investigation—when teachers make use of the outdoor learning environment. Most traditional science teaching ignores this environment.

The task to be accomplished exceeds what we might expect of professional development. It requires participation and commitment on many levels, from community and school to business and academia.

Orion (2003b) has reported on the outcome of a long-term (10 years) study within the "storm's eye" of the new Israeli "Science for All" curricula for junior high and high school. This intensive work included participating in the committees that designed the new "Science for All" curricula for junior high and high school; taking a central role in a team that has developed learning materials for these two programs; and leading and taking a practical role in hundreds of in-service training hours in each of the 10 years, both in in-service training centers and in the teachers' schools and classes.

This decade of investigation has produced four Ph.D. dissertations (Kali & Orion, 2003; Dodick & Orion, 2003b; Ben-zvi-Assaraf & Orion, 2005; Kapulnick,

Orion, & Gniel, 2004) and one master's thesis (Midyan, 2003). Altogether, these different studies examined the practice of science teaching and learning for about 1000 science teachers and their students. Most of the studies were conducted at the junior high school level but also included teachers and students from the elementary and the high school levels. In addition to observing teachers and evaluating student learning, these studies addressed systemic reform from the points of view of principals, superintendents, curriculum developers, academic scientists, the ministry of education, as well as in-service training and pre-service education programs for teachers.

From each of these studies came the conclusion that despite their participation in long-term, in-service training programs, the vast majority of the teachers did not undergo genuine professional development. Professional inertia was the rule. Results indicated a clear gap between teachers' perceptions of their development as expressed through questionnaires and interviews and their actual teaching practice.

In addition to teachers' reluctance to implement new teaching methods and incorporate new scientific topics, the interviews uncovered four additional factors preventing them from genuinely implementing reform. They felt, in general, apprehension toward change and that professional training institutes did not provide them with the practical tools needed to overcome their apprehension. Teachers believed that school administrators failed to provide them with the resources necessary for reform, such as laboratory equipment, smaller class sizes in the laboratory, computers, and access to outdoor learning environments. Reform placed, in their judgment, inordinate demands upon their time. Finally, teachers faulted the Ministry of Education and its science education inspectors for a double standard. On the one hand, the Ministry initiated reform and inspectors encouraged participation. On the other hand, resources were not forthcoming and the Ministry called upon the inspectors to implement a national testing regime. The focus of testing tended to institutionalize objectives antithetical to the Science for All paradigm and the earth systems approach.

The world is complicated and diverse, and the Israeli example is that of just one nation. Movement toward an earth systems approach in keeping with the spirit of the Science for All paradigm is a change many teachers cannot or do not really want to undergo. Yet the conflict between reform efforts and testing priorities is worrisome and is certainly experienced elsewhere. Most importantly, the Israeli case illustrates the need for research in science education to address many contexts, from integrating curriculum to changing teaching paradigms.

## CONCLUSION

The first decade of the twenty-first century finds earth science education in a more central place in science curricula than a decade before. The progress of earth science in schools all over the world is closely related to its central role in the development of environmental insight among future citizens. However, the ability of educators to establish earth science as a sustainable course of study in schools is highly dependent on the ability of science teachers to overcome many barriers, including their own lack of background and the persistently low stature of the field. This low stature is a function of the failure to understand "what's so special about learning earth sciences."

Learning earth sciences offers the distinct potential of seeing through the landscape and through time. Its many subjects unite to conceive of the world as dynamic, interacting systems, themselves composed of stabilizing cycles. These systems operate on many scales in time and place, some so vast as to challenge the limits of imagination. The earth sciences represent phenomena of interest in visual forms: contour maps, block diagrams, and virtual worlds of the interior earth, its surface features, its motion in space, and its changing climate. These representations place distinctive demands on the cognitive capacities of learners. Making sense of Earth's processes and patterns, structures and changes, and systems and cycles depends upon visualization and spatial reasoning as well as recognizing bias in the human-scale perception of events.

Understanding how the Earth works requires retrospection and retrodiction—making inferences about the past. By interpreting the present as the outcome of natural experiments on vast scales and sleuthing out its causal history, earth sciences set the stage for making extrapolations about possible futures. These extrapolations inform our actions with information about risks, from seismic to atmospheric. On local, regional, and global scales humans interact with earth's natural systems, becoming agents of geologic, climatic, and evolutionary change. This power carries heavy responsibility; learning earth sciences offers lessons students need in order to develop their capacity to exercise this responsibility as environmental insight.

This chapter presents a holistic view of earth sciences education and a holistic perspective for achieving meaningful learning of the earth sciences. This perspective combines an educational vision (development of environmental insight through adopting the earth systems approach) together with a research agenda (curriculum development for outdoor and indoor, laboratory and computer, as well as classroom, learning environments). This vision and agenda acknowledge the challenge of preparing teachers for the implementation of new curriculum materials and adoption of teaching strategies and tactics appropriate for each learning environment.

The vision encompasses how learning earth sciences may contribute to gaining insight into the nature of scientific investigation and scientific reasoning in several contexts. Nevertheless, the conclusion remains that depending upon the earth science disciplines in isolation, either from each other or from the humanities and social sciences, to set the agenda for learning earth sciences will fail to serve the public good. We need to respect students, their families, and their communities as sources of ideas, issues, and problems to solve through application of knowledge about earth systems.

Research has a central role in this holistic plan. It should provide an understanding of students' difficulties with the learning process and identify the appropriate learning and teaching strategies for overcoming cognitive barriers to spatial and temporal thinking, to retrospection, to understanding phenomena across scales, to integrating several subjects, and to developing the cognitive capacity for systems thinking. In addition, the research agenda should provide the basis for the development of curriculum materials, the sequencing of learning, and productive paths for teachers to follow in overcoming internally and externally imposed barriers to reform. We know much too little from a research perspective about thoroughly contextualized, fully integrated, earth systems thinking linked to environmental studies and centered on students' personal and social lives. If we are to have curricula

that do these things, then we must understand better what the obstacles are and how to overcome them.

The good news that emerges from this chapter is that there are sound studies that demonstrate the way for progress. The better news is that these studies are still few, and there is room for many young researchers to join the groundswell and make their mark in earth science education and on the future of humankind on Earth.

# CHAPTER 24

---

## Environmental Education

**Paul Hart**

*University of Regina, Canada*

The field of environmental education and associated research activities are experiencing a period of rapid growth as we settle into the new millennium. Many reasons are claimed to explain this relatively new focus, including increasingly more pervasive and global environmental issues, changing societal expectations, and educational reform. Societies are searching for new narratives that give guidance and inspiration to people and purpose to schooling. Within these narratives, that range from teaching young people to accept the world as it is, to those that encourage critical thinking more distanced from conventional wisdom and intended to change what is wrong, is one that insists on our moral obligation to the planet. It is a narrative of extraordinary potential, says Postman (1995), because it is a story of human beings as stewards of the Earth, caretakers with a global consciousness and a sense of educational responsibility.

The purpose of this chapter is to engage the thought and practice of environmental education research in debates about “Our Common Future,” debates that are occurring in many established curriculum fields. Because research within environmental education is characterized by both unity and diversity, the field is introduced, first, in terms of the contextual complexity of social, political, and cultural influences within which research in this field is situated. Second, environmental education research is described in terms of a variety of approaches to inquiry, with the use of example cases that illustrate the breadth and depth of research activity. Third, this requisite variety is situated within recent developments and current trends of both methodological and substantive issues in environmental education research. Finally, issues of quality in this field of inquiry are characterized within the politics of research that inscribe each of the research areas of the social sciences, including science education.

Although recent literature reviews have served to both characterize and provide substantive legitimacy to environmental education research (see, for example, Andrew & Malone, 1995; Hart & Nolan, 1999; Palmer, 1998; Posch, 1993; Rickinson, 2001; Williams, 1996), this chapter challenges researchers to regard these forms of

inquiry as political. This means taking seriously issues of epistemology/ontology that necessitate reconsideration about what counts as legitimate. For example, attempts to prescribe global research agendas have seldom led to change in practice because they are not well attuned to contextual needs, values, and cultures. Yet local issues often cannot be understood except in the global frame. Thus, tensions between powerful localizing and globalizing forces necessitate more comprehensive understandings of methodologies that may strain the boundaries of inquiry. Challenges for research in environmental education imply a need for broadened conceptions of research as well as innovative and sensitive responses if such meanings of research are to be understood.

Meaning in research is related to purpose. Environmental educators envision caring, responsible people who construct, for themselves, the values that underpin wise judgments and competent actions relating to their environment, whether physical or social (Smyth, 2002). This seemingly simple vision becomes complex because education involves people and organizations at many levels—international and national, governmental and nongovernmental, formal and nonformal, public and private. Together they form a cluster of systems interacting with each other and the societies to which they belong. According to Smyth (2002), although those not directly involved in environmental education may think of it as a formal subject to be taught as a distinct part of the curriculum, it might better be regarded as a competence, as a permeating quality extending from personal and social values and emerging as ways of thinking, acting, or being.

## WHAT IS ENVIRONMENTAL EDUCATION?

Arguably the largest of many networks of professionals and people working worldwide to promote environmental education, the North American Association for Environmental Education (see NAAEE, n.d.) represents some of the ideals that can be traced to definitions of environmental education resulting from international agreements at significant conferences such as those held in Stockholm in 1972, Belgrade in 1975, and Tbilisi in 1977 (Palmer, 1998). Along with counterparts in many countries, NAAEE rhetoric from the current website is reminiscent of the following classic definition of environmental education drafted as a result of the international working meeting on environmental education in the school curriculum sponsored by the World Conservation Union (IUCN) and the United Nations Educational, Scientific, and Cultural Organization (UNESCO): “Environmental education is the process of recognizing values and clarifying concepts in order to develop skills and attitudes necessary to understand and appreciate the inter-relatedness among man, his culture, and his biophysical surroundings. Environmental education also entails practice in decision-making and self-formulation of a code of behavior about issues concerning environmental quality” (IUCN, 1970).

However, definitions of environmental education most often referenced are from drafts of the Belgrade Charter and the Tbilisi Declaration. According to these documents, the goals of environmental education are:

- (i) To foster clear awareness of, and concern about, economic, social, political, and ecological inter-dependence in urban and rural areas.

- (ii) To provide every person with opportunities to acquire the knowledge, values, attitudes, commitment, and skills needed to protect and improve the environment.
- (iii) To create new patterns of behavior of individuals, groups, and society as a whole, towards the environment. (UNESCO, 1977)

These early statements continue to capture the sentiments of increasingly large educational associations globally, as evidenced by the recent rhetoric of sustainable development originating with the World Conservation Strategy (IUCN, 1980), which, according to Greenall (1987), is becoming more specific and focused:

Ultimately, the behavior of entire societies towards the biosphere must be transformed if the achievement of conservation objectives is to be assured. A new ethic, embracing plants and animals as well as people, is required for human societies to live in harmony with the natural world on which they depend for survival and wellbeing. The long term task of environmental education is to foster or reinforce attitudes and behavior compatible with this new ethic. (IUCN, 1980, section 13)

The essence of this strategy was reinforced and expanded by the World Conference on Environment and Development (WCED), widely known as the Brundtland Commission Report and published as *Our Common Future* (WCED, 1987).

## **Environmental Education and Sustainable Development**

The term *sustainable development* first gained widespread attention as a result of Brundtland in the run-up to the United Nations Conference on Environment and Development (UNCED) held in Rio de Janeiro in 1992 (Huckle, 2003). The concept was endorsed by 149 countries as Agenda 21, in the global action plan for sustainable development. Chapter 36 recommended that education in each country be re-oriented to include environment and development education. This rhetoric has continued to dominate the language of recent international conferences at Thessaloniki in 1997 and Johannesburg in 2003.

Although sustainable development could take different forms in different societies, it is generally defined to mean development that meets the needs of the present without compromising the ability of future generations to meet their own needs. It is widely acknowledged that sustainable development has ecological, economic, social, cultural, and personal dimensions, as a dynamic process that enables all people to realize their potential and improve the quality of life in ways that simultaneously protect and enhance the Earth's life-support systems (Huckle, 2003). The term is not uncontested, however, and although *environmental education* continues as the commonly used term, other concepts, such as environmental literacy, ecological citizenship, or learning for sustainability, have also been proposed (see *EER*, 8(1); Bonnett, 2002; Elliott, 1999; Jickling, 1992; McKeown & Hopkins, 2003; Stables, 1998; Stables & Scott, 2002).

According to Huckle (2003), all such definitions of environmental education or sustainable development rest on ethical foundations that are assumed to be about balancing four sets of values—environmental protection, quality of life, intergenerational equity, and intragenerational equity. These values are subsumed in a global

ethic for living sustainably as part of the Earth Charter (2000), which urges the world's people to live as global citizens with a sense of universal responsibility. Its 16 principles are based on respect and caring for the community of life, ecological integrity, social and environmental justice, and democracy through political processes. Although there is no consensus on how these ethics and values should be translated into action, a number of discourses operate to shape our thinking on environment and development issues. These discourses on environmental education need to be made visible to pupils so they can learn to critique its underpinning social values and beliefs. This kind of education for critical thinking represents a challenge to curriculum developers and teachers not unlike new visions proposed for science education (see Cobern, 1991, 2000a, 2000b; Coble & Koballa, 1996; Donnelly, 2002).

## Foundations of Environmental Education

It is worth considering whether the philosophical basis for environmental education or education for sustainable development in schools has been adequately conceptualized. It is worth the effort, according to Huckle (2003), because the cultural turn associated with the rise of postmodernism means that educators must now pay greater attention to ways in which social and ecological processes construct nature and environment. For, once constructed and represented, nature, environment, and environmental issues act as resources for identity formation, and, once formed, identity determines how we understand and evaluate social and environmental issues (Payne, 2001). Research in environmental education and in the social sciences has just begun to focus on identity formation in relation to young people's experiences in early and middle childhood (see Corsaro, 1997; Hutchison, 1998; Lee, 2001; Lewis & Lindsay, 2000; Panter-Brick, 1998; Pollard, Thiessen, & Filer, 1997).

As environmental education for sustainable development continues to grow and evolve, an active research community has emerged and has raised questions about education, which, like environmental education itself, often run counter to the dominant social paradigm. Whereas environmental education was once viewed as a conglomerate of nature study, conservation, and outdoor education groups, these tributaries have somehow merged into a stream of professional practice supported by research that seeks to investigate personal intents and values, and social structures that are believed necessary to organize understandings and actions that improve the quality and sustainability of natural and social environments (Palmer, 1998). Thus, research efforts have been directed toward examining which experiences might contribute to the creation of informed, active citizens capable of playing a part in creating societies that are caring about all living things and directed against forms of social and ecological injustice. Such aims and purposes, according to Fien (1993, 2000a, 2000b), are tantamount to a change in worldview from the dominant social paradigms of twentieth century industrial societies toward a new environmental paradigm of postmodern societies.

Given that these ideas are contestable presents practitioners and researchers with a curriculum problem (see, for example, Bowers, 1991, 2001, 2002). Environmental education brings into sharp relief the notion that education is not value-free: all teaching is embedded in an ideological background (see also Cobern, 1996, 2000b). However, only when the ideology strays from the taken-for-granted assumptions of

the dominant social paradigm does this become problematic. Whereas a liberal orientation tacitly approves the reproduction of existing social relations, many orientations to environmentalism cannot be understood except within the ideas and values of wider paradigms of social beliefs (see Dunlap & Van Liere, 1978, 1984; Lalonde & Jackson, 2002; Milbrath, 1984, 1989). These ideas and values may challenge major beliefs about concepts of economic growth and current forms of politics.

Socially critical environmental educators argue, for example, that education should seek to promote a vision of a just and sustainable world, thus acknowledging the express political purposes of environmental education. This claim begs the curriculum/pedagogical question of whether ideological critique should be integrated into education. Although the WCED (1987) recognized that environmental education is clearly aimed at transforming the dominant social paradigm through changes in national and international systems of politics, economics, and technology, an idea that has been sustained in more recent international forums in Rio de Janeiro (1992), Thessoliniki (1997), and Johannesburg (2002), it is not at all clear that this rhetoric informs current school practices. Whether mainstream education is ready for such change represents a genuine dilemma, according to many environmental educators. The real issue is ontological that is, whether mainstream education itself can be transformed.

## Goals and Directions

One way to view this dilemma from the perspective of science educators is to interpret the goals of environmental education in terms of those characteristics that coincide with Bybee and Deboer's (1994) description. The debate about goals in science education also relates to the priority and emphasis given certain goals in the historical structure of the science curriculum (Roberts, 2000; Roberts & Chastko, 1990). Although there has always been some tension between curriculum models that emphasize knowledge/skills acquisition and those that emphasize personal/social development, it was, according to Hurd (1969, 1970, 1998, 2000), social/environmental realities of the late twentieth century that resulted in a shifting of the goals toward humanism (see Donnelly, 2002). This new conceptualization of science education as a means to scientific literacy, defined more broadly to cohere with societal and technological issues, was reaffirmed by the 1980s in National Science Teachers Association (NSTA) goal statements that provided strong reaffirmation of the personal/social goal emphasis. These goals were operationalized, by the mid-1980s, as a science education research literature actively investigating science-technology-society (STS) approaches to science education, approaches that were overtly humanistic, values-oriented, and relevant to a wide range of social/environmental concerns (see also AAAS, 1993).

According to Bybee and Deboer (1994), one of the greatest forces behind the STS movement within science education was the tremendous growth in environmental awareness. A more aware public was beginning to associate environmental issues, energy conservation, and use of natural resources as well as global concerns about ozone depletion and greenhouse gases as ultimately tied to science and technology. Virtually every writer who advocated for scientific literacy within an STS context raised environmental/ecological concerns as potential subject matter for school sci-

ence. However, at that time, although recognized as a separate entity within the wider field of education, environmental education remained problematic as a curriculum organizer, arguably because it forced science educators to reexamine priorities as well as older arguments about cognitive, social, and political aspects of the field. While scientific literacy has remained a central goal for science education in the 1990s and 2000s (Hurd, 1998; Roberts & Östman, 1998; Ryder, 2001), the new, large-scale curriculum projects of the American Association for the Advancement of Science (AAAS) (Project 2061), the NSTA, and the National Center for Improving Science Education (NCISE) attempt to balance traditional goals of learning scientific conceptual knowledge and process skills with the study of personal/social/environmental issues. Thus, environmental education remains an issue in science education precisely because the social/environmental realities described by Bybee (1997), Hurd (2000), and others since the 1970s have not gone away.

It should not be assumed that environmental educators necessarily agree on matters of purpose and form. There is a rich diversity of opinions about goals and directions, as in science education, but perhaps more demanding of educational reform (see Jickling, 2001; Stables, 2001). Because environmental education aims at the construction of environmental ethics, it is inherently focused on the personal/social emphasis. Even so, environmental educators differ over the ideological ends served by adopting a values pluralism approach as well as on claims to the neutrality of liberal approaches to the incorporation of values within education. For example, critical environmental educators argue that a liberal orientation fails to recognize education and schooling as already embedded within a system of values that are taken-for granted, and therefore are unexamined and unquestioned (Fien, 1993). Similar cases have been advanced by teachers advocating for consideration of competing perspectives through critical discourse with regard to religious or multicultural education.

In practice, many educators have developed professional strategies that have safeguarded students from forms of indoctrination or unethical teaching practices (Harris, 1990; Huckle, 1985a; Kelly, 1986; Richardson, 1982). Huckle (1983, 2003), for example, argues for approaches that link environmental concerns to wider political agendas, thus viewing environmental education as a form of political (i.e., citizenship) education. Such an approach could provide students with understandings and skills of political literacy and democracy through active citizen participation—those critical thinking and decision-making skills that, along with attention to human intentionality, inscribe forms of environmental education that go beyond behaviorist objectives and toward what Jensen and Schnack (1994) describe as action competence.

There is nothing that should be considered subversive, coercive, or heavy-handed about teachers who adopt institutional guidelines toward student understanding of a wide range of intellectual, action, and communication skills that enable active involvement in human decision making. In respect of environmental learning, Huckle (1985b, 2003) outlines development of critical environmental consciousness, critical thinking skills, environmental ethics, and processes of political literacy (i.e., environmental citizenship) as necessary to understand how current political systems work, appreciate variety in beliefs and policies, and evaluate alternatives. It should be possible to nurture and strengthen democratic values such as freedom of choice, tolerance, fairness, and so on, through learning how to adopt a critical

stance, articulate reasons for particular views, assess evidence within political opinion, engage multiple perspectives, and tolerate diversity of ideas, beliefs, interests, and values (see Aikenhead, 1996; Crick, 1978; Porter, 1981). At its most basic level, environmental education is essentially about creating the conditions for citizen participation whereby citizens are educated to take responsibility for shaping and managing their own environments (see Breiting, 1988; Brubaker, 1972; Bull et al., 1988; Fien, 1993; Greenall-Gough, 1990; Hungerford, Peyton, & Wilke, 1980; Ryder, 2002; Wals, 1990).

Whereas earlier movements in nature study, conservation and outdoor education, did not challenge the socioeconomic fabric of society, environmental education has the potential, and some would argue the intent, to do so. The environmental movement signals fundamental changes in social consciousness, as environmental education does for educational consciousness. Socially critical and political action goals of environmental education stand in stark contrast to more conservative goals of science education (see Jenkins, 1994; Millar, 1989; Millar & Osborne, 1998). Thus, it should not be surprising that by the 1980s environmental education researchers began to observe what Stevenson (1987) described as pronounced discrepancies between the contemporary philosophy of environmental education and those of traditional educational programs (see, for example, Fien, 1993; Greenall, 1981; Lowe, 1998; Robottom, 1982; Sterling, 2001; Volk, Hungerford, & Tomera, 1984). Historically, schools were not intended to develop critical thinkers or encourage active participation in social/environmental decision making. Yet the goals of environmental education continue to emphasize critical thinking, problem solving, and decision making as a basis for active involvement in the resolution of environmental problems (Davis, 2003). That these goals are not easily accommodated in the goals and organization of schools poses challenges to existing subject area curricula such as science.

Quite recently there are some indications that pressures to reform curriculum areas such as science are tending, once again, to reduce the grip on rigid adherence to one set of goals (i.e., knowledge and skills) at the expense of others (i.e., personal/social development). Reasons have been articulated for more constructivist approaches as organizers for science curricula (e.g., Cobern, 1998b; Leach & Scott, 2002). These tendencies, though not uncontested (see Matthews, 1998, 2000; Solomon, 1994), may be more likely to align with the social constructivist inclinations among the goals of environmental education. Thus, the recognition that the relevance of one dominant conception of scientific knowledge as authoritative, objective, discipline-centered, and technical is once again being tempered by the recognition of other, equally legitimate ways of knowing (see Duschl & Osborne, 2002).

## ENVIRONMENTAL EDUCATION RESEARCH

Recognition of multiple epistemologies within the research community of science education would seem to create some space for more constructive consideration of commonsense knowledge of everyday experience in science courses, transfer some control for learning to students, and provide openings for more in-depth studies of relevant social/environmental issues and problems (see Jenkins, 1994; Ryder, 2001, 2002). Parallel developments in research in both science and environmental educa-

tion engage new methodological approaches and new research foci on, for example, the ideas, interests, and thinking of practitioners as important in school pedagogies. The following sections illustrate how environmental education research may represent challenges to traditional conceptions of (science) education research in ways that parallel those just described in pedagogical theory and practice.

## Research as Inquiry into the Theory and Practice of Environmental Education—Early Research

Any discussion of research in environmental education must account for perspectives on both its theory and its practice. Increasingly, researchers in environmental education have begun to acknowledge their differences as a sign of health in intersubjective inquiry. Evolving understandings of even the most fundamental terms such as environmental education itself, as well as sustainability and sustainable development, makes inquiry far from straightforward (see, for example, Gough & Scott, 2003; Palmer, 1998; Scott & Gough, 2003; Scott & Oulton, 1992; Smyth, 2002). Problems of definition surrounding terms such as *environmentalism*, *deep ecology*, and *ecocentrism* that have been debated in philosophy-oriented journals such as *Environmental Ethics* and *Trumpeter* over many years remain interesting because they constitute broad ontological and epistemological frames for environmental education research.

It should not be surprising, then, when journal editors such as Gough and Scott (2003) attempt to sort through some matters of definition surrounding not only environmental education but education for sustainable development. In so doing they raise questions about educational perspectives as framed by larger goals of education in ways that enable the process of dealing with uncertainty, complexity, and risk, that is, by taking a position yet remaining open to, even encouraging, critique (see Rauch, 2002). Given the notion that problems of definition will and should remain problematic provides new perspectives on the relationships between theory and practice in both environmental education and environmental education research.

Although a rhetoric-reality gap remains an underpinning for research in environmental education (as it does for science education), linking these contested goals to the complex pedagogical tasks associated with classroom contexts represents a new challenge. Whereas attention in the early years of environmental education research was focused on establishing connections between knowledge, attitude, and behavior within traditional school practices, more recent work expands this focus methodologically and philosophically. As Reason (1988) suggests, our basic philosophical stance for new approaches to human inquiry follow from worldviews that merge systems thinking, ecological concerns, feminism, and education in ways that are critical of overreliance on reductionist applied science methods. Such a stance is characterized by research that questions how and why reality comes to be constructed in particular ways. Given that educational systems tend to sustain sets of social values that can be influenced by self-interests, these questions remain largely unscrutinized (Robottom, 1987).

It was Robottom's (1987) contention that the early research agenda in environmental education was shaped by an instrumentalist view of educational change. As a consequence, center-periphery research strategies retained characteristics of

objective-based rationalist inquiry that served to reinforce, rather than reconstruct, key features of institutional education. Control over the language of the goals (e.g., through UNESCO-sponsored international forums) influenced decision making, resources, and research practices. By the late 1980s, however, forms of control over the research agenda were openly questioned and contrasted with alternative views of interpretive, participatory, community-based inquiry based on more socially critical forms of environmental education. Such challenges to dominant perspectives in environmental education research were responsible for exposing contradictions in environmental education practices (in schools) as incapable of meeting their socially critical charter. Although subsequently challenged from poststructuralist perspectives, these critiques of existing orthodoxies in environmental education research represented a turning point in how research was considered in environmental education (see Hart & Robottom, 1990; Robottom & Hart, 1993).

### **The 1990s—Debating Perspectives in Environmental Education Research**

By the early 1990s several research symposia and conference workshops were organized to debate perspectives in environmental education research (see Mrazek, 1993). Forums such as these raised questions of epistemology and philosophy that followed wider debates in the field of education. Reviews of environmental education research prior to that time lacked the influences of a broadened consideration of methodological perspectives. For example, according to Palmer (1998), the majority of research studies in the 1970s and 1980s reflected positivist characteristics and a concern for congruence between goals and outcomes, legitimated by the use of applied science methods. Published studies, primarily in the U.S.-based *Journal of Environmental Education*, sought to derive cognitive and affective factors (variables) as determinants of responsible environmental behavior (see, for example, Hungerford, Peyton, & Wilke, 1980, 1983; Hungerford & Volk, 1990; Ramsey & Hungerford, 1989). Meta-analytic studies that posited up to 15 variables associated with environmental behavior resulted in the construction of models of responsible environmental behavior (see Hines, Hungerford, & Tomera, 1986/87). Despite limitations raised in critiques of positivist-based research, reviews by Palmer (1998), Williams (1996), and others recognize the contributions made by these researchers within the context of the times, and, as others have argued, as forms of inquiry that continue to inform our understandings in environmental education research (see Connell, 1997; Oulton & Scott, 2000; Palmer, 1998; Walker, 1997).

Science education is not immune to these debates about research philosophy and methodology, given its educational roots in the social sciences. According to Fien and Hillcoat (1996), the paradigm upon which research methodology is based is often neglected when one paradigm is so dominant that it is viewed as independent of ideology. However, arguments for a meta-research agenda in science education are reflective of growing interpretive and critical movements in education that frame research based on alternative epistemologies and worldviews (see Robottom & Hart, 1993). The importance of these debates is not in the distinctiveness of research methods (i.e., the tools in the researcher's toolkit), but in the assumptions that prefigure what is to count as legitimate ways of knowing and of knowledge

(i.e., epistemological distinctiveness) as well as legitimate ways of finding out (i.e., methodologies and methods). Trends toward more humanistic approaches are evident in recent forms of environmental education research (Williams, 1996) and science education research (Donnelly, 2002). The significance of this epistemological shift is that educational researchers are now obliged to ground their work philosophically within several research perspectives and methodologically beyond only technical efficiencies of method.

Educational researchers now have considerably more scope in framing research questions. Perspectives ranging from feminist (including ecofeminist), gendered, race-based, and cultural studies overlie philosophically distinctive interpretive, critical, and poststructural approaches in ways that are often "blurred" (see Denzin & Lincoln, 2000). That this diversity is manifested in environmental education research is reflected in recent reviews of research (Hart & Nolan, 1999; Rickinson, 2001), in articles in an expanding array of journals that report environmental education research in North America, the United Kingdom, Australia, and southern Africa, for example, as well as in special editions of science education [e.g., *International Journal of Science Education (IJSE)* 15(5), *Studies in Science Education (SSE)* 25] and education journals [e.g., *Cambridge Journal of Education (CJE)* 29(3), *Journal of Curriculum Studies (JCS)* 34(5), *Prospects* xxx(1), and *Educational Philosophy and Theory* 33(2)].

Expansion of research perspectives in environmental education has been accompanied by an elaboration of different views of knowledge within social science and educational research. While environmental education has been concerned about investigating empirical questions posed by environmental problems within educational settings, its distinctive concern, according to Robottom (2000), is with political, sociocultural, and ethical implications of environmental change. Unlike most science education (see, for example, Millar, Leach, & Osborne, 2000; Solomon & Thomas, 1999), environmental education sees the role of education as a post-empiricist concern with social and philosophical forms of inquiry. Knowledge is generated not only by scientific inquiry, but also by addressing philosophical issues about people's intentions and predispositions as subjective, interpretive constructions of the democratic process. Accordingly, professional dilemmas associated with the philosophical and contextual nature of environmental issues remain significant for teachers (Robottom, 2000).

Palmer's (1998) review is useful in consolidating political aspects of these shifts in thinking about what counts as environmental education research. For example, juxtaposing Robertson's (1994) examination of constructivism in science education with interpretivist forms of environmental education research illustrates how representation, implicated in both forms of inquiry, builds on earlier work by Driver and Oldham (1986) in eliciting students' personal conceptualizing and understandings of scientific principles and natural phenomena (see also Driver, Leach, Millar, & Scott, 1996). Given her own work in eliciting and interpreting children's emergent environmentalism, Palmer acknowledges a need for incorporation of growing bodies of research in ethnography, phenomenology, and narrative forms of inquiry in environmental education research.

Examination of critical perspectives in such projects as Environment and School Initiatives (ENSI) (Elliott, 1995; Posch, 1988, 1990, 1996) and in Fien and Hillcoat (1996) generates additional issues. For example, Posch (1996) and Elliott (1995) describe ENSI as action research involving a theory of learning related to active en-

agement in relevant, real-life problems. As such, the approach has struggled to overcome existing curriculum and school structures. Evaluative criteria, drawn from socially critical theory, are quite formidable, particularly those involving children in social action and social critique (see Walker, 1996). Thus, despite widespread success of the ENSI Project, particularly in European countries, practical pedagogical application, involved in the process of uncovering and making explicit the values and interests of individuals and groups who adopt certain positions with respect to social/environmental issues as a means to individual emancipation or social transformation, has proved challenging.

Ideas underpinning critical education *for* the environment (in contrast to education *about*, or *in*, or *through* environment), built up through the 1980s, have exerted extensive influence in environmental education research, particularly outside the United States. Although critical theory has been useful in overcoming limitations of positivist and interpretivist inquiry, Oulton and Scott (2000) see contradictions in the so-called politics for emancipation. If such a position involves proffering specific and specified values, then critical theory is simply the means to yet another orthodoxy. However, if viewed as a means of self-reflection and social scrutiny without particular ends, then environmental education researchers may in fact be engaged in methodological debates that are more characteristic of poststructuralist than critical forms of educational inquiry, involving more sophisticated philosophical arguments about social constructions of social science research. Obviously, no one research perspective is appropriate to environmental or science education research, and debates about intersubjectivity are as necessary among one group of researchers as another. The point, according to Oulton and Scott (2000), is to look beyond various interests if we are genuinely interested in finding ways—multiple and contextual ways—of resolving problems faced by teachers and schools in implementing environmental education. Such strategies are necessarily multiparadigmatic, reflexive, and iterative.

## Recent Research in Environmental Education—Diversity and Critique

Whereas environmental education was virtually unknown until the late 1960s, the last 30 years, according to Rickinson (2001, 2003), have seen growing recognition that environmental challenges have important implications for education. Virtually unknown and frequently misinterpreted in earlier years, environmental education research has gained recognition globally, forming the basis of national frameworks and international policy agreements (Fensham, 1978; Tilbury & Walford, 1996). The research community that drives this activity has expanded so rapidly since Posch's (1993) review of research that it almost defies review, if indeed reviews can be viewed as appropriate forms of reporting the literature (see *EER*, 9(2); Hart, 2003a). This expansion has been complicated by the increasing variety in forms of inquiry that are now viewed as legitimate within the social sciences.

Although the case for diverse forms of inquiry, capable of responding to complex questions of human intention and social relations, has been taken up by environmental education researchers, the nature of this endeavor is difficult to describe.

At this point, it seems that research in environmental education can be characterized by requisite variety, but also by debate about the relative adequacy of several genres of inquiry. Thus, current research in environmental education reflects the need to develop a more reflexive posture toward meta-theorizing in environmental education so that respective methodological assumptions and political theories can be rendered more transparent and open to appraisal (O'Donoghue & McNaught, 1991; Robottom & Hart, 1993).

Rickinson's (2001) portrayal of research on environmental learning illustrates how important methodological critique becomes, given a rapidly expanding evidence base within a methodologically diverse field of inquiry. His findings reveal the need for more sophisticated conversations about the nature and direction of such inquiries as well as the integrity of different theoretical perspectives and methodological applications. Reminiscent of reviews of research that once filled entire volumes of *Science Education*, Rickinson's (2001) review serves to integrate multiple perspectives as a representation of research foci and methodological variety in ways that challenge existing conceptions of learning in complex environments (see Barron, 1995; Bonnett & Williams, 1998; Keliher, 1997; Payne, 1998a, 1998b; Wals, 1994a, 1994b).

First, the Rickinson (2001) review provides evidence that recent studies are likely to be qualitative, often with interests in poststructural forms of interpretive or critical understanding. Claims tend not to be expressed as generalizations but as situational, descriptive, and tentative, reflecting postmodernist sensibilities (see Ballantyne, Connell, & Fien, 1998a, 1998b; Jensen, Kofoed, Uhrenholdt, & Vognsen, 1995). Second, a strong science education influence persists, related particularly to studies of science-based knowledge in environmental issues (see Simmons, 1998) and to studies of environmental education found within science-based school programs (see Bogner, 1998). Common to these types of studies is evidence of inadequacies and misconceptions in students' understanding of environmental issues across many countries (Gambro & Switzky, 1999). This evidence is reflected in the disciplinary background not only of science teachers who primarily engage in this activity, particularly in middle and secondary schools, but of environmental education researchers themselves. However, there is also evidence that this trend may be weakening, given new methodological foci on the nature of students learning experiences and student perceptions rather than on learning outcomes.

Third, a rapid expansion of the geographical base of environmental education research is evident in Rickinson's (2001) review. Although environmental education research has tended to concentrate in North America, Europe/UK, southern Africa, and Southeast Asia, the recent First World Environmental Education Congress (FWEEC) (Azeiteiro et al., 2003) testifies to concentrations of activity in many other countries and regions such as Brazil and Central America. It is interesting that marked variations in methodological approach appear to be somewhat regional and that the dominance of quantitative approaches in certain areas has limited the range and scope of these inquiries in this area of learning (Rickinson, 2001). Other reviews of environmental education research reflect increasing concern about the appropriateness of methodology in areas such as environmental knowledge, attitude, and behavior (see Zelezny, 1999); learning outcomes (Leeming, Dwyer, Porter, & Cobern, 1993); outdoor experiences (Keighley, 1997); environmental sensitivity (Chawla, 1998); and student understanding of global environmental issues (Boyes

& Stanisstreet, 1996). This concern with methodology is also reflected in more comprehensive and in periodic reviews of the research literature in environmental education (see Andrew & Malone, 1995; Iozzi, 1981, 1989; Marcinkowski & Mrazek, 1996; Wagner, 1997).

Although review studies of particular areas of environmental education research have provided indications of, for example, students' weak knowledge or misconceptions of environmental issues, these results are often contested, as they have been in science education (see Brody, 1996; Clark, 1996; Ivy, Lee, & Chuan, 1998; Koulaidis & Christidou, 1999; Wylie, Sheehy, McGuinness, & Orchard, 1998). Methodologically, the concern is that most of these studies were short-term and did not seek to investigate *why* respondents viewed environmental issues in particular ways. The weakness of this evidence was magnified when the knowledge-attitude relationship was extended to attempts to quantitatively connect knowledge and attitude with behavior (Chan, 1996; Connell et al., 1998). Evidence based on questionnaire or self-reported data varied so greatly that it remains difficult to suggest that this line of inquiry can help us understand what motivates young people to participate in proenvironmental behavior or how this is connected to cognition or affect (see, e.g., Leal Filho, 1996; Kahn & Friedman, 1995; Prella & Solomon, 1996).

Questions about the quality of evidence from large numbers of these studies, as well as several methodological critiques, remain (see Hungerford, 1996; Smith-Sebasto, 1998a). Despite claims of positive learning outcomes and, in a few cases, behavioral change (see Bogner, 1998; Emmons, 1997; Leeming, Porter, Dwyer, Cobern, & Oliver, 1997; Uzzell et al., 1995), a number of researchers have begun to focus on questions about the nature of student thinking, using metaphors and more robust models of student understanding (see Boyes & Stanisstreet, 1997; Boyes, Stanisstreet, & Papantiniou, 1999). Increasingly researchers are exploring how and why certain processes such as role-modeling and collaborative, community, or direct outdoors experiences bring about positive learning outcomes (Rickinson, 2001, 2003).

Reviews of this literature also provide evidence that researchers can vary their research strategies, given a much wider array of legitimate methodologies (see Hart & Nolan, 1999). For example, in recent studies of students' ideas and perceptions of nature, evidence of learning is often more descriptive, reflecting phenomenological or narrative inquiries as opposed to explanations (see Barron, 1995; Bonnett & Williams, 1998; Keliher, 1997; Palmer & Suggate, 1996; Payne, 1998a, 1998b; Wals, 1994a, 1994b). Although it remains unclear whether these investigations will provide meaningful directions for teachers, researchers were encouraged by the complexity and richness of data about young people's views of nature. These research findings appear to correspond to research with teachers who trace environmental sensitivities and sensibilities to significant life experiences, often from middle childhood, with important adult mentors (see Chawla, 1994, 1998; Kaufman, Ewing, Hyle, Montgomery, & Self, 2001; Palmer, Suggate, Bajd, et al., 1998; Palmer, Suggate, Robottom, & Hart, 1999). Although somewhat speculative, such studies into the nature of these conceptions and about how young people socially construct their ideas and images of nature and of environment appear to warrant further investigation.

Given recent trends in education toward more interpretive forms of inquiry, Hart and Nolan's (1999) review of environmental education research illustrates how epistemological/ontological broadening has, on the one hand, opened inquiry methodologically and raised questions of representation, legitimacy, and quality on

the other. Inquiry in environmental education is now a complex, multiparadigmatic array of methodological thought and practice. New forms of research are emerging as researchers' identities are altered to include participatory action as well as perspectives of women, people of color, gays and lesbians, and differently abled people of many kinds. These theoretical perspectives form part of the responsibility of new research texts that together with emergent critical and poststructural theory are changing the face of inquiry in education. As Crotty (1998) suggests, the idea of inquiry is not in adopting an existing paradigm, but in articulating the epistemological and theoretical perspectives that have influenced, rather than determined, their work. New languages are needed so that we can engage more sophisticated discussions about the meanings and purposes of our work, embedded as it is, within a politics of method.

Looking beyond correspondence in knowledge-attitude-behavior relationships involves a complex of perceptions that implicates people's reasons and feelings, reciprocally and dialectically, with their actions. A number of studies in environmental education research are beginning to conceptualize human "actions" as more complex subjective explorations of thought, meaning, and understanding attached to certain ways of being in the world (i.e., ontologies) (see Hicks, 1993; Payne, 1999). These arguments have been extended to include issues of gender, class, race, and cultural identities and relations (see Lousley, 1999).

Smith-Sebasto (1998) contrasts these perspectives with research in science education, where demands are for more rigor in the application of existing behavioral measurements rather than a questioning of the goals of such endeavors themselves. Whatever the reasons, environmental education researchers have concerns that we may have persisted in asking the wrong questions, or questions that do not warrant answers (Scott, 2003). Journal editors and publishers are now obliged to address the politics of publications characterized by methodological diversity, evaluative criteria appropriate to genre as a means of maintaining quality, and justification not only of methods but of philosophical perspective. Suffice it to say that environmental education journals have diverged from their science education prototypes.

Soltis (1984) has argued that a useful way of viewing tensions within a research community is to place them within the broader context of philosophical perspectives. That is to say, different approaches to research are always underpinned by different assumptions about what counts as knowledge or as reality (May, 2001). In Eisner's (1990) terms, there is more than one way to partition reality. Mixing methods is now a matter of methodology that requires addressing issues at theoretical conceptual levels. Whereas object-based inquiries attempt to overcome uncertainty through detachment and analytic procedure, subject-based research seeks to transcend the subject/object binary by acknowledging narratives of primary subjective experience as legitimate knowledge within certain boundaries of credibility and authenticity. Journals such as *EER* have been active in raising meta-theoretical and meta-methodological issues of open engagement and debate. Special editions have examined issues related to research on significant life experiences [*EER* 4(4), 5(4)], qualitative methods [6(1)], language of sustainability [7(2) and 8(1)], reviews of research [9(1)], and case study research (forthcoming). Special issues of the *CJEE* have focused on issues of research involved in narrative approaches [7(2)] and cultural awareness [7(1)]. Educational journals such as *Educational Philosophy and Theory* (see Stables & Scott, 2001), the *CJE* (see Bonnett & Elliott, 1999), and *IJSE* have addressed

environmental education for various reasons, including its relevance to educational thought and practice, the adequacy of current approaches, and its significance for education as a whole.

Inquiry in environmental education is finding a place within educational research because researchers are using methods that address questions and issues that the positivist paradigm failed to address. Narrative forms of inquiry (Bruner, 1990, 1996; Polkinghorne, 1995) and analysis (Cortazzi, 1993) grounded in epistemological arguments about the value of storied forms of understanding teachers' philosophies are now forming a niche within environmental education research (see *CJEE* 7(2); Chenhansa & Schleppegrell, 1998; Gibson, 1996; Monroe & DeYoung, 1996; Wirth, 1996). Williams's (1996) review of the role of research in geographical and environmental education includes chapters on interpretive approaches (Gerber, 1996), critical research (Fien & Hillcoat, 1996), grounded theory (Tilbury & Walford, 1996), discourse analysis (Bennett, 1996), and case study research (Roberts, 1996).

Beyond these reviews, a number of exemplary dissertations have established precedents for new approaches to inquiry. For example, Malone (1996) described her study as critical ethnography, Mahony (1994) as ethnography, Brody (1996) as phenomenology, and Rentel (1997) as hermeneutic phenomenology. Various forms of participatory (action) research provide cases of active engagement of participants, intellectually and practically, in critical inquiries within their own contexts (e.g., Andrew, 1997; Elliott, 1991; Kyburz-Graber, Rigendinger, Hirsch, & Werner, 1997; O'Donoghue & McNaught, 1991; Papadimitriou, 1995; Posch, 1994; Robottom, 1987; Wals & Alblas, 1997). As is the case with all forms of qualitative inquiry, these approaches are subject to critique. Thus, researchers have the added task of addressing demands of critical reflexivity and intersubjective scrutiny (see Davis, 2003; N. Gough, 1999; Payne, 1999).

Case study has also been used extensively across various genres of research to represent environmental education activity (see Emmons, 1997; Gayford, 1995; O'Connor, 1997; Page, 1997). Wals and Alblas (1997) describe a case study of curriculum reform through an action research process, where teachers openly reflected on their struggles to incorporate an environmental dimension into their practices (see also Payne & Riddell, 1999). Andrew's (1997) historical case study research exemplifies Robottom's (1987) concern that community-based case-study research, as inclusive of the enactment and consequence of economic rationality as well as context, does not define the research approach that is generated through both the researchers' assumptions and the case experience itself. In other words, the case merely determines the form of a particular study, which is why it can exist within a number of contemporary research forms and discourses, including feminist, critical, and poststructural methodology.

Although many case studies of environmental education programs tend to use participatory research (e.g., Turner, 1998; Walker, 1996), action research (e.g., Schreuder, 1994), critical action research (e.g., Fien & Rawling, 1996), or community-based action research (e.g., Pace, 1997; Peel, Robottom & Walker, 1997), many others remain as basic descriptive evaluations of environmental education programs that struggle for methodologies that can identify crucial dimensions (i.e., factors) in the development of community-based programs. These positivist tendencies, while understandable, remain a concern among interpretive and critical researchers who are more interested in the uniqueness of individual context-sensitive cases.

How we “make sense” of these large numbers of descriptive “reports” that address curriculum issues ranging from integrating environmental education into formal school subjects (e.g., Randall, 1997; Shin, 1997) or art and literature (e.g., Soetaert, Top, & Eeckhout, 1996), drama (e.g., Cabral, 1998), or special education (e.g., Lock, 1998) across many regions and countries (e.g., Adedayo & Olawepo, 1997; Lee, 1997) remains to be determined.

The environmental education research literature also contains examples of out-of-school integrated programs that involve outdoor education (e.g., Nelson, 1996; Richardson & Simmons, 1996; Yerkes & Haras, 1997), experiential education (e.g., Luckman, 1996), or global education (e.g., Selby, 1999). Within these programs, students have explored ecological concepts and environmental issues by using a wide variety of curriculum areas and nonformal approaches, including agriculture (e.g., Miller, 1997), ecotourism (e.g., Cork, 1996), botanical gardens (e.g., Spencer, 1995), parks (e.g., Darlington & Black, 1996), or nature centers (e.g., Wilson, 1993a, 1993b) or by using special topics as foci for these experiences, such as water issues (e.g., Goodwin & Adkins, 1997; Ho, 1997) or endangered species (e.g., Martinez Rivera, 1997).

As the field of environmental education has matured, research has assumed a role in the reporting of large-scale status studies intended to provide more comprehensive “measures” of, for example, science learning achievements, program evaluations, and teacher education. Many of these reports use multiple methods to evaluate formal and informal programs such as Project WILD or Project Learning Tree (e.g., Collins & Romjue, 1995) or the Great Lakes Program (e.g., Nevala, 1997). Studies of specialized programs in many countries have contributed to a more globalized portrait of the nature of environmental education worldwide [e.g., Scotland (Smyth, 1999), Guyana (Leal Filho & Bynoe, 1995), Korea (Sang-Joon, 1995), Germany (Bolscho, 1990), England and Wales (Reid & Scott, 1998); Uganda (Mucunguzi, 1995); the South Pacific (Taylor & Topalian, 1995), New Zealand (Springett, 1992), and southern/eastern Africa (Taylor, 1998)]. These reports and those in the newsletter *Connect* (UNESCO-UNEP) reveal many variations and stages of development in environmental education programs related to local issues. They are valuable in encouraging researchers to consider their research in terms of “western” goals, ideals, and evaluative criteria as part of a “politics of transfer” issue in cultural terms. Justification of programs has often resulted in positivist evaluation models that may be inappropriate in different cultures and contexts (see Courtenay-Hall & Lott, 1999; Fien et al., 2001; Sauv e, 1999).

Research in environmental education is also characterized by inquiries focused on personal and social issues related to environmental education programs and experiences. For example, studies centered around teacher thinking include studies of teacher beliefs about and/or perceptions of nature, environment, or social/environmental issues (e.g., Ajiboye, Audu, & Mansaray, 1998; Bachiorri, 1995; Kasper, 1998; Nando Rosales, 1995). Increasingly, it seems, these studies go beyond quantitative comparisons among measured variables using fixed instruments in search of connections related to teachers’ beliefs, perceptions, and predispositions/assumptions that may result from life history (e.g., Stocker, 1996), early life experiences (Hart, 2003b; Todt, 1995), sense of place (e.g., Chawla, 1994; Hug, 1998; Stephens, 1998), autobiographical memory (e.g., Conway, 1990), and children’s concern for the environment (Chawla & Hart, 1995; P. Hart, 1999; R. Hart, 1997). Motivation for provision of environmental education is also the interest in explorations of significant life experiences (SLE) (e.g., Corcoran, 1999; Elliott, 2002; Palmer, 1998; Palmer & Suggate,

1996; Tanner, 1998a, 1998b; Wilson, 1996). As an instance of memory work, this inquiry has generated some useful critical commentary [see *EER* 5(1)] that has informed subsequent discussions such as AERA's research interest group in environmental education and environmental education research.

As an example of focused critical discourse, the SLE debate has raised important methodological issues that affect all areas of post-positivist inquiry (see N. Gough, 1999; Payne, 1999). This research debate has led to suggestions for explorations, for example, that seek to explain how the structuring and continuity of embodied experience (or inner nature) are immersed and embedded in the historical, social, and ecological environment (or external nature) and, thus, how individuals actively construct experiences, and their significance, in the face of equally problematic social constructions of the environment and nature (Payne, 1999b). This active debate has also led to methodological developments, including the use of certain post-structural understandings of human subjectivity and agency in environmental education research (see A. Gough, 1999). In turn, this debate reiterates the epistemological distinction, in research in the social sciences and education, between inquiry as a neutral technical process and inquiry as engagement in the social construction of knowledge. As well, it considers the ontological distinction whereby a mode of inquiry is incumbent upon the assumptions and practices not only of the research paradigm but the worldview, in this case the ecophilosophical worldview of environmental education (Robottom & Hart, 1993).

Environmental education research has also focused on children's ideas, perceptions, or perspectives, with particular emphasis on the role of nature (e.g., Keliher, 1997; Payne, 1999), early experience (e.g., Hart, 2000; Wilson, 1995, 1996, 2000), story, sense of place (Chawla, 1998; Sobel, 1997), and curriculum/school experiences (e.g., Eagles & Demare, 1999; St. Maurice, 1996) in informing children's emerging ecological and social ontology (see R. Hart, 1997; Palmer, 1995; Peters & Wilson, 1996). Numerous studies have sought to understand children's perspectives and ideas about environment and a variety of environmental issues (e.g., Boyes & Stanistreet, 1997; Hillcoat, 1995; Williams & Bonnett, 1998). Specific issues such as air pollution (Wylie et al., 1998), the greenhouse effect (Fisher, 1998; Mason & Santi, 1998), the ozone layer (Christidou, Kouladis, & Christidis, 1997), municipal waste (Glazer, Vrtacnik, & Bacnik, 1998), endangered species (Ashworth, 1995), and radon gas (Thrall, 1996) appear to be widespread, internationally, depending on local/regional circumstances.

Research focused more specifically on student thinking as a result of course-based experiences (e.g., Mangas, Martinez & Pedauye, 1997; Tyler-Wood, Cass, & Potter, 1997), as well as experiential courses/programs (e.g., James, 1997; Leeming, 1997), has resulted in questionable findings (see Cobiac, 1995; Kuo, 1994). Thus researchers have begun to look more holistically at students' values and beliefs (e.g., Ballantyne & Clacherty, 1990; Greaves, Stanistreet, Boyes, & Williams, 1993; Wals, 1992). Jurin (1995) and Fason (1996) report disparities between quantitative and qualitative findings in mixed-method studies, speculating, with Boyes & Stanistreet (1998), that mixed-belief structures may exist simultaneously and that such disparities in student thinking of this complexity cannot be addressed adequately through short-term, one-shot measures.

This research literature on students thinking illustrates a concern to probe for deeper understanding about how we come to know and think about social/environmental issues in ways that reflect more sensitivity to gender (e.g., Barron, 1995;

Mansaray & Ajiboye, 1997; Yeung, 1998) and culture (e.g., Chan, 1998; McIlveene, 1996). Payne (1997, 1998a) argues that it is these forms of inquiry, involving contexts and life experiences research, that are essential to understanding children's minds, ontologically, as being "in" environment, as opposed to belief structures attached to particular personality factors or environmental issues.

### WHY SCIENCE EDUCATION RESEARCHERS SHOULD ATTEND TO RESEARCH ISSUES IN ENVIRONMENTAL EDUCATION

So, what is distinctive about inquiry in environmental education? Why should science educators be interested in what environmental education research is saying or in how it is engaged critically and reflexively? Perhaps it is a function of the age of a discipline or of its place in society, or its natural association with dominant forms of inquiry that led to N. Gough's (1999) comment about research in science education that makes little acknowledgment of the limits to scientific explanations within the complexity of decision-making in real-world events such as environmental issues resolution. "Environmental educators," he says, "do not have the science educator's mandate (or excuse) for privileging 'scientific' knowledge and methods. Thus, environmental education researchers need to recognize the contested nature of epistemology . . . and problematize the cultural construction of scientific knowledge" (p. 39). The point is that, within environmental education research, as in educational research generally, considerable space is now devoted not only to issues of methodology, but to issues of epistemology and ontology. Thus, where research in science education hastened to focus on method and to relegate these arguments to the philosophy of science, environmental education research has raised theoretical issues that necessitate serious philosophical consideration by researchers themselves (see Osborne, 2002; Warwick & Stephenson, 2002).

According to Robottom (2000), recent developments at levels of policy, practice, and organization raise new issues for environmental education and render past characterizations of the field as problematic. For example, the policy perspective provided by UNCED's Agenda 21 (UNCED, 1992) has asserted a distinct social change agenda for environmental education that challenges the field's historical disciplinary relationships. If Agenda 21 is taken seriously, then education is critical for promoting sustainable development and improving society's capacity to address social/environmental issues. Robottom (2000) views this emphasis as the basis of arguments for forms of education that address fundamental questions of ethics and values, and encourages public participation in citizen decisions about social/environmental issues as well as cooperation in redressing existing economic, social, racial, and gender inequities. These issues involve philosophical questions (of the "ought" and "should be" kind) that are not exclusively scientific and can only be resolved through considerations of intergenerational equity, health, peace, human rights, ethnicity, gender, age, and class matters concerning democratic process, social justice, and quality of life (Robottom, 2000).

Implied in the consideration of philosophical dimensions to forms of environmental (and science) education, with an interest in individual and collective issues of ecologically sustainable development, are challenges to existing research prac-

tices. These challenges foreshadow deeper ontological/epistemological concerns that have been neglected within mainstream education (see R. Hart, 1997; Rivkin, 1995, 1997; Smith, 1998). They require active engagement of methodological considerations about forms of inquiry available to educational researchers (see Ahlberg & Leal Filho, 1998; Greenall-Gough, 1994; Groves, Jane, Robottom, & Tytler, 1998; Huckle & Sterling, 1996; Jensen, Schnack, & Simovska, 2000; Jickling, 1993; Kollmuss & Agyeman, 2002; Mrazek, 1993; Oulton & Scott, 2000; Palmer, 1998; Robertson, 1994; Williams, 1996; and recent issues of *EER* and *CJEE*). Although environmental education researchers have begun to address these challenges at various conference forums of NAAEE and special research seminars, fundamental issues remain unresolved. What seems to be evolving is a critical sociology of environmental education research that continues to problematize the assumptions, values, theories, and practices upon which research activities in this field are grounded. Continuing such engagements will immerse the field in critical and poststructural conversations that appear to be necessary for its survival.

What is interesting about this notion of functioning within multiple perspectives, beyond the essentially contested nature of key conceptualizations of environmental education or philosophical debates about ideas that drive theory and practice, is the rich ground they provide for researchers who can base inquiry in several perspectives and can construct positions on their own grounds (including practical experiences, say, as a teacher). Cases have been established, for example, for forms of environmental literacy (e.g., Disinger & Roth, 2003; Stables, 1998; Stables & Bishop, 2001; Stables & Scott, 1999), education for sustainability (e.g., Huckle & Sterling, 1996), sustainable development (Gough & Scott, 2003), sustainable futures (Turner & Tilbury, 1997), or learning and sustainability (Government of Canada, 2002) where each is contested (e.g., Jickling, 1992; Oulton & Scott, 1998; Plant, 1995). Cases have also been made for particular dimensions of research, including historical (e.g., Andrew, 1998; Marsden, 1998; Morgan, 1998) and constructivist (e.g., Hoffman, 1994; Robertson, 1994b) approaches and action competence (e.g., Breiting & Nielsen, 1996; Jensen & Schnack, 1997; Schnack, 2000). Centers for environmental education research activity and debate of such issues operate in several countries, including Denmark (Royal Danish University), England (University of Bath), Australia (Deakin University and Griffith University), and the United States (University of Michigan, Southern Illinois University, the Ohio State University). Researchers are also active in many other places in areas such as nonformal education (e.g., Heimlich, 1993), technology (e.g., Dillon, 1997), adult education (e.g., Clover, Follen, & Hall, 1998), cross-cultural education (e.g., Armstrong, 1997; Chou & Roth, 1995; Corcoran & Fien, 1996; Kyburz-Graber, et al., 1997), and teacher education (Scott & Oulton, 1995).

Although just a decade ago Posch (1993) identified an absence of viable alternative visions as one of the key obstacles to effective environmental education research, the opposite may be true today. Environmental education researchers have turned their attention from a "search for solutions" to a "search for causes" and have begun to search for answers beyond positivist approaches in order to address issues of value assumptions, social visioning, and mosaics of personal and social qualities, that is, toward a broadened view of learning as action-oriented. Yet concerns remain about educational systems not attuned to the social complexities and environmental uncertainties that threaten established decision-making processes. Thus, environmental education researchers continue to raise questions about education,

learning, and how to prepare students to cope with insecurity, decision making with incomplete data, and the contradictory demands of a plurality of values, or how to become citizens who participate in their various forms of government. It seems that environmental education is at a crucial point between destabilization, as prerequisite for incorporation of new elements, and stability, as a condition necessitating vigilance and skepticism. While these tensions create new opportunities for research, there are political aspects to change in subject-based curricula that make problematic the stability of systematic knowledge transmission and involve themselves in school-based initiatives full of uncertainty and risk.

### **The Politics of Environmental Education Research**

Although recognition of the political nature of environmental education research has allowed researchers and practitioners to reconstruct relationships and to reconsider some assumed binaries such as objectivity/subjectivity and expert/novice in a new light, these new modes of knowledge generation are always subject to challenge, as they should be. Developments in the theory and practice of education can be shown to underlie these challenges as part of a politics of inquiry. The context for such challenges becomes more acute when certain forms of inquiry are marginalized because they do not conform to traditions. Viewed as a series of sociocultural processes, however, environmental education research has contested many taken-for-granted assumptions about theory and about practice in educational research.

At the level of theory, a key research issue is how we come to value alternative ways of generating knowledge. Whereas researchers in the natural sciences use objective means to justify their research, knowledge in the social sciences is less clearly defined and is subject to problems of interpretation and representation. Addressing aspects of human behavior such as intents, motives, and values involves levels of indeterminacy that traditional researchers find difficult to comprehend, often leading to misinterpretations, misunderstandings, and unfair accusations. Because education as a human endeavor resists efforts by researchers to establish causal claims that are verifiable, definitive, and cumulative, researchers are left to try to understand sociopolitical processes that reflect sociocultural purposes embedded with contradictions, as well as conflicting criteria for appraisal of success (Larabee, 1997a, 1997b).

As Rickinson (2001) argues, impacts of teaching and curriculum on learning rely on human dimensions that shape outcomes in indeterminate ways that are irreducibly normative. Knowledge generated in one context may or may not apply to another, and even particular contextualized applications depend on perspectives of practitioners and researchers. Thus, constructed knowledge is not bound by foundational constraints. So, while methodological diversity is now valued, this position carries different responsibilities for ensuring quality and accountability. Hence, the new politics of educational research is organized around new debates characterized by attempts to justify methodologies rather than methods. For example, debates within interpretivism are no longer argued as a response to positivist critique (i.e., as paradigm wars), but as differing underlying philosophies about what counts as knowledge and about how reality is perceived.

Environmental education research is characterized by increasingly active debates about the form and content of its inquiry. Questions have been raised, for

example, about the legitimacy of various forms of inquiry, thus implicating the politics of methodology. Methodological approaches such as ethnography, phenomenology, and various participatory and poststructuralist perspectives are based on assumptions reflected in the languages and conceptual meanings of various philosophical discourses such as interpretivism, criticalism, and postmodernism (see Denzin & Lincoln, 2000). Unlike the past, when the dominance of positivism relegated such debates to the philosophy of science, questions of subjectivist epistemology and social constructivist ontology now challenge environmental education researchers to justify their narrative-based accounts of research in terms of what counts as legitimate knowledge or as adequate forms of representation in terms of what makes them seem credible, trustworthy, and authentic beyond subjective judgment. Several issues of *EER* and *CJEE* have attempted to raise such issues as we learn to negotiate our interpretations based on shared, intersubjective understandings among the community of interested researchers and practitioners. These discussions are recognized as political when inscribing legitimacy involves authority of a dominant discourse or perceived hierarchy of legitimacy. Those who do not conform may feel alienated or coerced into playing by certain rules. New methodologies that threaten existing orthodoxies may cause resistances and tacit or explicit sanctions from journal editors or granting councils. More deeply, however, the politics of methodology implicates language, sources of evidence, methods, and, ultimately, the ways in which we construct our thinking about research methodology.

At the methodological level, resistances or reactions to fields of inquiry outside our own may result in misinterpretation and misrepresentation of alternative positions whose justification depends on unfamiliar criteria. Statements that appear clear and coherent within one research genre may not be intelligible within another. The problem, according to Lather (1996), is in the assumption that it is acceptable for educational researchers to critique methodology without having studied the underlying philosophy. Thus, pleas for intelligence in debate about methodology can now be found in those special editions of *EER* that focus on helping researchers to rethink their methods within their methodologies without simplifying the complexities of research in practice. The idea is not to defuse debate so much as to engage the space over words as unstable as our clearly bounded territory, divided perhaps by theories and discourses, but centered by struggles to ground our work both theoretically and practically.

As a representational practice, environmental education research is always embedded in methodological commitments that are necessarily political. Researchers speak through particular discourses that understand and close the world in particular ways. Given this embeddedness within theory and the micropolitics of research practice, there are no best practices or superordinate methodologies. Thus, researchers are responsible for becoming more conscious of this politics of methodology as a means of addressing the values and beliefs that underpin our understandings and provide reasons for our research decisions. The methodology question then becomes one of how to account for our subjectivities as researchers and participants. According to N. Gough (1999), if we are to escape the automatic imprint of our own experience, we need to surpass our personal histories through acts of critical reflection, that is, to make more explicit that underlying frame of ideas, assumptions, and beliefs that guide our practices. Once articulated, and subject to critique, we may become more conscious of our values, motives, biases, and unexamined,

taken-for-granted assumptions—those personal and social dimensions through which our research practices become intelligible.

Environmental education research in this sense can only be understood as an activity of interpretation where representation is always reflexively problematic. Because reality is constructed through representation, and thus is fictional, reflexivity becomes an issue of problematizing methodology by surfacing preconceptions, finding out how meanings were constructed, and how understanding is bound up in language and writing. In other words, research accounts can no longer function unproblematically as “true” representations, and grounding for accounts of research must be approached through political judgment about whether the interpretation is adequate (in contrast to reliance on foundational criteria). However, reflexivity by itself, as an issue of overcoming blind spots through a kind of self-consciousness, may be far from a neutral process. If constituted as an ability to mobilize across gender, race, and culture, critics can apply this capacity unevenly in inscribing new reflexive hierarchies of speaking positions hidden by claims that critical reviews are progressive within the politics of methodology. The irony is that critical responses to particular lines of inquiry may consciously or unconsciously privilege certain lines of inquiry through critique of others, thus engendering forms of exclusivity in the very act of denying it.

In environmental education research, we continue to search for critically reflexive approaches. In my own work with teachers who struggle to construct stories of their environmental education practice, the point is not that such narratives are true but that they may become truthful fictions through frequent repetitions across a range of contexts and through their credibility to practitioners of all sorts. Research accounts become reasonable in their resonances with broader collectives of meaning (see Hart, 2003). Without such attempts to interpret affect, emotions, feelings, and motivations as meaningful dimensions of human identity and place, we have virtually no way of understanding people’s lived experiences as they exist in their imperfect, partial, historical, and contextual accounts of their experiences, full of contradictions, and as imposed fictions in memory as well as the exigencies of everyday life. We believe, as researchers, that our accounts of lived experience may ring true, however fragmented, contingent, and multiple within the social contexts inhabited. And our research will always be confronted by such anxieties and by the politics of intersubjectivity, so we had better get used to it. Rather than recoil in some fit of existential angst, we know that some stories are important and must be told, even as we, as researchers, learn how to accept critique warranted by our necessarily subjective process.

What we need to do, according to Skeggs (2002), is to use reflexivity as a way of sensitizing our research process as we learn to live responsibly in privileged positions; that is, we must try to ensure that our epistemological authority does not compromise our moral authority. Learning to see research as political (as well as multiple, historical, and contextual) involves more than casual appropriation of philosophical concepts or methodological approaches, but rather the serious study of the roots of our ontological/epistemological perspectives. Removal of the notion of certainty in research does not mean anything goes, but that we learn to acknowledge multiple truths and multiple ways of knowing. Environmental education research (as environmental education itself), in affirming that we cannot provide an ultimate rationale (foundation) for any given system of values, does not imply that

one considers all views to be equal (i.e., relative). The question is not whether one position is right so much as why we have come to occupy and defend it. Our responsibility is to read widely and deeply and to engage in discussions and debates that expose our ideas and research practices to forms of reflexivity and to become more conscious of the politics of methodology, and of knowing and being, toward improved research praxis.

## END NOTE

Those who regard science teaching as engaging in the disciplines of science and education where the serious processes of knowing are stressed and “the virtue of instrumental content knowledge” is valued may have at best a passing interest in examples of environmental “science” that provide relevance to their activities. However, those science educators who understand science from a wider, more encompassing perspective, and particularly those who value the virtue of social values and adopt a pluralist nature of science, may share considerably more philosophical ground with environmental educators. For example, Cobern (1998a), from the perspective of science education, argues that science as a social endeavor should be informed by constructivist epistemology and that the image of science portrayed to students should represent a variety of perspectives, such as cultural, political, economic, critical theory, and theological. This position counters the older view of science as culturally neutral and of science education that uncritically reproduces western or modern versions of universal truths in schools (see N. Gough, 1999).

According to Bybee (1993), Bybee and Deboer (1994), and Hurd (1969, 1970, 1998, 2000), the history of science education is one of oscillations among espoused goals that sometimes include an emphasis on the social aspects of science and sometimes eschew them. These arguments aside, constructivism and social constructivism, as theoretical constructs that provide perspective, seem to encourage a dialogue among science and environmental educators who accept that science is a socially mediated and value-laden activity and that social constructivism allows a more authentic version of science to be represented to students. If science is understood to be part of the social world in dialectical relationship with the natural world, then environmental and science educators have more to talk about, as do researchers in both arenas. With an underlying social constructivist epistemology in common, the scope of a research activity can expand to encompass constructivist/interpretivist, critical, and postmodern ways of knowing and the creation of knowledge, not only in scientific but in educational research, recognized as a social endeavor as well as a cognitive construction. This means science educators’ views of research must include conceptions of knowing and understanding as socially/culturally influenced. It also means conceiving of inquiry in science and education as subjective as well as political.

The point is, from research perspectives encountered by many environmental educators, although science is not totally explainable in social, political, or cultural terms, neither is it the pristine, monistic, acultural, ahistorical way of knowing it is purported to be by many devout interpreters of science education (Benson, 2001). The problem has been, in taking a social constructivist position to teaching, that teachers often do not know the presuppositions of teaching from that position. And

the same is true for researchers who have not understood the epistemological/ontological presuppositions among the various ways of knowing. Benson's (2001) explanation of social constructivism, as rooted in the sociology of knowledge, where construction of meaning is rooted in social settings, is instructive for researchers who work beyond positivist methods. The way an individual interprets the world and creates personal understanding, he says, is influenced by five features: knowledge of history (as learned in culture), the particular social context of the research, the researcher's personal life history, the purposes attached to the research (as a sense-making process), and the research act itself (as an act of creating meaning). Thus, we can have similar understandings, but they may be created individually and contextually in ways that influence how we understand this knowledge/understanding.

Extended to social science and to educational research, the suggestion is that researchers use a socially based interpretive method to account for methodological choice and to establish evaluative criteria according to that choice. So conceived, it is absolutely crucial that the researchers lay out epistemological/ontological and methodological assumptions from which their arguments are constructed. This obligates researchers to know why they are researching from a social constructivist, critical, poststructuralist, or any other perspective or combination of perspectives. If research in science education and environmental education is to be recognized and justified as a human creation influenced by social/cultural issues, it implies that science education researchers who maintain a strict realist view of research might be ignoring developments in educational/social science research, as illustrated by the requisite variety in environmental education. More seriously, such researchers may be ignoring recent developments in the philosophy of science and how the nature of research (and of science) is interpreted. It is necessary to engage in these discussions in any attempt to portray a field of research as distinct from science education, but also to engage in the politics of research that this engagement entails. To do less would be to abrogate our responsibilities as social science researchers to theorize our practices, a matter as serious as the failure to ground our theories in practice.

# PART IV

---

## Curriculum and Assessment in Science

# CHAPTER 25

---

## Scientific Literacy/ Science Literacy

**Douglas A. Roberts**

*University of Calgary*

The title of this chapter deliberately includes two terms—*scientific literacy* and *science literacy*, abbreviated together as SL. The literature on SL has mushroomed in the past two decades. The concept has come to be used more and more extensively, in many countries, to express what should constitute the science education of all students—to the point where one author claims (perhaps overenthusiastically) that SL now enjoys “worldwide cachet” (McEneaney, 2003). At the same time, it is well known in the science education community that no consensus exists about the definition of SL.

In fact, there is a veritable deluge of definitions for SL. The term is used in research studies, in discussions and analyses of science education goals, in assessment programs, and in curriculum embodiments such as policies, programs, and teaching resources. Closely related literature, which cannot be ignored in a review of international scope, uses three other terms as well. In the context of analyzing European science education, Solomon (1998) uses the terms *scientific culture* and *la culture scientifique* (the latter term is also used in francophone Canada, for example). Public understanding of science (PUS—such an unfortunate acronym) is a phrase widely used in England (e.g., Durant, 1994; Hunt & Millar, 2000) and increasingly elsewhere (e.g., Miller, 1992). Incidentally, a colleague informs me that the term *public understanding of science* is becoming less popular because it “assumes a homogeneity of publics and of understandings”; hence the term *public engagement with science* is being used (J. Osborne, personal communication, July 19, 2004).

I shall argue that all of this diverse literature can be better understood if one comes to grips with a continuing political and intellectual tension that has always been inherent in science education itself. I refer to the role of two legitimate but potentially conflicting curriculum sources: science subject matter itself and situations in which science can legitimately be seen to play a role in other human affairs. These two sources have long been used to generate components of science learning—whether in pre-collegiate formal schooling or informal science education in museums and the like. At issue is the question of balance. What has become increasingly noticeable in the SL literature is a growing polarization between advocacy positions

that argue for pressing these two sources to the extremes. That is, there seem to be two *visions* of SL that recently have come to represent the extremes on a continuum. I shall call them, simply, *Vision I* and *Vision II*, where a vision is a much broader analytical category than, say, a definition.

Vision I gives meaning to SL by looking inward at the canon of orthodox natural science, that is, the products and processes of science itself. At the extreme, this approach envisions literacy (or, perhaps, thorough knowledgeability) *within science*. I shall argue that the approach taken in producing *Benchmarks for Science Literacy* (American Association for the Advancement of Science, 1993) approximates what I intend by identifying Vision I. Against that, Vision II derives its meaning from the character of situations with a scientific component, situations that students are likely to encounter as citizens. At the extreme, this vision can be called *literacy* (again, read *thorough knowledgeability*) *about science-related situations* in which considerations other than science have an important place at the table. The recent volume *Rethinking Scientific Literacy*, by Roth and Barton (2004), exemplifies Vision II. Whereas that volume comes from North American experience and scholarship, Vision II has older roots in England. Layton, Davey, and Jenkins (1986) introduced and exemplified the concept of “science for specific social purposes” nearly two decades ago. The same concept was presented later in elaborated form, in a slim and oft-cited volume titled *Inarticulate Science?* (Layton, Jenkins, Macgill, & Davey, 1993), whose title signifies that often the science taught in schools does not mesh, or articulate, with the science needed to come to grips with science-related situations.

Although the two visions have quite different starting points and ends in view, it should be kept in mind that these are, in my construction, idealized extremes developed as a heuristic device. Assessment programs and curriculum embodiments partake of these two visions in a kind of mating dance wherein they complement one another. Vision I, rooted in the products and processes of science, has historically been the starting point for defining SL, which has then been exemplified by reaching out to situations or contexts in which science can be seen to have a role. Recently, however, an increasing number of voices have stressed the importance of starting with Vision II, that is, with situations, then reaching into science to find what is relevant.

The scope of the review is broad. Following the completion of this introduction, three major sections analyze approaches to defining SL, and a further section examines how assessment programs affect, and are affected by, the influence of the two visions. A sixth section, on implications of the review, completes the chapter.

## WHAT'S IN A TITLE?

The chapter title is intended to be broadly inclusive. *Scientific literacy* is the more familiar term for many science educators. The term is predominant in the literature, and it has widespread current use in a number of countries. *Science literacy* is also familiar—especially to American science educators—as the term used in materials and publications of Project 2061 (American Association for the Advancement of Science [AAAS], 1990 and subsequently). For some authors the distinction seems to be unimportant (e.g., Hurd, 1958, compared with Hurd, 1998; Shen, 1975; Carson, 1998). For others it is significant (e.g., Mayer, 2002; Marshall, Scheppler, & Palmisano, 2003).

It is interesting that Project 2061 used the term *scientific literacy* at the outset, when *Science for All Americans* (AAAS, 1989), or SFAA, was first published. Then, when the Oxford University Press edition of SFAA was published (AAAS, 1990), the term was changed to *science literacy*, and it has remained so in subsequent AAAS publications. I found this puzzling. At the suggestion of Project 2061 staff (J. E. Roseman, personal communication, January 9, 2003), I contacted the project's director emeritus to inquire about the reasons for the change (F. J. Rutherford, personal communications, January 16 and May 12, 2003). Here is his response. "... 'science literacy' refers to literacy with regard to science, while 'scientific literacy' properly refers to properties of literacy, namely literacy that is scientifically sound no matter what content domain it focuses on. . . . As far as I know, you are the only one who has raised the question, and most people seem satisfied with either construction." Actually, Champagne and Kouba (1997) did raise a point about this matter. They comment that AAAS "uses the adjectival form science," while the equally prominent (in the United States) *National Science Education Standards* (National Research Council, 1996) "uses the adjectival form scientific"—yet "the organizations have not publicly stated that the difference is significant" (p. 89). Strictly speaking, the word *science* is not an adjective, so the terms are not exactly parallel. Nonetheless, for purposes of this review I shall use the abbreviation SL, except where there is reason to distinguish the terms.

## SL ON THE SCIENCE EDUCATION RADAR SCREEN

In devoting a full chapter to research on SL, the present handbook departs from the approach taken in earlier, similar handbooks. Hence the remainder of this introductory section is devoted to surfing previous handbooks and some other milestone collections, to document the noticeable increase in the amount of attention to SL in recent years. This will also serve as an overview of one particular subset of the SL literature—one that reveals the extent to which SL has been on the collective radar screen and research agenda of science educators, whether in a handbook or in a collection that reports on a forum, a symposium, or a research conference.

### Seven Handbooks

In the past 10 years, two handbooks were devoted entirely to science education research. In one of them, Bybee and DeBoer (1994) included a brief section on the origins of SL (two pages) in their chapter about goals for the science curriculum. In the other, SL is mentioned at eight spots (12 pages in all), the most significant of which are in chapters by van den Akker (1998) and Bybee and Ben-Zvi (1998)—once again, on aspects of the science curriculum. *Science literacy*, as an independent term, does not appear in the index of either handbook.

The American Educational Research Association (AERA) has sponsored four versions, or editions, of a handbook of research on teaching and one handbook of research on curriculum, each of which has a chapter devoted to science education. Watson (1963) did not mention SL at all in his review. In the review by Shulman and Tamir (1973), the term is mentioned in passing in two places: one alludes to objec-

tives for science education and the other concerns assessment. The term SL does not appear at all in the review by White and Tisher (1986); the handbook index shows no SL entries.

In the most recent edition of these AERA handbooks, White (2001) took quite a different tack from previous reviewers. He presents a picture of a revolution in research on science teaching by attending to such features of published research as questions, topics, method, etc., and showing how these features have shifted since Watson's review was published in 1963. White analyzed the ERIC science education summaries, in five-year increments spanning 1966 through 1995, according to their topics (the indicator of most interest here), as well as other features. He devised a very clever means for comparing the *proportions* (not the absolute number) of summaries devoted to different topics. In the case of scientific literacy (p. 459), the trend is as follows: 94 for 1966–70, 58 for 1971–75, 76 for 1976–80, 142 for 1981–85, 252 for 1986–90, and 209 for 1991–95. White did not discuss the substance of these summaries concerning SL, but it is clear that the topic has been active in the literature to varying degrees in the past 40 years—peaking in the 1986–90 period but remaining still quite robust in 1991–95. The index to this most recent AERA handbook does contain a reference to SL, but it refers to a chapter on assessment. No index entries appear for science literacy, as a separate term, in any of these handbooks.

There is almost casual mention of SL in the four AERA handbooks on teaching, and then only as a topic. In the AERA handbook on curriculum, by contrast, Fensham (1992) essentially—without explicitly saying so—used SL as one of the backbone concepts around which his chapter is built. The scope of Fensham's review includes both science education and technology education. For the science curriculum, he presents a major section about influences that have changed its substance internationally during two periods he labels "1950s/1960s" and "1980s and Onward" (p. 790 and p. 792, respectively). Noting the two "distinct targets" of school science, namely "a scientifically based work force" and "a more scientifically literate citizenry," he points out that "At first sight it can appear that the achievement of either of these two targets . . . will also be a contribution to the other" (p. 793). He uses the 1960s reform projects to illustrate how "the apparent even-handedness" of statements of intent about serving both groups "gave way in practice to the interests the first target represents. . . . By giving priority to the curricula for these students [the specialist work force], the projects were explicitly rejecting the interests of the larger target group in scientific literacy" (p. 794). Despite Fensham's substantial discussion of SL, the index for this handbook contains no entries for either scientific literacy or science literacy.

## **Five Research Volumes from Europe, One Forthcoming**

In April 1995, the European Science Education Research Association (ESERA) was formed at a European Conference on Research in Science Education held at the University of Leeds (Retrieved April 18, 2005, from <http://www.esera.net>). In the compilation of selected papers from that conference, there are no index entries for SL, but there is passing mention of the concept in the paper by Ratcliffe (1996, p. 126). ESERA has sponsored four biennial conferences since then. (The fifth is planned for Barcelona in August 2005). From the first conference in Rome, in 1997, there are

no index entries for SL in the published volume (Bandiera, Caravita, Torracca, & Vicentini [1999]). The volume based on the second conference, held at Kiel in 1999, contains two substantial papers on SL—one by Harlen (2001a) and one by Gräber, Nentwig, Becker, et al. (2001)—both in an entire section (one of six) devoted to SL, suggesting that SL had a relatively high profile at the conference. The third conference was held in Thessaloniki in 2001. The index to the volume of published papers (Psillos, Kariotoglou, Tselfes, et al., 2003) contains a single reference to SL, which Robin Millar discussed briefly in his Presidential Address. A published volume is forthcoming from Kluwer, based on the fourth ESERA conference at Noordwijkerhout in 2003.

Another volume on science education research in Europe reports an earlier conference in Malente, Germany, in late 1976, under the aegis of IPN (Institut für die Pädagogik der Naturwissenschaften) and the Council of Europe. I could find no mention of SL in this report (Frey, Blänsdorf, Kapune, et al., 1977). It is interesting from a historical viewpoint that the volume contains concrete proposals for establishing a European journal of science education and a European society for research in science education.

## Four European Symposium Proceedings

In June 1989, the Royal Swedish Academy of Sciences organized a symposium, as one event to mark its 250th anniversary, with the title *Science Education for the 21st Century*. Torsten Husén chaired the symposium, and there were participants from Australia, England, France, Germany, Hungary, Japan, Sweden, USSR, and the United States. In his Preface to the proceedings, Husén notes that three questions were mentioned as major problems for science education, and the first is of most interest here. “What do we mean by ‘science literacy,’ the common core of science knowledge that citizens in a highly technological society ought to possess? How have the school systems in various countries been able to achieve this goal as evidenced by the IEA surveys of outcomes of science teaching?” (Husén & Keeves, 1991, p. vii).

In September 1996, an international symposium devoted entirely to the concept of SL was held at IPN. In their summary of the symposium, Gallagher and Harsch (1997) report that 30 participants from Germany, England, and the United States “examined the meaning of scientific literacy as an educational goal for secondary school students, its current status in secondary school science classes, impediments to achievement of scientific literacy, and what can be done to help more secondary school students achieve higher levels of scientific literacy” (pp. 13–14). In total, 25 papers were published in the symposium proceedings. To the best of my knowledge, this symposium was the first in science education research history to be devoted exclusively to SL as a research topic.

In November 1996, a symposium was convened in Oslo on “converging research interests in the issues of ‘public understanding of science and technology’ (PUST) and ‘scientific and technological literacy’ (STL)” (Sjøberg & Kallerud 1997, p. 5). The relationships among SL, PUS, PUST, and STL are of particular interest for this review. The published volume consists of seven papers by participants from Norway, England, and the United States.

“In the autumn of 2000, the 2nd Utrecht/ICASE [International Council of Associations for Science Education] Symposium brought together a variety of European

colleagues to discuss about Teaching for Scientific Literacy." So wrote Eijkelhof (2001) in the Preface to the proceedings. Twelve papers make up the published volume, produced by symposium participants from The Netherlands, England, Northern Ireland, Estonia, and Portugal. Other countries represented by the 40 participants were Belgium, Cyprus, Germany, and Poland.

### **Three Multi-national Initiatives: UNESCO, ICASE, and OECD**

The sixth volume of the series *Innovations in Science and Technology Education* is introduced by Edgar Jenkins with the comment that the series (Jenkins is the current editor) was launched when the International Network for Information in Science and Technology Education (INISTE) was established by UNESCO in 1984. *Volume 6*, devoted to STL, is noteworthy for purposes of this review on two counts. First, Jenkins (1997) provides a thorough and most interesting review of "meanings and rationales" for STL in Part I. This serves to set the stage for Parts II and III, which are, respectively, about "theoretical perspectives" for STL and "realizing" STL. The conflation of meanings of scientific literacy (SL) and technological literacy (TL), a relative newcomer to the literacy literature, has a distinct embodiment in the purposes and substance of school programs in a number of countries, as described in the papers in Part III.

The STL theme appears also in the title of an international project—*Project 2000+ : Scientific and Technological Literacy for All*—co-sponsored by UNESCO and ICASE. The first phase of this project included an international forum held in Paris in 1993. "400 participants from more than 80 countries enthusiastically demonstrated their commitment to the task of achieving scientific and technological literacy for the peoples of all nations" (Retrieved April 18, 2005, from [http://nerds.unl.edu.icasel/ I\\_2000+.htm](http://nerds.unl.edu.icasel/ I_2000+.htm)). In preparation for the forum, Penick (1993) prepared an annotated bibliography on SL containing "more than 250 published and unpublished sources" (p. ii). This item, a book based on "every article we could find that had something to do with scientific literacy," was produced in limited quantity, but it remains available from the ICASE website (J. E. Penick [personal communication, November 25, 2003]). An augmented and updated version of Penick's bibliography was compiled for the third phase of the project (Layton, Jenkins, & Donnelly, 1994).

An initiative begun in 1989 by the Centre for Educational Research and Innovation of OECD concentrated on science, mathematics, and technology education, resulting in the volume titled *Changing the Subject* (Black & Atkin, 1996). This volume is based on a set of 23 case studies of innovation in 13 OECD countries, and I mention it because of the periodic reference to SL in some of its chapters on science education case studies. Based on the OECD initiative, there is a subsequent three-volume set on the case studies in the United States, called *Bold Ventures*; this review will draw from Volume 2 (Raizen & Britton, 1997).

### **Reflections and a Current Indicator**

As White's (2001) review indicated, SL has become much more prominent as a concept on the science education landscape in the past 20 years. That the concept has

also become more significant within the science education research community is indicated by its inclusion as one of 12 major themes and topics in the *SciEd Resource Assistant*, initially produced by ERIC. According to the successor to the ERIC website (Educational Realms), the list of research strands used for organizing NARST conference programs “was modified slightly for our purposes to reflect what we felt were the topics of most immediate interest to education professionals and the scope of the ERIC collection” (Retrieved April 14, 2005, from <http://www.stemworks.org/CD-1/>). Actually, SL is not mentioned in the current NARST program strand titles and descriptors. Nevertheless, the CD contains 15 titles of available full-text ERIC documents and a further 15 recent research journal articles, all dealing with SL (Retrieved April 18, 2005, from <http://www.stemworks.org/CD-1/CD/topics-sciliteracy.htm>).

### **DEFINING SL, PART I: FOR WHOM, TYPES-AND-LEVELS, JUSTIFICATION ARGUMENTS**

With very few exceptions, definitions of SL have concentrated on identifying what is of value for students over the long haul of a lifetime, irrespective of their career preferences and aspirations. The term was used initially in the late 1950s and early 1960s to call attention to the need to specify science curriculum appropriate for students not planning to pursue further science studies (see, e.g., Fitzpatrick, 1960; Johnson, 1962). Thus from its beginning SL has signified a curriculum orientation intended to be different from pre-professional preparation for scientifically oriented careers—the distinction to which Fensham (1992, p. 793) alludes. More recently, the familiar term science for all has come to be equated with SL appropriate for all students, whether they intend further science-related studies or not.

#### **Two General Observations**

The definitional literature for SL is anything but straightforward and focussed, yet two aspects of this literature became clear as I reviewed it. It is worth summarizing these at the outset, to provide the reader with some signposts for the three sections of the chapter that deal with definitions.

My first observation is this. There is no consensus about the meaning, or even the constituent parts, of SL—with one exception: everyone agrees that students can't be scientifically literate if they don't know any science subject matter. The literature contains many expressions of frustration about implications of the lack of consensus for both research and practice. On the face of it, that is a fair complaint. It is difficult to communicate about research results, such as international student assessments of SL, or to compare programs and teaching approaches that claim to advance SL, in the absence of a common definition. Yet, it is a simple statement of fact, in the practical world of policy formation, that a selected definition of SL is very much a function of the educational context in which the policy is to take effect. Once a definition has been selected, specified, and announced as an anchoring basis, the work of program development can go forward. In the case of SL, one of the best examples of tracing the conceptual flow entailed by this fact is Bybee's comprehensive

treatment of “purpose, policy, program, and practice” (1997a, p. 1) as integrated and interdependent components of educational planning. Thus, for reasons of context dependence especially, perhaps consensus about one definition throughout the worldwide science education community is a goal not worth chasing.

DeBoer (2000) expresses that very point thus, at the close of his recent review of SL: “instead of defining scientific literacy in terms of specifically prescribed learning outcomes, scientific literacy should be conceptualized broadly enough for local school districts and individual classroom teachers to pursue the goals that are most suitable for their particular situations” (p. 582). McEneaney (2003, p. 217) allows that there is no consensus on defining the specifics of SL. She describes its “worldwide cachet” in terms of a “scientific literacy approach” that, in her view, enjoys worldwide attention as a science education goal. Her analysis is based on examples from curricular statements, textbooks, and assessment materials in a variety of countries.

My second general observation is that the literature can be grasped more easily by considering the approaches, or conceptual methodologies, that authors have used. Five of these are discernible, and they are used to organize the material that follows. One cluster of literature is historical, embedded in the discourse of professional science educators who have tried to synthesize and make sense of the multitude of definitions between about 1960 and 1980. Another concentrates on “types” and “levels” of SL in terms of justification arguments based on presumed learners’ needs. A third cluster seeks meaning for SL by concentrating on the word literacy, and a fourth seeks its meaning by focussing on science and scientists. Finally, there is the approach that draws on situations or contexts in which aspects of science are presumed and/or demonstrated to be valuable for students’ everyday lives. In the course of presenting the definitional literature according to these five categories, I shall weave in the substance of some quite different critiques of SL—by Shamos (1995); by Sjøberg (1997); by Garrison and Lawwill (1992); by Eisenhart, Finkel, and Marion (1996); and by Roth and Lee (2002, 2004) extended in Roth and Barton (2004).

## **Historical Development of SL as a Term in Science Education**

Some 20 years ago I did an analysis of early historical development of the term SL, based on science education literature published in North America from the late 1950s until the early 1980s, in order to make sense of the diversity of definitions (Roberts, 1983). The starting point of this approach was to examine discussion of the term from the point of view of the logic of educational slogans. SL was introduced in professional science educators’ discourse as a slogan—a way to rally support for re-examining the purposes of school science (see, e.g., Hurd, 1958). At first, the SL discourse was primarily (although not entirely) on behalf of curriculum planning for the “90% of students” who are not “potential scientists” and who should therefore experience a “scientific literacy stream” (Klopfer, 1969).

### *From Slogan to Multiple Definitions*

Slogans don’t help professional science educators get on with their research and the practical work of specifying policy, planning programs, organizing teaching, and

designing assessment. Definitions are needed instead. Between the late 1950s and the early 1980s, a very large number of writers in North America expressed their views about the definition of SL. In my analysis, I drew attention to a characteristic feature of the logic of educational slogans. Slogans must be interpreted, thus anyone moving (in the logical sense) from slogan to definition provides his or her own interpretation—within reasonable bounds. It is therefore not surprising that definitions appeared in abundance, and in considerable variety.

### *Striving for Consensus*

Several authors have attempted to consolidate the definitions of this era into a synthesis that represented the meaning of SL for the science education community. I have selected three illustrative papers, all based on science education in the United States. (See Bybee [1997a, chapters 3 and 4] for a more extensive review and analysis of the consensus-building character of the American literature of this era, including the statements of professional associations such as NSTA, the [US] National Science Teachers Association.)

In 1966, Milton Pella and his colleagues in the Scientific Literacy Center at the University of Wisconsin in Madison reported a study of the “referents” authors had made to SL. On the basis of a comprehensive literature analysis, they identified 100 papers for further analysis and characterized SL with a composite picture based on six referents: “The scientifically literate individual presently is characterized as one with an understanding of the basic concepts in science, nature of science, ethics that control the scientist in his [sic] work, interrelationships of science and society, interrelationships of science and the humanities, [and] differences between science and technology” (Pella, O’Hearn, & Gale, 1966, p. 206).

Building on Pella’s analysis and continuing the theme of consolidation, eight years later Michael Agin expressed the following concern. “Many individuals use the term ‘scientific literacy’ but fail to give it an adequate meaning. . . . A frame of reference should be established to help consolidate and summarize the many definitions” (Agin, 1974, p. 405). Agin used Pella’s six categories to organize his own paper, drawing on even more literature (much of it post-1966) to embellish the categories by adding “selected dimensions” from among “the concerns and opinions of scientists and science educators” (p. 407).

The most exhaustive example of consensus seeking I have found is the doctoral study by Lawrence Gabel (1976). Gabel developed a theoretical model of SL based for the most part on statements of, or suggestions about, science education objectives related to interpretations of SL. His model expanded (refined, actually) Pella’s six categories to eight, which constituted one dimension of a matrix. The other dimension included the six major categories of cognitive objectives and three categories of affective objectives from Bloom’s taxonomies. Gabel reported that from the literature he was able to find examples for all but 16 of the 72 cells in this matrix (p. 92). He provided examples of the missing ones himself, to complete a consolidated picture of all of the possible objectives associated with SL—which, of course, is why it is a theoretical model, despite its substantial empirical basis for 56 of the cells (the complete matrix is shown in Gabel, 1976, p. 93). Thus did SL become an umbrella concept with a sufficiently broad, composite meaning that it meant both everything, and nothing specific, about science education.

A related but slightly different approach to analyzing the history of SL is to start with significant events in the educational history and culture of science education, especially the changing societal demands on the curriculum. The purpose of this approach is to understand how events have made a difference in science education policy statements over time, with specific reference to SL. DeBoer (1991, chapter 6) provides an excellent example of such analysis in the United States. (See also Bybee & DeBoer, 1994, and Matthews, 1994, chapter 3). Mayer (2002, chapter 2) has taken a similar approach, analyzing the history and place of Earth science education in the United States. He used for his book the inviting title “Global Science Literacy” to emphasize the point that he sees SL about the science of the globe itself as a viable curriculum platform for SL around the world. (See the review by Roberts, 2003.) Along the same conceptual and methodological lines, Jenkins (1990) presents a picture of the evolution of the SL concept in England.

Returning about a decade later to the historical events approach, DeBoer (2000) used as the significant event for his analysis the recent onset of contemporary standards-based reform efforts in the United States. He presents nine summary statements of science education goals that represent “a wide range of meanings of scientific literacy” (p. 591), essentially echoing Gabel’s finding of a quarter century earlier to the effect that SL has now come to mean one, all, or some combination of the major goals to which science educators subscribe. DeBoer comments as follows, in a manner somewhat reminiscent of the initial intent of the SL slogan, “The one specific thing we can conclude is that scientific literacy has usually implied a broad and functional understanding of science for general education purposes and not preparation for specific scientific and technical careers” (p. 594).

### *Reflections on the History-of-Usage Approach*

There is something comforting about a historical synthesis of definitions for an educational slogan such as SL. One gets a sense that despite the diversity of its definitions, SL did after all express a unity of purpose and meaning for science education by the beginning of the 1980s. In one sense, that is accurate. The focus of SL in the science education literature shifted from an image of curriculum appropriate solely for non-science-oriented students to aspects of science education appropriate for all students.

Definitional activity did not cease, however. Bybee (1997a) points out that during the 1980s, in the United States, “the term [SL] began to take on a symbolic value distinct from its past conceptual development because individuals used it in a variety of ways” (p. 59). This resulted in a substantial increase in the definitional literature—but that should not surprise us, as proliferation of definitions is to be expected in the case of educational slogans. Particular impetus for proliferation came from a variety of challenges to science education worldwide, during the 1980s. Fensham (1992) offers the example that many countries had begun retaining a higher percentage of young people in school for a longer time. As these students reached senior levels of schooling, it became increasingly imperative to pay attention to a curriculum in science that made provision for a “scientifically literate citizenry” as well as a “scientifically based work force” (pp. 793–795). (The reader can refer to Bybee [1997a] and DeBoer [2000] for accounts of further elaboration of the SL concept into the 1990s.)

The consolidation efforts of such writers as Pella, Agin, and Gabel show the manner in which Vision II of SL originated. For example, of the six categories of Pella's composite definition, science itself is the appropriate source for three of them (basic concepts in science, nature of science, and ethics that control the scientist's work). Those are based on Vision I. The other three (interrelationships of science and society, interrelationships of science and the humanities, and differences between science and technology), are based on Vision II—science-related situations.

## **Types and Levels of SL Needed by the Learner: Distinctions, Not Consensus**

This approach takes a different starting point, concentrating on differences instead of consensus. Its purpose is the invention of categories that specify different types of SL according to what learners will be able to do with their SL. A number of writers cite Shen (1975) as their inspiration for this methodological approach. What did Shen actually say? "We may define science literacy as an acquaintance with science, technology, and medicine, popularized to various degrees, on the part of the general public and special sectors of the public through information in the mass media and education in and out of schools" (pp. 45–46). He defined three types of SL. (1) *Practical*—"possession of the kind of scientific knowledge that can be used to help solve practical problems . . . [such as] health and survival" (pp. 46–47). (2) *Civic*—"to enable the citizen to become more aware of science and science-related issues so that he and his [sic] representatives would [bring] common sense to bear upon such issues and thus participate more fully in the democratic processes of an increasingly technological society" (p. 48). (3) *Cultural*—"motivated by a desire to know something about science as a major human achievement. . . . It is to science what art appreciation is to art" (p. 49).

### *Types and Levels in a Curriculum Sequence*

Shen's three categories represent qualitatively different types of SL, but I did not detect any suggestion that he placed them in a hierarchical arrangement. By contrast, the next two authors who take the types-and-levels approach (Shamos and Bybee) are talking about types and levels of SL for learners advancing through a curriculum.

Shamos (1995) proposed that different amounts of science are necessary for achieving Shen's three types of scientific literacy, thus converting them to levels in a hierarchy. His own three levels, a clear example of Vision I, "build upon one another in degree of sophistication as well as in the chronological development of the science-oriented mind" (p. 87).

- "1. *Cultural* scientific literacy. Clearly the simplest form of literacy is that proposed several years ago by Edward Hirsch, . . . by which he means a grasp of certain background information that communicators must assume their audiences already have" (p. 87). The reference is to Hirsch (1987). Related works along the same line are those by Hazen and Trefil (1991), and by Brennan (1992).

- “2. *Functional* scientific literacy. Here we . . . [require that] the individual not only have command of a science lexicon, but also be able to converse, read, and write coherently, using such science terms in perhaps a non-technical but nevertheless meaningful context” (p. 88).
- “3. ‘*True*’ scientific literacy. At this level the individual actually knows something about the overall scientific enterprise . . . the major conceptual schemes . . . of science, how they were arrived at, and why they are widely accepted, how science achieves order out of a random universe, and the role of experiment in science. This individual also appreciates the elements of scientific investigation, the importance of proper questioning, of analytical and deductive reasoning, of logical thought processes, and of reliance upon objective evidence” (p. 89).

About his third level, Shamos comments that it is a “demanding” definition. “But it only means that the term itself, ‘scientific literacy,’ has been used too loosely in the past and that, when viewed realistically, true scientific literacy, as defined here, is unlikely to be achieved in the foreseeable future” (p. 90). He goes on to estimate the number of individuals in the US and England who are truly scientifically literate to be on the order of 7%, respectively: approximately the number of professional scientists and engineers in each country. (This estimate cites the work of Jon Miller, discussed later in this review.)

It is unfortunate that Shamos used his analysis to attempt to discredit the idea of using SL as a way to express an overall orientation of science education goals. Much of what is otherwise a highly informative and thoughtful piece of work might be lost or neglected if readers react negatively to this apparent desecration of a current science education icon—i.e., dismissing SL as a “myth.” Essentially, Shamos sequesters “true” SL as an appropriate goal for science-oriented students only, but later in the book he drops the other shoe in a section titled “Science Awareness: A New Scientific Literacy.” There, he presents “three guiding principles for presenting science to the general (nonscience) student” (p. 217, emphasis original). Notice that these map directly onto Shen’s three categories.

- “1. Teach science mainly to develop appreciation and awareness of the enterprise, that is, as a *cultural* imperative, and not primarily for content. . . .
- 2. . . . focus on technology as a *practical* imperative for the individual’s personal health and safety, and on an awareness of both the natural and man-made environments. . . .
- 3. For developing social (civic) literacy, emphasize the *proper* use of scientific experts, an emerging field that has not yet penetrated the science curriculum.”

This last point is presented as an alternative to what Shamos sees as the “impossible task” of “educating all Americans in science to the point where they can reach *independent* judgments on [socioscientific] issues” (p. 216, emphasis original).

In a similar vein, Bybee (1997a, 1997b) has derived a framework that “presents scientific and technological literacy as a continuum in which an individual develops greater and more sophisticated understanding of science and technology” (Bybee, 1997a, p. 84; see also Bybee & Ben-Zvi, 1998, p. 490). (More is said about

the conflation of science and technology later in this review.) This is a four-level framework.

- “In *nominal* literacy, the individual associates names with a general area of science and technology. . . . the relationship . . . [to] acceptable definitions is small and insignificant” (Bybee, 1997a, p. 84). Bybee includes misconceptions, naïve theories, and inaccurate concepts as features of this level of SL.
- “Individuals demonstrating a *functional* level of literacy respond adequately and appropriately to vocabulary, . . . they can read and write passages with simple scientific vocabulary . . . [They] may also associate vocabulary with larger conceptual schemes . . . but have a token understanding of these associations” (pp. 84–85).
- “*Conceptual and procedural* literacy occurs when individuals demonstrate an understanding of both the parts and the whole of science and technology as disciplines. . . . At this level, individuals understand the structure of disciplines and the procedures for developing new knowledge and techniques” (p. 85).
- “*Multidimensional* literacy consists of understanding the essential conceptual structures of science and technology as well as the features that make that understanding more complete, for example, the history and nature of science. In addition, individuals at this level understand the relationship of disciplines to the whole of science and technology and to society” (p. 85). Bybee points out that his multidimensional SL reflects the composite definitions and frameworks for SL as described by Pella et al. (1966) and Agin (1974), among others.

### *Reflections on Types and Levels of SL*

Shamos has made a sharp distinction between science education for science-bound students and non-science-bound students. That is, neither “true” SL nor “science awareness” has been defined as a broad curriculum goal appropriate for all students. This approach is at odds with the majority of the science education community’s efforts, yet at the same time it is a stark and forthright acknowledgment that science education has to somehow resolve the problems associated with educating two very different student groups (at least two). It is tempting to think that Vision I (looking inward to science itself) could serve as the sole source or generator of curriculum for science-bound students, while Vision II (looking inward from situations to science) has emerged as the appropriate source of planning for non-science-bound, or general, students. This would be wrong-headed. Even Shamos doesn’t think so. He notes the importance of Vision I for all students in the following terms: “Every science curriculum, regardless of its professed goals, should at least make clear to students what science is and how it is practiced” (p. 224). Similarly, he remarks on the importance of Vision II for the science-bound student, when he details the contents of a “curriculum guide for scientific awareness.” He points out that the science-bound student “might well be exposed to such topics early in his or her educational career” (p. 223).

Bybee does not differentiate between SL for science-bound and non-science-bound students. Indeed, his framework and his entire discussion is about making

SL possible for all students, but he freely admits that “no one could possibly achieve full scientific and technological literacy” (p. 85), that “some [students] will develop further than others at all levels or within one, depending on their motivation, interests, and experiences” (p. 85). Bybee’s framework is very much an idealized, complete and comprehensive universe of meanings from which curriculum developers can choose.

## Justification Arguments

Closely associated with the methodology of identifying types and levels of SL is Millar’s (1996) review and critique of several arguments (Thomas & Durant, 1987) promoting the public understanding of science, a term closely related to SL and used frequently in England (cf. Durant, 1994, p. 83). Noting that “The science curriculum functions as: first stages of a training in science, for a minority, and access to basic scientific literacy, for the majority” (p. 10), Millar raises two questions: “What would a science curriculum designed to promote scientific literacy for the majority look like?” and “Later, as a separate question, we might wish to ask: would such a curriculum also be a reasonable preparation for further study in science for the minority who so chose?” (p. 10). He clustered the arguments into four groups: economic, utility, democratic, and cultural/social.

### *Justification According to Situation*

Ryder (2001), building on Millar’s analysis and critique, identified *functional* scientific literacy as “science knowledge needed by individuals to enable them to function effectively in specific settings” (p. 3). Among Millar’s groups of arguments, this notion of SL emphasizes “the utility, democratic and (to a lesser extent) the social arguments for why people should know something of science” (p. 3). Ryder analyzed 31 “published case studies of individuals not professionally involved with science interacting with scientific knowledge and/or science professionals” (p. 5) in such settings and activities as public inquiries, parental discussions with health care workers, media reporting, and judicial proceedings.

The analysis is developed around six main areas of science understanding featured in the studies: subject matter knowledge, collecting and evaluating data, interpreting data, modelling in science, uncertainty in science, and science communication in the public domain. Ryder reports extensively on the issues concerning individuals’ understanding associated with each area. Granting that “An understanding of subject matter knowledge is necessary for individuals to engage in many science issues,” he goes on to point out that “Overall, much of the science knowledge relevant to individuals in the case studies was knowledge about science, i.e., knowledge about the development and use of scientific knowledge rather than scientific knowledge itself” (p. 35).

Ryder concludes with implications of the notion of *functional* SL for compulsory science curriculum. It is important to keep in mind that he reported these implications at a time when the English National Curriculum for Science was being reviewed in rather fundamental ways—especially in terms of the possibility of instituting a compulsory course on SL for students at Key Stage 4 (14 to 16 years old). Some of the implications, then, were already being realized in changes underway as

a result of the recommendations put forward in *Beyond 2000: Science Education for the Future* (Millar & Osborne, 1998). Ryder reminds the reader that two of Millar's justification arguments are missing from his (Ryder's) *functional* SL concept: "science for cultural purposes, and science as a preparation for future science professionals," and he comments also about "the conceptual challenge of communicating about many of the issues . . . to school age students"—suggesting that for some of his findings the concepts and issues may be "beyond the level of compulsory science education" (p. 38). He cites a new post-compulsory course called "Science for Public Understanding" as having already identified many of these more difficult concepts and issues. (See the student text *AS Science for Public Understanding* [Hunt & Millar, 2000] for this most interesting development. "AS" is the designation for an "Advanced Subsidiary" GCE qualification.)

Three further implications round out the paper, two of which have to do with the content of a compulsory course that would facilitate "the process of learning to engage with science as an adult." These deal with important conceptual ideas of science (but not the usual more-than-needed packaging of typical science curricula) and "some coverage of social and epistemological issues." The final implication has to do with encouraging in all students "a sense that science is a subject that they are capable of interacting with in later life" (pp. 38–39). All of Ryder's implications further buttress the recommendations for a compulsory course in SL for English schools, as presented in Millar and Osborne (1998). The latter document is discussed in more detail later in this review.

Christensen (2001) echoes many of the points in Ryder's paper. Because "science education has a crucial role to play in preparing future citizens to make personal and collective decisions on socio-scientific issues," her argument goes, "new conceptions and approaches to scientific literacy are needed" (pp. 142–143). She points to "a shift over the past fifty years from a focus on content knowledge towards placing more importance on, and making more specific, the aspects of science by which it is involved with society and with individual lives" (p. 145), yet "this shift is only a beginning towards defining scientific literacy in ways appropriate for future citizens in a 'knowledge/risk' society" (p. 146). Citing "consistent findings of recent research into public understanding of science," she finds a gap: "dimensions of scientific knowledge not usually considered in school science are foregrounded: [including] the uncertainty of much scientific knowledge, the evaluation of evidence, the use of experts and an entirely pragmatic conception of content knowledge" (p. 146). Christensen draws on the way literacy is framed in such disciplines as language education—more in terms of literacy as language practice (reading, writing) and as social practice, embedded in social situations and contexts—as she sketches a view of SL that is appropriate for (adult) PUS, "including proper understanding of the social construction of scientific knowledge and a critical ability to evaluate sources of scientific knowledge" (p. 152).

### *Justifying Science, or Technology?*

Sjøberg (1997) also used a set of four clustered categories similar to Millar's, listing and describing them for the purpose of asking "the impertinent question: Are these sound, well-founded and valid arguments—or do they just constitute a convenient ideology for scientists and science educators?" (p. 17). He does not cite

either Millar's article, or the one by Thomas and Durant on which it is based, but the four clusters are readily recognizable from Sjøberg's description. He presents them as follows.

- "The *economic* argument: science for preparation for work
- The *utilitarian* or practical argument: science for mastery of daily life
- Science for *citizenship* and democratic participation
- Science for *cultural literacy*, science as a major human product" (p. 17).

In a lively and very interesting discussion of counter-arguments for each of the four, Sjøberg draws attention to the significance of technology (more than science) in the first two, and the complexity of the science needed to deal intelligently with socioscientific issues in the third (reminiscent of Shamos). He notes his "sympathy" with the fourth (p. 22), recounting several problems with the idea. In the summary of his critique he returns to the conflation of S and T, thus. "[The] distinction between Science and Technology [is] important . . . because some of the arguments that are questionable for having science in the curriculum (and for the entire adult population) are indeed very valid arguments for including *technology!*" (p. 23, emphasis original). Thereafter, he returns to the question "What do we mean by 'scientific literacy'?" and he, too, opts for specifying *functional* scientific literacy—although he does so "to draw attention to the culture- and context-dependency" of the term (p. 24).

### *Broader Justification through STL*

The conflation of scientific and technological literacy (STL) is also a theme in the paper by Jenkins (1997), mentioned earlier. He notes that "The arguments for [STL] can be categorized in ways which reflect the different views of stakeholders" (p. 14). His categories for the arguments have much in common with those used by Millar and by Sjøberg. He begins with three, and identifies the stakeholders: "reference to national economic prosperity, raising the quality of decision-making or enriching the life of individuals, arguments which Layton has associated respectively with economic instrumentalists, with the defenders of participatory democracy and with liberal educationists (Layton, 1994, pp. 15–16)," (cited in Jenkins, 1997, pp. 14–15).

To these, Jenkins adds a fourth; no extrinsic justification is needed because S and T "are themselves important cultural activities" (p. 17). That is, "science offers a distinct and powerful way of understanding the natural world which justifies its claim to a seat at the table of those who would profess to be liberally educated" (p. 17). Similarly, "the history and philosophy of technology . . . offers some support to the claim that technology, as a unique and irreducible form of cognition, also has [an equal] seat at the same table" (p. 18). Finally, a fifth argument is noted. "[STL] offers . . . a means of redressing some social, economic or other injustices and imbalances . . . [and] an opportunity for a radical overhaul of scientific and technological education" (p. 18). Jenkins' paper sets the stage for the rest of the volume, yet he brings it to a close with a cautionary note. "Although much of modern science and technology constitute an integrated system with research socially rather than theory driven, scientific and technological literacy are not the same and there is a need to explore distinctions and establish such common ground as may exist" (p. 33).

### *Reflections: Justification Arguments and Curricular Arrangements*

Arguments justifying SL are used in two different ways. The first has reference to students and/or adults, in terms of the attributes that characterize a scientifically literate person. These we can call student-centered justifications. Invariably, such arguments have to be plausible from a student's point of view. The second has reference to system-wide (national, regional, local) curriculum policies. These we can call policy-centered justifications. Such arguments justify the arrangement of curricular offerings, so that systems can provide SL for students.

Among the most noticeable student-centered justifications is the argument behind the original SL slogan, to the effect that a special kind of program is needed for the large number of students who do not intend to pursue further study in science-related fields (cf. Klopfer, 1969; Fensham, 1992). In a similarly student-centered way, Shamos's "true" SL is reserved for science-bound students, and his "scientific awareness" refers to the non-science-bound. Shamos proposed a different kind of program for each group, as did Klopfer (1969) a quarter century earlier.

More recently, the phrase science for all has come to be equated increasingly with SL for all (regardless of future plans). Implications for curricular arrangements that could advance SL for all are seen in two very different approaches to curricular arrangements.

The first arrangement is the establishment of a separate, compulsory course that concentrates on SL. Hints of this development in England were seen above in the review of Ryder's paper, where reference was made to the report titled *Beyond 2000* (Millar & Osborne, 1998). The second of that report's ten recommendations deals specifically with SL for 14- to 16-year-olds (Key Stage 4): half of their science time would be devoted to a mandatory (statutory) course on SL. (Options would be provided in the other half, for diversified interests in future general and applied science study.) The basis for this curricular arrangement is specified in the recommendation itself. "At Key Stage 4, the structure of the science curriculum needs to differentiate more explicitly between those elements designed to enhance 'scientific literacy', and those designed as the early stages of a specialist training in science, so that the requirement for the latter does not come to distort the former" (p. 10). In other words, the intent is to "unhook" students' development of SL from pre-professional science education. The justification argument for SL in this particular case draws on "the cultural and democratic justifications for an understanding of science" (p. 11); the reader will recognize this language from Millar (1996). The definition of SL embodied in this recommendation is found in the description of the experimental project called *21st Century Science*.

"We would expect a scientifically literate person to be able to:

- appreciate and understand the impact of science and technology on everyday life;
- take informed personal decisions about things that involve science, such as health, diet, use of energy resources;
- read and understand the essential points of media reports about matters that involve science;
- reflect critically on the information included in, and (often more important) omitted from, such reports; and

- take part confidently in discussions with others about issues involving science.”  
(Retrieved April 14, 2005, from <http://www.21stcenturyscience.org>).

The project has been developing a Core Science course on SL for all Key Stage 4 students, and Additional Science courses, both Applied and General. (These courses are experimental and developmental at this time.) It is clear that the mandatory course on SL is based on Vision II, in that the overall learning outcomes flow from situations, not from the formal structure of science itself. The science content for the course is presented in “science explanations,” and students develop skills and background to reflect on science itself through a set of “ideas about science,” within which the content is contextualized. Along the same lines, a textbook has been developed for a post-compulsory course on public understanding of science (Hunt & Millar, 2000). So far as I can tell, the only other example of a separate, compulsory course on SL is the one developed in The Netherlands (De Vos & Reiding, 1999) for all grade 10 students. Further discussion of that course is reserved for a later section of this review.

The second curricular arrangement flowing from policy-centered justifications is to use an all-inclusive collection of justification arguments as the basis for the overall goals of a science curriculum. In this way, science curriculum policy can incorporate possibilities that accommodate all students—whatever their abilities, interests, and future plans—but do not necessarily provide every student with the same exposure to SL (as a compulsory course would do). In one sense, then, the intent is that SL permeates the entire science curriculum. The composite definitions that evolved in the North American science education community by the late 1970s are examples of this approach to specifying the basis for an SL curriculum policy. Other sources of a composite definition include the collection of five stakeholder arguments on behalf on STL, as stated by Jenkins, the totality of the argument clusters in Millar’s paper, and Bybee’s sequence of types of SL, to which I shall return in a moment. All of these composites define the universe that a whole curriculum has to incorporate. In other words, the policy is rich and comprehensive enough to allow for varying degrees of development of SL by students with different abilities, motivation, and future plans.

An example of combining justification arguments, which actually predates the publication of Millar’s (1996) paper, is found in a policy advisory document released by the Science Council of Canada (1984). There it was recommended that: “the goal of scientific literacy for all can be achieved through a balanced curriculum in which science is taught with four broad aims in mind:

- To encourage full participation in a technological society;
- To enable further study in science and technology;
- To facilitate entry to the world of work;
- To promote intellectual and moral development of individuals (p. 10).

The document is the final report of a three-year study of science education in Canada (see Orpwood, 1985; Orpwood & Souque, 1985), and it has influenced science curriculum revision in Canada for the past two decades. Notice that the justification arguments do not apply in equal measure to every student. That is what makes such a stipulated definition of SL policy-centered, rather than student-centered.

Bybee's sequence of types of SL is an important conceptual basis for the approach taken to SL in the United States. The Call to Action at the beginning of the US *National Science Education Standards* (National Research Council, 1996)—hereafter *NSES*—begins with “This nation has established as a goal that all students should achieve scientific literacy” (p. ix). SL is defined as follows. “Scientific literacy is the knowledge and understanding of scientific concepts and processes required for personal decision making, participation in civic and cultural affairs, and economic productivity. It also includes specific types of abilities. In the [*NSES*], the content standards define scientific literacy” (p. 22). The elaboration of the definition includes the following points:

- “a person can ask, find, or determine answers to questions derived from curiosity about everyday experiences
- a person has the ability to describe, explain, and predict natural phenomena
- entails being able to read with understanding articles about science in the popular press and to engage in social conversation about the validity of the conclusions
- implies that a person can identify scientific issues underlying national and local decisions and express positions that are scientifically and technologically informed
- [as] a citizen, should be able to evaluate the quality of scientific information on the basis of its source and the methods used to generate it
- implies the capacity to pose and evaluate arguments based on evidence and to apply conclusions from such arguments appropriately” (p. 22).

This definition has a strong Vision II flavor (as in Bybee's *multidimensional SL*). It is a policy framework that must be flexible enough to accommodate curriculum and course development for all students, so it is to be expected that students with different career goals (“different types of abilities,” noted above) will experience different kinds of courses. Nevertheless, there is no distinction in the SL definition for students who wish to pursue science-related careers and those who do not.

Seven “content standards” define SL, in this document. They are presented in clusters according to grade levels, namely K–4, 5–8, and 9–12, and there is an eighth (K–12) that is superimposed on all of the others, dealing with such overarching ideas as systems, models, change, equilibrium, etc. (pp. 115–119). Within each grade cluster, the seven topics are the same:

- Science as inquiry
- Physical science
- Life science
- Earth and space science
- Science and technology
- Science in personal and social perspectives
- History and nature of science (pp. 121–207).

There is an intended relationship between the three traditional subject matter standards (physical science, life science, Earth and space science) and the four

context standards (inquiry, science-technology, personal/social perspectives, and history/nature of science). The intent is that subject matter is to be blended with contexts. However, having elevated the context standards to the status of content, *NSES* is open to implementation problems, in my view. That is, one reading of the standards suggests that, in each year of a student's experience, a seventh of the time will be spent on the content and skills of each of the seven standards—meaning 3/7 on traditional science subject matter and 4/7 on the contexts. Elsewhere I have commented on this potential problem (Roberts, 2000), but it is clear to me that the approach to be taken in accomplishing all seven standards is to blend the traditional subject matter with the context standards. In fact, that point is stated clearly in the document (*NSES*, p. 113).

## DEFINING SL, PART II: FOCUS ON LITERACY, FOCUS ON SCIENCE AND SCIENTISTS

### The Focus-on-Types-of-Literacy Approach

In what has been presented so far, there have been some brief forays into exploring adult SL. By and large, however, the preceding approaches to sorting out the definitional deluge reflect the preoccupations of science educators and science education policy makers, typically for primary and secondary school systems. Laugksch's (2000) review includes three other groups that have an interest in defining SL. A second group, "social scientists and public opinion researchers concerned with science and technology policy issues," has an interest in such matters as public support for science and technology, and the public's attention to science and technology policy. A third, "sociologists of science and science educators employing a sociological approach to scientific literacy," concentrates on individuals' everyday interpretation and negotiation of scientific knowledge. The fourth group is "the informal and nonformal . . . science education community, and those involved in general science communication" (through science museums, science centers, botanical gardens, and zoos, e.g.), including "science journalists and writers, and relevant personnel involved in science radio programs and television shows" (p. 75).

Laugksch reminds us that the four interest groups direct their attention at different populations. The science education group (the first named) focuses largely on the SL of children and adolescents, while the social science approach of the second and third groups targets the SL of out-of-school individuals (i.e., adults). The "general science communication" (fourth) interest group, however, concentrates on promoting the SL of a combination of the three audiences—"that is, children, adolescents, as well as adults" (p. 76). According to Laugksch, it is important to specify the different audiences because a different conception of literacy is being used by each of the interest groups. "Three different interpretations and uses of 'literate' are considered here: literate as *learned*; literate as *competent*; and literate as *able to function minimally in society*" (p. 82, my emphasis).

Laugksch comments on the three conceptions as follows. Regarding the *learned* category, "interpretations appeared to be proposed only for the intellectual value of

being scientifically literate" (p. 83). Shen's *cultural* SL and Shamos's *true* SL qualify. This is the only conception that is clearly Vision I. The *competent* category is described thus: "when a context was suggested in which a scientifically literate individual needed to operate . . . , or if a particular activity was required to be performed . . . . Competent relates . . . to the extent of the ability to carry out such tasks" (p. 83). Laugksch included the Project 2061 concept of SL and Shamos's *cultural* and *functional* SL in this category. The *able to function* category "was used if the suggested definition required the scientifically literate individual to play a particular role in society, such as, for example, that of a consumer . . . or citizen" (p. 83). In this category are Shen's *practical* and *civic* SL, as well as Jon Miller's SL (discussed below); the Project 2061 concept of SL is included here also. The significance of Laugksch's work, in my view, is its link to general conceptions of literacy.

Bailey (1998) has reported an analysis based also on conceptions of literacy in a more general sense. She used Scribner's (1986) three metaphors of literacy as a basis: Literacy as *Adaptation*, Literacy as *Power*, and Literacy as a *State of Grace*. Literacy as *Adaptation* refers to "the pragmatic value of literacy skills. Scribner links this metaphor to discussions of functional literacy or the level of literacy skills required to function effectively in a range of everyday situations in our society . . . a degree of acceptance of the status quo" (Bailey, 1998, p. 53). By contrast, "the Literacy as *Power* metaphor has an emancipatory interest. . . the possession of literacy skills has been a powerful tool of elite groups within some societies, employed to maintain their relative position of advantage. Conversely, development of literacy skills is viewed as a means for poor or politically disempowered individuals to claim their place in society" (p. 53). Finally, "*State of Grace* is a very old [concept]. Scribner links this metaphor to the tendency of many societies to attribute special virtues to the literate person. . . to be literate is considered synonymous with being cultured. . . the literate person derives meaning for his or her life from participation in humankind's accumulated knowledge, available through reading and writing" (p. 53). Bailey used these three conceptions of literacy as the basis for an analytical framework to review a Canadian curriculum document (Council of Ministers of Education, Canada [CMEC], 1997). She concluded that it portrays Literacy as *Adaptation*, on the basis that "the document reflects a concern for preparing students to work in science- and technology-related jobs [and links] this effort to the improvement of Canada's relative place in the global economy" (p. 58).

The kind of SL conception Bailey developed for Scribner's Literacy as *Adaptation* metaphor had earlier attracted quite a drubbing in a critique by Garrison and Lawwill (1992), in light of their interpretation of reform efforts at that time in the US. After examining a variety of influential documents about educational reform, they conclude: "With notable exceptions much of the current call to reform science education and achieve something called 'scientific literacy' seems directed toward [the] *end* [of 'economic competitiveness']" (p. 338, emphasis original). Their critique calls special attention to morality. "Frequently educational reform, especially in mathematics and science education, is intended to improve human capital. There is something very chilling about describing human beings . . . in such an exclusively quantitative and reductionistic way. . . Chaining science and science education to the goal of maximizing the economic production function . . . is immoral . . . because it treats students as means to the pecuniary ends of others" (p. 343).

## Reflections on the Types-of-Literacy Approach

Until recently it has been unusual to find constructs and insights from the study of literacy in the literature on SL. The literature has tended to concentrate on specifying the details of two components of science curriculum that are closer to home, so to speak. Typically, learning outcomes or goals have been specified *within* science (scientific knowledge) and *about* science (“companion meanings”—i.e., meanings derived from such focus areas as the nature of science and STS [Roberts, 1998]). The following brief comments are about literacy’s links to SL—first to Vision I, then to Vision II.

In their case study of AAAS Project 2061, Atkin, Bianchini, and Holthuis (1997) point out that “Use of the word ‘literacy’ . . . is noteworthy,” as the term “was not generally employed during the 1960s round of science curriculum reform.” They offer an explanation to the effect that the 1970s emphasized the “basics,” stressing “core skills, traditionally associated with subjects like reading, computation, and communication.” They suggest that “Many of those interested in promoting and improving science education began to . . . talk about scientific *literacy*,” implying that to know about science is as necessary “as to know how to read, compute, and communicate” (p. 191).

That explanation comes, obviously, from the perspective of curriculum politics, yet the meaning of literacy in the SL concept itself is left as something of a black box. Opening that black box from the point of view of Vision I has been the agenda of a significant strand of more recent research and writing. For example, Norris and Phillips (2003) begin by distinguishing between a fundamental sense of SL—“reading and writing when the content is science”—and a derived sense of the term—“being knowledgeable, learned, and educated in science” (p. 224). They argue that conceptions of SL “typically attend to the derived sense of literacy and not to the fundamental sense” and contrast the fundamental sense (which they link closely to understanding text) against “a simple, word-recognition-and-information-location view of reading that remains prominent in literacy instruction” (pp. 224–225). One of the most significant implications of their distinction has to do with the distortion of meaning that can come from assessment programs, and they comment specifically about Jon Miller’s work (discussed in a later section of this review). They point out that “his vocabulary dimension risks equating successful reading with knowing the meaning of the individual terms” and that it “appears to assume that only scientific constructs need to be known to understand scientific text” (p. 227). As well, “focussing upon the derived sense of literacy as knowledgeability in science has . . . created a truncated and anemic view of scientific knowledge as facts, laws, and theories in isolation from their interconnections” (p. 233).

A more elaborate framework for literacy in Vision I SL—particularly the educational implications—is found in a recent editorial description (Hand, Alvermann, Gee, et al., 2003) of an international conference held in September, 2002, on Vancouver Island, Canada. (The participants, including Norris and Phillips, refer to themselves as the “Island Group.”) They maintain that research and practice in all of the recognized language arts (including reading, writing, speaking, listening, and representing) are highly significant for understanding and realizing SL in the fundamental sense just described. Researchers in cognitive science, linguistics, language education, and science education informed one another and addressed “key issues

not normally emphasized by the science education research community” (p. 609). They present the structure of their discussions according to four perspectives: students’ formal and informal literacies, vernacular language, reading in science, and writing in science.

In this review, it is Laugksch’s work that sets the stage for recognizing literacy in a Vision II sense. His *learned* category acknowledges Vision I. The *competent* and *able to function* senses of literacy reflect the broader picture of situations (Vision II) in which SL is being promoted as important for purposes other than those of the academic science culture.

## The Focus-on-Science-and-Scientists Approach

### *Mining the Scientific Canon*

The Project 2061 term *science literacy* is now common parlance among science educators in the United States. I have identified this term as Vision I on the basis of two considerations: the substance of the definition itself, and the source of its legitimation in the orthodox scientific canon.

The Project 2061 conception of SL was established initially on the basis of five reports developed in the period 1985–1989 (Phase I) under the aegis of “the National Council on Science and Technology Education—a distinguished group of scientists and educators appointed by the American Association for the Advancement of Science—on what understandings and habits of mind are essential for all citizens in a scientifically literate society” (AAAS, 1989, p. 3). “Five independent scientific panels” developed the reports, and the council solicited broad consultation and review. All told, the process involved “hundreds of individuals” and culminated in the sixth report of the collection, the familiar *Science for All Americans* (SFAA), which was unanimously approved by the AAAS Board of Directors (p. 3). The definition of SL is presented thus, in SFAA:

the scientifically literate person is one who

- is aware that science, mathematics, and technology are interdependent human enterprises with strengths and limitations;
- understands key concepts and principles of science;
- is familiar with the natural world and recognizes both its diversity and unity; and
- uses scientific knowledge and scientific ways of thinking for individual and social purposes. (p. 4, my bullets; not changed in OUP edition)

(The details of this definition were not changed in the OUP edition of SFAA although, as noted earlier, the term *scientific literacy* was changed to *science literacy*.)

Two aspects of this process and its resulting definition of SL are significant for the present review. The first is the impressive sense of authority that results from a process of consulting so many scientific experts, and subsequently obtaining the endorsement and continuing support of one of the world’s premiere scientific organizations. The second is the unusual breadth of the subject matter considered to be science. The scope of Phase I included technology, information sciences, engineering,

social sciences, health sciences, and mathematics, in addition to the attention typically paid in such ventures to the more familiar cluster of natural sciences, such as physics, chemistry, biology, and geology. To be sure, the panels were not given free rein to include every single concept from their disciplines, or even their favorite ones. On the contrary, the “national council” was under a tight rein. The curriculum had been characterized for them as already “overstuffed and undernourished” as a result of growing over the years “with little restraint” (p. 15). These aspects of Project 2061, and many others, are examined in great and very interesting detail in the case study mentioned previously (Atkin, Bianchini, & Holthuis [1997]). My comments about each will therefore be brief, rather than comprehensive.

(1) Asking scientists to define, or at least suggest, the essential subject matter content for school science has often been a part of science education, to varying degrees. Nevertheless, the sheer investment of time and resources in Phase I of Project 2061 is staggering to contemplate, until one reflects on what is involved in a thoroughgoing delineation of Vision I. The impetus for the project is total, systematic reform of science education K–12, over decades, which requires enormous commitment from a society. An expressed and repeatedly confirmed endorsement by such an organization as AAAS can be seen, then, as a way of garnering lasting support for the effort as well as reaching a clear understanding of what constitutes SL—at least, in the eyes of the scientific community. The cornerstone of Phase I is the belief that we can have enough confidence in science itself to make it worthwhile to see the reform through to its distant conclusion. Such confidence is expressed in this way: “Science, energetically pursued, can provide humanity with the knowledge of the biophysical environment and of social behavior that it needs to develop effective solutions to its global and local problems; without that knowledge, progress toward a safe world will be unnecessarily handicapped” (AAAS, 1989, p. 12).

(2) It was certainly unusual to include such a broad array of disciplines in the early stages of defining SL. That is, the five panel reports developed as the basis for SFAA are *Physical and Information Sciences and Engineering*, *Biological and Health Sciences*, *Mathematics, Technology*, and *Social and Behavioral Sciences*. Other definitions of SL have incorporated understandings from some of these “outlying” disciplines, such as engineering and social sciences, but have done so as components of the contexts or “companion meanings” (Roberts, 1998) within which natural science subject matter itself is to be studied. In the case of AAAS, such understandings—as well as understandings from such disciplines as history and philosophy of science—appear to be part of the subject matter base of science education, all under the umbrella of scientific knowledge and “habits of mind.” As a consequence, the subsequent documents *Benchmarks for Science Literacy* (AAAS, 1993) and *Atlas of Science Literacy* (AAAS, 2001) provide quite specific academic content requirements for understanding such aspects of SL as the nature of science, human society (including decision-making), and nature of technology (including its interdependence with science and society).

Thus, for example, the “map” for Social Decisions in *Atlas* (AAAS, 2001) shows the following understanding in the group of 9–12 benchmarks: “In deciding among alternatives, a major question is who will receive the benefits and who (not necessarily the same people) will bear the costs” (p. 103). The implication is that understanding the statement (among others) makes one an informed decision-maker. This is decidedly a Vision I approach to SL. By contrast, other definitions (e.g., Ryder’s

[2001] *functional* SL) take socioscientific situations as a starting point (Vision II) and inquire about what understandings people actually use when they make a decision, not what they understand about scientists' understanding of the decision-making process. To be sure, Project 2061 has separated issues of defining SL from curriculum and implementation issues, as elaborated in *Designs for Science Literacy* (AAAS, 2000). Nevertheless, this feature of their definition of SL is noteworthy for its focus on scientists' academic understanding of such endeavors as societal decision-making, to the exclusion of such considerations as morality and values. (By contrast, a recent volume [Zeidler, 2003] is devoted entirely to examining the role of moral reasoning about socioscientific issues in science education discourse.)

### *The Scientists Communicate*

Another view of what scientists have to say about SL displays the sense of science as a cultural product—a thing of beauty and elegance in its own right. In this genre of writing about SL, one example is the recent volume titled *Science Literacy for the Twenty-First Century* (Marshall, Scheppler, & Palmisano, 2003). This collection of essays includes contributions by prominent, articulate scientists who describe—often eloquently—their experience in science (frequently, as well, the joy they find in teaching it). Scientists who prepare essays and books of this sort do not so much try to define SL as try to express their sense of it. This genre is probably the oldest writing about SL we have—it is no doubt the kind of thing C.P. Snow was writing about in his famous “two cultures” essay. It may also be reflective of the *true* SL Shamos described, and the sense of SL as a *State of Grace* noted by Bailey/Scribner. The best of this writing is highly cultured and inspiring through its elegance.

Similarly, an emerging field of studies called science communication rests on a multi-faceted message about SL and PUS—multi-faceted because it appears to be motivated both intellectually and politically. Professionals in this field concentrate on analysis of what and how scientists, journalists, and others should and do communicate about science to the general public. In a recent collection of essays about science communication, the editors begin their introduction and overview with the assertion that “It is widely accepted that the importance of the communication of science to the public can be summarised under five headings . . . economic, utilitarian, democratic, cultural, and social” (Stocklmayer, Gore, & Bryant, 2001, p. ix). Although the source of those categories—Millar (1996) and Thomas & Durant (1987)—is not explicitly acknowledged at this point, the categories themselves are by now familiar to the reader. The editors review and critique the five arguments, but their vantage point is not the same as Millar's—nor do they reach the same conclusions. Their interest is in the consequences of having an impact on the public's understanding of science, rather than in justifying the arguments for shaping school science.

The collection itself is wide-ranging. SL, as a concept, is mentioned seldom in its 18 chapters. Overall, the discourse has an aura of proselytizing, of transmitting the scientist's message to the public, from the scientist's point of view.

Those of us who find scientists' reflective writings eloquent and informative are already educated in science. The discourse belongs to the academic science culture, to borrow a term from Joan Solomon (1998). If the intention of such writing is to increase public understanding of science, surely it is important to recognize a distinction Solomon makes between two kinds of scientific cultures. “One, ‘popular’

scientific culture, refers to the concerns of the public, so important within their own local culture and often having a scientific and technological basis. Against that, a culture of academic science is much more restrictive" (p. 170). The distinction has its counterpart in different kinds of school science offerings. Noting that STS courses "have popular scientific culture as one of their objectives," she points out that classroom discussions based on moral positions and value judgments take place and create "an element of full-blooded popular communication with all its moral and political elements of argumentation" (p. 170). (Solomon's [1992] account of the Discussion of Issues in School Science [DISS] Project provides informative examples of, and insights about, 16- to 18-year old students' deliberations on socioscientific issues.)

Solomon (1998) continues, "Academic science itself bids to be . . . common across the invisible college that unites professional scientists from around the world." This comparison leads her to raise two questions. "Can science be taught so that it connects with attitudes, personal values, and political issues? This would indeed make science a part of popular culture. But would it still be science?" (pp. 170–171). Such questions express the crux of the tensions between Vision I and Vision II.

In further discussion of the culture concept as it applies to European science education, Solomon distinguishes the French term *la culture scientifique* from both Public Understanding of Science in the United Kingdom and Scientific Literacy in North America. "The European nations pride themselves on their long history of prestigious knowledge. It includes such venerable subjects as philosophy and the arts, without which a person in previous ages might not have been considered fit to take an honorable place in educated discourse. Culture, in this sense, holds a more elitist place in general estimation than does literacy" (pp. 171–172). Granting that the concept of culture itself applies in many contexts and does not represent only some elitist self-contained reality, Solomon concludes her paper by distinguishing three purposes for school science education (p. 176).

- "'Academic' scientific culture . . . must be cultivated [for] those who may become the next generation of science scholars."
- "vocational preparation in science-related fields . . . for example, engineering, medicine, and computer technology. It is harder to identify these with any particular 'kind' of school science program."
- "'Popular' scientific culture is just as significant: the promotion of a wide scientific and technical culture . . . in order that everyone can appreciate new developments and can evaluate them for their own and others' styles of living."

### *Reflections on the Focus-on-Science-and-Scientists Approach*

The AAAS definition of "science literacy" focuses on the way science views all aspects of the natural world and of human behavior, excluding from consideration such societal concerns as morality, values, and politics. The science communication enterprise is strikingly similar in its effort to put across the message that science, and a scientific perspective, is the preferred way to think about the objects and events of experience, and by extension about decision making with regard to socio-

scientific issues. Both of these are distinctly Vision I. By contrast, Solomon's description of popular science culture, and its counterpart in STS courses, embodies much more than scientific understanding and a scientific perspective on situations. Her phrase "full-blooded popular communication with all its moral and political elements of argumentation" captures the essence of Vision II.

## DEFINING SL, PART III: FOCUS ON SITUATIONS

### Questioning Vision I

Eisenhart, Finkel, and Marion (1996) have questioned in some detail whether the Project 2061 definition of SL—Vision I—is appropriate. They also question the results, in their view, of implementation of the US *National Science Education Standards*. Even acknowledging that the vision of SL in *NSES* is "democratic, socially responsible uses of science," they characterize current implementation in the US as concentrating "narrowly on key content: specifying what facts, concepts, and forms of inquiry should be learned and how they should be taught and evaluated" (p. 266). The authors point out that, in the implementation efforts, there seems to be an assumption "that producing citizens who can use science responsibly and including more people in science will naturally *follow from* teaching a clearly defined set of scientific principles and giving students opportunities to experience 'real' science" (p. 268, emphasis original). Their paper includes interesting examples of teaching approaches and materials designed to foster what they call "socially responsible science use" (p. 283)—a concept that entails learning science in situations where it will actually be used (Vision II of SL).

The focus-on-situations approach to SL has a familiar ring, for anyone acquainted with the work of David Layton and his colleagues on Science for Specific Social Purposes (discussed below). In two recent articles, Roth and Lee (2002, 2004) follow up on the line of thinking expressed by Eisenhart et al., and take it further on theoretical grounds. They assert that "reformers [an unidentified group] have consistently used a limited view of what scientific literacy might be; that is, they always maintained the scientists' version of science while disregarding the version of others. Consequently, . . . [science] in high school and university textbooks [is] said to be the prerequisite for appropriately coping in a modern world." This view of SL amounts, then, to requiring "a certain amount of scientific knowledge *on the part of the individual*" (Roth & Lee, 2002, p. 34, emphasis original). Against that, the authors "conceive of scientific literacy as a property of collective activity rather than individual minds" (p. 33).

The two articles report on a number of aspects of a three-year study centered on an environmental problem in a community in the Pacific Northwest ("Oceanside," a pseudonym). Middle school children participate with other community members to develop the knowledge base appropriate for taking action about a local creek, in which water quality has been seriously compromised over time. "Parents, activists, aboriginal elders, scientists, graduate students, and other Oceanside residents . . . constituted the relevant community in the context of which our seventh-graders learned" (Roth & Lee, 2004, p. 273). From these two richly detailed accounts, the

authors describe an alternative perspective on SL that emphasizes its collective (rather than individual) quality, the idea that in a democratic society “all forms of knowledge that contribute to a controversial or urgent issue are to be valued” (science being but one of many), and the point that experiencing an everyday situation as a learning context can mean that the students “could continue this participation along their entire life spans” (p. 284).

Roth and Barton (2004) continue exemplifying and promoting consideration of Vision II SL, in their presentation of case studies of project-based successes of marginalized persons—poor, female, minorities, homeless, aboriginal, and “coded” (e.g., ADHD). Roth’s chapters in the book draw on further analysis of the Ocean-side study. Barton’s chapters concentrate on two different settings: working with children and teenagers in after-school programs at homeless shelters in New York City, and narrative accounts of the working lives of three female science educators in an urban area of Pakistan. The authors argue for a broad definition of SL in these situations, sometimes straining the reader’s credulity to accept that the several kinds of knowledge exemplified can actually be said to fall under the SL umbrella. It is the real-ness of the situations and the participants’ experience (a familiar feature of project-based work) that prompts the authors to raise questions about science curriculum policy and planning. School science activities are said to be artificial, disconnected from the real purpose of participation in (genuine) community affairs. Even “school-based mock activities . . . designed to empower students to deal with science and scientific experts on emerging socio-scientific issues” are deemed to be inadequate, because “students have to *play* the roles of scientists, environmental activists, or local residents in a pretend activity” (p. 176, emphasis original).

### Science for Specific Social Purposes (SSSP)

Pre-dating Roth and Barton by roughly two decades, Layton, Davey, and Jenkins (1986) presented a picture of situated knowledge—motivated especially by their concerns about the inadequacy of assessment programs. Basic to their argument is the point that PUS and civic (public, adult) SL are manifest in specific situations, hence the scientific knowledge people employ in those situations is contextualized according to what the situation requires. This is, of course, Vision II. Nevertheless, they point out, many testing programs for adult SL (and student SL also, I would add) incorporate a set of decontextualized knowledge items selected on some arbitrary basis. Thus there is something of a strained connection between a correct response to such items as “Which travels faster, sound or light?” and the extent to which an individual can be said to understand and/or engage intelligently in debate about a socioscientific issue. In a word, as noted earlier, the scientific knowledge being tested does not articulate or mesh well with the contexts in which one might expect learners to use it. Layton et al. (1986) introduced the term *science for specific social purposes (SSSP)* to capture the point that the context or situation of a socioscientific issue (or even an explanation) has a strong influence on the knowledge people bring to bear on it.

To clarify and exemplify the SSSP concept, the authors present a most engaging overview of adult SL in England during the nineteenth century, which suggests that “different social groups saw in science an instrumentality for the fulfillment of their

specific intents" (Layton et al., 1986, p. 32). For example, "Chemistry for precious metal prospectors . . . was different from chemistry for agriculturalists and again from chemistry for public health officials" (p. 30). In commenting on the importance of SSSP to the assessment of public SL, Jenkins (1997) notes that "any estimation is likely to be most useful when it relates to a particular group of citizens addressing a specific issue of common concern to that group, for instance, . . . a community exploring how best to provide and maintain a supply of clean drinking water" (p. 23, and cf. Roth & Lee [2002, 2004]). Obviously, to use that issue and situation in an assessment program, one would have to contextualize reasonable and pertinent items about water chemistry, water biology, ecology, etc, in the situation.

The impact of re-framing the vision of adult SL and civic SL in this way is to get away from the idea that a generalized test of "cognitive deficit" in scientific knowledge is a meaningful way to make a connection to SL at all. Jenkins continues, "Fundamental to the notion of science for specific social purposes is a rejection of the so-called 'cognitive deficit' understanding of scientific literacy in favour of a more interactive model (Layton et al., 1993)" (Jenkins, 1997, p. 23). The differences, laid out in tabular form by Jenkins (p. 24), are described in terms of adult SL, or PUS. I want to single out two of those differences just to provide a flavor of the two models.

The cognitive deficit model sees PUS as highly dependent on science itself (Vision I of SL)—i.e., "central to decisions about practical action in everyday life"—whereas in the interactive model science "is often marginalized or 'off-centred' when integrated with other kinds of knowledge relevant to such decisions." (That's Vision II.) Also, "Scientific thought is the proper yardstick with which to measure the validity of everyday thinking" in the cognitive deficit model, while the interactive model holds that "everyday thinking and 'knowledge in action' are more complex and less well understood than is scientific thinking." This is not to say that scientific knowledge is unimportant. It is, however, to point out the significance of taking the situation as a starting point, rather than the scientific canon itself, when planning assessment. One is, after all, assessing a reasoning pattern that resembles Aristotelian *praxis* in these situations, and knowledge premises are a significant part of the logic and coherence of the practical syllogisms that characterize the *praxis* thinking pattern. The knowledge has to be carefully selected, however, and integrated with other features of the situations such as value premises. Layton (1991) explores these matters further.

### **A Third Curricular Arrangement: Recognizing the Significance of Vision II**

Science curriculum revision that recognizes and mandates embedding science subject matter in situational contexts has been underway in Canada for the past decade. This curricular arrangement obviously differs from the approach taken by 21st Century Science. It also differs from the arrangement of the *NSES* framework, where the contexts are identified, but inclusion of them in local curriculum development would have to be mandated at the state level.

Canada does not have a national curriculum. Jurisdiction over educational matters resides with the governments of the ten provinces and three territories. The

most recent science curriculum revision has been based on a nation-wide “framework” (Council of Ministers of Education, Canada [CMEC], 1997) to which provincial ministers of education subscribed in hopes of providing common ground and more consistency in learning outcomes for science across the country. The framework “is guided by the vision that all Canadian students, regardless of gender or cultural background, will have an opportunity to develop scientific literacy.” SL is defined as “an evolving combination of the science-related attitudes, skills, and knowledge students need to develop inquiry, problem-solving, and decision-making abilities, to become lifelong learners, and to maintain a sense of wonder about the world around them” (p. 4).

The definition is made operational by specifying four “foundation statements,” one each for skills, knowledge, and attitudes, and a fourth for “science, technology, society, and the environment (STSE)” (p. 6). Acquisition of science-related skills, knowledge, and attitudes, according to the document, “is best done through the study and analysis of the interrelationships among science, technology, society, and the environment (STSE)” (p. iii). Implicit in that statement, and more explicit in several provincially mandated curricula based on it, are two important features of the meaning of SL. First, the “science-related skills, knowledge, and attitudes” specified in the respective foundation statements for those three areas are to be developed through the STSE situations and challenges comprising the fourth. That is, the expectation is that curricula and textbooks will provide opportunities for students to learn about STSE interrelationships at the same time they are learning science subject matter, skills, and attitudes. This simultaneous learning is envisioned as happening through contextual communication, in which units of science subject matter are organized to stress three (one at a time, essentially) “broad areas of emphasis:

- a science inquiry emphasis, in which students address questions about the nature of things, involving broad exploration as well as focussed investigations [this is an emphasis on the nature of science];
- a problem-solving emphasis, in which students seek answers to practical problems requiring the application of their science knowledge in new ways [this is an emphasis on science and technology];
- a decision-making emphasis, in which students identify questions or issues and pursue scientific knowledge that will inform the question or issue [this is an emphasis on socioscientific issues]” (p. 8).

Second, although this is not stated explicitly in the document, these three areas of emphasis correspond to the Aristotelian trilogy (*theoria, techne, praxis*) that classifies three different human purposes, namely seeking warranted knowledge, making beautiful and useful things, and arriving at defensible decisions, respectively. A different pattern of reasoning is used in each, and the skill set associated with each emphasis is identified accordingly. Hence SL is operationally defined as the student’s grasp of the way science itself permeates human affairs across this broad trilogy of purposes. (Predating the Pan-Canadian framework, this organization of a science curriculum policy was implemented in the province of Alberta, as described by Roberts, 1995.)

## Reflections on the Focus-on-Situations Approach

Writers who advocate Vision II SL raise three serious challenges for science education, in my view. I shall comment very briefly on these, according to the topics of assessment, curriculum planning, and the character of science classroom discourse.

Assessment programs—especially if cross-national—are made much more complex, if Vision II SL is taken into account. This matter is pursued in the section immediately following. Two points are important here. First, students' experience of situations, especially as described in Roth and Barton (2004), is local and virtually one-of-a-kind. This feature of Vision II creates significant problems for cross-national, or even national, comparisons. Second, a related concern is the daunting challenge of getting away from the "cognitive deficit model" of assessment in science, as discussed by Jenkins (1997).

Curriculum planning and implementation are complicated by the fact that Vision II takes as its starting point a context, rather than a formal knowledge structure. In the case of Canada's framework (CMEC, 1997) and provincial curricula based on it, the most likely chance of success has been to mandate that certain units of study (e.g., Heat) be taught in a selected context or emphasis (e.g., science and technology). Instructional resources that are approved follow suit. Supporting materials often recommend (in some cases, mandate) that teachers use the familiar learning cycle approach to planning, in order to ensure that situations receive attention and that subject matter is integrated as required for understanding the situation.

The increasing attention to inclusiveness in science education is part of what animates discussion about Vision II. It is imperative, in Vision II SL, that situations be an important focus of science classroom discourse, yet such discussions require teachers to embrace "discourse universes" that are unfamiliar—such as the aboriginal oral history that was an important part of the Oceanside case study (Roth & Lee, 2002, 2004). A number of writers cite Jean Lave's work on situated cognition as an important source for understanding (e.g., Lave & Wenger, 1991). Others concentrate on the character and quality of argumentation in classroom discussions about socioscientific issues (e.g., Zeidler, Osborne, Erduran, et al., 2003). Wynne (1995) describes one research approach based on "the reconstruction of the 'mental models' that laypeople appear to have of the processes that are the object of scientific knowledge" (p. 364). He cites, for example, lay models of home heating to illustrate how knowledge based on such mental models differs from "theoretical knowledge, handed down from science as the 'correct' knowledge against which to measure public understanding" (p. 372). All such matters as these are challenges to science educators, if Vision II is taken seriously.

### WHAT IS BEING ASSESSED, IN THE NAME OF SL?

This section concentrates on the meaning of SL used as a basis for measurement in four prominent assessment programs. Two of these are independent of professional science education: the work of Jon Miller in the US and increasingly in other countries, and that of John Durant in England. The other two are used in international testing programs and have involved science educators worldwide: the mathematics and science literacy (MSL) component of the Third International Mathematics and

Science Study (TIMSS) and the OECD-sponsored *Programme for International Student Assessment* (PISA). In each case, the conceptualization of SL is described first, and a commentary follows.

## Jon Miller's Assessments of Scientific Literacy

There is good reason to go into a bit of detail about Miller's estimates of SL, whether or not one agrees with them. Miller maintains a high profile as a commentator on SL especially in the US but increasingly around the world, since his methodology has now been used for replication studies in more than 20 countries. He is Director of the International Center for the Advancement of Scientific Literacy, founded by the Chicago Academy of Sciences in 1991, now located at Northwestern University (Retrieved April 13, 2005, from [http://www.cmb.northwestern.edu/faculty/jon\\_miller.htm](http://www.cmb.northwestern.edu/faculty/jon_miller.htm)). For more than two decades, he has designed and conducted the periodic national studies *Science and Engineering Indicators*, polled regularly by the (US) National Science Board. The results of these assessments play a role in his estimates of SL among both adults and students in schools and colleges. In the US, such results are potentially a direct reflection on the school system—especially now that his *Longitudinal Study of American Youth* (LSAY) results have generated equations that “predict” SL on the basis of a large number of curriculum-related (as well as home-related) factors (see Miller, 2000).

### *The Definition Shifts*

Miller's work is based on Vision I, but initially it was planned to embrace Vision II as well. The paper most frequently cited in the literature (Miller, 1983) appeared in an issue of the journal *Daedalus* that was devoted entirely to SL (American Academy of Arts & Sciences, 1983). In that paper, SL is presented as a construct with three components. The first two are defined in terms of the history of assessment in science education, as two separate strands: “definition and measurement of the scientific attitude” by science educators in the US starting in the 1930s, and assessment of “the level of cognitive scientific knowledge” among various groups in the school population as part of the postwar (WWII) growth of standardized testing, also in the US. These two strands were combined in the (US) National Assessment of Educational Progress (NAEP) studies beginning in the mid-1960s—“the first to measure systematically both the understanding of the norms, or processes, of science and the cognitive content of the major disciplines.” To these Miller added a third component—one that essentially reaches out to embrace Vision II: “awareness of the impact of science and technology on society and the policy choices that must inevitably emerge” (p. 31).

The assessment procedure specified that an individual must achieve minimal competence on all three dimensions, or components, in order to be declared scientifically literate. Here are examples of the results. In a 1979 survey, the instrument “included all of the items necessary to measure each of the three dimensions of scientific literacy” (Miller, 1983, p. 36). “On the basis of this measure, only 7 percent of the respondents [ $N = 1635$ ]—primarily males, individuals over thirty-five, and col-

lege graduates—qualified. . . . But even among holders of graduate degrees, only a quarter could be called scientifically literate” (Miller, 1983, p. 41; cf. Shamos, 1995, p. 90). Later, he reported “approximately 7 percent of American adults qualified as scientifically literate in the 1992 study. . . . [This] estimate . . . shows no significant change from the results of previous studies in 1979, 1985, 1988, and 1990” (Miller, 1996, pp. 193–194).

In three later, related publications, Miller (1997, 1998, 2000) took a different tack in two ways. First, the studies described are more elaborate and include longitudinal student data based on a more comprehensive methodology. Two of the articles (Miller 1997 and 2000) tell essentially the same story, but the later one is more complete, has a larger database, and represents a refinement of the earlier one, so it is the basis for the following discussion. Second, the original third dimension of SL (awareness of the impact of science and technology on individuals and society) is called into question on the following basis. “In more recent cross-national studies of civic scientific literacy, Miller found the third dimension—the impact of science and technology on individuals and society—to vary substantially in content among different nations and adopted a two-dimensional construct for use in cross-national analyses” (Miller, 1998, p. 206; he cites Miller, Pardo, & Niwa [1997] as the basis for this point.) In other words, no significant factor loaded for the third dimension, when the factor analysis was performed. Miller (1997) pointed out that it is “difficult to construct accurate cross-national measures of this dimension because science and technology may be experienced differently, depending on the emergence of public policy issues in a given country” (p. 124). He also expressed the view that an understanding of scientific knowledge and scientific inquiry items is sufficient for declaring that a respondent comprehends the impact dimension (Miller, 2000, pp. 27–29).

### *Commentary on Miller’s Contribution*

From a measurement standpoint, Miller had no choice about dropping the third dimension from his original construct of SL. Quite simply, no third factor emerged from the factor analysis. However, the impact on defining SL is more significant: the definition has been squeezed and distorted. In the process, any gestures in the direction of Vision II have been lost. Miller claims “There is general agreement among scholars engaged in national surveys . . . that a reliable two-dimensional measure of civic scientific literacy would be useful in a wide range of national and cross-national research (Miller, 2000, p. 26). As well, he equates “scientifically literate” with “well informed,” in that same paper (p. 29). From a conceptual standpoint, it appears that he is downplaying the significance of educational experience related to an understanding of the impact of science and technology on individuals and society. One interpretation would be that Miller truly believes that understanding science and science inquiry somehow prepares individuals for understanding the impact of science and technology. He would not be alone; that seems to be the cornerstone of Vision I.

There are two further implications of Miller’s marginalization of Vision II. First, there is the point that cross-national comparisons, and even cross-national discourse about SL, run the risk of talking at cross-purposes if the “impact” dimension is included in a testing program. Science educators involved in PISA and the MSL com-

ponent of TIMSS are well aware of this point. Second, Miller asserts in two publications intended for science educators that “issue-oriented” courses are not conducive to developing SL (Miller 1996, p. 201, and 2000, p. 44). That claim surely merits further empirical investigation. It would be difficult for many in the science education community to swallow, since analysis of controversial issues is held to be an important instructional context in which students learn the science needed to understand an issue, and simultaneously develop their grasp of decision-making processes about socio-scientific issues in a democracy.

A final point is in order. The decontextualized nature of the probes used in Miller’s assessment items (e.g., the Earth goes around the Sun once a year—True or False?) raises issues about validity of the measurements. In turn, questionable validity about claims of SL makes assessments such as his questionable as a component of curriculum policy deliberation (cf. Norris & Phillips [2003]). Nevertheless, in the US but increasingly in other countries as well, Miller’s contribution is one to be reckoned with politically.

## **Assessing Public Understanding of Science as SL: John Durant and Colleagues**

As noted earlier, the term public understanding of science is used more frequently in England than the term SL. In some of John Durant’s work the two terms are nevertheless linked explicitly. Durant is no stranger to informal science education. His academic credentials include a Visiting Professorship in the History and Public Understanding of Science at Imperial College of the University of London. He has also held posts as Assistant Director of the Science Museum in London and, currently, as Chief Executive of At-Bristol, a science and discovery center bringing to the general public an increased access to science, technology, natural history, and the environment. I wish to explore three papers for which he was either sole author or co-author.

### *Wavering on the Vision*

Thomas and Durant (1987) examined the relationship between PUS and SL in the first issue of a publication by the Scientific Literacy Group in the University of Oxford Department of External Studies. At the conclusion of the paper, they point out that their “preliminary account of the nature of the public understanding of science in terms of the concept of scientific literacy” rests on the relationship between science and the rest of society, “promoting the public understanding of science which is concerned with decision-making about science-related issues in a democratic society” (p. 13). The vision of SL expressed here is Vision II.

In 1988, the year after that paper was published, an empirical study was launched to test a hypothesis about the relationship between PUS and levels of support for science (Evans & Durant, 1995). Despite professing Vision II in the paper just discussed, Durant and his colleague used Vision I almost exclusively to define PUS for this study. Two of the independent variables are generated directly from Vision I: familiarity with products and processes of science. There is a vague nod in the direction of Vision II. The third independent variable is called “interest in sci-

ence," measured on the basis of TV and magazine consumption and a self-reported estimate of how likely respondents were to read headlines with scientific content (p. 58). The authors use the phrase "attitudes towards science" to signify a conceptually related group of dependent variables that are taken to indicate "more or less support for, or a more or less positive evaluation of, science, scientists, and scientific activities" (p. 59).

Following discussion of the results of their regression analysis, Evans and Durant conclude that (1) "measures of general attitudes [toward science] are inadequate as a guide to what the public may think of specific areas of scientific research," (2) "there is some evidence that higher levels of knowledge are associated with more supportive attitudes for science in general and for 'useful science' [probably thought to be socially relevant]," (3) "the well informed are more strongly opposed to morally contentious and non-useful areas of research than are the less well informed," and (4) "interest in science may predict attitudes better than scientific understanding will" (p. 70). They bring the paper to a close with the caution that for anyone promoting greater PUS in order to mobilize public support for science, "the results presented in this paper suggest that such attempts cannot always be relied upon to be straightforwardly beneficial" (p. 71).

Durant (1994) returned to defining SL in the following way: "what is it reasonable to hope and expect that ordinary citizens will know about science in order to equip them for life in a scientifically and technologically complex culture?" (p. 83). He structures the argument around three possibilities for defining SL: "knowing a lot of science, knowing how science works, knowing how science really works" (p. 84). The contrast between the second and third is deliberate, of course. The definition is Vision I. In concluding his paper, Durant contrasts the SL of scientists and the SL of the general public. He points out that scientists have first-hand experience of the checks and balances of knowledge production, while most members of the general public do not have any experience of scientific research at all. Allowing that formal science education about the nature of science ameliorates this situation somewhat, he notes that "informal science education has attempted to convey something of the spirit of scientific inquiry through, for example, hands-on exhibits that foster curiosity and the sense of discovery among children" (p. 89).

### *Commentary on Durant and Visions of SL*

The vision of SL inherent in these three papers is not uniform. In the defining article of 1987, it is Vision II, yet Vision I predominates in the 1995 study and in the 1994 article (which is Durant's alone), but the latter is an elaborated form to include some institutional characteristics of science. Regarding this elaborated form of Vision I, Miller, Pardo, and Niwa (1997) comment in the following way. "In recent work [the 1994 article], Durant discusses a three-dimensional model (a comprehension of basic scientific concepts, an understanding of scientific methodology, and an understanding of the institutional dimension of science) but has used for analysis [in another study, namely Bauer, Durant, & Evans (1994)] only a single summated scale that merges the vocabulary and process dimensions" (p. 39).

The shifts between Vision I and Vision II are a significant matter for anyone concerned about the validity of SL and PUS assessments such as Miller's and Durant's.

The concern of these two researchers is more for reliability in cross-national measures than in validity of the definition of SL or in the character of science education.

### **SL in the Third International Mathematics and Science Study (TIMSS)**

At about the same time Miller (1997 ff.) was withdrawing from the use of the impact dimension in his assessments of SL, TIMSS was developing and incorporating items from just such a dimension in a mathematics and science literacy (MSL) component. (Readers will be aware that the “T” in TIMSS has recently begun to stand for “Trends in . . .” rather than its original “Third.” This discussion relates to the original meaning.)

Unlike other components of TIMSS, MSL testing was not curriculum-bound. For this component, students were tested in their final year of secondary school. “These students may have studied mathematics and science in their final years of school or they may not have; they may regard themselves as specialists in mathematics and science, in other subjects, or in none; they may be entering occupations or further education related to mathematics and science, or they may have no intention of doing so. . . . The role of the literacy study within TIMSS . . . is to ask whether school leavers can remember the mathematics and science they have been taught and can therefore apply this knowledge to the challenges of life beyond school” (Orpwood & Garden, 1998, pp. 10–11).

In addition to Vision I dimensions in the MSL test (mathematics and science content, and “Reasoning in Mathematics, Science, and Technology”), the distinctively Vision II dimension is called “Social Impacts of Mathematics, Science, and Technology.” For testing purposes, the third and fourth dimensions were combined into one grouping known as “RSU”—“reasoning and social utility in mathematics, science, and technology” (pp. 30–31). This became the working framework for developing test items. In the end, the item pool contained 12 RSU items—five multiple choice, three short answer, and four extended response, for a total testing time of 31 minutes out of 121 (Orpwood, 2000, p. 55).

In reflecting on the development of the items, Orpwood commented, “many draft items that went beyond strict knowledge of science or mathematics content were either eliminated on psychometric grounds or on the grounds of unacceptability to participating countries” (p. 56). These two reasons will not surprise the reader at this point, since these problems reflect some of the same concerns that Miller claims to be his reasons for retreating from the inclusion of an impact dimension in his assessments. Orpwood’s account provides many more pertinent details for science education than we find in Miller’s work. Indeed, in a later paper Orpwood (2001) presents a convincing case for paying serious attention to the lag between major curriculum changes in science education, which he terms “curriculum revolutions” (p. 137), and the development of assessment techniques that are appropriate for evaluating the impact of the changes. Commenting on the 1960s curriculum revolution to incorporate goals related to the nature of science and the acquisition of science inquiry skills, he notes that “teachers and national/international assessment projects continued to use traditional assessment measures—measures that, in the

main, called for recall of memorised scientific knowledge" (p. 143). About the delay in shifting assessment techniques to those that match the change, he noted "It was the 1980s before performance assessment even made its first significant appearance and the 1990s before it became at all widespread" (pp. 143–144).

"The second period of revolutionary change," as Orpwood described it, "began slowly in the early 1980s and has now (in the late 1990s) gathered significant momentum . . . outward [from science itself] towards society and the complex relationships among science, technology, society, and the environment" (p. 139). Yet, at this time, "assessment of the curriculum goals . . . for the STS revolution in science curriculum has barely surfaced at all beyond the research level" (p. 144). He describes RSU items from the MSL component of TIMSS, presenting sample items and commenting on both their structure and some of the issues associated with their acceptance or rejection by the project committee and/or participating countries. He also describes items from his experience with another assessment program, in the Canadian province of Ontario, related to goals for a science-technology curriculum. The overall thrust of the article is to express concern that lack of appropriate assessment procedures can distort and stifle curriculum innovation, and the examples give point and substance to Orpwood's argument.

### **SL in the OECD Programme for International Student Assessment (PISA)**

This assessment is planned to test 15-year-old students in participating countries, on a three-yearly basis, in three domains: reading literacy, mathematical literacy, and scientific literacy. This review is concerned only with the conceptualization of SL inherent in the science assessment. The conceptualization initially adopted for PISA states the following: "Scientific literacy is the capacity to use scientific knowledge, to identify questions and to draw evidence-based conclusions in order to understand and help make decisions about the natural world and the changes made to it through human activity" (OECD, 1999, p. 60). The meaning of, and the purpose for including, particular phrases in the definition, such as "scientific knowledge" and "evidence-based conclusions," are elaborated in the OECD document and, as well, in two very informative papers by Harlen (2001a, 2001b).

The following points about the conceptualization paraphrase Harlen (2001b).

- This conceptualization of SL is about what learners should achieve in terms of their needs as citizens—"understanding that will improve their future lives" (p. 87). This suggests a view that future scientists also need such understanding.
- The roots of SL are in school experience, even though it can be "developed throughout life" (p. 87), which is a recognition of the significance of informal science education.
- SL is not equated with vocabulary, but connotes "general competence or being 'at ease' with scientific ways of understanding" (p. 87). This also suggests a broader, different kind of understanding than suggested by knowing how to "do science."

- A key feature of a student's SL is skilfulness at relating evidence to claims: how evidence is used and collected in science, "what makes some evidence more dependable than other, what are its shortcomings and where it can and should be applied" (p. 87).
- This SL conceptualization contextualizes scientific knowledge and scientific thinking in relation to problems, issues, and situations "in the real world" (p. 91)—thus students can apply what they learn in laboratory settings to non-school settings.

Assessments were conducted in 2000 and 2003, and a third is planned for 2006. All three domains of literacy are tested in each assessment, but one is a major feature and the other two are minor: reading literacy was the major domain in 2000, mathematical literacy was major in 2003, and science is the major domain for the 2006 assessment. The conceptualization of SL used in the 2003 assessment is the same as stated above for 2000 (OECD, 2003, p. 133. Retrieved April 13, 2005, from <http://www.pisa/oecd.org>).

The PISA Governing Board has approved the framework for the 2006 assessment (R.W. Bybee [personal communication April 19, 2005]). The Science Forum, responsible for advising, and the Science Expert Group, responsible for developing specific aspects of the framework, have revised the 2000/2003 framework. The 2006 conceptualization of SL is as follows. (This is taken from a document prepared for the Science Forum and Science Expert Group Meetings held in Warsaw, July 12–15, 2004, and is reproduced here by permission of R.W. Bybee [personal communication April 19, 2005].)

Scientific literacy refers to an individual's:

- Scientific knowledge and use of that knowledge to identify questions, to acquire new knowledge, to explain scientific phenomena, and to draw evidence-based conclusions about science-related issues;
- Understanding of the characteristic features of science as a form of human knowledge and enquiry;
- Awareness of how science and technology shape our material, intellectual, and cultural environments; and
- Willingness to engage in science-related issues, and with the ideas of science, as a reflective citizen.

This conceptualization is clearly specifying Vision II as the basis for PISA in 2006. From the beginning, this project has concentrated on assessment within situations. The 2006 framework emphasizes and strengthens that intention.

The story of SL in PISA is an amazing tale of deliberation and consensus seeking in an area of science education policy formation, namely student assessment, which is not known for wasting time on deciding about what goals of science education to test. Harlen (2001b) notes that "What PISA assesses is what participating countries have agreed are desirable outcomes, whether or not they reflect the current curriculum of a particular country" (p. 85). The implications of that statement are astonishing, and some of the sample test items presented in Harlen's paper, as well as on the OECD/PISA website, are most interesting. Although any more

specifics about the assessment program itself are beyond the scope of this review (and are more appropriate elsewhere in this handbook), this is a venture well worth watching from the standpoint of the thoughtfulness that has gone into conceptualizing and measuring SL—especially the challenges of taking Vision II seriously in an assessment framework.

## IMPLICATIONS

The most challenging aspect of this literature is trying to get clear on what is actually being claimed, in the name of SL. To be sure, a definition of SL is always provided when a research article, an assessment program, or a curriculum policy is described, discussed, or advocated. The variety among the many definitions pales in significance, though, in comparison to the fundamental differences we can see between Vision I and Vision II. Conclusions and implications of this review are clustered according to four areas. Special attention is paid to implications for further research.

- We can, logically speaking, expect differences in outcomes for students from SL programs and teaching based on Vision I, compared to Vision II.
- We can identify three types of curricular arrangements to make provision for SL and PUS to develop. Is any one arrangement better than the other(s)?
- Vision I and Vision II give rise to different assessment frameworks for making claims about students' and adults' SL and PUS. What are the implications for our discourse with each other, as science educators?
- Different combinations of "discourse universes" are appropriate for inclusion in Vision I and Vision II embodiments. What are the consequences of taking that statement seriously, for teachers, students, and teacher education?

### The General Character of Vision I and Vision II Program Outcomes

The identification of Vision I and Vision II of SL/PUS has been presented as a heuristic device intended to highlight the most significant conceptual divide in the literature reviewed here. What are the implications of adopting one vision or the other for program development?

The most serious problem with adopting Vision I is narrowing the student's experience with the breadth of science as a human endeavor. Between Vision I and Vision II, the most obvious distinction has to do with a student's way of conceptualizing and experiencing the character of controversial socioscientific issues and problems. As indicated in my earlier example based on the *Atlas of Scientific Literacy* (AAAS, 2001), Vision I would have students understand an issue as a scientist would. That is well and good, for one perspective on the issue. In several Canadian provinces, science curriculum policy requires that several other perspectives (e.g., economic, aesthetic, political, ethical, social) also be taken into consideration and used in deliberation about socioscientific issues. Roth and Barton are particularly scathing in their comments about the inadequacy of a single perspective. "Just imagine, every individual taking the same ('scientific') perspective on GMO's,

genetic manipulation of the human genome, or use of drugs (such as those used to dope certain kinds of children, labelled with [ADHD], to make them compliant)" (p. 3). Eisenhart et al. (1996) seem to be making a similar point. "We disagree with the implicit assumption . . . that teaching students key concepts and scientific methods of inquiry will necessarily lead to socially responsible use [of science] or to a larger and more diverse citizenry who participate in discussion and debate of scientific issues . . . no clear conceptual connections, strategies to achieve, or empirical support are offered . . ." (pp. 268–269).

There are actually two points here. One is an empirical claim that implementation efforts in the US are over-emphasizing Vision I—or, at least, the portion of it contained in the "Science as Inquiry" standard of *NSES* (the other portion is contained in the "History and Nature of Science" standard). I'm not sure sufficient evidence is presented for that claim. The second point probably is more accurate. The assertion that students don't automatically develop a Vision II grasp of SL if they are exposed only to Vision I is based on a logical point. It has to do with the variety of discourses included in each vision. A curriculum based on Vision II discourses potentially encompasses all four of the *NSES* context standards. Similarly, the "ideas about science" in the Vision II project 21st Century Science include "the practices that have produced it; the kinds of reasoning that are used in developing a scientific argument; and on the issues that arise when scientific knowledge is put to practical use." These are grouped into six broad categories: "data and its limitations; correlation and cause; theories; the scientific community; risk; and making decisions about science and technology" (Retrieved April 19, 2005 from <http://www.21stcentury science.org>).

A Vision I curriculum, though, can be developed in the absence of some of the Vision II discourses, namely the substance of the *NSES* standard on "Science in Personal and Social Perspectives" and, perhaps as well, the standard on "Science and Technology" (NRC, 1996, p. 113). In brief, Vision II subsumes Vision I, but the converse is not necessarily so.

### *How Visions of SL Materialize*

Visions of SL materialize from the contexts in which science subject matter is taught. No science curriculum, textbook, or lesson is "context-free." The contexts for science education are (1) expressions of the reasons students are expected to learn the subject matter and, therefore, in a classroom or textbook, (2) sets of coherent messages (discourse universes, essentially) about the purpose for learning it. I have dubbed these contexts *curriculum emphases* (Roberts, 1982, 1988). Curriculum emphases can be communicated either explicitly, by what is said in the classroom, or implicitly, by what is implied or excluded.

Seven distinct curriculum emphases can be discerned in science curriculum history during the past century. Even a syllabus of subject matter topics has a curriculum emphasis, which I have dubbed "Solid Foundation." This is a default emphasis—meaning it is communicated implicitly. The contextual message it communicates to students is "The reason for learning this material is to get ready for next year, and the year after that." In other words, it is a purpose based on the orderliness of a recognizable sequence. A closely related default emphasis I called

“Correct Explanations.” This one communicates that the purpose of learning science is to get your world-view right. Although examples of these two can be found in science education curriculum history, they are not of much interest to the present discussion.

Vision I incorporates two of the emphases I identified. One is called “Scientific Skill Development” and the other “Structure of Science.” Together, I would say these two make up two US *NSES* context standards—Science as Inquiry, and History and Nature of Science. Vision II partakes of those, and also the remaining three: “Personal Explanation,” “Science, Technology, Decisions,” and “Everyday Coping/ Applications.” The first two of these are found in the *NSES* standards as Personal and Social Perspectives on Science, and the third is found in Science and Technology.

### *The Potential Effects of Over-emphasizing One Curriculum Emphasis*

Science curriculum history is littered with examples of throwing out the baby with the bathwater. Major changes in science curriculum have been due to changes in curriculum emphasis, although of course there have been changes to subject matter as well. When a curriculum emphasis changes, for whatever reason, the rhetoric usually cries out “Stop doing *any of that*, and start doing *all of this!*” Neither Vision I nor Vision II is immune from this possibility.

Vision I programs run the risk of including situation-oriented material (Science and Technology and/or Personal and Social Perspectives on Science) in a token fashion, only as a source for motivating students in lessons. By the same token (pardon the pun), Vision II programs run the risk of paying insufficient attention to science. Aikenhead (1994) presents an analysis of materials development, research, and teaching approaches in STS according to eight categories that show different blends of science content and attention to situations, or “STS content” (pp. 55–56). At one extreme is “Motivation by STS Content,” described as “Traditional school science, plus a mention of STS content in order to make a lesson more interesting. Not normally taken seriously as STS instruction. . . . Students are not assessed on the STS content.” At the other extreme is “STS Contents,” described thus: “A major technology or social issue is studied. Science content is mentioned but only to indicate an existing link to science. . . . Students are not assessed on pure science content to any appreciable degree.” There is a message here, as well as an analytical scheme, about what can happen in implementation efforts involving both Vision II and Vision I.

Roth and Lee (2002, 2004) and Roth and Barton (2004) have pushed Vision II to the extreme by redefining SL as “collective praxis”—as if there is no such thing as “individual” SL. All of their case studies, so far as I can determine, are based on teaching science through the same single context: Personal and Social Perspectives on Science. There is a comment in a “Coda” (Roth & Lee 2004, p. 288) that “Much research remains to be done to study the forms distributed and situated cognition take in the approach we propose.” Indeed. More research is also needed on whether, and how well, students can shift from one context to another as appropriate in different situations. For example, suppose students learn about water chemistry in the context of a Personal and Social Perspectives on Science. Would that inhibit,

contribute to, or have no effect on their understanding of appropriate features of the Scientific Inquiry and/or History and Nature of Science context, such as the system-theory character of ecological inquiry? I would submit we don't have enough research to answer questions of this sort. To be sure, we have substantial research on the impacts of teaching science within a single context, or curriculum emphasis (e.g., the research on learning about the nature of science, about STS, etc.). The point here is about multiple contexts and how those affect learners, therefore feeding back implications for the way SL is defined in curriculum policies and implemented in instructional materials. There are risks in over-emphasizing either Vision II or Vision I.

### **Curricular Arrangements to Deliver SL and PUS**

This review identified three approaches to organizing curriculum in order to achieve SL and/or PUS. I shall summarize them first. The most direct approach—a special course on SL or PUS mandated for all students—is, so far as I can tell, also the most rare. The two examples I have found are the course in England known as 21st Century Science, which is clearly based on Vision II, and a grade 10 course in the Netherlands that began with the intention to embody Vision II.

The second approach, by far the most common, is to work from an overall curriculum framework that is permeated by SL and, generally speaking, identifies SL as its potential outcome for all students. I would say that the approach taken by *NSES* in the US reflects this approach. Another example is a recent report from Australia. According to Rennie, Goodrum, and Hackling (2001), the current curriculum framework emerged from a recent large-scale research project examining the quality of science teaching and learning in Australian schools. Their paper draws from the full report of the study (Goodrum, Hackling, & Rennie, 2000). Most significant for purposes of this review is the conception of SL expressed as the “ideal” approach to science curriculum in the several states (the eight states and territories of Australia do not have a single mandatory or official national curriculum). All of the recommendations of the study are based on five premises, including one that specifies the purpose of science education as developing SL. “Scientifically literate persons are interested in and understand the world around them, are sceptical and questioning of claims made by others about scientific matters. They participate in the discourses of and about science, identify questions, investigate and draw evidence-based conclusions, and make informed decisions about the environment and their own health and well-being” (Rennie, Goodrum, & Hackling, 2001, p. 494).

Such frameworks as *NSES* and the Australian example typically reflect elements of both Vision I and Vision II, just because they are broad, idealized, multi-purpose, and intended to be enabling and facilitating. That is, as Bybee expressed about his types-and-levels definition of SL, not everyone is expected to develop the same degree, or the same kind, of SL. Curriculum frameworks of this sort must accommodate some students who want and/or need pre-professional training in science, as well as preparing students for citizenship.

The third arrangement, used by a number of Canadian provinces, is to ensure that objectives related to Vision II are mandated through the requirement to teach certain units of study according to curriculum emphases (typically called program

emphases, in Canadian provinces) that take Vision II situations (technological problem solving and societal decision making) as their starting point.

### **The Potential for Retreating from Vision II to Vision I**

Vision I and Vision II express broadly different views of what it means to be scientifically literate, or to have developed knowledge, skills, and attitudes consistent with public understanding of science. What is important to recognize is that advocates of Vision II stress that all students in democratic societies—regardless of their career plans—need to develop SL that is appropriate to situations other than conducting scientific inquiry. Thus, for example, an understanding of scientific inquiry is not only important for potential scientists, in Vision II thinking. It is a vital component of a citizen's ability to keep a scientific perspective in balance with others. Thus, students need classroom experience with situations in which different perspectives are deliberately brought to bear on socio-scientific issues. Indeed, Roth and Barton (2004) argue that even classroom simulations are not adequate for such learning, but in any event, to paraphrase Eisenhart et al., an approach to SL based on Vision I does not, clearly does not, provide the opportunity to learn what is involved in Vision II. As noted earlier, Jon Miller believes the reverse is also true.

I think this is an area where empirical evidence is needed on two matters. One is the claim by Roth and Barton, to the effect that vicarious, in-class experience with issue analysis is phoney—that students do not learn from simulations, but instead need the real thing, immersion in real socioscientific problems in the community. The second is the claim advanced by Jon Miller that STS courses are not the way to develop an understanding of science. Both of these are sweeping claims, each one sure to create a stir among some science educators (not necessarily the same ones). At very least, such claims should be qualified. Do some students learn better from simulations? Do no students learn science in STS courses? What kinds of STS courses (cf. Aikenhead, 1994)? Shouldn't such claims be qualified at least in terms of specific instances of opportunity to learn?

There is a more insidious problem, whenever curriculum arrangements do not mandate Vision II outcomes. Fensham (1998) has discussed three Australian cases in which proposals to mount courses with a Vision II thrust have been defeated in curriculum committees by academic scientists. Blades (1997) has analyzed a similar phenomenon in the Canadian province of Alberta. In these two examples, the retreat from Vision II to Vision I occurred as a result of power politics within curriculum committees. In the case of the mandatory course on public understanding of science in The Netherlands, there was evidence of a retreat during the implementation. De Vos and Reiding (1999) describe the teaching materials developed for the course as turning out to have "a 'science-plus,' or science-oriented approach" consisting of "fragments of a science curriculum with added information on history, philosophy, society or economics" (p. 717). The nature of the teaching materials is presented as one factor that interfered with establishing a separate identity for the course. "The experience in The Netherlands shows that once a science-oriented approach is adopted, it becomes extremely difficult to escape from the shadows of the science teaching tradition" (p. 718).

## Talking to Each Other About the Meaning of SL Assessments

Both Jon Miller and John Durant retreated from Vision II to Vision I, as the basis for their assessments of SL and PUS, respectively. Yet, in the other two assessment programs discussed in this review—namely, the TIMSS MSL assessment and PISA—there is a continuing effort to define SL in a manner that respects the importance of context and situation in Vision II. It seems to me the jury is out, on the matter of whether Vision II can be assessed satisfactorily in international comparisons. I don't mean to be facile about this. It won't be easy. (See papers by Bybee and others on 2003 results in the US context [BSCS, 2005], and the insightful volume *Learning from Others: International Comparisons in Education* [Shorrocks-Taylor & Jenkins, 2000].) However, I think this matter is sufficiently significant that it is worth following the development of PISA 2006 and waiting for the results and some further research on the process.

At issue for cross-national studies is the concern that assessment items might be situated in contexts that are more familiar to students in some nations than in others. This is a valid concern, if an assessment item requires that the situation itself either be understood, or viewed in the same way culturally, in order for students across nations to have a "fair" chance when they respond. Orpwood (2001) provides a detailed account of the measurement problems encountered with TIMSS MSL items that were designed to incorporate situations, and concludes his paper with some serious concerns about the relationship between assessment procedures and curriculum change. "Leadership is therefore required from all quarters to ensure that innovations such as performance assessment and STS assessment are not allowed to be regarded as 'second-class' or entirely 'optional' ways of assessing achievement in science education" (p. 149). My point is that this state of affairs—namely the potential for a retreat from Vision II—is hauntingly familiar. It is just what Miller did, and for the same reason, namely measurement issues.

## Expanding Our View of Legitimate Discourse Universes for SL/PUS

One of the most striking differences between Vision I and Vision II is the nature and content of the discourse appropriate and legitimate for each. Curriculum policy statements, assessment items, and instructional resources and activities acknowledge and privilege some discourses and ignore or marginalize others. The discourse of orthodox science and scientific inquiry is the most familiar, of course. Others that have been identified in this review include discourse about moral reasoning (cf. Zeidler, 2003); the oral history provided by the aboriginal elders, as part of the community-based stream study in the Oceanside case study (Roth & Lee, 2002, 2004; Roth & Barton, 2004); the discourse about technological reasoning and problem solving, which is a vital part of STL; and the discourse with which members of different occupations think and talk about the tasks they perform, as displayed in the SSSP work by Layton, Davey, and Jenkins (1986).

### *Which Discourse Universes are to be Legitimate?*

A discourse universe always has situated legitimacy in its own right. Sometimes legitimacy comes from recognized status as a discipline. Technological reasoning and problem solving, for example, are the bread and butter discourses of engineering. Again, the discourse of moral reasoning and ethics is recognized and accepted in philosophy. There is nothing inherently better or worse about such discourses. The decision to include or exclude them from science education is a matter of deliberation and choice.

For illustrative purposes, here is an example of a curriculum policy document that explicitly acknowledges the significance of a discourse universe other than that of orthodox science. A recent version of South Africa's national curriculum policy for natural sciences states that "The Natural Sciences Learning Area deals with the promotion of scientific literacy. It does this by:

- the development and use of science process skills in a variety of settings;
- the development and application of scientific knowledge and understanding; and
- appreciation of the relationships and responsibilities between science, society and the environment" (Department of Education, Pretoria, 2002, p. 4).

The document elaborates on each of these three aspects of SL, synthesizes their intended meaning in three broad learning outcomes, and provides an extended discussion of how the three components can be assessed. The third outcome, described as "challenging, with potential to broaden the curriculum and make it distinctively South African" (p. 10), is of special interest because it includes attention to relationships between science, on one hand, and traditional practices and technologies as these relate to traditional wisdom and knowledge systems, on the other. "One can assume that learners in the Natural Sciences Learning Area think in terms of more than one world-view. Several times a week they cross from the culture of home, over the border into the culture of science, and then back again. How does this fact influence their understanding of science and their progress in the Learning Area? Is it a hindrance to teaching or is it an opportunity for more meaningful learning and a curriculum which tries to understand both the culture of science and the cultures of home?" (p. 12). This curriculum document, as well as others related to South African science education, is in a state of flux. In the corresponding version of the document for Physical Science 10–12, "scientific literacy is a clearly stated purpose" and, while it is not an explicitly stated aim in the Life Science 10–12 document, "it is clear that the attainment of scientific literacy is most definitely a tacit goal" (R.C. Laugksch [personal communication, June 6, 2003]).

### *Discourse: How Visions of SL Materialize (Or Do Not) in Classrooms*

Discourse is the basis for creating meaning in classrooms. A curriculum policy decision to embrace one or the other vision of SL entails making it both necessary and possible for appropriate discourses to come to life in classrooms. For example,

arguing on behalf of the importance of moral reasoning as a component of SL, Zeidler and Lewis (2003) put it this way. "Arming our students with improved understandings of nature of science and scientific inquiry does not provide a complete picture of the scientifically literate individual. Moral development and ethical reasoning play an important role as students consider what is best for the common good of society or whether the 'common good' is relevant to the issue at hand" (p. 290). Put another way, the extent to which students can create a meaningful grasp of moral and ethical reasoning depends on whether or not the appropriate discourse is even present in the classroom at all. Some discourses, such as the ones to which Zeidler and Lewis allude, are simply not present in the education of science teachers. As well, such discourses may not be part of a science teacher's image of what is appropriate for a science classroom, and/or the teacher may not feel competent or comfortable teaching such material. The implications for research on implementing curriculum focussed on Vision I, compared to Vision II, of SL are as interesting to contemplate as they are daunting.

An acquaintance of mine once commented to the effect that a substantial change of the dominant curriculum emphasis for science education makes everyone a novice teacher again. There is some truth in that assertion, in the sense that teachers (and teacher educators) have to learn and come to accept new types of discourse—not only to understand the discourse and grasp its significance, but also to comprehend and experience how to teach it. Even some aspects of the nature of science within Vision II (e.g., uncertainty, risk)—which one would consider closer to home for science teachers—present serious challenges in understanding, planning, and actually conducting classroom activities. These matters, and others, are illuminated in detail in a recent study about teaching the "ideas-about-science" domain within the 21st Century Science project. The authors "explore the factors that afforded or inhibited the [11] teachers' pedagogic performance in this domain" (Bartholomew, Osborne, & Ratcliffe 2004, p. 655). Of special interest here is the way the authors link their findings to discussion and implications associated with the characteristics of summative assessment used in science education, and the characteristics of the school science culture (pp. 678–679).

Research of the kind just presented must follow development, rather than lead it, in the sense that a classroom practice has to be instituted before there are any phenomena to study. In a more theoretical vein, one other area of research about discourse is presented, namely on the topic of how discourse produces meaning and, inevitably, learning. Using teaching vignettes and excerpts from Swedish science textbooks, Östman (1998) analyzed the way discourse provides "companion meanings" (including curriculum emphases) in science education. All such analyses are, of course, based on theoretical frameworks (e.g., the use of Toulmin's argument-pattern in the study of discourse about socioscientific issues by Zeidler, Osborne, Erduran, et al. [2003]). In Östman's work, the framework is "grounded in poststructural theory, and it depends on having available some alternative possibilities (about what could have been said and how)" (p. 55). One important outcome of the analysis is the documentation, in specific terms, of differences in discourse about several different companion meanings. An extension of the framework was used in a later, related study by Wickman and Östman (2002). There, the discourse of two students is analyzed, in a laboratory situation in which students had pinned insects in front of them, instructions to reflect on the relationship between structure

and function, and the expectation that they “should find out the morphology of insects by observation” (pp. 606–607). The analysis is a fascinating fine-grained (“high-resolution,” in the authors’ words) documentation of a point that cuts to the heart of discourse about one view of the nature of science: “laboratory work in school is often based on inductive epistemology, as if theory would become evident from the observations students make during laboratory work” (p. 621).

These examples show that discourse is what makes visions of SL come to life in science classrooms. The same can be said for written discourse—in textbooks, in curriculum policy statements, and in assessment programs. Clearly, more research is warranted about the development of SL and PUS through an examination of how discourse is understood, enacted by teachers and students, taken up in student learning, measured, and discussed in the science education community and beyond.

## AFTERWORD

The literature on SL cries out for clarity of expression and meaning, as we discuss issues in our professional capacity. In working my way through this literature, I was repeatedly reminded of Humpty Dumpty’s scornful admonition to Alice, in Lewis Carroll’s *Through the Looking Glass*. “When I use a word, it means just what I choose it to mean—neither more nor less.” I found it helpful to identify Vision I and Vision II, in an effort to reduce the Humpty Dumpty effect surrounding definitions of, and proposals about, SL and PUS. I trust the reader will find that heuristic device helpful as well.

## ACKNOWLEDGMENTS

Thanks to Rodger Bybee and Jonathan Osborne, who reviewed this chapter. Additional thanks to Edgar Jenkins, Rudi Laugksch, Graham Orpwood, Senta Raizen, and Léonie Rennie, for their advice on earlier drafts.

# CHAPTER 26

---

## History of Science Curriculum Reform in the United States and the United Kingdom

**J Myron Atkin**

*Stanford University*

**Paul Black**

*King's College London, United Kingdom*

This chapter examines the history of curriculum reform in science education in the United States and the United Kingdom. For the United States, it identifies several periods of marked change from the mid-1700s to the 1980s and highlights some emblematic features of each one; more recent American curriculum developments are examined in all the other chapters in this section of the *Handbook*. In the case of the United Kingdom, the scope extends into the twenty-first century.

While certain parallels are evident in the development of science education in the two countries, educational change is influenced by both national culture and indigenous organizational structures. Thus there are noteworthy differences. The United Kingdom is a “unity” of England, Northern Ireland, Wales, and Scotland. For all except Scotland, government legislation in education emanated from the London Parliament until devolution of power was introduced in the 1990s. Scotland has always been different, but nevertheless was controlled from London until recently. For most of the twentieth century, about 90 percent of the schools (secular and denominational) were supported by central government, and pupils paid no fees. Yet, until 1988, these schools had a great deal of individual freedom to choose what they taught, the textbooks they used, and the teachers they recruited.

In the United States, the Constitution does not mention education, which means (by provision of the Tenth Amendment) that responsibility for schools resides ex-

clusively in the individual states. Nevertheless, funds have been provided since 1917 by the federal government to meet special national priorities (initially to improve vocational education for industry and agriculture). Such was the case in 1959, for example, when Congress appropriated funds to improve science and mathematics education after the launch of Sputnik I by the Soviet Union. At the present time, about 7 percent of total education expenditures come from the federal government, mostly to assist “special-needs” students and those in low-income neighborhoods. As with many federal programs, however, the influence on the states is often disproportionate to the amount of money provided. “Unfunded mandates” from Washington are a continuing source of tension in the federal system. Historically, and on balance, however, there has been considerable latitude at the state level with respect to schools—and rhetorically at least, the principle of local control is unchallenged.

Two distinctive features have limited such latitude in the United Kingdom. One has been the influence of the universities: they established several examining boards that assigned, through their tests, school-leaving certificates. These have been the main requirement for university entrance, so they acquired status sought by parents and employers. Schools were constrained to ensure pupils’ success in these tests, and the curricula became more uniform. Moreover, because they were driven by the needs of the professors for well-qualified freshmen, the aims that dominated the testing in science were to prepare future scientists.

The other feature has been the class structure of British society, reflected in the disproportionate power of a small number of fee-charging and independent schools. The upper classes sent their children to such institutions and expected them to be prepared for the best universities and for the professions. In the government-maintained schools, a system of selection at age 11 supplied an upper tier of academic secondary schools with the high attainers, predominantly middle-class children whose parents also wanted education to secure the most favorable life chances for their children. Between them, these selective schools and the independent schools had the best teachers. Reform tended to be biased in their interests because they had both political power and the people most competent to fashion changes.

From the beginning, the United States had more egalitarian principles, and its social class structures were more fluid. With heavy immigration, “common schools” were created in the nineteenth century to help all children become “Americans.” Test scores did not become a significant factor in college admission until the latter half of the twentieth century. Some of the greatest American universities, especially in the Midwest, had been public since the creation of the land-grant colleges during the Civil War (Michigan, Ohio, Illinois, Wisconsin, and Indiana, for example). Through World War II, they accepted *all* high school graduates—despite the fact that about 80 percent did not remain after the freshman year. The principle, fully honored in practice in the land-grant institutions until the late 1950s, was that any high school graduate should have a chance to earn a college degree.

In both countries, the most significant initiatives in science education began in the nineteenth century and first affected primarily institutions of mass education: the schools for young children. Since then, development in these schools has been driven, until very recently, by forces quite different from those of external certification and the elite professions that were dominant at the secondary level (especially in Britain). For this reason, the account of the United Kingdom begins with an ex-

amination of primary-school science, and this educational level is also singled out for special description and special analysis in the American section.

## THE UNITED STATES: THE EARLY YEARS

European education at the time of the American colonial period emphasized classical languages for older children and skills in reading and arithmetic for the younger ones. This curriculum was the starting point for education in what was to become the United States. But even before the American Revolution, there were seeds of something educationally different from a focus on language study alone: an emphasis on more practical work. This development was led and epitomized by Benjamin Franklin's creation of the Philadelphia Academy in 1750. The new subjects Franklin introduced focused on fields like agriculture, navigation, and surveying. Although the classics were still taught, his aim was to broaden schooling for those who may not have been preparing for the clergy. The idea of preparing students for a broader world of work struck a responsive chord in a developing country, and such schools proliferated rapidly and continued to grow in number for more than 100 years.

Science and science-related practical subjects thereby entered the American education scene early and on a relatively large scale. They began to compete with the subjects featured in the Latin grammar schools. (The new subjects gradually entered the colleges, as students sought a curriculum of greater usefulness at that level, too.) This is not to suggest that science in the academies was taught well. "The teachers [in the academy] were poorly prepared. . . . The courses were primarily book-taught, with the recitation of memorized texts the mode of instruction" (DeBoer, 1991, p. 20).

The picture for younger children was different. At this level, children's literature for the purposes of instruction began to appear in the late eighteenth century. Many of them were full of first-hand science experiences and featured directed observation of and contact with natural phenomena. They seem to have been intended initially to be read at home, but they soon were recommended for use in schools. Frequently they were reviewed and advertised in education journals (Underhill, 1941).

Typically a book would tell a story set in a family, in which the focus of the activities and conversation among children and adults was about subjects like the planets, or the water cycle, or the structure of a housefly. Writing about these books decades later, one authority commented, "Sometimes the learned tutor takes his pupils for a walk and discourses on all they see; or else Harry, thirsting for knowledge, extracts it by questions from a remarkably accurate and omniscient mamma" (Field, 1891, p. 256, cited in Underhill).

Although these children's books were rich in science content, it is far from clear that the teaching of science was their main purpose. Early formal education in western societies centered on piety and moral instruction, in addition to classical languages. It is true that the introduction of science in these books was intended to encourage children to learn more about natural phenomena. The science, however, was to be put in the service of a larger purpose, that of moral uplift and religious reverence. Although education was becoming more secular in the early 1800s—with natural history and geography replacing fables in books for children—the emphasis was usually on the moral virtues and the wonders of the Deity. ". . . [T]he sciences may be taught not only experimentally, but religiously. The pupil may be led to God

through the material world, after having once become acquainted with the nature of the divine mind. . . . When the natural sciences can be taught in this manner, there can be no doubt of their beneficial effects" (American Journal of Education, 1828, authorship not ascribed).

In one story for young children drawn from children's literature of the period, a family is sitting around the kitchen table, and the daughter observes a cloud of steam over the water kettle. (Girls seemed in these books to ask questions as often as boys.) Her observation stimulates the father to deliver a short lecture and demonstration about vaporization and condensation by placing a cool metal sheet in the cloud of steam. In another book, the family comes across a compound flower during a walk. Using a hand lens, the father identifies the parts with precision—then emphasizes that the flower surpasses the ingenuity of man, thus proving the existence of God. When his son trips, father spends several pages on the matter of untied shoestrings. The point is that if he had obeyed his mother by being more careful, he might have avoided a bloody knee. Thus, using science as a vehicle, the aim was to promote moral virtues like obedience, modesty, courtesy, and even thrift—along with religious awe (Hughes, 1818; Alfred, or the Youthful Inquirer, 1824).

## DEVELOPING THE MIND

Thus, by the mid-nineteenth century, there was significant attention in American elementary schools and in the academies to common objects and events within the experience of the students. The development was loosely unified by a range of principles enunciated by education philosophers and theoreticians like Rousseau, Pestalozzi, Froebel, and Herbart. Though different from one another, all of the theories were based on some form of sense realism, that true learning comes through experience. Methods of teaching emphasized principles like the importance of children being active participants in their own learning, a focus on the individuality of the pupil, and learning proceeding from the simple to the complex and from the proximate to the distal. Additionally, the learning process should be enjoyable.

Principles like these were often considered to be in harmony with nature, and a "natural method" was seen as uplifting and harmonious. "The postulation of a natural method rests on the assumption that there is a unity in nature and that nature is purposive and has direction. *Man* must work *with* nature rather than *against* nature . . . Nature becomes exalted and even deified" (Underhill, p. 31, emphasis in original).

By about 1860, a new theory of learning had emerged called faculty psychology. It was built on the belief that the mind is composed of faculties, and that the function of the school subjects was to develop one or another of the faculties, to train the mind. The faculties included observation, memorization, generalization, and reasoning. In the case of science for children in elementary schools, faculty psychology was grafted onto the science-of-common-experiences enunciated by Rousseau and others, which had become popular by the time of the Civil War. In the case of the secondary schools, the result was often the opposite—an education less related to immediacy and practicality, more dependent on reading and reciting, and more focused on mental discipline as an end in itself.

For the elementary schools, Object Teaching was introduced. Imported from England, it took firm root in the United States by the 1870s. Children studied and

described objects brought to class: different rocks, metal wire, a piece of wax, camphor, ivory, a mustard seed, leaves, india rubber, various household chemicals, and much more. Theory in faculty psychology stated that although elementary school children are not capable of “reasoning” or “generalization,” they can observe and memorize. If the Object Teaching manuals for teachers that were published at the time are any indication of classroom activity, the nine-year-old students were expected to demonstrate their growing ability to observe by accurately using adjectives like the following (not wrenched terribly out of context): *argillaceous*, *farinaceous*, *astringent*, *acidulated*, *chalybeate*, *iridescent*, *ligneous*, *oleaginous*, *malleable*, *vitrifiable*, *unctuous*, and many more (Mayo, 1876). The faculty of memorization was honed when the children were asked to recall the adjectives that were appropriate for the various objects. In the history of science teaching, the Object Teaching curriculum may be the one most pervasively influenced by a particular theory of learning, namely faculty psychology. Although very popular at the time, and actively promoted in teacher preparation programs, Object Teaching declined rapidly in the late nineteenth century because it was increasingly seen as sterile and remote from the lives of children. The objects were concrete, and many senses were employed by students in studying them, but there was little connection to matters of consequence in children’s lives.

### THE COMMITTEE OF TEN

The most influential development at the high school level at the end of the nineteenth century was the report of the Committee of Ten (National Education Association, 1893). This seminal document was intended to give consistent form to the high school curriculum and standardize college admission requirements. Charles Eliot, president of Harvard University, chaired the group, which was composed of university presidents, high school principals, and the U.S. Commissioner of Education. James Baker, principal of Denver High School at the start of the study (and president of the University of Colorado at the end), was chair of the coordinating group that synthesized the reports of nine, separate subject-based “conferences”: Latin; Greek; English; other modern languages; mathematics; physics, astronomy, and chemistry; natural history (biology, including botany, zoology, and physiology); history, civil government, and political economy; and geography. The conferences consisted of professors, high school principals, and teachers. (Woodrow Wilson, then a professor at the College of New Jersey—later Princeton—was a member of the conference on history, government, and political economy.)

Recommendations were made about the age at which each subject was to be introduced, the number of years it should be taught (and the number of hours each week), the topics to be included at the secondary-school level, the form in which the subject should be factored into college admission requirements, and whether or not the subject matter should be different for those headed for college as compared with others and (if so) at what age.

The recommendations were extensive and detailed. Four sample programs were listed to offer some flexibility, particularly with respect to the study of classical languages (National Education Association, 1893, pp. 264–265). Perhaps the most provocative recommendation was that all students should study many of the same sub-

jects and topics, the only difference being the number of years that students of different abilities and interests should pursue those studies. A close second was the diminished role of the classical languages and the recommendation that a relatively new subject, the sciences (including geography) constitute 25 percent of the high school curriculum.

## NATURE STUDY

The late nineteenth century saw the continued ascendancy of educational theories that focused on links with nature. Louis Agassiz, a charismatic Harvard biologist well known to the public for his attempts to popularize science (and for his opposition to Darwinian theories of evolution) was often credited by his many followers with the slogan “Nature not Books.” The ideas he espoused are easily traced to Rousseau, Herbart, Pestalozzi, and others. G. Stanley Hall, a noted psychologist and educator, extolled the virtues of studying nature, though he expanded the scope to include all human relationships—possibly because he was one of earliest of the psychologists who saw the field as a science and themselves as scientists (Holder, 1893, chapter xv; Underhill, 1941, p. 107).

The broader canvas against which these developments played out was one in which emphasis on connections between education in the schools and the broader community were in the ascendancy. From the days of Franklin’s Philadelphia Academy, there were steady pressures to relate work in school to the world in which students lived. By the 1890s and particularly in elementary schools, the emphasis shifted from utility in a narrow sense of personal living and individual advancement to one that encompassed broader social purposes, particularly the conditions in which people lived, and the requirements of good citizenship.

This emphasis took many forms, including the introduction of materials that taught about the dangers of alcohol, stimulated by the growing influence of the Women’s Temperance Union. By 1895, 41 of the 44 states had passed laws about teaching temperance (U.S. Commissioner of Education, 1902). However, it was at Cornell University in the early 1900s that Nature Study took definitive shape as a defined subject for elementary-school students. It reflected a social movement, as well as a curriculum—and it originated in Cornell University’s College of Agriculture.

A key purpose of Nature Study was to glorify the rural life. As America entered the twentieth century, the citizenry was associating major societal problems with rapid urbanization. The early 1900s saw the rise of the “muckrakers,” people like Upton Sinclair (1906) and Lincoln Steffens (1904), who wrote fact and fiction about corruption, exploitation, and disease in the rapidly growing cities. Cities were seen as evil, dirty, and sinful, the country as pure and beautiful. How are people to be kept on the farm?

Led by the Cornell College of Agriculture, materials were developed for children to instill a love of nature, so that they would resist the migration away from farms. During the first two decades of the twentieth century, the movement was led by professors at Cornell like Anna Botsford Comstock and Liberty Hyde Bailey, both respected biologists. Bailey frequently emphasized that the love of nature he valued so highly is deepened through intellectual understanding. “The best thing

in life is sentiment; and the best sentiment is that which is born of the most accurate knowledge" (Bailey, 1903).

The College of Agriculture established a Department of Education to promulgate the new curriculum, both inside and outside New York State. (The Department resides in the College of Agriculture to this day, though not to promote the virtues of the country life.) The *Cornell Leaflets* (later the *Cornell Rural School Leaflets*) represented one of the first attempts at broad-scale and systematic dissemination of an educational philosophy and technique. Four issues per year were distributed, and the publication continued until the 1970s.

In much of the Nature Study literature for children, especially in the early decades of the movement, there was direct appeal to children's feelings to generate a deep sympathy with nature. The emotion-laden approach is illustrated by this excerpt from an article intended to help laypeople understand Nature Study in the schools: "Take for instance, the very common subject of trees. . . . One short sentence alive with love and inspiration, spoken concerning an oak tree for instance, will live on. The children will remember, if not the words, the idea or emotion that came when the burning word was spoken. Therein lies the secret of success—the word spoken must be a burning word" (Morely, 1901, cited in Underhill, p. 175).

It was only a short step to anthropomorphism. To elicit sympathy for and love of nature in children, mature flowers in the books began to talk to flower buds, and birds began to talk to trees. The conversations were almost always about their respective parts, and in that way many detailed aspects of taxonomic botany and zoology were conveyed to children. To introduce one typical story, the author asks, "We are going to hear a story about a little tree that did not like its leaves." The children are asked about the kinds of leaves they collected that fall. "Do you think of any tree whose leaves you slighted; one whose leaves you never thought of calling pretty? How do you suppose it felt, then, when it saw that its leaves were so different from those of the other trees?" The story of "The Discontented Pine Tree" then emphasizes that non-deciduous trees also have a special and valued function (McMurry, 1895).

Teaching of science came to focus on the biological world during the Nature Study period, altering the balance between biological and physical science that had existed for more than 100 years. But the same general approach was taken to physical science. At the Oswego Normal School in New York, an institution that had been particularly influential in spreading object teaching, the prospective teachers were taught about questioning and sequencing of ideas in a lesson. The following was cited as a laudable example of definite, clear, and sequential statements, beginning with experiments and observations and ending with conclusions and generalizations:

#### EVAPORATION

We put some water in a cup on Friday.

We put the cup in the window.

Monday there was not so much in the cup.

The water went into the air.

Who took the water?

The air fairies took the water.

The water evaporated.

Friday we put a cup of water on the window and on the radiator.

The air fairies took the water from both cups.

Which cup had the least water in it on Monday?

The cup in the warm place had the least water in it on Monday.

Why did the cup in the warm place have the least water in it?

The heat fairies helped the air fairies to take the water from the cup in the warm place.

If the heat fairies help the air fairies, the water goes away quicker. (Scott, 1900)

Advocates claimed that such an approach enlists students' interests and cultivates their imaginations. Often in human history, it was said, myths were the accepted explanation of natural phenomena and therefore were acceptable for young children at a certain level of development (Fistiam, 1908, cited in Underhill, p. 199). There were critics of the approach, of course, including no less a figure than Theodore Roosevelt, who called it "nature faking" (Sullivan, 1930). While the Nature Study movement, with its strong emphasis on children's emotions and commitment gradually atrophied after the first decade of the twentieth century, the emphasis on curricula that stressed students' interests did not.

### **APPLICATIONS OF SCIENCE; GENERALIZATIONS; PROBLEM SOLVING; ATTITUDES**

The yearbooks of the National Society for the Study of Education (NSSE) are dependable benchmarks for understanding how experts in a field view promising and desirable developments at a particular time. The committees responsible for developing the yearbooks are chosen from among those who represent forward-looking perspectives in a given period, and the committee composition itself generally serves to produce a volume that proffers a consensual view.

Yearbook publication began in 1902 and has continued ever since, usually with two volumes a year. There was one on nature study in 1904, then nothing on science until the publication of *A Program for Teaching Science* 28 years later (NSSE, 1932). S. Ralph Powers of Teachers College, Columbia University, chaired the committee.

The authors of the 31st *Yearbook* captured many of the issues that concerned science educators during the first part of the twentieth century. They strove to ground their analysis and recommendations within an overall conception of schooling, including theories about learning and the development of children. They were attentive also to the fact that increasing numbers and percentages of students were entering and completing programs of secondary education and that a relatively new institution, the junior high school, had been created to facilitate transition from elementary to high schools.

They took pains to separate themselves from the kinds of psychological theories (G. Stanley Hall's, for example) and educational practices (Nature Study, for example) that had preceded those that shaped their own thinking. All of Chapter II was devoted to a critique of such approaches to science education. The authors of the 31st *Yearbook* found their intellectual foundations in the writing of such figures

as William James, John Dewey, and Edward Thorndike, all of whom stressed the centrality of experience and social context. At the elementary-school level, Nature Study drew especially harsh criticism from the authors, primarily for emphasizing facts over principles and for expounding a theory of discontinuous intellectual development that claimed that intellectual processes in children are different from those in adults. The authors stated that Nature Study had inherited from faculty psychology the view that younger children could not generalize, for example.

At the secondary-school level, the 31st *Yearbook* drew heavily from *The Cardinal Principles of Education* published more than a decade earlier (U.S. Bureau of Education, 1918), a landmark report commissioned by the National Education Association, pointing out that “the manner in which the needs of society and . . . the schools that were purporting to meet these needs were out of harmony” (NSSE, 1932, p. 18). *The Cardinal Principles* had recommended a continuous program from kindergarten to university, greater attention to individual differences in students’ intellectual ability and interests, and that educational objectives recognize the needs of individuals and of the society. It also outlined and elaborated upon what it defined as the main objectives of secondary education: fostering good health, gaining command of fundamental processes (reading, writing, elements of oral and written expression), learning to participate in “worthy home membership,” preparing for a vocation, participating in civic affairs, fostering in students the worthy use of leisure time (something relatively new in America), and developing of ethical character (U.S. Bureau of Education, 1918, pp. 5–10).

Associated with awareness of the increasing usefulness of science to society was an interest in and respect for the methods that were used to produce scientific ideas and their application. Thus secondary-school science programs were advocated that helped students understand that science is a “problem-solving” kind of inquiry, as well as a body of basic “generalizations” about the natural world. In the *Yearbook Committee’s* words,

The search for objectives will be one that seeks to determine the major generalizations and the associated scientific attitudes that have come from the field. . . . This Committee stresses the importance of subject matter and recognizes the responsibility for selection of subject matter which shall be functional for . . . a more satisfactory adjustment of the individual to the society of which he must be a part. In this society man must meet and solve problems. The schools will prepare children for their responsibilities by providing experiences with a body of subject matter (1) that has been tested for truthfulness, (2) that exercises methods that have been used in solving problems, (3) that furnishes practice in these methods—in short, with subject matter that contributes to the ultimate comprehension of major generalizations and the development of associated scientific attitudes. (NSSE, 1932, p. 40)

The first two decades of the twentieth century ushered in a period in which Americans became increasingly aware of the impressive impact of science in daily life. The methods of science were powerful. Led largely by the science education group at Columbia University Teachers College, the goal of science teaching gradually became one of helping students to understand the applications of science, especially in technology. Electrification and central heating were emphasized. Science texts also described how refrigerators and automobiles worked. Every student

learned how a gasoline engine works in an automobile, including the names of the four strokes in each cycle. There were demonstrations of how how fuses work. Models were built to illustrate the wiring of houses.

At the same time, there was an underlying conviction that “the program for curriculum work in science for the public schools [should] be directed toward the determination of those major generalizations and associated scientific attitudes which together define the field” (NSSE, 1932, p. 43). For example, in the course of providing a detailed description of how students might study the age of the Earth, two major generalizations that frame their respective topics are offered: 1. The Earth seems very old when its age is measured in ordinary units of time, and (2) The surface of the Earth has not always had its present appearance and is constantly changing (p. 48).

### AFTER WORLD WAR II: SCIENCE FOR SCIENCE’S SAKE

Changes in science education during the 25-year period after World War II were a sharp departure from the science-in-everyday-life focus of the 31st *Yearbook* and were characterized primarily by a dramatic increase in active participation in curriculum matters by outstanding scientists, primarily those from the academic research community. The programs that were developed from the 1950s and into the 1970s are often characterized as the “post-Sputnik reforms” because of major new infusions of federal funds in the years immediately following the Soviet Union’s launch of the first artificial earth satellite, *Sputnik I*, in October 1957.

However, the new curriculum movement actually had begun in the early 1950s. It focused on mathematics. Max Beberman at the University of Illinois pointed out that the mathematics curriculum commonly used in schools at that time contained few mathematical ideas developed after 1700. Consistent with the science curriculum of the 1920s, 1930s, and 1940s, the mathematics program in the early 1950s stressed applications—mathematics in daily life. Students in elementary and junior high schools balanced checkbooks, calculated compound interest, and noted differences among different retail discounts, for example. In high school, as preparation for calculus and college, they were introduced to Euclidian geometry, algebra, and trigonometry. Beberman and his colleagues developed a program that introduced “new” mathematics—number theory and set theory, for example (Beberman and Vaughn, 1964). These were topics, among others, that corresponded more closely to ideas that contemporary mathematicians, particularly those engaged in research, found important.

A few years later, in 1955, proposals similar to Beberman’s were made for high school physics. Scientists newly interested in curriculum for the schools said that it may or may not be interesting for students in physics to learn about the principles of refrigeration, the four-stroke-cycle gasoline engine, or the Bernoulli effect—topics commonly found in the textbooks—but these ideas hardly reflected those that university-based researchers in physics considered interesting. And so, in 1955, the Physical Science Study Committee, a group centered at the Massachusetts Institute of Technology, developed a course that began with an examination of the ways in which light could be viewed as both wave-like and particulate (Physical Science Study Committee, 1960), a topic considered much more characteristic of the kinds

of issues that matter to research-oriented physicists. For the first time, the country moved into a period wherein the teaching of science, as identified by the most advanced scholars in the field, became an end in itself.

Offering something of a counter-example, there was a project across the Charles River in which a physics curriculum was developed that depended somewhat less than the one at MIT on contemporary university-based research. Harvard Project Physics included modern topics, to be sure, but it focused also on how ideas in science develop over the centuries (Harvard Project Physics, 1968). In focusing somewhat more on historical perspectives, the Harvard group was more explicit about the human elements that are integral to the generation of scientific ideas.

A key factor in the marked influence of the country's outstanding research scientists on the curriculum was the extraordinary prestige the group had acquired in helping to win the war. Seemingly arcane and abstract theory had been shown to have extraordinary consequences. Radar and the atom bomb were seen not only as shortening the war but as making victory possible. Just as important, many scientists involved in wartime projects turned their attention to matters of improving science education—several of them never to return to research in science.

This movement led by research scientists crystallized conceptually at a conference in Woods Hole, Massachusetts, in 1959. Thirty-five scientists, psychologists, and curriculum developers were convened under the auspices of the National Academy of Sciences to discuss and try to unify their work, which by that time was receiving impressive support from the National Science Foundation. (The Foundation had been created by the Congress in 1950 and assigned two broad missions: to support basic scientific research and to improve American science education.)

Jerome Bruner, an eminent psychologist, was given the responsibility of preparing the conference report (Bruner, 1960). The report pivoted around the concept of "structure." Each field of intellectual study has a general framework that helps its practitioners understand a relatively small number of major ideas (about patterns, about overarching concepts, about modes of inquiry), which in turn can be used to scaffold new observations and facts. Furthermore, "Mastery of the fundamental ideas of a field involves not only the grasping of general principles, but also the development of an attitude toward learning and inquiry, toward guessing and hunches, toward the possibility of solving problems on one's own" (Bruner, 1960, p. 20). Only those deeply knowledgeable about a field are capable of identifying those principles and habits of mind. "It is a task that cannot be carried out without the active participation of the ablest scholars and scientists" (p. 32). And, capturing what many saw as the essence of the report, "[T]he argument for such for such an approach is premised on the assumption that there is a continuity between what a scholar does on the forefront of his discipline and what a child does in approaching it for the first time" (p. 28).

With support primarily from the National Science Foundation, projects were launched in biology, chemistry, and earth sciences at the high school level. There were also several at the elementary-school level during the 1960s undertaken on the same convictions and assumptions. No other curriculum movement in science so centrally involved the nation's most accomplished scientists in work at elementary- and secondary-school levels as those that flowered from 1955 to the early 1970s. Never had so much public money been devoted to the task of developing new curricula for the schools.

But by the 1970s, however, new curriculum priorities arose that began to edge out those of the research scientists. Since the pre-war year of 1939, the percentage of the 20-year-old cohort that had completed four years of high school had jumped from 25 to 75 percent. In many ways, the major story of American education after World War II was its rapidly growing inclusiveness. At the same time, the U.S. by the 1970s had been the first country to put a person on the Moon. These facts, and the steepening decline of the Soviet Union, eased the country's concern about its military strength. Now the balance of trade and the country's competitiveness were sources of alarm. As with the panic after Sputnik, the education system had to respond. Education policy conversations began to center on educating *all* students, partly because they were now coming to school and partly because they were the future workforce. Better education was one crucial way to stem the perceived decline in the country's economic competitiveness (National Commission on Excellence in Education, 1983). A decades-long focus on "standards" began.

### THE UNITED KINGDOM: THE PRIMARY PHASE

In Britain, universal elementary education was achieved in the latter half of the nineteenth century. This period also marks the beginnings of science education in schools. Impetus was given by two ordained Cambridge academics: Dawes, a mathematics fellow, and Henslow, a professor of botany, who moved to country parishes and started schools in which they developed the teaching of a science of everyday things (Layton, 1973). However, the scientific ideas that were at the core of their work tended to be lost in the hands of most teachers. One important approach in elementary science classrooms was the use of "object lessons" (deBoo, 2001), each centered on a common object such as a snail or a lump of coal; these were similar to the object lessons used in the United States, but they gave more emphasis to exercises in observation and classification skills only. There was also much emphasis on nature study, but the aim here was confused: some "naturalists" were interested in the understanding of nature, and others taught only the identification and naming of natural objects. Moves to link physical science concepts to everyday observation (e.g., by measuring the velocities of different rivers) made little progress.

The movements to teach a science of everyday things lost momentum because many reacted by objecting to the time being given to science, both in schools and in teachers' training. Influential scientists also pressed for a much sharper focus on the main ideas of science, arguing for science as a training of the mind and against trapping children in the very restricted view of the science of everyday objects and phenomena. Although such views prevailed, they helped to create a tension, between the pure and conceptual on the one hand, and the applied and everyday on the other. This tension has continued to bedevil school science to this day.

As elementary schooling grew in the 1850s and 1860s, concern to justify the escalating costs led a system of the state grants for primary schools to be based on their performance in inspectors tests limited to the 3Rs; science then shrank, since it did not feature in the payable results. There were few funds to provide apparatus, so that some districts appointed peripatetic demonstrators, who went from school to school with a handcart of apparatus to present demonstrations. The scientists in the British Association for the Advancement of Science (BAAS) recommended in

1908 that this use of demonstrations be abandoned, as it led to superficial presentations that teachers ignorant of science were not able to follow up.

Progress with reforms promoted by the BAAS was halted by the 1914–18 war, with its dire effects in the loss of teachers on the battlefields and in the 1920s recessions in the economy. A further inhibition was the growth in the importance of examinations at the end of primary schooling. These would determine whether or not a pupil could proceed to the “academic” grammar schools, or to the lower status and more vocationally oriented secondary. Since the examination tested only arithmetic and English, science was neglected.

In the same decade, the influence of such thinkers as Montessori, Dewey, and Froebel began to take effect, so that official reports called for a new emphasis on the physical, mental, and emotional development of children (Hadow/Board of Education, 1931, 1933). However, World War II impeded progress, as facilities were damaged, all schooling was disrupted by mass evacuation of pupils out of cities, large numbers of teachers were conscripted for military service, and few were being trained. A nearly bankrupt country could afford little until the 1950s. Although signs of change, from teacher-dominated lessons to child-centered activity, began to be evident, the main obstacle was the lack of training in science of most teachers, so that many primary schools did not feel able to teach science at all: even up to the early 1960s courses for primary teachers taught only biology. Both the national inspectorate and the ministry supported moves to reform, which aimed to develop pupils’ interests in the physical sciences and to involve them in their own science investigations. Yet one of the leaders of reform in Scotland stated that “the aim of teaching science in a primary school is not really to lay the foundations of scientific knowledge, still less to offer elementary introductions to different sciences” (Blackie, 1967), so expressing a belief that the aim was to teach only such processes as observation and pattern seeking in order to develop general reasoning.

The child-centered movement of the 1950s and 1960s did lead to excesses in that children often came to be engaged in unguided play. As one observer put it, “the ripples of change moving out from the centres of quality became distorted with distance and repetition” (Wastnedge, 2001, p. 43). Wastnedge became a leading figure when he was appointed to lead a Junior Science Teaching Project in 1964, funded by a private charity, the Nuffield Foundation. The aim was to foster a child-centered approach to teaching, with the children observing, asking questions, and making and testing hypotheses. Given the poor training in science of primary teachers, it was judged that the stress should be on an approach that depended less on scientific knowledge (i.e., a process approach).

In consequence, as Wastnedge explained (2001, p. 50), “At present we must concern ourselves more with how children learn than with what they learn,” even though this was often interpreted as “it doesn’t matter if they don’t learn anything.” However, this project, and its successors, were only adopted by about 20% of schools, schools being free at that time to choose the curriculum approach that they preferred.

The general approach was consistent with the growth of a child-centered philosophy of education, which was canonized as national policy backed by a government-sponsored report on primary education, the Plowden Report (Central Advisory Council, 1967). In the 1980s two developments countered this combination of child-centered and process-only approach. One was unease expressed by several science

educators about the neglect of content, on the grounds that to present science as a set of commonsense processes was a travesty, and that pupils needed to begin to engage with subtle and apparently unnatural concepts (e.g., that moving objects, if left to themselves, will go on moving forever) that had been the basis of the power of scientific thought (Black, 1983). This thinking led, in 1987, to the Nuffield research project titled the Science Processes and Concept Explorations project (SPACE) (Black and Harlen, 1989), which led to a curriculum development project with a strong basis in new research about the levels of concept that young children could understand (Osborne et al. 1993; Nuffield Primary Science—see Nuffield, 2003).

The other source of change was the belief of the Conservative government that primary education had been undermined by the child-centered ideology—the influence of Dewey, Plowden, and the like had to be destroyed, together with other malign influences of the “educational establishment” (Lawton, 1994). Such thinking was one of the motivations for the setting up in 1988–89 of the United Kingdom’s first National Curriculum. Primary science was established as one of only three subjects with national tests at ages 7 and 11, with three content targets and a fourth target on experimental investigations. This stimulated an increase in the effort devoted to helping teachers deal with science. The tests for content were so dominant, that investigations were given low status and low priority. In the late 1990s new requirements to spend designated teaching time each day on prescribed schemes for literacy and numeracy undermined yet again the time given to science education.

## SECONDARY SCHOOL SCIENCE

Science at the secondary level was first developed in the late nineteenth century in the elite private schools. For some pupils, the study of science was an alternative for those who could not manage a classical-literary education, but positive impetus came from two sources. One was the changes in medical education, the other was the need for civil engineers, particularly for the military. Both of these professions called for a stronger scientific basis, so higher education, where these professions were trained, required their main providers, the private schools, to teach science at school. The curriculum innovations that were a response to these pressures were largely led by chemistry educators, with some also promoting geology. Biology, having a weaker science basis, was justified by the intrinsic value accorded to the study of nature. Physics suffered because it was not a well-defined subject, and the ownership by mathematicians of the teaching of mechanics curtailed its scope.

Expansion outside the small group of private schools came more slowly. The growing status of science and scientists in the latter half of the nineteenth century, and the evidence that the country’s industrial lead over others was fast being eroded, led to pleas for more science education. In response, in 1904 new government regulations, which applied to the schools that were maintained by government funding rather than by collection of fees, required at least seven hours per week to be devoted to mathematics and science and that the science being taught should be taught without bias toward technical or vocational needs. Yet 12 years later a report deplored the fact that in the private schools many pupils were not studying science, while others studied only general science, which had a low status as a school subject for many years (Waring, 1979).

The coordination of the various school leaving examinations, which were provided by several university-led agencies, developed from the setting up by the government of a Secondary Schools Examinations Council in 1917, gave support to the government's new requirements to teach mathematics and science, but it remained possible for candidates to choose between mathematics and science despite pressures to make science compulsory. Over the next 25 years, controversy focused on the choice between having three separate science subjects in biology, chemistry, and physics, and having a single general science course (Jenkins, 1979). The latter eventually became the course for the less able; later still, it became a course for all at ages 11 to 13, with the separate subjects taught by separate subject specialists from 14 to 16. However, despite pleas that schools give more time to science, most required the more able pupils to choose only one or two of the three science subjects for their examination courses, while the general science courses for the less able were constrained by the time allocation for only a single subject.

At the same time, many reports pressed for science education to develop understanding of the nature of science, although this was understood in terms of a "commonsense" model in which principles arose from the data by induction. There were also pleas by the BAAS that the "broader aspects of scientific discovery and investigation as human achievements and applications by which mankind is benefiting" should find a place in the curriculum (Waring, 1979, p. 37). Yet a teacher trainer writing in 1918 painted a gloomy view: "It is disturbing to discover how many young people . . . find their school science uninspiring and even boring . . . [teachers and examiners] . . . both attach too much importance to the formal and theoretical aspects of science, and too little to those which give the subject value in the eyes of boys and girls" (Nunn, 1918, p. 162).

Nunn's priority was to make pupils interested in science as the finding of new knowledge as an end in itself, but he pointed out, with a criticism which has continued to be relevant up to the present day, that "This is an uncomfortable doctrine to two very different types of persons. One is the 'practical man' who supports the teaching of science in schools because he believes in its cash value. The other is the 'high-browed' person who assesses all educational effort in terms of 'mental discipline'" (p. 162).

Practical work was also subject to change and counter-change in this period. The first outstanding influence in Britain was a chemistry professor, Henry Armstrong, who used his status as a university scientist to argue, strongly and effectively, for its importance as an exercise in "guided heurism" (van Praagh, 1973). As the scientific journal *Nature* put it at the time (in 1901): "Two things are essential for Professor Armstrong's plan, first that the pupils should perform experiments with their own hands, and second that these experiments should not be the mere confirmation of something previously learned on authority, but the means of elucidating something previously unknown, or of elucidating something previously uncertain" (quoted in Woolnough and Allsop, 1985, p. 16).

This approach became widespread in schools in the early years of the century, the emphasis being on practical work as experience of enquiry rather than for developing subject knowledge. However, the impact was blunted in 1918 by a report that criticized the approach as inefficient use of pupils' time. It argued that experimental work should be restricted, with a focus on experiments that could establish links with general scientific principles and with everyday life, and that careful

demonstrations could often be the most efficient way of using lesson time. So there developed a convergent “cookbook” approach to school laboratory work, with an emphasis on practical skills, following instructions, and confirming well-established results.

It was inevitable that when recovery from the after-effects of the 1939–45 world war allowed serious debate about education to re-open in the United Kingdom, the position of school science education was still problematic. A 1960 report of the national inspectorate called for a new integration of practical work with the central task of learning, and for an end to “cookbook” experiments:

There is nothing as a rule to correspond to the clear formulation of a question by the pupil himself; this is provided for him and no value is placed on curiosity. Nor is there any necessity to construct a plan of investigation, to design or make ad hoc experimental devices or to modify them in the light of experience. Nor again, if the answer comes out ‘right’, is there much inducement to consider the results, to estimate their validity or to discuss their further improvements. Finally there is missing the ultimate satisfaction of having really found something out. (Ministry of Education, 1960, p. 38)

The Association for Science Education (ASE), which had a strong membership and support among school science teachers, attempted to foster improvements by the collaborative efforts of their own members, but soon found that its resources were inadequate to the task. The government was sympathetic, but its stance at that time was that it should not play any part in specifying the curriculum.

The outcome was that in 1962 the Nuffield Foundation agreed to fund, but also to direct itself, large-scale curriculum development projects, starting with courses in physics, chemistry, and biology designed for study from ages 11 to 16 for the most able pupils. The steering bodies for these projects were led by eminent professional scientists, and the ASE had hardly any part to play. However, the teams recruited to do the work were composed largely of practicing science teachers. The reform plan was comprehensive, involving extensive school trials, commercial publication, negotiations with equipment manufacturers to provide new apparatus, and arrangements with the examination agencies to provide tailor-made school-leaving examinations and the linked certificates, and with teacher training institutions to provide in-service training for the new courses.

Schools were free at that time to choose whether or not to replace their traditional courses with these offerings, and although no more than about 20% of schools decided to implement them in full, they had widespread influence on many aspects of school teaching. The teams in the three subjects were allowed a fairly free hand, so the styles that emerged were quite different: the physics scheme was tightly prescriptive (the oft-quoted slogan was “if you cut it, it bleeds”), whereas the chemistry course was described as “a sample scheme” to emphasize that schools should feel free to pick and choose the parts that they liked. All gave new emphasis to teaching for understanding rather than rote learning, while also calling for the pupil to be “a scientist for the day.” However, the emphasis on the conceptual structure of pure science was strong: applications of science and social implications were given scant attention. With all the Nuffield innovations, the influence of Bruner’s dictum was explicit: “The schoolboy [*sic*] learning physics is a physicist, and it is easier for him to learn physics behaving like a physicist than doing something else” (Bruner, 1960, p. 60).

Thus, for the new physics course, the ideal was that all lessons be conducted in a laboratory so that pupils could move to and fro in a coordinated way between practical exploration and theory development. However, partly because of the stress on this link, the practical investigations of pupils were largely constrained to “illustrate” theory, and the first introduction to this course attempts to make clear that Armstrong’s *heurism* was not being adopted. The new chemistry course laid more stress on “open investigation,” whereas biology showed a mixed economy, with some work designed for confirmation, and some for genuinely open exploration.

These three projects for students aged 11 to 16 were followed by projects for the advanced study of sciences from ages 16 to 18, projects to devise courses in general science for the “less able,” and courses for all in the age range 11 to 13. These last two types of course gave more emphasis to applications of science and to themes likely to be of interest to pupils. A government decision in the 1970s to ban selection of pupils by ability at the transition from primary to secondary schools implied that all schools had to teach across the full ability range. This change made the division, between pure science for the most able and applied everyday science for the rest, problematic, and when separate examinations for different “ability” bands were replaced by a single system, these curricula had to be revised. The revisions were a compromise between the different aims of science education, but many saw that “academic science” still prevailed.

As ever, the messages of reform for science teaching that underpinned the new Nuffield curricula were weakened in dissemination: one evaluation judged that many “Nuffield” teachers had not “thought through the full implications of changes in philosophy and method presented by the Project team” (West, 1974—quoted in Waring, 1979, p. 207). A study of classroom teaching styles found that most Nuffield teachers used an approach characterized by teacher direction, presenting science as a problem-solving activity and telling pupils to make hypotheses and predictions, but not relinquishing control to the extent required for pupils to personally engage in problem-solving (Eggleston et al., 1976).

Nevertheless, school science in general still defied efforts at improvement. Although experimental work became a more salient part of pupils’ experience, it was, with a few notable exceptions, still largely fixed in the “cookbook” mold, and the national inspectorate was again hinting in a 1979 report that more time should be spent on demonstration lessons and less on class practical work (DES, 1979, p. 184). A review written in 1985 concluded that there had been no significant development in practical work in secondary schools since the Nuffield innovations in the 1960s (Woolnough and Allsop, 1985, p. 28). A report by the ASE expressed a more general criticism: “Science appears to exist outside any valid social context. It is objective, value free and totally aseptic” (ASE, 1979, p. 24).

At the same time, a government report drew attention to the failure of schools to require, or make provision for, students to study more than one of the three science subjects: “No school was found, however, which provided balanced science courses for all pupils up to the age of 16-plus. The majority of pupils in secondary schools of all types were taking either no science or only one science in the fourth and fifth years” (DES, 1979, p. 196).

Such dissatisfactions led to a project in the 1980s, the Secondary Science Curriculum Review (SSCR; see West, 1982), which was jointly sponsored by the government agency responsible for curriculum matters (the Schools Council) and the professional

association of science teachers (the ASE). This project had two main outcomes. One was the fostering of numerous teacher-led initiatives to improve science education, for the leaders set their face against any centralized curriculum development in the belief that the only way to secure reform lay through the professional development of teachers who would initiate and own their own reforms. The second outcome was quite different. The project conducted a campaign to establish a single science course for the age range 11 to 16, which would have the lesson time and the examination value of a double subject, and which would cover in a combined and comprehensive manner all of the main aims hitherto pursued in the separate subjects of biology, chemistry, and physics. The point was to replace the situation in which the pupil had to choose between a low-status single-subject science course and high-status courses in the separate sciences: with the latter choice it was almost impossible for a pupil to take more than two of the three science courses. An existing "integrated science" course had already attempted to establish a double-subject and comprehensive science course, but had run into fierce opposition from parents who thought that their children were being offered a course of low market value. The SSCR project therefore worked to gain support for a new "double-subject" scheme from leading scientists, educators, government, and the teaching profession. This campaign was successful, and "double-subject" science became a viable option for schools. Most new courses within this framework did not attempt the controversial label of "integrated" (Black, 1986), and in most schools the "double-subject" was taught in separate sections by specialist teachers of the three subjects.

New directions for change also arose from national sample surveys of science performance set up by the government's Assessment of Performance Unit (APU; Black, 1990). The government brief for these was biased in favor of "science process skills" rather than on science content. Of the six main areas to be assessed, two, one on practical skills and one on conducting open-ended investigations, concerned pupils' work with equipment, and a third assessed capacity to design investigations using written tests. The findings established that short open-ended investigations could be so composed that pupils could work through them in a one-hour assessment session, and that standards of performance on written exercises were far lower than on matched exercises in which pupils could actually explore the phenomena with equipment.

Everything was changed with the establishment for the first time, by a law passed in 1988, of a national curriculum for the United Kingdom. Science was one of the mandatory subjects in this curriculum, required to be studied by all from ages 5 to 16, with progress tested by national tests at ages 7, 11, 14, and 16. The task of drawing up the specification for this curriculum was given to a group composed of teachers, teacher trainers, and academics in science education. Their recommendations were quite radical in both structure and content, based on a set of 22 sets of learning goals, expressed in a scheme of progression in learning from ages 5 to 16. These 22 "attainment targets" were grouped as four "profile components." Of these, 16 were grouped under the profile component Knowledge and Understanding, reflecting the established content areas, but adding astronomy and new topics titled Information Transfer and Human Influences on the Earth. A second profile component, Exploration in Science, had two more targets, one for carrying out investigations and one for working in groups. The third profile component was titled

Communication and included the targets Reporting and Responding and Using Secondary Sources. The fourth profile component, titled Science in Action, combined Technological and Social Aspects and The Nature of Science. Taken together, these called for a significant broadening of the science curriculum and one that would have linked it more closely with other school subjects. A final recommendation was for a single double-subject requirement to take 20 percent of curriculum time at the secondary level.

The government minister could not accept these proposals. He asked for an extra proposal for an optional alternative—a subject having single rather than double-subject weight, and in both options for more weight to be given to knowledge and understanding, and for the number of profile components to be reduced. The proposals were sent out for consultation. Only 10 percent of replies supported provision of a single subject option, only 10 percent supported the reduction in the number of profile components, and 80 percent opposed the recommendation to change the weightings (Boyle, 1990). Nevertheless, the single-subject option, a reduction to two profile components—Knowledge and Understanding and Exploration in Science—and an increase in the weighting, in teaching time spent and in mark assignments in examinations, for knowledge and understanding at secondary level from the 40 percent recommended to between 65 and 70 percent, were all put into effect in the final government orders. Five of the original targets were removed, leaving 17: 16 in Knowledge and Understanding and one in the Exploration of Science. The attempt of the profession to reform its subject had failed, probably because of the right-wing government's suspicion of the educational establishment, fueled by lobbying from conservative teachers in the influential private schools.

It turned out that within three years the curriculum had to be revised, because of widespread teacher opposition to the excessive load of the contents of the new curriculum, and the number of the content attainment targets was then reduced to three, covering the conventional areas of biology, chemistry, and physics respectively, and losing the last of the novel topics, The Nature of Science (Black, 1995). The curriculum was revised again in 1995 (DfE, 1995) and yet again in 2000, but without further radical change.

Practical work, as required in the fourth attainment target, now called Experimental and Investigative Science (profile components were now abandoned), was particularly problematic. The requirement was that the work should:

... encourage the ability to plan and carry out investigations in which pupils:

- (i) ask questions, predict and hypotheses;
- (ii) observe, measure and manipulate variables;
- (iii) interpret their results and evaluate scientific evidence. (Black, 1995, p. 171)

Many teachers were disoriented by this requirement, which went well ahead of current practice and experience (Jenkins, 1995). Even those who did experimental investigations valued them for motivation, not for the learning of concepts (Simon et al., 1992), reflecting a bias that was also evident in the earlier tests of experimental work established by the APU, which had influenced the target's formulation. Many used comparative exercises as used by agencies testing retail products to

advise consumers about the "best buy," which usually involved no application of science concepts. Evaluations also reported that too little time was being given to this activity (NCC, 1991) and that some teachers conducted investigations as isolated exercises designed only for assessment purposes (Russell et al., 1995) while having difficulty in conducting the assessments of this work that they were required to make (OFSTED, 1993a, b; Buchan, 1992; Buchan and Jenkins, 1992).

An overarching problem was still the impact of testing. The testing agencies had to set up a system for including scores for practical investigations in the assessment for school-leaving certificates, and this system had to require exercises that the pupils' own teachers could conduct and assess in normal laboratory time. To secure reliability and comparability, the agencies set up very strict rules about the choice and conduct of such assessments. Teachers, under pressure to secure maximum scores, could not afford to take risks, so many specified for their pupils the same stereotyped exercises year after year and thereby made the work yet again into the old cookbook type of exercise. Ways out of this dilemma have yet to be found.

Although several agencies produced guidance material to help teachers with this new area (Jones et al., 1992; Solomon et al., 1994) and others began to research the problems involved (Millar et al., 1994), there were groups who argued that the target should be abandoned, leading others to publish affirmations of support (Hannon, 1994). However, when the curriculum was again revised in 1995, the investigation's target survived, although the stated aims moved it in the direction of more traditional work.

Foreseeing the revision planned for the year 2000, a group of science educators obtained a grant from the Nuffield Foundation to support a set of expert seminars, followed by consultation including open meetings, to reconsider the science curriculum, and hopefully to influence the revision. Their report (Millar & Osborne, 1998) attracted wide attention. Their main plea was that the science curriculum, from ages 5 to 16, should have the main aim of enhancing a broad and general education in science to meet the needs of all citizens, represented by the title "scientific literacy"; only in years from 14 to 16 should there be an aspect devoted to the early stages of specialist training in science, which should not be allowed to distort the primary aim of promoting scientific literacy.

The report also developed an argument that science education had focused too much on detail, so that pupils had lost sight of the major ideas. This was to be offset by organizing the curriculum in a new way, deploying the power of the narrative form to make ideas "coherent, memorable and meaningful." Stories should be organized around such major themes as "the particle model of chemical reactions" or "the earth and beyond." Examples of questions that could form the basis of particular explanatory stories would be How do we catch diseases? or How old is the Earth and how did it come to be? The report also stressed, "Young people need some understanding of the social processes internal to science itself, which are used to test and scrutinize knowledge claims before they can become widely accepted" (p. 20).

Ironically, the government's anxiety about the low morale and decline in numbers in the teaching profession, due largely to the burdens of frequent change in the curriculum and testing rules, made it reluctant to make any significant changes when it was revised in 2000, so the report's ideas, despite the widespread support that they had evoked, produced only a limited response. The investigation's target was renamed as "Scientific Enquiry." The earlier prescription for investigative skills

remained but was accompanied by a second section on "Ideas and Evidence in Science." This latter section includes study of:

- how scientific ideas are presented, evaluated and disseminated
- how scientific ideas can arise
- how scientific work is affected by the context in which it takes place
- the power and limitations of science, including social environmental and ethical questions

However, there are other signs of change that can clearly be seen as outcomes of the report. A wholly new course, Science for the 21st Century, has been developed and has gained official sanction, in that its trials can be supported by tailor-made examinations leading to nationally approved certificates (Nuffield, 2003). Its proposal is to divide the double-subject science into two components. One, Core Science, is for all, based on current issues, bringing in moral and social implications, and leading to a single-subject examination certificate. For the second, there is a choice between Applied Additional Science, which should provide a basis for technical, pre-vocational, and vocational courses involving science, and General Additional Science, which should provide a basis for further advanced study in the sciences. Either of these options is to lead to a second single-subject examination certificate. If this scheme succeeds, it will at last help the science curriculum to address themes of interest and concern to the young, rather than to require all of them to undertake studies fashioned only in the image and structures of established pure science.

### **SOME CONCLUDING COMMENTS ABOUT THE UNITED STATES AND THE UNITED KINGDOM: THE DRIVE OF SOCIAL AND TECHNOLOGICAL CHANGE**

The changes described in our histories are driven in part by social and technological change, although the influences are often indirect. The movement toward education for all, first at the primary/middle level, then at the high school level, and now toward college level, has meant that science education, like all features of formal schooling, has had to expand from serving only future specialists at the upper level to serving the needs of all.

The change from agrarian to mainly industrial economies has meant that the contexts in which pupils learn and into which they carry their learning at the end of their education have changed. Rural-oriented science now has split into the high-tech needs of a far smaller number of agricultural producers, and the quite different needs of all citizens who need to understand how to protect the environment. Similarly, an aim of helping young people to understand how things work in a technological world is being transformed because the objects that are produced are losing transparency as they gain sophistication. The self-sufficient adult who used to be able to fix things for him- or herself now has changed into one who knows how to read the instructions and when to throw the artifact away.

## Aims of Science Education

Above all the other external pressures, the increasingly powerful influence of science and technology on all societies makes judgments about the aims of science education more complex and yet more critically important. As it is realized that “scientists’ science,” oriented toward the painstaking construction of conceptual frameworks that explain how the world works, is of limited use to the vast majority, new ways of enabling the citizenry to comprehend and operate in a scientific and technological culture have to be sought. Education must be fashioned in ways that are evocative for young people who are being shaped by rapidly changing societal influences. Indeed, one overarching problem is whether science education can keep up, given that educational change often appears glacial.

Such a change of aims could develop in several directions. A recasting of a “love-of-nature” orientation, so prevalent at the turn of the twentieth century, into the context of preserving the future of the planet, a growing international concern in the twenty-first, would lead to an emphasis on interactions in complex systems. It thus might offset the drive to reductionist analysis that has characterized many of the sciences. And a focus on social influences, if it is not to be unrealistic, must introduce moral questions, values, and clashes of belief into the science classroom. The particular attraction of science as a training in dispassionate judgment based on evidence will then have to be protected within carefully delineated boundaries if it is to continue to be a contribution to education. In all of this, studies of the lessons of history, particularly of contexts that are not too dissimilar from those of the present, might be valuable.

All of these possibilities make clear that the changes in aims that are being, or ought to be, pursued now create new problems for the teaching profession. Any discussion of the effects of scientific and technological change has to confront issues of conflicting social priorities. Many events in the last century have made it clear that the idea of a value-free and unbiased science is a dangerous myth. Yet many science teachers, themselves educated in the shadow of this myth, feel uneasy in confronting controversy. It may be that alliances with teachers of humanities and social science will be the best way forward, for conflicting values are often at the heart of these studies.

## Who Has the Power of Control?

In the United Kingdom, the teaching profession has highly qualified science teachers at the secondary level—the majority possessing university degrees in the separate disciplines of physics, chemistry, or biology. The most influential of these have been in the elite schools. The heads of those schools always have had the ear of the government minister and of other private institutions, as well as having the most highly qualified science teachers to formulate and carry through changes.

The picture in the United States is different. Many high school teachers of physical science are not credentialed in the subjects they teach. School districts in most states can assign any credentialed teacher to teach physics or chemistry. They also can award “emergency” credentials to people with no regular license in any subject field. It is not unusual to find a biology teacher, or even a physical education teacher,

teaching chemistry or physics. Consequently there has not often been a recognized cadre of science teacher-leaders. One may be emerging, however. In recent years, a system of National Board certification has been established, along the lines of specialty board certification in medicine. There is a rigorous and expensive assessment system, with those who earn national certification receiving extra pay, and influence, in many states.

Reform movements in the United Kingdom have been fashioned mainly by inspiring the teachers. Although academic scientists had oversight on behalf of the funding agencies, they entrusted most of the work to the best practicing school teachers, and to professors whose main interest and experience was in science education. The efforts focused on the professional development of teachers. The new curricula were given a strong framework by providing tailor-made tests that were not limited by any tradition of inexpensive multiple-choice testing. For example, one Nuffield 16-to-18 curriculum led to nationally recognized certificates with their own tests that comprised two three-hour written tests, each with separate parts in a variety of question styles, together with a test in a laboratory and teacher assessment of experimental projects. The cost of running this centrally for 30,000 candidates was of course high but was seen as acceptable. There was no serious attempt to make new curricula "teacher-proof." Heavy emphasis was not placed on the textbook as the instrument to implement the reform; indeed, one Nuffield curriculum had no pupils' textbook and advised that pupils might consult several as the needs arose.

In the United States, the picture was more mixed. Curriculum revision in the post-Sputnik era was undertaken mostly by university-based scientists, with only modest involvement by teachers. Considerable emphasis was placed on writing new textbooks, sometimes with the explicit intention of limiting the latitude of teachers to make changes. There were few external examinations in science until late in the twentieth century.

There is no single answer that emerges from the histories of the two countries to the question of who has special policy influence in the field of science education. At various times, industry and the professions, the academies of the sciences, the academies of education, the teaching profession, and governments have exerted pressures to produce changes. It would not be easy to judge, even in hindsight, whether or not the influence of any of these has been benign or malign, for in the end the judgment would often come down to a choice among core values—as will any prognosis for the future.

Two trends in the power struggles seem important at the moment. One is that education researchers are now developing more powerful tools (in their theories of cognition and of affect, for example) and can therefore claim credibility in attempting to influence curriculum and teaching. Indeed, they are developing more effective relationships in collaborative reform with teachers and school administrators. It is no accident that the scientific academies now recognize this point, as can be seen in the ways in which the U.S. National Academies of Science and the UK Royal Society involve leaders in science education, including researchers from universities, in their deliberations about education. The second trend is that the move to mass education has made the education budget such a large part of all national economies that governments can hardly leave education alone: what matters then is whom politicians choose to listen to. These two trends could be in harmony, but equally well come into conflict.

## The Student Perspective

At the secondary-school level in both countries, there have been few influential voices with the power to speak and act for the needs of the majority who were not going to be scientists. That concern has increased in recent decades, but only modestly. Two forces are influencing the scientific community to now speak to these needs. One is that the pupils have been voting with their feet: The numbers of those choosing to continue to study science after age 16 and so become qualified for degree training in science and engineering has declined. The other is that the new public distrust of scientists is seen by many in the scientific community to reflect the weakness of science education in not preparing the young to fully appreciate and use the accomplishments of science.

The feature here that now commands the most attention is that of connecting school science with the broader world. It is assumed that such an approach is more likely to engage the preponderance of students who are not likely to choose scientifically oriented careers. Therefore curricula grounded in contemporary problems of importance to young people have been developed in many countries, including the two highlighted here. Close engagement with the science embedded in these contemporary issues might be shifting toward somewhat less activity in the school laboratory and more in the street, the home, industry, and the countryside.

To attract students who now are uninterested in science will not be enough, however. There clearly is danger of superficiality when students engage in real-world problems. The challenge—for curriculum, design, pedagogy, and assessment—will be to build from the initial enticement to develop sustained and serious work by students in arenas hitherto considered unappealing. The particular power of the discipline of scientific inquiry must be made evident in the way that problems are explored. And the extraordinary intellectual heritage of science must emerge for students as the power of its tools and concepts is made evident. Embedded in this purpose is development in students of a sense of wonder, even awe, at the structures and processes to be seen in the natural world. The histories in this chapter have demonstrated that this goal of science education goes back more than 250 years. It is sometimes subdued, but in one form or another seems to arise for each educational generation. It will do so again as the twenty-first century unfolds, perhaps in ways that will be more comprehensible with a knowledge of the history of these aims and challenges in the eighteenth, nineteenth, and twentieth.

# CHAPTER 27

---

## Inquiry as an Organizing Theme for Science Curricula

**Ronald D. Anderson**

*University of Colorado, Boulder*

Inquiry has been a prominent theme of science curriculum improvement efforts ever since the post-Sputnik era NSF-funded science education endeavors appeared in the headlines of the late 1950s. By the beginning of the next decade, inquiry was a big idea in science education, as is well illustrated by the work of the Biological Sciences Curriculum Study (BSCS), including their rationale statements prepared by Joseph Schwab and their materials themselves, their *Invitations to Inquiry* being an especially good exemplar. With a certain amount of ebb and flow, inquiry has persisted as a major science education theme ever since, with its current relevance well illustrated by the *National Science Education Standards* (1996) and a more recent National Research Council (NRC) publication, *Inquiry and the National Science Education Standards* (2000).

The prominence of inquiry has persisted for nearly half a century, with no indication that it will soon disappear. Recognizing that its popularity does not prove its merits, there is reason to ask for evidence-based answers to many questions that can be raised about the place of inquiry in science curriculum improvement. Just what is inquiry? Does it mean the same thing to everyone? Does it mean the same thing in varied contexts? When someone talks about science as inquiry, learning through inquiry, or teaching by inquiry, are they talking about the same inquiry? What are the goals of science instruction that go under this label? Does it result in increased learning? Is it realistic for the average teacher? In summary, does it make sense to use inquiry as an organizing theme for science curricula?

The answer to this summary question that you will get here is yes, but it is a very nuanced affirmation. So much depends on what understandings you have of inquiry, and more specifically on your understanding of the nature of science, how people learn, the nature of society and its schools, and the process of teaching.

Inquiry has become a catch phrase encompassing many aspects of science education, but it is also a useful label that summarizes many important ideas and can serve to integrate various facets of educational practice. The many aspects of science education to which the label is applied are among its most important dimensions. So, even though using inquiry to describe an approach to science education can be a tricky exercise in communication, it is worth doing. Other labels could be used; it would be easy to talk about quality science education without ever using the word *inquiry*. The word is in widespread usage, however, and for broad public discussions, it probably is essential to make use of it in any conversation about contemporary science education.

Such conversation will be much more profitable, however, if we recognize that *inquiry* is an imprecise word. Using the word in a conversation about science education is a bit like using the word *romance* in a conversation about human relationships. It has different meanings in varied contexts, and is hard to guess what particular meaning a given speaker has in mind when the word is used. If the word is to continue to be useful we will have to press for clarity when the word enters a conversation and not assume we know the intended meaning.

## INQUIRY IN THE NATIONAL SCIENCE EDUCATION STANDARDS

Current discussion of inquiry is shaped by the *National Science Education Standards* (NSES), the common baseline for defining what quality science instruction should be in contemporary U.S. education. If one reads this landmark publication with care, it is apparent that *inquiry* is not only widely used in the book, it is used in different ways. Three main usages stand out: there is discussion of scientific inquiry, inquiry learning, and inquiry teaching. These three versions are fairly distinct from each other, even though they also have many connections. In addition, each of the three has various nuances and may be applied somewhat differently, depending on the context (Anderson, 1998).

### Scientific Inquiry

“Scientific inquiry refers to the diverse ways in which scientists study the natural world and propose explanations based on the evidence derived from their work” (p. 23). The work of scientists, the nature of their investigations, and the abilities and understandings required to do this work are at the heart of this usage of the word *inquiry*. These scientific endeavors are considered as independent of our schooling enterprises, although an understanding of them is a goal of education.

If we wish to move beyond the discussion of scientific inquiry as found in the NSES and address it in more depth, the extensive literature on the nature of science becomes relevant (see Chapter 29 of this *Handbook*). We are dealing with scientific inquiry and the nature of science as curriculum content or goals of instruction.

### Inquiry Learning

As used in the NSES, inquiry learning refers to an *active* process of learning—“something that students do, not something that is done to them” (p. 2). Although

used to describe a learning process, the NSES generally portrays this inquiry process as having some relationship to scientific inquiry; it is suggested that inquiry learning should reflect the nature of inquiry in the scientific context. Within the formal school context, this active learning process is expected to be one that “encompasses a range of activities” (p. 33) with multiple stages, including “oral and written discourse” (p. 36).

Although the NSES connects its rationale for inquiry learning to scientific inquiry—undoubtedly a valuable approach in communicating with a science-oriented audience—we need to understand inquiry learning more deeply. Studies of human learning give us understandings an earlier generation did not have—well portrayed in *How People Learn* (Bransford et al., 1999)—and we need to utilize these understandings. Although the term *constructivist* is not used in the NSES, it is clear that what is called inquiry learning is very similar to what others call constructivist learning.

As with inquiry, the constructivist label can be applied to the nature of science, learning and teaching, but it has even greater potential for misunderstanding. In contemporary discussions of the nature of science, for example, there are opposing positions—in what is sometimes referred to as the “science wars”—and *constructivist* is a “good” word in one camp, but not in the other. Thus, *inquiry* has more potential for being a useful word that can be applied in these three contexts without undue miscommunication, which is probably one reason why *inquiry* is used in the NSES but *constructivism* is not. Nevertheless, in a discussion of learning, *constructivist* is probably the more useful word, in that it has some generally understood meanings in the context of learning—as distinct from the contexts of science and teaching. Note, however, as used here to discuss learning, *constructivism* is not the same *constructivism* used in discussions of the nature of science and which is the subject of debate there. It is the same word, but it used in different contexts to make different distinctions.

As used in this chapter, constructivist learning—as well as inquiry learning—is understood to carry with it the following four elements:

1. Learning is an active process of individuals constructing meaning for themselves; significant understandings are not just received.
2. The meanings each individual constructs are dependent upon the prior conceptions this individual already has. In the process, these prior conceptions may be modified.
3. The understandings each individual develops are dependent upon the contexts in which these meanings are engaged. The more abundant and varied these contexts are, the richer are the understandings acquired.
4. Meanings are socially constructed; understanding is enriched by engagement of ideas in concert with other people.

Obviously, this four-part characterization includes perspectives that resonate with both cognitive and sociocultural views of knowledge construction. Differences between these and other varying theoretical perspectives are not the focus of our attention here. This four-part characterization, however, describes elements that generally are understood to be included in the learning process by those using constructivist/inquiry terminology.

## **Inquiry Teaching**

When used to describe teaching in the NSES, inquiry is employed in quite varied ways. As noted earlier, the NSES writers' understanding of learning is such that "inquiry is central to science learning," (p. 2) and as a result it must be central to teaching as well. They note, however, that this focus on inquiry learning "does not imply that all teachers should pursue a single approach to teaching science" (p. 2). Even so, they expect that, "Inquiry into authentic questions generated from student experiences is the central strategy for teaching science" (p. 31). Given their inquiry-based understanding of learning, moreover, it is not surprising that when referring to teaching, they use a broad, process-oriented definition that includes significant attention to inquiry as a learning activity (p. 13). It "refers to the activities of students in which they develop knowledge and understandings of scientific ideas, as well as an understanding of how scientists study the natural world." (p. 23) They acknowledge that all inquiry is not the same by distinguishing between a "partial inquiry" and a "full inquiry" (p. 143). Inquiry is part of their picture of assessment as well, and they see it in the context of teaching. "Any boundary between assessment and teaching is lost" (p. 202).

In summary, as a form of teaching, inquiry has multiple manifestations and the NSES generally does not make careful distinctions between these varied forms of teaching, although it does have an entire section devoted to science teaching standards. At the end of the section on inquiry learning above, a four-part explanation was given of what was meant by inquiry or constructivist learning as used in this chapter. It is not possible to give such a concise description of inquiry teaching. It takes an abundance of forms, and the process of inquiry teaching is not as well understood as the desired product of these transactions, namely inquiry learning. It also is probably fair to say that a belief in the value of inquiry teaching probably carries with it a belief in inquiry learning. On the other hand, it probably is less certain that someone who understands inquiry learning as an accurate picture of how learning occurs also has equally strong convictions about the merits of inquiry teaching. In my judgment, belief in the merits of inquiry teaching among science teachers is not as strong as their belief in inquiry learning. Furthermore, common understandings of just what inquiry teaching is in practice are much more varied than understandings of inquiry learning. For further consideration of inquiry learning and inquiry teaching, including lots of examples, see Minstrell and van Zee (2000).

## **Other Views of Inquiry**

The three categories of inquiry described above were identified initially by a careful reading of the NSES. Inquiry has been defined in many other ways in the science education literature. Huffman (2002), for example, conceptualizes inquiry as having "three key components: abilities, procedures, and philosophy. The three different components are represented by concentric circles with abilities at the center, procedures encompassing abilities, and philosophy encompassing both procedures and abilities" (p. 225). Lederman and Niess (2000) contend that the NSES and Project 2061 present inquiry as having three different perspectives. "Inquiry is viewed

as a teaching approach, as process skills, and as content" (p. 113). Different category systems may have varied utility, depending upon the context. For our purposes here, neither of these definitional sets seems to have an appropriate place for inquiry as a form of learning.

As noted earlier, the NSES does not set out clear definitions of what constitutes inquiry in various contexts. Possibly in response to a failure to provide clear operational definitions of inquiry in the NSES, the National Research Council released a follow-up publication in 2000 titled *Inquiry and the National Education Standards: A Guide for Teaching and Learning*. In this book, the focus is largely on the activities and transactions of people in classrooms, both students and teachers. It is a pragmatic book that addresses the real world of classrooms; as with the NSES itself, depth of understanding about the nature of learning in a more theoretical sense is not featured.

We need both the practical and theoretical. In general, the NSES and the more recent NRC book reflect an appropriate understanding of the underlying theoretical issues, even though their focus is on the pragmatic, and the theoretical is not explicitly developed. The NSES was informed, of course, by the earlier work of Project 2061, and the theoretical was given explicit attention there, for example, in the chapter on learning and teaching in *Science for All Americans* (AAAS, 1989). We will need to go beyond the NSES and the later companion publication, however, not as a corrective, but as an extension to make more explicit the underlying issues and develop the ideas needed in considering the place of inquiry in developing science curricula.

Although some may prefer to avoid using the word *inquiry*, because of the lack of clarity in its meaning, it is employed here because of its value in making connections between content, learning, and teaching and because it would be difficult to avoid it. In addition to its many meanings, its use seems to be ubiquitous. The choice being made here is to use the word and make the effort required to clarify what is meant in a given context. In the process one is addressing many of the fundamental issues in science education.

## HOW IS CURRICULUM UNDERSTOOD?

As we have seen, *inquiry* has many meanings, but it does not get any easier to define when we get to curriculum. Professional conceptions of curriculum are markedly diverse. The goal of this chapter is to address in depth the potential of inquiry as an organizer for curriculum. If we are to do so, we also must come to some understanding of what is meant by various individuals and groups when they talk about curriculum.

Schubert (1986) has presented a set of categories for describing alternative conceptions of curriculum. Although there are substantial differences among these categories, there also is considerable overlap in the sense that they may pursue similar goals. At the same time it must be noted that the form of instruction implied in these different characterizations of curriculum could lead to quite different forms of education. A brief summary of these images or characterizations of the curriculum is presented below. After examining them we can consider their implications for using inquiry as a guiding theme for curriculum.

### **Curriculum as Content or Subject Matter**

This image equates curriculum with the subjects taught: "Educators who use this image intend to explicate clearly the network of subjects taught, interpretations given to those subjects, prerequisite knowledge for studying certain subjects, and a rationale for the ways in which all subjects at a particular level of school fit together and provide what is needed at that level" (Schubert, 1986, p. 26).

### **Curriculum as a Program of Planned Activities**

In this image the curriculum is characterized as a collection of planned activities: "The end of planning is to see that certain desired activities are delivered to students. Granted, all these plans have purposes for which the activities are vehicles. Yet it is the activity—what students do—that is the curriculum" (Schubert, 1986, p. 28).

### **Curriculum as Intended Learning Outcomes**

In this case, the curriculum is defined in terms of intended learning outcomes. The focus is ends, with lesser consideration of the means of reaching them. Purpose is specified by the intended outcomes. The current focus on various forms of standards and the growing use of standardized tests obviously is compatible with this orientation to the curriculum.

### **Curriculum as Cultural Reproduction**

This image of the curriculum focuses on perpetuating the extant culture, thus the curriculum is expected to reflect that culture: "The community, state, or nation takes the lead in identifying the skills, knowledge, and appreciations to be taught" (Schubert, 1986, p. 29).

### **Curriculum as Experience**

A curricular focus on student experiences has been prominent in much discourse about education. It has been commonly associated with John Dewey and his writings, but it can take varied forms: "This position holds that educational means and ends are inseparable parts of a single process: experience. To attend to one's experience reflectively and to strive continuously to anticipate and monitor the consequences of one's thought and action relative to the good that they bring is a continuously evolving curriculum. The teacher is a facilitator of personal growth, and the curriculum is the process of experiencing the sense of meaning and direction that ensues from teacher and student dialogue" (Schubert, 1986, p. 30).

### **Curriculum as Discrete Tasks and Concepts**

Yet another way of conceptualizing the curriculum is as tasks and concepts students should acquire: "The curriculum is seen as a set of tasks to be mastered, and

they are assumed to lead to a prespecified end. Usually that end has a specific behavioral interpretation such as learning a new task or performing an old one better. This approach derives from training programs in business, industry, and the military" (Schubert, 1986, p. 31).

## Curriculum as an Agenda for Social Reconstruction

Rather than personal development, the focus in this image of the curriculum is social ends. A quite radical curricular view, it promotes the idea of students becoming agents of societal change: "This view of curriculum holds that schools should provide an agenda of knowledge and values that guides students to improve society and the cultural institutions, beliefs, and activities that support it" (Schubert, 1986, p. 32).

## Curriculum as "Currere"

The emphasis here, as with curriculum as experience, is personal growth:

One of the most recent positions to emerge on the curriculum horizon is to emphasize the verb form of *curriculum*, namely *currere*. . . [It] emphasizes the individual's own capacity to reconceptualize his or her autobiography. . . [T]he individual seeks meaning amid the swirl of present events, moves historically into his or her own past to recover and reconstitute origins, and imagines and creates possible directions of his or her own future. [T]he curriculum becomes a reconceiving of one's perspective on life . . . [and] . . . a social process whereby individuals come to greater understanding of themselves, others, and the world through mutual reconceptualization. The mutuality involves not only those who are in immediate proximity but occurs through the acquisition of extant knowledge and acquaintance with literary and artistic expression. The central focus, however, is autobiographical. The curriculum is the interpretation of lived experiences" (Schubert, 1986, p. 33).

It involves more than transmitting knowledge, skills, and cultural values; it centers on self-understanding. It depends upon a high level of students' empowerment and students' responsibility for their own learning.

Schubert's characterizations of the curriculum are expressed in fairly concrete terms that, in the majority of cases, are relatively easy to visualize and understand; they are largely expressed in the practical language of schooling. As a result they are good companion categories for our discussion of inquiry in its more pragmatic form, such as found in the NSES. Embedded within Schubert's different characterizations of the curriculum, however, are varied purposes of education, understandings of the nature of learning, perspectives on teaching, and more. And a bit like in our discussion of inquiry, we could introduce more subtleties and nuances if we left this practical language and probed more deeply for underlying conceptual and theoretical frameworks. To do so here is beyond the scope of this chapter, but I would encourage the interested reader to refer to a chapter by Elliot Eisner in the *Handbook of Research on Curriculum* (Jackson, 1992) titled "Curriculum Ideologies." In it Eisner claims that in any given school there is an ideology or "value matrix" that justifies choices made and gives direction to the curriculum. He notes that in some ways

these ideologies are rooted in underlying worldviews. Eisner describes six major ideologies that he finds in American education. Schubert and Eisner are not in conflict with each other; they operate at somewhat different levels.

Two words—*inquiry* and *curriculum*—each of which has so many different meanings—have been conjoined as the focus of this chapter. We will address them together at the more practical level of language found in the NRC publications and in Schubert's curriculum writing, but in the process will attempt to go deep enough to seriously attend to matters of educational purpose, the nature of learning, and approaches to teaching. Without this depth of analysis we cannot accomplish the purposes at hand.

## THE LITERATURE ON EDUCATIONAL CHANGE

In addition to the literatures on inquiry and curriculum, there is a third area that needs attention before we can attend more directly to the role of inquiry in developing science curricula, namely the extensive literature on educational change. Implied in most discussions of inquiry in science education is the notion that there should be more of it, that is, that our current science education practices are not up to par and we need to change them to include more inquiry, whether that be inquiry as content, learning, or teaching. Assuming this notion as part of our operating perspective here, it is essential that we attend to understandings found in the literature on educational change because they strongly influence how we can expect to connect inquiry and curriculum.

The literature on educational change is extensive and rich. It includes work done from many different perspectives and offers many insights into school practice. For the reader wanting a one-stop overview, the best source probably is the third edition of Michael Fullan's landmark book, *The Meaning of Educational Change* (2001). Of his many books, this one stands out as a good overview of what the research has to say. Other scholars who stand out among the many who have shaped the field include Seymour Sarason (e.g., 1990, 1996), Larry Cuban and David Tyack (1997), and Matt Miles (1993). It is interesting to note that the field has been influenced by scholars who have approached their work from a variety of theoretical and methodological perspectives, for example, social psychology, organizational development, and history. In addition to this work, which has addressed educational change in a general sense, there is literature that is specific to particular subject fields, such as science and mathematics.

For purposes of this chapter, some highlights of this literature need to be identified. To begin with, we need to recognize that changes of the kind under consideration here are not easy. What may seem simple to the uninitiated is in reality a very complex matter. Individual learning itself is complex, and we are addressing it here in the complex social context of a classroom, which in turn is located within the broader context of a school, which furthermore is profoundly shaped by its franchising society, with its many social, political, and economic forces. Failure to recognize this complexity is rampant not only among the public and politicians, but among practitioners and professionals. The educational landscape is strewn with the wreckage of educational innovations that foundered on the misconception of simple solutions.

This complexity may be better understood if we consider the situation from multiple perspectives. A diagram employed in a journal article on this complexity (Anderson, 1992) may be helpful at this point (see Fig. 27.1).

As portrayed here, processes intended to produce changes in educational practice must include both curricular and instructional aspects, and they occur in a broader social context. To understand fully these arenas of action, we need to view them from multiple theoretical perspectives, including philosophical, psychological, sociocultural, economic, and subject matter (in our case, science). The importance of recognizing this complexity and the futility of pursuing simple solutions has never been more obvious than it is now in this day of mandated changes based on the results of standardized tests.

This complexity leads to a second fundamental point—to be successful, change efforts must be systemic in nature. Changing curriculum materials by itself will not bring successful change. New teaching approaches are not the answer. Professional development has not evidenced significant results. Site-based management will not

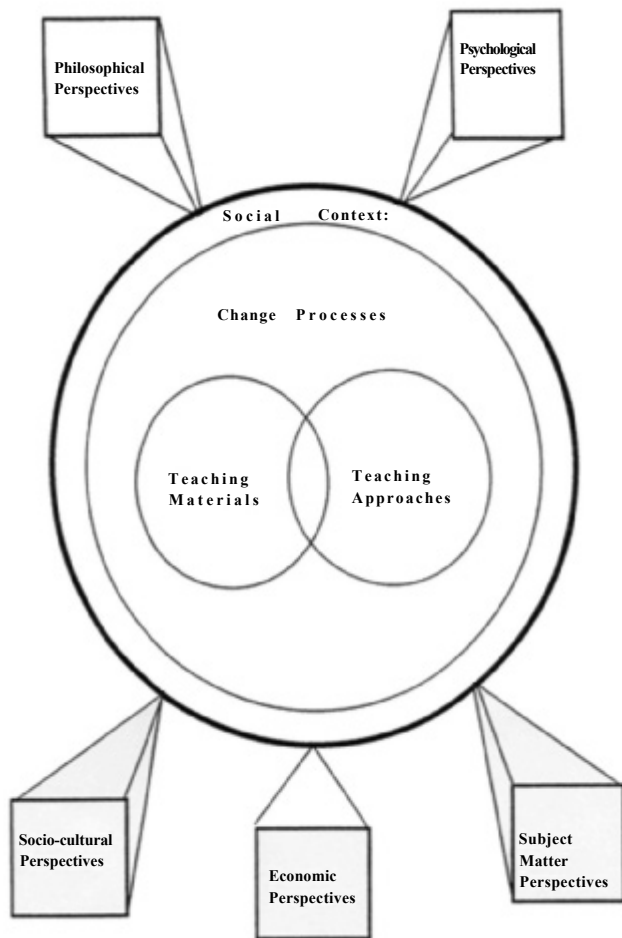

FIGURE 27-1. A model of complexity (Anderson, 1992).

do the job. The list goes on. Even doing all of these together will not work unless it is the right mix of initiatives done in the context of just the right climate and support.

Providing a full picture of what such a successful systemic approach would be is beyond the scope of this chapter, but it may be helpful to point out a few elements of what such a systemic approach would address. What follows are a half-dozen key elements of what research tells us about the complex situation we are facing. Describing these elements may tend toward a reductionist outlook that does damage to the very notion of a systemic approach, so it is done here with caution. Recognize that this description of key elements from the research literature is not intended to imply a list of initiatives which, if successfully pursued, will result in the systemic approach being advocated here. With this caution, some detail is provided about these important facets of the situation.

## Teachers Face Many Dilemmas

Case studies of teachers attempting to move to more inquiry-oriented science education (Anderson, 1995, 1996) show many of the dilemmas science teachers face—situations in which all of the alternative actions available seem to have undesirable consequences, along with what is desired. Teachers experience a tension between alternatives. Although some of these dilemmas may be more perceived than real, they are nevertheless a part of the teacher's reality. Among these dilemmas are the following:

1. *Time.* There is never enough time to do everything a teacher thinks should be done, and the changes promoted in the *National Science Education Standards* only make the situation more difficult. Inquiry (however you chose to define the term) takes more time, and the teacher wanting to give more emphasis to inquiry faces a dilemma of significant proportions.
2. *Ideal vs. reality.* From the perspective of the teacher in the science classroom it generally appears that the NSES portrays an ideal that is in conflict with the realities of the classroom. This tension highlights the fact that change that introduces more inquiry is not easy.
3. *Changing roles and work.* The school culture has deeply ingrained within it expectations for both students and teachers. It is hard for teachers to change their roles, not just because of the school culture, but because it is difficult for people to change such roles in any context and because the process of learning new roles is more complicated and time consuming than generally thought. And these changes in teacher roles probably are essential if the fundamental desired change is to be achieved, that is, changes in the roles played by students and the nature of the work they do.
4. *The preparation ethic.* The culture of schools, especially among science teachers, is permeated with the idea that preparation for the next level of schooling is the driving value for their work. As a result, science teachers find it difficult to devote significant efforts to a more inquiry-oriented form of science education because they fear preparation will suffer. Teachers feel that this is a real dilemma, even though empirical research shows these fears to be largely groundless.

5. *Equity.* Consideration of the preparation ethic leads to yet another dilemma science teachers perceive—what does it mean to provide “science for all”? Many teachers see a tension between providing a strong education for the able and willing students and at the same time providing for the uninterested or less able students.

### **Significant Changes in Educational Practice Require Changes in Teachers’ Beliefs and Values**

Many of the above teacher dilemmas are grounded in beliefs about science, students, and teaching and in values concerning what is important. The influence of teachers’ values and beliefs is well grounded in the research literature and is well illustrated in the case studies cited above (Anderson, 1996), as is the relationship between changes in these values and beliefs and changes in classroom practice. Some of these beliefs are related to the nature of high school subjects (Grossman & Stodolsky, 1995) and to teachers’ understanding of the nature of science. The potential relationship between teachers’ beliefs about the nature of science and classroom transactions and what students learn has been explored in the literature (Lederman, 1992; Duschl & Wright, 1989; Brickhouse, 1990; Russell & Munby, 1989; Koulaidis and Ogborn, 1995). Changes in educational practice related to the preparation ethic are tied to teachers’ beliefs (Mitchener & Anderson, 1989), as are teacher decisions related to matters of students’ ability, gender, and race (Bianchini, Cavazos, & Helms, 1999).

### **School Departments Are Important Settings for Change**

Although a large proportion of the research on educational change addresses whole school change (Fullan, 2001), the research indicates that deep and lasting change requires intensive department-level efforts. The previously cited case studies illustrate this point (Anderson, 1996), and Talbert (1994) shows that the department is primary among the various embedded contexts where professional identities are formed. Other research pointing to the centrality of the department as the context for educational change has been reported by Grossman and Stodolsky (1994), Little (1993), and McLaughlin (1993). The importance of this context may be related to the next point emerging from the literature, the power of collaboration.

### **Teacher Collaboration in the Work Context Is a Powerful Influence on Teacher Values and Beliefs**

Working together with fellow teachers on day-to-day educational actions—not just in an in-service education context—can be powerful. Talking about the issues raised in the National Science Education Standards is not the same as working together to put ideas into practice. Case studies have shown that this is a setting in which teachers have to come to grips with their values, beliefs, and assumptions and find themselves challenged in this regard as they work with others to develop instruction (Anderson, 1995, 1996). Even though all of the science teachers in a given group

may not have the same philosophical perspectives, this sort of collaborative context is where such internal changes emerge. Although new forms of assessment are often presented today as the most influential means of fostering educational change, the research points elsewhere. For further detail on collaboration as an influence on teacher values and beliefs, see Little (1994) and Helms (1995). See also Groarke, Ovens, and Hargreaves (1986); Nolfke and Zeichner (1987); and Tikunoff, Ward, and Griffin (1979); all cited in Richardson (1994).

### **Parental Support of Reforms Is Essential**

Parental support—or probably more important, the absence of resistance—is essential for initiating significant educational reforms. The case studies mentioned above provide striking examples of this situation, with portrayals of changes started in response to new national standards in science and mathematics being seriously restrained by parental opposition. This situation has been studied thoroughly in the field of mathematics (e.g., Peressini, 1996; Romagnano, 1994), with evidence that the assumptions and beliefs of parents are an important part of the overall context in which reform efforts operate.

### **New Student Roles and New Forms of Student Work Are the Real Indicators of Meaningful Change**

This is the moment of truth; if inquiry science education has been installed, it will be evident in new roles played by students and new forms of student work. Even if a number of meaningful changes have been introduced—collaboration among teachers and new roles for them, for example—many reforms seem to fall short when it comes to this “bottom line” of results. Case studies show the possibilities of such significant change, as well as the frequent failure to reach them (Anderson, 1996).

Teachers are at the center of most of the aspects of educational change discussed above. A professional status for teachers that enhances professional decision making clearly is an essential (although by itself not sufficient) element of meaningful educational change.

## **CONNECTING INQUIRY, CURRICULUM, AND CHANGE**

From this description of key elements of the research on educational change, it may be obvious that reforming science education toward a more prominent presence for inquiry will demand a multifaceted approach. It will be essential to have new instructional approaches, revised teaching materials, substantial means of implementation including teacher support and contexts for collaboration, and careful attention to the social context, among others. The issue at hand is how to do it with full attention to the particular forms of inquiry being sought, the understandings of curriculum selected, and the nature of the educational change processes that prevail in the given context. Making these connections is the focus of the remainder of this chapter.

To avoid possible confusion, it is important to relate this discussion to contemporary political events that often carry a label of educational reform. The “stan-

dards movement," with its focus on specified expectations—in the case of science, what is the equivalent of selected portions of the content (only) standards from the NSES—coupled with standardized testing and the imposition of penalties for the failure of schools to reach predetermined levels, is far from an adequate expression of what the research on educational change suggests that we do. Such efforts are not systemic in character. Although such standards and testing may be of some help within a broader endeavor, by themselves they have little potential. Furthermore, these contemporary efforts include little attention to inquiry, in any of the various senses that the word is being used here. In fact, anecdotal information and comments from school personnel lead me to conclude that if anything, these efforts are reducing inquiry as science content, inquiry learning, and inquiry teaching.

In pursuing the goal of relating our understandings of inquiry, curriculum, and educational change, the remainder of this chapter is organized in terms of the three notions of inquiry, that is, inquiry as an expression of the nature of science, inquiry learning, and inquiry teaching. Each form of inquiry is explored as a potential guiding theme for positive science curriculum change.

### **Inquiry as an Aspect of Science Content**

In one sense, adding inquiry to the *content* of a science course is relatively easy. Abstractions about the nature of science can be put into text materials, student tests, and teacher presentations, in the same manner as any other knowledge. In other ways, the task is far from easy. To what extent can words in a book capture an understanding of the nature of science inquiry? To what extent must it be experienced?

To address these questions we need to return to our various definitions of curriculum. For discussion purposes, I will set aside Schubert's characterizations of curriculum as cultural reproduction and as an agenda for social reconstruction and divide his other six characterizations of curriculum into two clusters. The first cluster includes curriculum as content, program of planned activities, intended learning outcomes, and discrete tasks and concepts. I am giving it the label of *external*, since in these characterizations of the curriculum the goals and choice of student experiences have origins largely external to the students. In contrast, the other two images of curriculum—curriculum as experience and as *currere*—are more personal and have origins more internal to the student—hence the label *internal*. Obviously there are many ways to categorize these images, but this particular dichotomy may be useful to us in our consideration of inquiry as science content, as well as when we consider inquiry learning and teaching.

Whichever of these two views of curriculum are employed—*internal* or *external*—science as inquiry can be placed in the curriculum, but one cluster of curricular images may be more useful than the other for the purpose at hand. If a full understanding of the nature of science is dependent upon personal experience—including attention to the emotional aspects of the experience of being engaged in science inquiry—and related intellectual transactions, the *internal* understandings of curriculum may be more helpful. Rather than having these experiences predetermined, there is value in having student choice of hypotheses tested, means of doing such testing, and interpretations to be placed on the results. As with actual scientific experimentation, the student can experience the frustrations and excite-

ment inherent in the endeavor, even though in some senses it is a simulated rather than “real” engagement in science. There is a value in students reflecting on this experience and monitoring the outcomes of their personal thoughts and actions, or—to take it a step further—seeking meaning in past related experiences and reconceiving their perspectives on life and what they are projecting for themselves in the future.

While personally favoring the *internal* cluster of curriculum images, I recognize that students can experience science inquiry to a considerable degree in curricula whose image is found within the *external* cluster as well. It is of interest to note, in particular, that Schubert’s characterization of curriculum as planned activities appears to be quite congruent with the portrayal of inquiry learning and teaching found in the NRC publication *Inquiry and the National Science Education Standards*. Upon reflection, I do not find this surprising, in that the publication is written for practitioners, with an apparent motivation to communicate with them without becoming unduly involved in debates over the nature of the curriculum. Whether one has an external view of the curriculum as determined largely independently of the student, or a view that gives more consideration to the internal dimensions of student interests and prior experiences, the portrayal of the curriculum as planned activities is useful and practical. Descriptions of planned activities can be used to communicate both internal and external conceptions of learning as well as teaching. Furthermore, practitioners with varied understandings of the nature of learning and teaching can engage in meaningful discussion of classroom transactions without foundering on what may seem to be abstract issues.

On the other hand, it may be possible to have such discussions without uncovering fundamental differences among the participants that are truly important to clarity of communication. What is the nature of learning and teaching that is assumed? What understanding of the nature of science do the various participants have? Can practitioners really collaborate with each other in classrooms without getting to these underlying issues? Although I think this publication, *Inquiry and the National Science Education Standards*, is an important and useful tool for practitioners, I would urge dialogue among fellow teachers about its meaning that reaches to the deepest theoretical levels possible.

This deeper understanding on the part of teachers is important if they are to facilitate deep and personal student engagement with the intellectual dimensions of inquiry that students should have. This intellectual engagement generally demands the aid of a teacher who is knowledgeable of the nature of both science and student intellectual development.

Inquiry as science content in the curriculum is well established. It appeared in a rich form in the biology materials of the Biological Sciences Curriculum Study (BSCS) in the early 1960s, with considerable influence coming from Joseph Schwab (Sarther, 1991). It is apparent, however, that there is no one particular understanding of the nature of this science to put into the curriculum (Rudolph, 2003; Lederman, 1992) and that what can be captured in the school curriculum is only a partial portrayal (Rudolph, 2003). The understanding of the nature of science that students acquire through an appropriate curriculum can be rich, intellectually challenging, and emotionally fulfilling, but it must be experienced in significant ways for this to be possible (Magnusson & Palincsar, 1995). The nature of the learning experience is a crucial consideration if this goal is to be attained.

## Inquiry Learning

In the sense used here, inquiry learning is foundational and essential for a first-rate education. As noted earlier, it is viewed here as synonymous with what is generally called constructivist learning; that is, learners construct meaning for themselves, such meanings are dependent upon prior constructions, the understandings are context dependent, and they are socially constructed. Although some people may view this statement as an ideal, to a much larger extent it is simply a description of how research tells us learning actually occurs. For optimum learning, curriculum and pedagogical practices should be created that enhance this learning process.

Two clusters of curriculum images were identified above—*external* ones where the origins of the curriculum were largely independent of the students and *internal* ones where the learners themselves significantly shape the curriculum. Inquiry learning can be incorporated into any of Schubert's eight characterizations of the curriculum, but it is not inherent in the *external* versions to the same extent that it is in the *internal* portrayals of curriculum. Inquiry learning is not as easy to add to the former as it is to add the latter. A full flowering of inquiry learning is more feasible in the *internal* versions because students are more likely to shape their own learning in a direct manner.

A fuller explanation of this point will be easier if it can be made more concrete through a means such as Table 27.1. This table describes two orientations to teaching found among teachers in a series of case studies done of schools engaged in curriculum reform of the kind espoused in the NSES (Anderson, 1996). The schools were selected for the case studies because they were successfully implementing such approaches, but within these schools there was a range of approaches. This table describes a continuum where the extremes were labeled *old orientation* and *new orientation*, with the new end of the continuum being consistent with the NSES and constructivist forms of learning. No teacher was totally on one extreme end or the other, but generally teachers displayed a predominance of one or the other. The differences here are described in terms of teacher role, student role, and student work. Because our focus at this point is student learning, our attention is on the latter two. Later we will attend to teaching and what is described in the table as teacher role.

In Table 27.1, the new student orientation is described as a student role as self-directed learner—in contrast to passive receiver—and student work that is student-directed as well—in contrast to student work that is teacher-prescribed activities. Under the new orientation, students process information, not just record it; interpret and explain information, not just memorize it; design their own activities, not just follow teacher directions; and form their own interpretations of data (such as from a laboratory investigation), not just depend upon the teacher's understandings. In addition to this role change, they do different forms of student work. To a considerable extent they direct their own work rather than just complete worksheets, engage in tasks that vary from student to student, design tasks for themselves rather than depend upon teacher-directed tasks, and do work that emphasizes reading and writing for meaning, solving problems, building from existing cognitive structures, and explaining complex problems.

Determiners of the nature of both student role and student work include the nature of the curriculum as well as the role of the teacher. Comment on the teacher's role will be saved for the section on inquiry teaching below. The nature of the cur-

**TABLE 27.1**  
**Traditional–Reform Pedagogy Continuum**

<i>Predominance of Old Orientation</i>	<i>Predominance of New Orientation</i>
<b>Teacher role</b>	
<i>As dispenser of knowledge</i>	<i>As coach and facilitator</i>
Transmits information	Helps students process information
Communicates with individuals	Communicates with groups
Directs student actions	Coaches student actions
Explains conceptual relationships	Facilitates student thinking
Teacher's knowledge is static	Models the learning process
Directed use of textbook, etc.	Flexible use of materials
<b>Student role</b>	
<i>As passive receiver</i>	<i>As self-directed learner</i>
Records teacher's information	Processes information
Memorizes information	Interprets, explains, hypothesizes
Follows teacher directions	Designs own activities
Defers to teacher as authority	Shares authority for answers
<b>Student work</b>	
<i>Teacher-prescribed activities</i>	<i>Student-directed learning</i>
Completes worksheets	Directs own learning
All students complete same tasks	Tasks vary among students
Teacher directs tasks	Design and direct own tasks
Absence of items on right	Emphasizes reasoning, reading and writing for meaning, solving problems, building from existing cognitive structures, and explaining complex problems

*Note:* From Anderson (1996).

riculum is the matter at hand. As noted previously, the new orientation to student role and work is possible in any image of the curriculum, but it is more likely in the *internal* cluster of orientations.

As in the case of inquiry as science content, our discussion of inquiry learning deserves special attention to one particular image of the curriculum, curriculum as planned activities. As noted earlier, the NRC publication *Inquiry and the National Education Standards* portrays inquiry in concrete terms through an emphasis on planned activities. A curriculum based on planned activities has the potential of fostering inquiry learning, but realization of this potential is highly dependent upon the teacher's ability to occupy various roles and commitment to particular values and beliefs about such matters as students' capabilities and how they learn. It may be particularly useful to examine curriculum as planned activities here because it is compatible with the above NRC publication and the NSES, and it has the potential of being conducted in a manner that fosters either inquiry learning or its alternatives. Thus, we need to attend closely to the topic of inquiry teaching.

## **Inquiry Teaching**

As noted earlier, inquiry learning is better understood than inquiry teaching. Inquiry learning can be described in the terms provided for us by cognitive science

research or in more pragmatic language, such as that used in Table 27.1 to describe student roles and work. Inquiry teaching is more ambiguous. The description of teaching in this table contrasts a teaching orientation that is predominantly dispenser of information with an orientation as coach and facilitator. The distinction is valuable but not sufficient to distinguish between teachers who foster inquiry learning and those who do not. It is possible to play a teaching role as a coach and facilitator—as described in the table—and not foster inquiry learning among students. There is a strong correlation between the teacher role described in the *new orientation* and the student role and work found there, but it is not a perfect correlation. A teacher role that looks to be what is described there may not yield the indicated student role and work. The only real test of the presence of inquiry teaching is whether or not students are engaged in inquiry learning.

If we again use the curriculum as planned activities image, and put it into practice in the sense advocated in *Inquiry and the National Science Education Standards*, we are well on the way to inquiry teaching. But it must be operationalized in a manner that really results in inquiry learning. The teacher so engaged is actively reflective about questions such as the following: Are the students actively constructing understandings rather than memorizing the constructions of others? To what extent are they interpreting and explaining information that comes their way and developing hypotheses about relationships within data sets? Do the students have an opportunity to design and direct some of their own activities rather than just engage in carefully scripted planned activities? Do they have the opportunity to develop—and defend—conclusions they personally draw from the information at hand? Do they engage in activities chosen individually or by a small group, or are they rather consistently engaged in the same tasks as everyone else in the class? Does the students' work in the class emphasize reasoning, include reading and writing that focus on developing meaning and understanding, stress problem solving of varied types, and address complex problems that provide a context for building understandings from existing cognitive structures?

It is possible to employ a curriculum image from the *external* cluster—in particular, curriculum as planned activities—and implement it in a fashion that has many of the characteristics of an *internal* curriculum image, such as curriculum as experience. The most basic issue is not the particular choice of a curriculum image, but whether or not it is put into practice in a manner that fosters inquiry learning; in other words, is something that is called “inquiry teaching” really deserving of this label? A partial basis for answering this question is whether or not it fosters inquiry learning.

Obviously, inquiry teaching is a major topic on its own and an active area of research. It is certainly more than actively reflecting on questions such as the above. In-depth treatment of inquiry teaching, however, is beyond the scope of this chapter. We have touched on it as it pertains to using inquiry as an organizing theme for the curriculum. Research on inquiry teaching, in turn, of course, must attend to context and address many of the matters included in this chapter, such as curriculum content, the nature of the curriculum, and student learning.

## Putting It into Practice

As noted earlier, inquiry in its various forms has been put into the science curriculum in various ways for decades. In more recent years—both before and after

publication of the NSES—a variety of initiatives have gone in this direction, often in ways that attend to inquiry in its many forms, that is, as science, learning, and teaching. A prime example is project-based science (Blumenfeld, 1994; Krajcik et al., 1994; Marx et al., 1994), a form of instruction that potentially can foster inquiry learning and can bring students in touch with science understood as inquiry. Zuckerman et al. (1998) describe a Vygotskian approach to developing “students’ ability to engage in persistent and systematic inquiry.” It is an elaboration of an instructional approach; inquiry is defined here as an instructional process that includes an elaboration of a learning cycle of inquiry. The goal here is for students to acquire a certain mode of learning, that is, to be able to do inquiry, in contrast to a goal of having students understand the nature of inquiry in science itself. On the other hand, Ahlgren and Wheeler (2002) describe the foundation of the Project 2061 *Atlas of Science Literacy*, with its many maps, and how the portion on inquiry can be used to teach something about science itself. Cartier and Stewart (2000) provide another example of how science as inquiry is built into a science curriculum, in this case, a high school genetics curriculum. There are a number of examples, but there is still the question of how to put it into wide practice.

## CHANGING TOWARD INQUIRY

Inquiry is a viable guiding theme for science curriculum in terms of content, learning, and teaching, but we still face the issue of how to change teaching practices in classrooms to attain the desired inquiry orientation. Whether one is approaching this task as an individual teacher, a science department within a school, or a school system, it is a difficult task; our brief review of the literature on educational change is clear on this point. It also is apparent that beyond an individual teacher, any change endeavor must be systemic, that is, it must attend to many aspects of the situation and it must be done in a manner that attends to the interrelationships among these many facets. Among these many aspects, two stand out—the curricular materials and the teacher. We will address each of them before moving on to the overall systemic situation.

### Materials

Curriculum materials have been given highly varied degrees of importance at different times and in different contexts. The attempts to introduce inquiry science education in the 1960s, for example, were centered on innovative new curriculum materials. Although they may not have been billed as such, they often were viewed as teaching materials that should be “teacher proof.” In other words, they were developed with the expectation that most any teacher could use them rather easily in his or her classroom in a manner that would result in inquiry learning and student understanding of science as inquiry. In general, the materials did not live up to this expectation.

On the other hand, the particular materials selected are sometimes thought to be of little importance, at least in the hands of a good teacher. It is assumed that what happens in the classroom depends upon the teacher, and if the teacher is competent, it doesn’t make much difference what materials are used.

Neither of these extremes is a good grounding for introducing positive educational change. Quality inquiry science materials are of major importance and influence in classrooms; they can be the foundation of quality education. On the other hand, the materials themselves will not do the job independently of a well-qualified teacher. In an analysis of the role that curriculum materials can play—and their relationship to individual teachers, professional development, and school culture—Powell and Anderson (2002) concluded that an answer to questions about the place of materials is dependent upon the given context and situation. Professionals who ignore the value of good materials typically find that an important element of their attempts at educational reform is missing. There are multiple reasons for seeking out the best available inquiry-oriented materials.

The desired materials reflect the vision of science education found in the standards of such documents as the *National Science Education Standards* (NRC, 1996) and *Benchmarks for Scientific Literacy* (AAAS, 1993). In particular, these curriculum materials should have four distinguishing characteristics as follows:

1. are standards-based in that the science content, instructional strategies, and assessment tools optimize student learning as reflected in current research on teaching and learning.
2. are inquiry-based, which includes support for inquiry as a teaching strategy as well as the inclusion of content that addresses the abilities to do inquiry and the understandings about science as inquiry.
3. are based on a carefully developed conceptual framework that reflects the science disciplines and connects factual information to larger ideas, themes, and concepts.
4. are revised as a result of thoughtful and comprehensive field testing, which provides developers with data about the effectiveness of the materials used by teachers and students. (Powell & Anderson, 2002, p. 114)

Good curriculum materials have been presented here as an important vehicle for facilitating inquiry-oriented science education. But some may ask if it would not be possible—maybe even preferable—for a teacher to enter the classroom without such well-developed materials and use one's teaching competence to develop a particular image of the curriculum into reality in the lives of students. This teacher could, for example, begin with a conception of the curriculum as experience (following the tradition of John Dewey), build on student experiences with science-related matters, and facilitate the students' growth in inquiry, science, and applications of this science to personal and social applications. Yes, I think it is possible, but within the reality of the public school context I also think that literally only one in a hundred teachers has the competences required to do it and do it well. Widespread educational change toward inquiry is not possible without appropriate materials.

Furthermore, I think even the teacher with this desired vision and the necessary competences would find such materials helpful in the typical school context. In the early 1990s I conducted a case study over a period of two years, of a high school science department that was developing and implementing a new inquiry-oriented science program that integrated content from the full range of natural sciences. They had found no published materials with which they were satisfied and had

decided to write their own. In an interview near the end of the case study with the science department chair—the leader of the innovative effort and writer of the majority of the materials—we discussed the materials and their development. His firm opinion was if he had to do it over again, he would have purchased the best materials available—even though they were highly unsatisfactory from his standpoint—and adapted them as they went along. Personally, I favor the *internal* cluster of curriculum images and am attracted to pursuing curriculum as experience or as *curere*. Even so, in teaching a secondary school science class I would prefer to start with the best inquiry-oriented materials available and use them as a foundation in a classroom that is more “freewheeling” and individually adapted than the materials developers had in mind. Materials are of major importance, even though, by themselves, they do not come close to doing the job.

## A Teacher Focus

Assuming quality materials—such as one would expect from a process with the four characteristics given above—the materials themselves are making demands on teachers that are both substantial and meaningful. The best materials are asking teachers to conduct their classes in a manner that is far from routine, introduce multiple forms of inquiry, and lead to student engagement and empowerment. As a result, teachers are being encouraged to move out of their comfort zone, attempt new practices, and challenge some of their personal values and beliefs. Most teachers find such a venture to be very challenging. Teachers have to be the focal point of a move toward more inquiry-oriented science education.

It is inevitable that teachers who move out of their comfort zone to attempt more inquiry-oriented teaching practices find challenges to their values and beliefs. To what extent are these new educational experiences valuable to my students? Are they valuable for all kinds of students? What is most important for them to learn? Will my students miss certain important knowledge if I use this inquiry approach instead of my usual approach? Do I have enough time to use inquiry? These questions are only samples from the many issues that pass through teachers’ consciousness as they attempt innovation. Changing educational practice is not just a matter of learning some new techniques. It is a process of reassessing one’s entire understanding of the educational process (Anderson, 1995, 1996; Keys & Bryan, 2001)

Professional development is an important aspect of this process of change, but of necessity it must be a transformative process; routine inservice education is not sufficient. Among characteristics of such in-depth professional development are the following (Thompson & Zeuli, 1999):

1. Cognitive dissonance is created, which disturbs the existing equilibrium between the practices and beliefs of teachers and their experiences with the subject matter, learning, and teaching.
2. Discussion, reading, writing, and revised thinking can lead to resolution of such dissonance when teachers are given the appropriate context, time, and support.
3. The professional development experiences are connected to the teachers’ particular context and their own students.

4. A means is provided for the teachers to develop new classroom practices that are consistent with the new understandings they are developing.
5. As new issues and problems arise, teachers are given the support needed to understand them and put these new understandings into classroom practice.

A bit of reflection makes it apparent that professional development of this sort requires more than creating and scheduling an inservice education class. It must be tied to the inquiry materials being used, have an intimate connection with the participants' day-to-day work in their own classrooms, and have strong connections to their fellow teachers and the support system provided by their school. It is not an isolated endeavor.

Research makes it clear that collaboration among colleagues is a powerful part of such an initiative, not just in the context of a professional development experience *per se*, but in the ongoing work context. Collaborative work among teachers can be a powerful influence with a transformative result (Anderson, 1995, 1996). In this context there is a real opportunity for teachers' beliefs to change as they have reason to think deeply about what scholarship about learning and teaching (e.g., Lambert & McCombs, 1998; Bransford et al, 1999; Mayer, 2002) means as applied to their own "real world" situations. They can become dissatisfied with past beliefs, find viable alternative practices, and connect new beliefs with previous understandings. They can become convinced that new approaches will result in improved student learning (Prawat, 1992; Berlin & Jensen, 1989).

## Systemic Support

There is abundant evidence that educational change (whether toward inquiry or anything else new) will go nowhere without systemic support, that is, multifaceted support that addresses all aspects of what is obviously a loosely coupled system of interconnecting components. This generalization has been well established in the field of science education in a cost-effectiveness analysis of interventions to improve educational practice (Anderson, 1990) and in case studies of curriculum reform (Anderson, 1995, 1996). With respect to education in general, it has been shown throughout the general literature on educational reform (e.g., Fullan, 2001; Sarason, 1996). Systemic support means support for teachers' professional growth as described above and a lot more.

With respect to inquiry-oriented science education, this systemic support must be centered on this vision of education, including the various understandings of inquiry regarding content, learning, and teaching. At its center must be the professional growth of teachers built on multifaceted means of support, including appropriate materials, collaborative work contexts, suitable forms of coaching, empowerment, and a supportive work environment. As noted earlier, however, it is far more and includes appropriate initiatives in many spheres of influence, including those of parents, the public in general, policymakers, and various administrative levels.

Finally, with respect to systemic support, it should be emphasized that it must be contextual. There is no gold-standard, all-purpose way of providing systemic support for changing toward inquiry-oriented science education. It must be situated in a particular time and designed for a given situation and for the people and place at hand.

## Structures as Well as Culture Must Change

Much of what has been described above with respect to systemic support addresses school culture and changes in teachers' values and beliefs. But that should not be the limit of our thinking. If we want to put in place a full new vision of science education, that is, inquiry science education in its many manifestations, something must be done to alter the prevailing patterns of school structures (Cuban, 1995). The literature on reform shows that even such seemingly simple changes as putting in place a common planning period for science teachers who are collaborating on their teaching or block scheduling for science classes (neither of which is presented here as a panacea) is very difficult. But structural changes of many kinds may be in order, and they need to be open for consideration, as must any deliberation about what constitutes inquiry science education and how it can be put in place.

This chapter opened with the assertion that it made sense to use inquiry as an organizing theme for science curricula, but that this assertion had many qualifications. It should be apparent at this point not only that these qualifications are many, but that they have to be considered in concert. The vision of inquiry science contained in the *National Science Education Standards* is powerful, has great merit, and is viable in the practical world of schools. In addition, however, it is a lofty goal that is difficult to attain. It deserves the careful attention and concentrated effort that research tells us will be required to put it into practice.

## ACKNOWLEDGMENTS

# CHAPTER 28

---

## Nature of Science: Past, Present, and Future

Norman G. Lederman

*Illinois Institute of Technology*

### CONCEPTUALIZING THE CONSTRUCT

The construct “nature of science” (NOS) has been advocated as an important goal for students studying science for approximately 100 years (Central Association of Science and Mathematics Teachers, 1907). Most recently, NOS has been advocated as a critical educational outcome by various science education reform documents worldwide (e.g., Australia, Canada, South Africa, United Kingdom, United States). To be blunt, when it comes to NOS, one is hard pressed to find rhetoric arguing against its importance as a prized educational outcome. Still, detractors do exist (Winchester, 1993). The observation that NOS has been a perennial goal of science education, and is now receiving increased emphasis, can be construed to mean that high school graduates, and the general citizenry, do not possess (and never have possessed) adequate views of NOS. The research reviewed later in this chapter provides clear support for such a notion. That said, has anything been lost? Is it really important for students and the general citizenry to understand NOS? What have we not accomplished because our students do not have good understandings of NOS? What can we make of the obsession with NOS?

At a general level, understanding NOS is often defended as being a critical component of scientific literacy (NSTA, 1982). This just begs the question of what it means to be scientifically literate. Perhaps the most concise way of answering the question of why understanding NOS is important is to consider the five arguments provided by Driver, Leach, Millar, and Scott (1996). Their arguments were as follows:

**Utilitarian:** Understanding NOS is necessary to make sense of science and manage the technological objects and processes in everyday life.

**Democratic:** Understanding NOS is necessary for informed decision-making on socioscientific issues.

**Cultural:** Understanding NOS is necessary to appreciate the value of science as part of contemporary culture.

**Moral:** Understanding NOS helps develop an understanding of the norms of the scientific community that embody moral commitments that are of general value to society.

**Science learning:** Understanding NOS facilitates the learning of science subject matter.

Certainly, these are all important and noble reasons for why science educators value NOS as an instructional outcome. However, at this point, the arguments are primarily intuitive, with little empirical support. Much like the general goal of scientific literacy, until we reach a critical mass of individuals who possess adequate understandings of NOS, we have no way of knowing whether achievement of the goal has accomplished what has been assumed. If we become generally more successful at teaching NOS to our students, will they become better decision-makers? Will their science achievement improve? My goal is not to contradict or cheapen my life's work. Rather, my goal is to emphasize that the jury is still out. Most important questions are still left to be answered, and there are most assuredly many questions that have yet to arise. Students' and teachers' understandings of NOS remain a high priority for science education and science education research. As mentioned before, it has been an objective in science education (American Association for the Advancement of Science [AAAS], 1990, 1993; Klopfer, 1969; National Research Council [NRC], 1996; National Science Teachers Association [NSTA], 1982) for almost 100 years (Central Association of Science and Mathematics Teachers, 1907; Kimball, 1967–68; Lederman, 1992). Indeed, "the longevity of this educational objective has been surpassed only by the longevity of students' inability to articulate the meaning of the phrase 'nature of science,' and to delineate the associated characteristics of science" (Lederman & Niess, 1997, p. 1).

## WHAT IS AND WHAT IS NOT NATURE OF SCIENCE

With all the support NOS has in the science education and scientific community, one would assume that all stakeholders possess adequate understandings of the construct. Even though explicit statements about the meaning of NOS are provided in well-known reform documents (e.g., NRC, 1996), the pages of refereed journals and the conference rooms at professional meetings are filled with definitions that run contrary to the consensus reached by the *National Science Education Standards* (1996) and other reform documents. Some would argue that the situation is direct support for the idea that there is *no* agreement on the meaning of NOS (Alters, 1997). More recently, Hipkins, Barker, and Bolstad (2005) have expressed concerns about the lack of consensus about NOS in New Zealand curricula. However, counterarguments by others (Smith, Lederman, Bell, McComas, & Clough, 1997; Smith & Scharmann, 1999) point out that more consensus exists than disagreement. Others (Lederman, 1998) are quick to note that the disagreements about the definition or meaning of NOS that continue to exist among philosophers, historians, and science educators are irrelevant to K–12 instruction. The issue of the existence of an objective reality as compared with phenomenal realities is a case in point. There is an acceptable level of generality regarding NOS that is accessible to K–12 students and

relevant to their daily lives that can be found in the writings of the aforementioned authors as well as the more recent comments of Elby and Hammer (2001) and Rudolph (2003). Moreover, at this level, little disagreement exists among philosophers, historians, and science educators. Among the characteristics of scientific knowledge corresponding to this level of generality are that scientific knowledge is tentative (subject to change), empirically based (based on and/or derived from observations of the natural world), and subjective (involves personal background, biases, and/or is theory-laden); necessarily involves human inference, imagination, and creativity (involves the invention of explanations); and is socially and culturally embedded. Two additional important aspects are the distinction between observations and inferences, and the functions of and relationships between scientific theories and laws.

Before attempting to review the research on NOS it is important to provide some general parameters for the meaning of the construct. What is NOS? It might help to back up to the proverbial question, What is science? The most common answer to this question in the literature is: 1) body of knowledge, 2) method, and 3) way of knowing. NOS typically refers to the epistemology of science, science as a way of knowing, or the values and beliefs inherent to scientific knowledge and its development (Lederman, 1992). What follows is a brief consideration of these characteristics of science and scientific knowledge related to what students should know. It is important to note that the aspects of NOS described below are not meant as a comprehensive listing. There are other aspects that some researchers include or delete (Osborne, Collins, Ratcliffe, Millar, & Duschl, 2003; Scharmann & Smith, 1999). And any of these lists that consider what students can learn, in addition to a consideration of the characteristics of scientific knowledge, are of equal validity. The primary purpose here is not to emphasize one listing versus another, but to provide a frame of reference that helps delineate NOS from scientific inquiry (and processes of science) and the resulting body of knowledge.

First students should understand the crucial distinction between observation and inference. Observations are descriptive statements about natural phenomena that are "directly" accessible to the senses (or extensions of the senses) and about which several observers can reach consensus with relative ease (e.g., descriptions of the morphology of the remnants of a once living organism). Inferences, on the other hand, go beyond the senses. For example, one may develop explanations about the observed morphology in terms of its possible contributions to function. At a higher level, a scientist can infer models or mechanisms that explain observations of complex phenomena (e.g., models of weather, evolution).

Second, closely related to the distinction between observations and inferences is the distinction between scientific laws and theories. Individuals often hold a simplistic, hierarchical view of the relationship between theories and laws whereby theories become laws, depending on the availability of supporting evidence. It follows from this notion that scientific laws have a higher status than scientific theories. Both notions, however, are inappropriate because, among other things, theories and laws are different kinds of knowledge, and one does not develop or become transformed into the other. Laws are *statements or descriptions of the relationships* among observable phenomena. Boyle's law, which relates the pressure of a gas to its volume at a constant temperature, is a case in point. Theories, by contrast, are *inferred explanations* for observable phenomena (e.g., kinetic molecular theory pro-

vides an explanation for what is observed and described by Boyle's law). Scientific models are common examples of theory and inference in science. Moreover, theories are as legitimate a product of science as laws. Scientists do not usually formulate theories in the hope that one day they will acquire the status of "law."

Third, even though scientific knowledge is, at least partially, based on and/or derived from observations of the natural world (i.e., empirical), it nevertheless involves human imagination and creativity. Science, contrary to common belief, is not a totally lifeless, rational, and orderly activity. Science involves the *invention* of explanations, and this requires a great deal of creativity by scientists. This aspect of science, coupled with its inferential nature, entails that scientific concepts, such as atoms, black holes, and species, are functional theoretical models rather than faithful copies of reality.

Fourth, scientific knowledge is subjective and/or theory-laden. Scientists' theoretical commitments, beliefs, previous knowledge, training, experiences, and expectations actually influence their work. All these background factors form a *mind-set* that *affects* the problems scientists investigate and how they conduct their investigations, what they observe (and do not observe), and how they make sense of, or interpret their observations. It is this (sometimes collective) individuality or mind-set that accounts for the role of subjectivity in the production of scientific knowledge. It is noteworthy that, contrary to common belief, science rarely starts with neutral observations (Chalmers, 1982). Observations (and investigations) are motivated and guided by, and acquire meaning in reference to, questions or problems. These questions or problems, in turn, are derived from within certain theoretical perspectives. Often, hypothesis or model testing serves as a guide to scientific investigations.

Fifth, science as a human enterprise is practiced in the context of a larger culture, and its practitioners (scientists) are the product of that culture. Science, it follows, affects and is affected by the various elements and intellectual spheres of the culture in which it is embedded. These elements include, but are not limited to, social fabric, power structures, politics, socioeconomic factors, philosophy, and religion. The practice of acupuncture, for example, was not accepted by western science until western science explanations for the success of acupuncture could be provided.

Sixth, it follows from the previous discussions that scientific knowledge is never absolute or certain. This knowledge, including "facts," theories, and laws, is tentative and subject to change. Scientific claims change as new evidence, made possible through advances in *theory* and technology, is brought to bear on existing theories or laws, or as old evidence is reinterpreted in the light of new theoretical advances or shifts in the directions of established research programs. The construct of punctuated equilibrium was developed through an interpretation of the fossil record from a different perspective. Rather than taking a Darwinian view of gradual change, the lack of transitional species, among other observations, led to a reinterpretation of classic evolutionary theory. It should be emphasized that tentativeness in science not only arises from the fact that scientific knowledge is inferential, creative, and socially and culturally embedded. There are also compelling logical arguments that lend credence to the notion of tentativeness in science. Some have taken issue with the use of the word "tentative" to describe scientific knowledge. Descriptors such as "revisionary" or "subject to change" are preferred by those who feel "tentative" implies that the knowledge is flimsy and not well founded. Whatever word is used,

the intended meaning is that the knowledge of science, no matter how much supported evidence exists, may change in the future for the reasons just discussed.

Finally, it is important to note that individuals often conflate NOS with science processes or scientific inquiry. Although these aspects of science overlap and interact in important ways, it is nonetheless important to distinguish between the two. Scientific processes are activities related to collecting and analyzing data, and drawing conclusions (AAAS, 1990, 1993; NRC, 1996). For example, observing and inferring are scientific processes. More complex than individual processes, scientific inquiry involves various science processes used in a cyclical manner. On the other hand, NOS refers to the epistemological underpinnings of the activities of science and the characteristics of the resulting knowledge. As such, realizing that observations are necessarily theory-laden and are constrained by our perceptual apparatus belongs within the realm of NOS. Distinguishing NOS from scientific inquiry for the purpose of providing focus to this chapter should in no way be construed to mean that NOS is considered more important for students to learn about. Certainly, both constructs are important and inquiry and NOS, although different, are intimately related. For this reason, a separate chapter in this Handbook is devoted to scientific inquiry (Chapter 27). Making a distinction between NOS and scientific inquiry was in no way meant to imply that the two constructs are distinct. Clearly, they are intimately related. Furthermore, there is much evidence that NOS is best taught within a context of scientific inquiry or activities that are reasonable facsimiles of inquiry. That is, inquiry experiences provide students with foundational experiences upon which to reflect about aspects of NOS.

The conflation of NOS and scientific inquiry has plagued research on NOS from the beginning and, perhaps, could have been avoided by using the phrase “nature of scientific knowledge” as apposed to NOS. However, the damage has already been done. Hence, the reader will note that many of the earlier studies (and even continuing to the present) are actually more focused on inquiry than NOS. These studies are nevertheless reviewed, rather than excluded, since they have become an accepted part of the history of research on NOS. The definition used by these studies for NOS is just not consistent with current usage of the construct. Again, the aspects of NOS presented here are not meant to be exhaustive. Other listings certainly exist. However, what has been presented is directly consistent with what current reform documents state students should know about NOS and is consistent with the perspective taken by an overwhelming majority of the research literature.

## THE CHANGING FACE OF NATURE OF SCIENCE

One of the most vexing issues for those who do research on the teaching and learning of NOS is that NOS can be a moving target. If one considers the differences among the works of Popper (1959), Kuhn (1962), Lakatos (1970), Feyerabend (1975), Laudan (1977), and Giere (1988), it becomes quite clear that perceptions of NOS are as tentative, if not more so, than scientific knowledge itself. In short, NOS is analogous to scientific knowledge. As a consequence, some individuals have dwelled too heavily on such differing perceptions (e.g., Alters, 1997). The recognition that our views of NOS have changed and will continue to change is not a justification for ceasing our research until total agreement is reached, or for avoiding recommenda-

tions or identifying what we think students should know. We have no difficulty including certain theories and laws within our science curricula, even though we recognize that these may change in the near or distant future. What is important is that students understand the evidence for current beliefs about natural phenomena, and the same is true with NOS. Students should know the evidence that has led to our current beliefs about NOS, and, just as with “traditional” subject matter, they should realize that perceptions may change as additional evidence is collected or the same evidence is viewed in a different way.

Regardless of the various “problems” associated with reaching consensus on the various aspects of nature of science, and issues created by the tentativeness of the construct itself, the nature of science has been the object of systematic educational research for approximately 50 years. Prior to this review, there were three reviews of research related to the teaching, learning, and assessment of the nature of science (Abd-El-Khalick & Lederman, 2000a; Lederman, 1992; Meichtry, 1992). In addition to revisiting the contents of previous reviews, this review builds on these prior works and, it is hoped, provides some guidance for future research in the field. For practical reasons, the research reviewed is restricted to published reports and to those studies with a primary focus on NOS. These studies have been divided into obvious thematic sections and are presented in a general chronological sequence within each section.

## RESEARCH ON STUDENTS’ CONCEPTIONS

Considering the longevity of objectives related to students’ conceptions of the nature of science, it is more than intriguing that the first formal instrument to assess students’ conceptions was developed about 50 years ago (Wilson, 1954). The development of instruments to assess NOS has a long history and is extensive enough to constitute separate treatment in this review. Although it can be argued that placing the discussion of assessment first would provide an important context for the review of the research, it can be equally argued that a discussion of the varied assessments would be too abstract without the context of the specific research investigations. Consequently, the review of NOS assessment has been placed at the end of the review. However, this should not impede those who wish to read the section on assessment first. In Wilson’s (1954) investigation, which was primarily an attempt to validate an instrument known as the Science Attitude Questionnaire, a sample of 43 Georgia high school students was found to believe that scientific knowledge is absolute and that scientists’ primary objective is to uncover natural laws and truths. The most extensive early attempt to assess students’ conceptions of the nature of science (Mead & Metraux, 1957) involved a nationwide sample of 35,000 student essays on the topic “What Do You Think About Science and Scientists?” Mead and Metraux drew a randomized sample that was representative with respect to age, gender, geographic distribution, and socioeconomic status. Their qualitative analysis of the data yielded findings that were consistent with Wilson’s (1954) findings on both attitude toward science and students’ understandings of the nature of science. It is interesting to note that the earliest studies related to the nature of science often included assessments of attitudes or conflated the nature of science with attitude toward science.

In 1961, Klopfer and Cooley developed the Test on Understanding Science (TOUS), which was to become the most widely used paper-and-pencil assessment

of students' conceptions. Using the TOUS and a comprehensive review of several nationwide surveys, Klopfer and Cooley concluded that high school students' understandings of the scientific enterprise and of scientists was inadequate. Miller (1963), also using the TOUS, found student conceptions that were considered totally inadequate. As research began to document that students possessed less than adequate views of nature of science, research in the field began to proliferate (National Science Teachers Association [NSTA], 1962). Early assessments of students' understandings were not limited to the United States. Mackay (1971) pre- and posttested 1,203 Australian secondary students spanning grades 7–10, using the TOUS instrument. He concluded that students lacked sufficient knowledge of (a) the role of creativity in science; (b) the function of scientific models; (c) the roles of theories and their relation to research; (d) the distinctions among hypotheses, laws, and theories; (e) the relationship between experimentation, models and theories, and absolute truth; (f) the fact that science is not solely concerned with the collection and classification of facts; (g) what constitutes a scientific explanation; and (h) the interrelationships among and the interdependence of the different branches of science. Similar findings resulted from the investigations of Korth (1969), Broadhurst (1970), and Aikenhead (1972, 1973).

Bady's (1979) work differed from early efforts in that he focused on a particular aspect of students' understanding of nature of science. Specifically, he investigated students' understandings of the logic of hypothesis testing. His sample included 20 9th-grade students and 20 11th-grade students from a large urban school, as well as 33 9th-grade and 41 12th-grade students from a small private boys' school. Using the Johnson-Laird and Wason (1972) task to assess subjects' understandings of hypothesis testing, he found that most students, regardless of school or grade level, believed that hypotheses can be adequately tested and proved by verification. He concluded that such students are likely to have a simplistic and naively absolutist view of the nature of scientific hypotheses and theories. Similarly, during the development of the Nature of Scientific Knowledge Scale, Rubba (Rubba, 1977; Rubba & Andersen, 1978) found that 30 percent of the high school students surveyed believed that scientific research reveals incontrovertible and necessary absolute truth. Additionally, most of Rubba's sample believed that scientific theories, with constant testing and confirmation, eventually mature into laws. With a sample of 102 high-ability 7th- and 8th-grade students, Rubba, Horner, and Smith (1981) attempted to assess students' adherence to the ideas that laws are mature theories and that laws represent absolute truth. The results indicated that the students, on the whole, tended to be "neutral" with respect to both of these ideas. The authors were particularly concerned about the results, because the sample consisted of students who were considered to be the most capable and interested in science.

During the past two decades a decreasing number of studies have limited themselves to the assessment of students' conceptions (Lederman, 1986a, 1986b; Lederman & O'Malley, 1990) at the secondary level and at the university level (Cotham & Smith, 1981; Gilbert, 1991), with no attempt to identify or test causal factors. However, a few notable studies are described here to illustrate the consistency of findings across the decades of research on students' understandings. Most recently, Kang, Scharmann, and Noh (2004) examined the views of 6th-, 8th-, and 10th-grade students in South Korea. With the use of a multiple-choice test, the views of 1702 students were assessed. Consistent with prior research, the South Korean students were found to have an empiricist/absolutist view of science. Zeidler, Walker, Ackett, and

Simmons (2002) investigated the relationships between students' conceptions of NOS and their reactions to evidence that challenged their beliefs about socioscientific issues. A total of 82 students from 9th- and 10th-grade general-science classes, 11th- and 12th-grade honors biology, physics classes and college-level preservice teachers comprised the sample. Although the authors did not clarify how many of the students in the sample adhered to the array of beliefs presented, it was clear that a significant number of students did not understand scientific knowledge to be tentative and partially subjective, and involve creativity. Although their primary purpose was to investigate relationships between NOS and students' handling of socioscientific issues, the understandings of NOS found are consistent with prior research. Overall, there were no clear differences in the understandings of students with respect to grade level.

In an interesting departure from the usual focus of assessments of students' views, Sutherland and Dennick (2002) investigated conceptions of NOS in students with clearly different worldviews. Historically, research on NOS has failed to consider the influence that world views may have on students' conceptions. The sample consisted of 72 7th-grade Cree students and 36 7th-grade Euro-Canadian students. Although all assessments were done in English, a significant portion of the Cree students spoke English as well as Cree at home. Data were collected with both quantitative (Nature of Scientific Knowledge Scale) and qualitative (interviews) techniques. Although the two groups differed on various aspects of NOS, both groups held views that are considered less than adequate with respect to the following aspects of NOS: tentativeness, creativity, parsimony, unified nature of knowledge, importance of empirical testing, and amoral nature of scientific knowledge. They also found that both language and culture affected students' views, in addition to those factors that affect western students' views. Certainly, the potential influence of worldviews, culture, and language may have on understandings of NOS is important in and of itself and is an area of much-needed research. However, the critical point here is that the findings in this study corroborate what has been found throughout the history of studies that simply aim to assess students' conceptions.

Obviously, all studies cannot be reviewed here, but doing so would simply confirm what the cited assessments of students' conceptions have indicated. As will be seen later, studies that have attempted to change students' views also document students' "starting points" as consistent with what has just been described.

Research on students' conceptions of science was a natural extension of the agreement among educators and scientists that promoting accurate students' understandings of NOS should be a primary objective of science education. The overwhelming conclusion that students did not possess adequate conceptions of the nature of science or scientific reasoning is considered particularly significant when one realizes that a wide variety of assessment instruments were used throughout the aforementioned research. Although evidence does exist that casts some doubt on the validity and reliability of some of the instruments used (Hukins, 1963), it is significant that all investigations yielded the same findings. A detailed analysis of these assessment instruments is included in a subsequent section of this review.

## RESEARCH ON TEACHERS' CONCEPTIONS

In general, researchers turned their attention to teaching the nature of science (which will be discussed in a later section) and teachers' conceptions as data emerged, in-

dicating that students did not possess what were considered adequate conceptions of NOS. The logic was simple: a teacher must possess an adequate knowledge of what he/she is attempting to communicate to students. Interestingly, however, the first assessment of teachers' conceptions (Anderson, 1950) was conducted prior to any assessment of students' conceptions. Fifty-six Minnesota high school teachers, including 58 biology teachers and 55 chemistry teachers, constituted the sample to be surveyed. Teachers were asked to answer a total of eight questions on scientific method, and it was revealed that both groups of teachers possessed serious misconceptions.

Behnke (1961) used a 50-statement questionnaire to assess the understandings of scientists and science teachers. Using a three-option response format (i.e., favoring, opposing, and neutral), the questionnaire attempted to assess four categories of information: (a) the nature of science, (b) science and society, (c) the scientist and society, and (d) the teaching of science. The teacher sample consisted of 400 biology teachers and 600 physical science teachers. The scientist sample was 300, but there was no differentiation based upon specific discipline. Although a number of differences were found between scientists and science teachers, only the data concerning the nature of science are relevant here. Over 50 percent of the science teachers felt that scientific findings were not tentative. Even more surprising was that 20 percent of the scientists felt the same way.

Miller's (1963) comparison of TOUS scores of secondary biology teachers and secondary students is one of the most often cited studies of teachers' conceptions of NOS. Five student groups consisted of prospective biology students, as well as those who had just completed a course in general biology. The student groups spanned grades 7–12. The 87 11th- and 12th-grade students were of high ability. Sixty-three 10th-grade biology students, 52 9th-grade, 328 8th-grade, and 205 7th-grade students constituted the remaining portion of the student sample. The sample of teachers consisted of 51 biology teachers from 20 Iowa high schools. Overall, a surprising percentage (ranging from 11 percent to 68 percent) of students in grades 9–12 scored higher on the TOUS than 25 percent of the science teachers. Of particular concern was the finding that 68 percent of the high-ability grade 11–12 students scored higher than 25 percent of the teachers. Although the students were considered as a group (and not specifically compared with their own teachers), Miller concluded that many teachers do not understand science as well as their students, much less understand science well enough to teach it effectively.

Replication studies are not common in science education, but Schmidt (1967) attempted to replicate Miller's findings several years later. A disconcerting proportion of students in grades 9 and 11–12 were found to score higher (14 percent and 47 percent, respectively) than 25 percent of the teacher sample. Schmidt concluded that the problem identified by Miller four years earlier still existed. A year later, Carey and Stauss (1968) attempted to determine whether 17 prospective secondary science teachers being prepared at the University of Georgia possessed a philosophy of science that exhibited an understanding of NOS. The Wisconsin Inventory of Science Processes (WISP) was used to assess NOS. In addition to attempting an initial assessment of the conceptions possessed by the preservice teachers, an attempt was made to investigate the effectiveness of a science methods course in improving such conceptions. Pretest scores on the WISP indicated that the science teachers, as a group, did not possess adequate conceptions of the nature of science. Correlations of WISP scores with academic variables such as high school science credits, college

science credits, specific science courses taken, grade-point average, and mathematics grades did not yield any significant relationships. Based on WISP posttest scores, it was concluded that a methods course "specifically oriented toward NOS" could significantly improve teachers' viewpoints.

Carey and Stauss (1970a) continued their line of research by now assessing experienced teachers' conceptions of NOS. Once again, they used the WISP exam. The results were consistent with their previous study: (a) teachers of science, in general, did not possess adequate conceptions of NOS; (b) science methods courses produce a significant pre- to posttest improvement of WISP scores; and (c) academic variables such as grade-point average, math credits, specific courses, and years of teaching experience are not significantly related to teachers' conceptions of science. They recommended that courses in the history and philosophy of science be included in teacher preparation programs.

Kimball (1968), using his own Nature of Science Scale (NOSS), compared understandings of NOS of scientists and science teachers. In no case were significant differences found between the groups. Kimball concluded that there is no difference in understandings of NOS held by scientists and by qualified science teachers when their academic backgrounds are similar. At the time, the results of Kimball's research were used to discredit public criticisms of teacher education programs as the cause of science teachers' poor understandings. Although research focused on teachers' conceptions of NOS (with no attempts to change such conceptions) proliferated during the period from 1950 to 1970, there have been several notable, more recent, assessments.

Beginning teachers' and preservice science teachers' views about scientific knowledge were described and compared by Koulaidis and Ogborn (1989). A 16-item, multiple-choice questionnaire was administered to 12 beginning science teachers and 11 preservice science teachers. The questionnaire items focused on scientific method, criteria for demarcation of science and nonscience, change in scientific knowledge, and the status of scientific knowledge. Based on their responses, the subjects were categorized into four predetermined categories of philosophical belief. The high frequency of individuals possessing eclectic views is consistent with previous research, which has indicated that teachers do not generally possess views that are consistently associated with a particular philosophical position. Overall, the authors concluded that although science teachers place value on scientific method, they see the procedures involved as contextually situated. King (1991) investigated beginning teachers' knowledge of the history and philosophy of science. Thirteen beginning students in Stanford's teacher-education program completed a questionnaire on the first day of their introductory course in curriculum and instruction in science. Eleven of the 13 were interviewed at the end of the course and after they had been student teaching for at least one week. Background information from the questionnaires indicated that only 3 of the 13 preservice teachers had taken formal courses in the history or philosophy of science. Additionally, evaluations of the introductory curriculum course (where the nature of science was discussed) indicated that most of the students felt it was more important to learn the nuts and bolts (e.g., lesson planning, evaluation, etc.) of teaching as opposed to the history and philosophy of science. Data from the interviews indicated that although most of the teachers felt that the history and philosophy of science were important, their lack of education in these areas left them lacking with respect to how such top-

ics could be integrated within instruction. The author concluded that the lack of science teachers' background in the history and philosophy of science clearly influences the teaching of science.

Using a case-study approach, Aguirre, Haggerty, and Linder (1990) assessed 74 preservice secondary science teachers' conceptions of NOS, teaching, and learning. Subjects were asked to respond to 11 open-ended questions about science, teaching of science, and learning of science. Qualitative analysis of the responses yielded the following general conclusions. Most individuals believed that science was either a body of knowledge consisting of a collection of observations and explanations or of propositions that have been proved to be correct. Subjects were evenly divided among the "dispenser of knowledge" and "guide/mediator of understanding" conceptions of science teaching. The authors concluded that these preservice teachers (even though they all possessed undergraduate science degrees) did not possess adequate conceptions of the nature of science. The authors further concluded that there could be some connection between teachers' views of NOS and their conceptions of learning and teaching (although observations of actual instruction were not attempted).

Research on teachers' conceptions of NOS is not limited in focus to secondary teachers. Bloom (1989) assessed preservice elementary teachers' understanding of science and how certain contextual variables contribute to this understanding. Using a sample of 80 preservice elementary teachers (86 percent female), enrolled in three methods courses, Bloom administered a questionnaire that contained six questions related to knowledge of science, theories, and evolution. Additionally, a 21-item rating scale pertaining to prior experiences with science, the nature of science, science teaching, and evolution/creationism was administered. A qualitative analysis of questionnaire responses revealed that the preservice teachers believed science is people centered, with its primary purpose being for the benefit of humankind. Much confusion concerning the meaning and role of scientific theories (e.g., theories are related to belief in one's own thoughts apart from empirical observation) was also noted. Of most significance was the finding that beliefs significantly affect preservice teachers' understandings of science. In this particular case, the anthropocentric nature of the subjects' beliefs significantly influenced their conceptualizations of science, the theory of evolution, and how one would teach evolution.

Finally, there have been some attempts to compare understandings of U.S. preservice teachers with those of other nations. Cobem (1989) used Kimball's Nature of Science Scale (NOSS) to compare the understandings of 21 U.S. preservice science teachers with 32 preservice Nigerian teachers. Two significant differences were noted between the groups. Nigerian preservice teachers were more inclined to view science as a way to produce useful technology. This result is consistent with the findings of Ogunniyi (1982) in his study of 53 preservice Nigerian science teachers. This viewpoint is different from that typically desired in the Western hemisphere, which distinguishes theoretical from applied science. However, an applied view regarding science should not be unexpected in a developing nation. (The author expressed an appropriate concern about the future rejection of science in such societies when it eventually fails to deliver solutions to emerging societal problems.) A second difference between the two samples was the Nigerians' view that scientists were nationalistic and secretive about their work.

At its beginning, research on NOS was fairly descriptive and served to establish that neither teachers nor students possessed what were considered adequate un-

understandings of NOS. Although such research makes no attempt to solve the problem, it did establish that a problem existed. Perhaps it is for this reason that virtually all of the research completed in recent years has made at least some attempt to either explain the impact of teachers' conceptions or effect change in students' and teachers' conceptions.

## TEACHING AND LEARNING OF NATURE OF SCIENCE (THE EARLY YEARS)

### Research on Students

Klopfer (Klopfer & Cooley, 1963) developed the first curriculum designed to improve students' conceptions of NOS. The curriculum was called "History of Science Cases for High Schools" (HOSC). The rationale for the curriculum was that the use of materials derived from the history of science would help to convey important ideas about science and scientists. A sample of 108 geographically representative science classes, including biology, chemistry, and physics (2,808 students), was used to assess the effectiveness of the HOSC curriculum as measured by the TOUS instrument. After a five-month treatment period, students receiving the HOSC curriculum exhibited significantly greater gains on the TOUS than the control groups. This result was consistent across disciplines. In addition, HOSC students showed significant gains on the TOUS subscales (i.e., the scientific enterprise, the scientist, and the methods and aims of science) as well as on the overall test. It was concluded that the HOSC instructional approach was an effective way to improve students' conceptions of NOS. The large sample size used in this investigation gave it much credibility, and it was followed by widespread curriculum development. Jones (1965) successfully "replicated" Klopfer and Cooley's results with a curriculum similar to HOSC and with a traditional physical science course at the college level. Crumb (1965) compared the Physical Science Study Curriculum (PSSC) with traditional high school physics with respect to gains on the TOUS exam. The PSSC program is a laboratory-centered, experimental approach to physics that is designed to emphasize process as opposed to simply science content. Using a sample of 1,275 students from 29 high schools, Crumb found that PSSC students showed greater gains on the TOUS than students exposed to the traditional physics curriculum.

In addition to the aforementioned research, several studies investigated the effectiveness of the 1960s curriculum projects. These curricula were supposedly designed, regardless of specific science discipline, to promote inquiry and process skills. The curricula were laboratory centered, as opposed to the long-lived tradition of lecture/demonstration (Ramsey & Howe, 1969). Yager and Wick (1966) investigated the effects of various curriculum emphases on students' understandings of NOS as measured by the TOUS. Three approaches were used, all of which revolved around the Biological Sciences Curriculum Study (BSCS) Blue Version. The textbook-laboratory approach (TL) utilized only the textbook and accompanying laboratory materials. The multi-referenced laboratory approach (MRL) utilized materials from the TL group as well as additional paperbacks, texts, references, and excerpts from original scientific works. The multi-referenced laboratory and ideas approach (MRLI) resembled the MRL group, but with the added dimension of attention

given to the historical development of the major concepts and principles in science. Experiments and their results were always viewed with respect to how they would have been viewed in various historical contexts. For all three groups an attempt was made to control the effect of teacher variation. The results indicated that the MRLI group exhibited the largest gains on the TOUS, with the MRL group placing second, and the TL group showing the smallest gains. Yager and Wick concluded that the MRL was superior to the more common TL approach. Increased emphasis on ideas and their development (MRLI group) was viewed as maximizing the effects of the MRL approach. The similarity of the MRLI approach, with its emphasis on historical development of ideas, to Klopfer and Cooley's (1963) HOSC program is obvious. Gennaro (1964) and Sorensen (1966) also found success with the MRL and MRLI approaches. Thus, it was accepted that a multi-referenced, laboratory-focused approach to the teaching of biology would produce increased student growth in understanding the nature of the scientific enterprise (Ramsey & Howe, 1969).

Aikenhead (1979) developed and field tested a curriculum titled "Science: A Way of Knowing." The primary goals of the curriculum were to have students develop (a) a realistic, nonmythical understanding of the nature, processes, and social aspects of science; (b) a variety of inquiry skills and a realistic feeling of personal competence in the areas of interpreting, responding to, and evaluating their scientific and technological society; and (c) insight into the interaction of science and technology and, in turn, into the interaction of these with other aspects of society. Using the Science Process Inventory (Welch, 1967) and the Test on the Social Aspects of Science (Korth, 1969), grade 11 and grade 12 students were found to make significant pre- to posttest gains on both instruments.

The findings related to the effectiveness of curriculum specifically designed to teach NOS effects were not all positive. Trent (1965) investigated the relative value of the PSSC course and traditional physics (as did Crumb, 1965). A sample consisting of 52 California high schools was used, and the TOUS exam was used to assess students' conceptions of science. Half of the students in the PSSC classes and half of those in traditional courses were not pretested on the TOUS, and the remaining students were. This methodological approach helped to ascertain the influence of any testing effect. No such effort was made in Crumb's (1965) study. At the end of the school year all students were given a posttest. When prior science understanding and student ability were statistically controlled, no differences were found between the students in the traditional and PSSC courses, as measured by the TOUS. Troxel (1968) compared "traditional" chemistry instruction with both CHEM Study and the Chemical Bond Approach (CBA). In theory, CHEM Study and CBA stress inquiry and are laboratory centered, which theoretically should promote better understandings NOS. However, when teacher background in terms of teaching within the discipline, experience in teaching the course, general philosophy, and student background relative to school size were held constant, no significant differences were found in students' conceptions of NOS.

Two other studies using the 1960s curricula were conducted with Israeli high school students. Jungwirth (1970) attempted to investigate the effectiveness of the BSCS Yellow Version, which was first introduced in Israel in 1964. A total of 693 10th-grade students (from 25 schools) comprised the sample. Scores on both the TOUS and the Processes of Science Test (Biological Sciences Curriculum Study [BSCS], 1962) were used to assess students' understandings of scientific knowledge.

Students were given pre- and posttests over the course of one academic year. No significant differences were found between those students studying BSCS biology and those in the comparison group. Thus, Jungwirth concluded, the curriculum was not any more effective with respect to the enhancement of students' conceptions of science. He concluded that pupil achievement in this area could best be enhanced through "redirected teacher effort and emphases." Tamir (1972) compared the relative levels of effectiveness of three curriculum projects with each other as well as with "traditional" instruction. Using the BSCS Yellow Version, CHEM Study, PSSC, and traditional instructional approaches, Tamir assessed changes in students' conceptions of the nature of science on the Science Process Inventory (Welch, 1967). A total of 3,500 students in grades 9–12 were randomly selected from the four types of Israeli high schools (i.e., city academic, cooperation settlement, agricultural, and occupational) so as to allow comparisons among the different school types. The results indicated no significant differences among students studying any of the curriculum projects and those following traditional courses of study. Comparisons among the four school types did not show any differences either. However, comparisons of the relative levels of effectiveness of curriculum projects showed that of the three, BSCS biology had significantly greater effects upon student conceptions of science than either CHEM Study or PSSC.

Durkee (1974) assessed the effectiveness of a special secondary science program, a six-week institute with content similar to that of PSSC. In short, this six-week summer institute was directly aimed at increasing students' scores on the TOUS exam. The sample consisted of 29 high-ability high school students. The students were given pre- and posttests on the TOUS, and the results did not indicate that the specially designed program significantly changed students' conceptions. More recently, Carey, Evans, Honda, Jay, and Unger (1989) assessed the effectiveness of a unit specifically designed to introduce the constructivist view of science on 7th-graders' epistemological views. Their instructional unit was designed to emphasize theory building and reflection on the theory-building process. All classes, in the three-week unit, were taught by the regular teacher, and each lesson was observed by one or two research assistants. Twenty-seven of the students were randomly selected to be interviewed prior to and after being exposed to the instructional unit. Interviews were selected, as opposed to existing instruments, so that assessments of students' understandings would not be limited by the inherent nature of the instrument format/design. The transcripts of the half-hour clinical interviews were qualitatively analyzed blindly with respect to whether the interview was conducted before or after instruction. In general, the pre-instruction interview indicated that most students thought scientists seek to discover facts about nature by making observations and trying things out. However, post-instruction interviews showed many students understood that inquiry is guided by particular ideas and questions and that experiments are tests of ideas. In short, the instructional unit appeared to have been at least partially successful in enabling students to differentiate ideas and experiments.

There was an implicit assumption that clearly guided research that focused solely on the development of curricula and/or instructional materials. It was assumed that student conceptions could be improved if a concerted effort was made in that direction. Certainly, few would deny the logic of this approach. Unfortunately, for the most part, the teacher's interpretation and enactment of the curricu-

lum were ignored. The following statement from two of the earliest investigators of the curriculum development movement (Klopfer & Cooley, 1963, p. 45) did little to establish the importance of the teacher: "The relative effectiveness of the History of Science Cases Instruction Method, in teaching TOUS-type understandings does *not* depend upon whether the teacher rates 'high' or 'low' in his initial understanding." The implication of this statement is clear. That is, a teacher could promote understandings of certain concepts without having an adequate understanding of the same concepts. Fortunately, others, such as Trent (1965), felt that the equivocal findings with respect to the effectiveness of NOS-oriented curricula could only mean that the instructional approach, style, rapport, and personality of the teacher are important variables in effective science teaching. After all, he reasoned, if the same curriculum is effective for one teacher and ineffective for another, and the variable of student ability is controlled, a significant factor must be the teacher.

### Research on Teachers

The rather equivocal results concerning the effectiveness of curricula designed to improve students' conceptions of NOS perhaps motivated other researchers to focus their attentions on the teacher as a significant variable, as opposed to the curriculum being used by the teacher. In the 1960s, the distinction between implementation and enactment of a curriculum had not taken hold in the science education community. Yager (1966) selected eight experienced teachers to use the same inquiry-oriented curriculum (BSCS Blue Version). All teachers utilized the same number of days of discussion, laboratories, examinations, and instructional materials. All extraneous variables were held constant, as nearly as possible, with the exception of teacher-student rapport. Students were pre- and posttested on the TOUS exam. An analysis of covariance indicated that differences in students' TOUS scores could not be completely explained by initial differences in mean TOUS scores for each class. It was concluded that there are significant differences in students' abilities to understand NOS when taught by different teachers. Further direct confirmation of the important influence of teachers upon students' conceptions came from Kleinman's (1965) study of teachers' questioning. When one considers the influence of the individual teacher on student learning, there are at least two directions that can be pursued. One would be to study what a teacher does that affects students' understandings of NOS. The other can be a focus on teachers' knowledge. Few would argue against the notion that a teacher must have an understanding of what he/she is expected to teach. Unfortunately, initially the latter was pursued in the research to the exclusion of attention to the former.

Carey and Stauss (1970b) had 35 prospective secondary science teachers and 221 prospective elementary teachers complete the WISP. Scores were correlated with background variables such as high school science courses, college science courses, college grade-point average, and science grade-point average. No relationship was found between either secondary or elementary teachers' conceptions of science, as measured by WISP, and any of the academic background variables. Thus, it was concluded that none of the academic variables investigated could be used to improve science teachers' conceptions of the nature of science. Gruber (1963) surveyed 314 participants of an NSF summer institute designed to improve teachers' understandings of NOS and found little success. During the validation of

the NOSS, Kimball (1968) noted that philosophy majors actually scored higher than either science teachers or professional scientists. He intuitively concluded that inclusion of a philosophy of science course as part of the undergraduate science major curriculum might improve the situation. Carey and Stauss (1968) had previously made such a recommendation. Welch and Walberg (1968) did find success in a summer institute designed for 162 physics teachers at four institute sites. The teachers at all four sites showed significant gains on both the TOUS and Science Process Inventory. No documentation of the specific activities at each of the various institutes was available. Thus, it was not possible to establish what goals and activities led to the differential gains in the understanding of the nature of science.

Lavach (1969) attempted to expand on the success that Klopfer and Cooley (1963) had documented with a historical approach. Twenty-six science teachers participated; 11 constituted the experimental group and 15 served as the control group. The experimental group received instruction in selected historical aspects of astronomy, mechanics, chemistry, heat, and electricity. Each three-hour class was divided into two hours of lecture/demonstration, followed by a one-hour laboratory in which an attempt was made to replicate or perform an experiment conducted by the scientist under discussion. The teachers in the control group did not receive lectures or laboratories presented from a historical perspective. All teachers were pre- and posttested on the TOUS. The teachers in the experimental group exhibited statistically significant gains in their understanding of NOS. Further analysis indicated that these gains were not related to overall teaching experience, subjects taught, undergraduate major, previous in-service participation, or length of teaching experience in the same subject.

Six years later Billeh and Hasan (1975) attempted to identify those factors that affect any increase in the understanding of nature of science by science teachers. Their sample consisted of 186 secondary science teachers in Jordan. The teachers were divided into four groups: biology, chemistry, physical science, and physics. A four-week course for the chemistry, physical science, and physics teachers consisted of lectures and demonstrations in methods of teaching science, laboratory investigations emphasizing a guided-discovery approach, enrichment activities to enhance understanding of specific science concepts, and 12 lectures specifically related to the nature of science. The biology group did not receive any formal instruction on the nature of science, thus establishing a reference group with which the other groups could be compared. The Nature of Science Test (NOST) was used to assess understanding of the nature of science. Those lectures that stressed the nature of science were not oriented toward the specific content of the NOST. Each group of teachers were administered pre- and posttests on the NOST, and an analysis of covariance showed significant increases in the mean scores of the chemistry, physical science, and physics groups. The biology group did not show a significant gain, a finding consistent with that of Carey and Stauss (1968). A second result was that there was no significant relationship between teachers' gain scores on NOST and their educational qualifications, a finding in agreement with previous research (Carey & Stauss, 1970a; Lavach, 1969). Additionally, teachers' gain scores were not significantly related to the subjects they taught. Finally, science teaching experience was not significantly related to NOST gain scores. The conclusion that teaching experience does not contribute to a teacher's understanding of NOS was also consistent with previous research (Carey & Stauss, 1970b; Kimball, 1968; Lavach, 1969).

Trembath (1972) assessed the influence of a "small" curriculum project on prospective elementary teachers' views of NOS. The curriculum project focused on participants' understandings of the ways in which hypotheses are developed and tested, the logical structure of theories and laws, and the ways in which theories and laws can be used to make different types of explanations. The program presented prospective teachers with a set of narratives. Each narrative put forth a certain situation and was divided into a set of "frames." Each frame required students to read several paragraphs and provide a short answer in the form of a hypothesis, prediction, or inference. Trembath (1972) seemed to have assumed that participants would develop adequate understandings of the targeted NOS aspects by simply "going through" the program activities. Trembath reported a statistically significant difference between the mean pretest and posttest score for the experimental group, but noted that this score only increased from 7.0 to 10.7 points out of 18 possible points.

Barufaldi, Bethel, and Lamb (1977) argued that "a major affective goal of science teacher education should be the enhancement of the philosophical viewpoint that science is a tentative enterprise and that scientific knowledge is not absolute" (p. 289). The study assessed the influence of elementary science methods courses on junior and senior elementary education majors' understandings of the tentativeness of science. The courses had no components that were specifically geared toward enhancing participants' views of the tentative NOS. Rather, consistent with the authors' view of NOS as an "affective" outcome, an implicit approach was used. Thus, Barufaldi et al. (1977) noted, in these courses: "Students were presented with numerous hands-on, activity-centered, inquiry-oriented science experiences . . . [and] . . . many problem-centered science activities . . . The uniqueness and the variety of the learning experiences in the courses provided the students with many opportunities to understand the tentativeness of scientific findings" (p. 291).

Barufaldi et al. (1977) thus concluded that a methods course that "stresses inquiry methods and procedures, emphasizing a hands-on approach integrated with individual problem solving, develops, alters, and enhances . . . preservice teachers' . . . philosophical view . . . toward the tentative nature of scientific knowledge" (p. 293). The authors, however, did not present enough evidence to support this rather sweeping generalization. Barufaldi et al. (1977) did not report the pretest mean VOST scores or the mean gain scores for the various groups. However, if we assume that the groups did not differ appreciably on their pretest VOST scores and that the control group mean score did not change appreciably from the pretest to the posttest, then the gains achieved can be assessed. The mean posttest VOST score for the control group was 141. The corresponding scores for the three treatment groups were 153, 149, and 148. As such, the approximate gains achieved were very small and ranged between 3.5 and 6 percentage points. It is difficult to conclude that the reported gains reflect a meaningful improvement in participants' understanding of the tentative nature of scientific knowledge.

Spears and Zollman (1977) assessed the influence of engagement in scientific inquiry on students' understandings of the process of science. Participants were randomly assigned to the four lecture sections and associated laboratory sections of a physics course. Data from only about 50 percent of the original sample were used in the final analysis. The authors, however, did not provide any data to indicate that the remaining participants were representative of the original population. Two

types of laboratory instructional strategies served as the treatments. The “structured” approach emphasized verification, whereas the “unstructured” approach stressed inquiry or discovery. Both approaches asked students to investigate problems related to physical principles discussed in the lectures and informed them about the available equipment. Beyond this point the two approaches differed in a major way. In the “structured” laboratory, students were provided with explicit procedures with which they attempted to verify the physical principles concerned. Students in the “unstructured” laboratory, however, were free to investigate the problem in whatever way they deemed appropriate. They made their own decisions regarding what data to collect, how to collect these data, how to treat the data, and how to interpret and present their results.

Data analyses controlled for participants’ major, years in college, and course lecture and laboratory grades, as well as the type of lecture presentation in each of the four sections. These analyses indicated that there were no statistically significant differences between the adjusted scores of the two groups on the Assumptions, Nature of Outcomes, and Ethics and Goals components of the SPI Form D (Welch & Pella, 1967–68).

Riley (1979) argued that teachers’ understandings of and attitudes toward science would improve as a result of first-hand, manipulative experiences and enhanced proficiency in the processes of science. Riley, like Barufaldi et al. (1977), explicitly labeled an understanding of NOS as an “affective” outcome and attempted to teach about NOS by involving teachers in “doing science.” The study investigated the influence of hands-on versus non-manipulative training in science process skills on, among other things, preservice elementary teachers’ understandings of NOS. The study had a  $3 \times 3$  factorial design, with the treatment and science grade point average as independent variables. The treatment had three levels: active-inquiry (hands-on), vicarious-inquiry (non-manipulative), and control. Participants were divided into three groups according to their grade-point average (high, medium, or low), and 30 students from each group were randomly selected and assigned to one of the three treatment levels. The four 1.5-hour-session treatment involved activities that focused on various science process skills, such as observing, classifying, inferring, predicting, communicating, measuring and the metric system, and using space/time relationships. The only difference between the aforementioned levels of treatment was student involvement. In the active-inquiry treatment, participants were trained in science process skills by a hands-on, manipulative approach. Participants in the vicarious-inquiry treatment group did not manipulate any materials. They were trained in science process skills by a demonstration approach where the instructor exclusively manipulated all materials. The control-group participants viewed science-related films for approximately the same amount of time. Data analyses indicated that there were no significant differences between the groups mean TOUS (Cooley & Klopfer, 1961) scores related to the treatments. As such, participants in the active-inquiry, vicarious inquiry, and control groups did not differ in their understandings of NOS.

Haukoos and Penick (1983) investigated the effects of classroom climate on community college students’ learning of science process skills and content achievement. The authors replicated their study two years later (Haukoos & Penick, 1985). They argued that gains in the development of students’ inquiry skills and science process skills might be related to aspects of the classroom environment, such as the

extent to which instruction is directive or non-directive. Implicit in this argument is the assumption that students learn about NOS implicitly through certain aspects related to the classroom environment. The studies featured two treatments: A Discovery Classroom Climate (DCC) treatment and a Non-discovery Classroom Climate (NDCC) treatment. In both studies, participants were enrolled in intact sections of an introductory biology course. Throughout the duration of the course, students in both groups received instruction on the same content. The only difference between the two treatments was the classroom climate that was determined by the extent to which the instructor used direct or indirect verbal behaviors. In the lecture/discussion sessions, students in the NDCC were presented with the content in a manner "that conveyed the impression that science was complete and final, and seldom did the students question it" (Haukoos & Penick, 1983, p. 631). With the DCC group, the instructor assumed a low profile, elicited student questions, and encouraged discussion of the lecture material. All student responses and interpretations were accepted and were not judged as right or wrong. In the laboratory portion of the course, students carried out the same experiments with the same materials. However, during laboratory sessions, students in the NDCC group were told exactly how to manipulate materials. Their results were either accepted or rejected by the instructor. Students in the DCC laboratory were alternatively encouraged to select and explore their own questions and to manipulate the available materials in whatever ways they deemed fit for answering their questions. The instructor kept explicit directions and judgments to a minimum. In this regard, the two laboratory environments were similar to the "structured" and "unstructured" or traditional and inquiry-based treatments that were employed by Spears and Zollman (1977). Data analyses in the first study (Haukoos & Penick, 1983) indicated that the DCC group had a significantly higher mean SPI score than the NDCC group. The reported difference was about eight percentage points. The authors concluded that the classroom climate influenced students' learning of science processes. However, Haukoos and Penick (1985) were not able to replicate these results. Analyses in the second study revealed no statistically significant differences, at any acceptable level, between the DCC and NDCC groups.

Akindihin (1988) argued that attempts to help science teachers develop adequate conceptions of NOS need to be *explicit*. The author assessed the influence of an instructional package, the *Introductory Science Teacher Education* (ISTE) package, on prospective secondary science teachers' conceptions of NOS. The package comprised nine units that included lectures, discussions, and laboratory sessions.

A statistically significant result was obtained for the experimental group. Out of 58 possible points on the NOSS, the grand mean score was 51.84. This mean score, it should be noted, was the highest reported NOSS score among the studies reviewed here. It should be noted, however, that the author did not report the mean pretest and posttest scores. As such, it was difficult to assess the practical significance of the gains achieved by the student teachers.

Scharmman (1990) aimed to assess the effects of a diversified instructional strategy (versus a traditional lecture approach) on freshmen college students' understandings of the nature of scientific theories, among other things. Participants were first given 30 minutes to individually respond in writing to four questions that asked about their feelings and beliefs concerning the evolution/creation controversy. Next, students were randomly assigned to discussion groups of three to five

students. They were asked to share their responses to the above questions and then respond to four new questions. These latter questions asked each group to provide reasons that would support teaching only evolution, teaching creation origins in addition to evolution, and teaching neither evolution nor creation origins in science classes. Students were also asked to decide whether, and explain why, one set of reasons was more compelling than another set. Ninety minutes were allocated for this phase of the treatment, during which the author did not interfere in the course of the discussions. For the next 30 minutes, spokespersons shared their groups' concerns, differences, and points of agreement with the whole class. Following a break, the author led a 90-minute interactive lecture/discussion that was intended to resolve any misconceptions that arose as a result of the group discussions and were evident in their presentations. Finally, during the last 30 minutes participants were given the opportunity to reflect on the discussion activity. Scharmann (1990) reported a significant difference between the pretest and posttest scores for both the experimental and control groups. Students in both groups achieved statistically significant gains in their understandings of NOS. Scharmann concluded that both classes provided students with opportunities to grow in their understandings of NOS, but that the diversified instructional strategy was superior in this respect. The author, however, did not provide any evidence to support this claim.

Scharmann and Harris (1992) assessed the influence of a three-week NSF-sponsored summer institute on, among other things, participants' understandings of NOS. The authors noted that "changes in an understanding of the nature of science can be . . . enhanced through a more indirect and applied context . . . and through a variety of readings and activities" that help participants to discuss their NOS views (p. 379). The NOSS (Kimball, 1967–68) was used to assess participants' understandings of the "philosophical" NOS, and an instrument developed by Johnson and Peebles (1987) was used to assess participants' "applied" understandings of NOS. The authors did not elucidate the distinction between "philosophical" and "applied" understandings of NOS. During the first two weeks of the institute, participants were presented with biological and geological content relevant to evolutionary theory. In addition, various instructional methods and teaching approaches, including lectures, small-group and peer discussions, field trips, and other inquiry-based approaches, were taught and modeled by the authors. The authors noted that the "theme" of promoting participants' conceptions of NOS pervaded all the aforementioned activities. However, no direct or explicit NOS instruction was used. Data analyses did not reveal significant differences between pretest and posttest mean NOSS scores. However, statistically significant differences were obtained in the case of the Johnson and Peebles (1987) instrument. The authors thus concluded that even though participants' conceptions of the "philosophical" NOS were not changed, their understandings of the "applied" NOS were significantly improved. Scharmann and Harris (1992), however, did not comment on the practical significance of the gain achieved by the participants. Out of 100 possible points for the latter instrument, the pretest and posttest mean scores were 61.74 and 63.26, respectively.

Shapiro (1996) reported on the changes in one prospective elementary teacher's thinking about the nature of investigation in science during her involvement in designing a study to answer a simple research question. This case study emerged from a larger research project that investigated the ways in which elementary student teachers' thinking and feelings about the nature of investigation in science

could be studied. The project was also intended to assess the changes in elementary student teachers' thinking and feelings about the nature of scientific investigation as a result of their involvement in independent investigations.

More than 210 elementary student teachers in four cohorts were involved in the study. During their science methods class, each cohort of student teachers worked on an assignment intended to help them develop an in-depth understanding of science and scientific procedures of investigation. Over the course of about seven weeks devoted to the assignment, student teachers were asked to pose a simple genuine problem, generate a research question, and then design a systematic procedure to answer their question. Throughout the assignment, student teachers kept journals of the various stages of their investigations. Twenty-one (out of the 38) fourth-cohort participants completed a repertory grid at the beginning of the science methods class and again after the conclusion of the investigation. Participants were interviewed following the second administration of the grid. The interviews focused on the changes that students made in their grids.

The repertory grid had two dimensions. The first comprised personal constructs and the second elements related to conducting scientific investigations. Ratings were given along a five-point scale between the opposite poles of each construct. Changes in student teachers' thinking about the nature of scientific investigations were assessed by comparing the grids completed prior to and after the independent investigations were conducted.

Shapiro (1996) only reported in detail on three "themes of change" that were evident in the case of one prospective elementary teacher. The first change theme was related to ideas about the nature of the steps and procedures of investigation in science. The teacher indicated that she often thought of doing science as being synonymous with following rules and checklists. After participating in the investigation, she came to appreciate the role of original thinking and imagination in devising ways to come up with answers to a research question. The second change theme was in the teacher's thinking about what science is. At the beginning of the methods class, Jan indicated that science is a body of information that has been tested and retested so that it now achieved the status of facts. After the completion of the investigation, the teacher came to view science more as a process of inquiry and less as a mere collection of facts. She also indicated that her experience helped her to appreciate the complexity of inquiring into everyday occurrences and the difficulty of drawing conclusions from the generated data. Finally, in the third identified change theme, there was a shift from an objectivist view of science to one that emphasized the role of researchers in creating new knowledge. Perhaps the most important features of the present study were its emphasis on reflection and its explicitness. Shapiro noted that students were often encouraged to reflect on their experiences. Moreover, the author emphasized the reflective nature of the interviews that allowed student teachers to have insights into changes in their thinking about science.

Looking at research investigations that attempted to change teachers' conceptions from an alternative perspective can be enlightening. Overall, these studies took one of two approaches. The first approach was advocated by science educators such as Gabel, Rubba, and Franz (1977), Haukoos and Penick (1983, 1985), Lawson (1982), and Rowe (1974). This approach is labeled the "implicit approach" for this review, as it suggests that an understanding of NOS is a learning outcome that can be facilitated through process skill instruction, science content coursework, and

“doing science.” Researchers who adopted this implicit approach utilized science process skills instruction and/or scientific inquiry activities (Barufaldi et al., 1977; Riley, 1979; Trembath, 1972) or manipulated certain aspects of the learning environment (Haukoos & Penick, 1983, 1985; Scharmann, 1990; Scharmann & Harris, 1992; Spears & Zollman, 1977) in their attempts to enhance teachers’ NOS conceptions. Researchers who adopted the second approach to enhancing teachers’ understandings of NOS (Akindehin, 1988; Billeh & Hasan, 1975; Carey & Stauss, 1968, 1970; Jones, 1969; Lavach, 1969; Ogguniyi, 1983) utilized elements from history and philosophy of science and/or instruction focused on various aspects of NOS to improve science teachers’ conceptions. This second approach is labeled the “explicit approach” for this review and was advanced by educators such as Billeh and Hasan (1975), Hodson (1985), Kimball (1967–68), Klopfer (1964), Lavach (1969), Robinson (1965), and Rutherford (1964).

### TEACHING AND LEARNING OF NATURE OF SCIENCE (CONTEMPORARY YEARS— A SHIFT IN PERSPECTIVE)

During the past 15 years, research on the teaching and learning of NOS has experienced a gradual but drastic change in perspective. This change in perspective has influenced how we attempt to change the conceptions of both teachers and students.

#### Research on Teachers

The results of the initial research on NOS (which are supported by more recent investigations) may be summarized as follows: (a) science teachers do not possess adequate conceptions of NOS, irrespective of the instrument used to assess understandings; (b) techniques to improve teachers’ conceptions have met with some success when they have included either historical aspects of scientific knowledge or direct, explicit attention to nature of science; and (c) academic background variables are not significantly related to teachers’ conceptions of nature of science. Two underlying assumptions appear to have permeated the research reviewed thus far. The first assumption has been that a teacher’s understanding of NOS affects his/her students’ conceptions. This assumption is clear in all the research that focused on improvement of teachers’ conceptions with no expressed need or attempt to do anything further. This rather intuitive assumption remained virtually untested, with the exception of two studies that only referred to the assumption in an ancillary manner. Unfortunately, both of these research efforts (Klopfer & Cooley, 1963; Rothman, 1969) contained significant methodological flaws. Klopfer and Cooley (1963) failed to properly monitor teachers’ conceptions of NOS throughout the investigation, whereas Rothman (1969) created a ceiling effect by sampling only high-ability students.

The second assumption underlying the research reviewed thus far is closely related to the first. If it is assumed that teachers’ conceptions of science affect students’ conceptions, some method of influence must exist; naturally the influence must be mediated by teacher behaviors and classroom ecology. In short, initial research concerned with teachers’ and students’ conceptions of NOS assumed that a

teacher's behavior and the classroom environment are necessarily and directly influenced by the teacher's conception of NOS. Although this assumption was explicitly stated by many, including Hurd (1969) and Robinson (1969), it remained an untested assumption into the early 1980s.

As can be seen from the research reviewed thus far, several decades of research on NOS focused on student and teacher characteristics or curriculum development to the exclusion of any direct focus on actual classroom practice and/or teacher behaviors. Although research designed to assess students' and teachers' conceptions continues to the present day, there is clearly less willingness to accept the assumptions that guided earlier research, and the focus is moving toward the realities of daily classroom practice.

The presumed relationships between teachers' conceptions of science and those of their students as well as that between teachers' conceptions and instructional behaviors were finally directly tested and demonstrated to be too simplistic, relative to the realities of the classroom, as a result of a series of investigations (Brickhouse, 1989, 1990; Duschl & Wright, 1989; Lederman, 1986a; Lederman & Druger, 1985; Lederman & Zeidler, 1987; Zeidler & Lederman, 1989). Using a case-study approach, Brickhouse investigated three secondary science teachers' views on the relationship between science and technology, the influence of such views on classroom practice (1989), and the relationship between the same teachers' conceptions of NOS and classroom practice (1990). Two of the three teachers (who were also the experienced teachers) exhibited classroom practices that were consistent with their personal views and philosophy, whereas the beginning teacher's classroom practices were not congruent with his beliefs. Duschl and Wright (1989) observed and interviewed 13 science teachers in a large urban high school. Their results convincingly indicated that the nature and role of scientific theories are not integral components in the constellation of influences affecting teachers' educational decisions. NOS was not being considered or taught to students as a consequence of perceived students' needs, curriculum guide objectives, and accountability.

Lederman and Zeidler's investigation (1987) involved a sample of 18 high school biology teachers from nine schools. The data clearly indicated that there was no significant relationship between teachers' understandings of NOS and classroom practice. Several variables have been shown to mediate and constrain the translation of teachers' NOS conceptions into practice. These variables include pressure to cover content (Abd-El-Khalick, Bell, & Lederman, 1998; Duschl & Wright, 1989; Hodson, 1993), classroom management and organizational principles (Hodson, 1993; Lantz & Kass, 1987; Lederman, 1995), concerns for student abilities and motivation (Abd-El-Khalick et al., 1998; Brickhouse & Bodner, 1992; Duschl & Wright, 1989; Lederman, 1995), institutional constraints (Brickhouse & Bodner, 1992), teaching experience (Brickhouse & Bodner, 1992; Lederman, 1995), discomfort with understandings of NOS, and the lack of resources and experiences for assessing understandings of NOS (Abd-El-Khalick et al., 1998).

Recently, Lederman (1999) attempted to finally put to rest (old habits die hard) the assumption that teachers' conceptions of NOS directly influenced classroom practice. In a multiple case study involving five high school biology teachers with varying experience, Lederman collected data on teachers' conceptions of NOS and classroom practice. All teachers were former students of the author and all possessed informed understandings of NOS. Over the course of a full academic year,

data were collected from questionnaires, structured and unstructured interviews, classroom observations, and instructional materials. Data were also collected on students' conceptions of NOS through questionnaires and interviews. The author was unable to find any clear relationship between teachers' conceptions and classroom practice. The two most experienced teachers (14 and 15 years of experience) did exhibit behaviors that seemed consistent with their views of NOS, but interview and lesson plan data revealed that these teachers were not attempting to teach NOS. Data from students in all teachers' classes indicated that none of the students had developed informed understandings of NOS. The results of the investigation indicated that, although the teachers possessed good understandings of NOS, classroom practice was not directly affected. Furthermore, the importance of teachers' intentions relative to students' understandings was highlighted. Even in the classrooms that exhibited some similarity with teachers' understandings, students did not learn NOS, because the teachers did not explicitly intend to teach NOS. Overall, the research was consistent with emerging findings about the relationship between teachers' understandings and classroom practice, as well as the research indicating the importance of explicit instructional attention to NOS. Although it is now clear that teachers' conceptions do not generally translate into classroom practice, concern about teachers' conceptions persists. As was previously mentioned, the past 15 years have been marked by a slow but definite shift in perspective related to how we go about changing teachers' conceptions of NOS. In short, there has been a shift to more explicit instructional approaches in research related to teachers' conceptions of NOS.

Hammrich (1997) used a conceptual change approach to influencing teacher candidates' conceptions of NOS. Students were asked to confront their own beliefs and the beliefs of classmates in cooperative group discussions. The rationale for the approach was that differences of opinions about NOS are inevitable among preservice teachers, and these individuals need opportunities to reflect on what they actually believe and/or know. Although the author claimed her approach to be successful, no documentation of specific understandings was provided, nor was the number of individuals involved mentioned. In addition, Hammrich was more interested in promoting change in students' views rather than having them change toward any particular views. Consequently, it is possible (although no data were provided) that some changes were in directions different from what reform documents have advocated.

In another study of preservice teachers' conceptions of NOS, Bell, Lederman, and Abd-El-Khalick (2000) looked at teachers' translation of knowledge into instructional planning and classroom practice. The subjects were 13 preservice teachers. The teachers' views of NOS were assessed with an open-ended questionnaire before and after student teaching. Throughout the student teaching experience, daily lesson plans, classroom videotapes, portfolios, and supervisors' clinical observation notes were analyzed for explicit instances of NOS in either planning or instruction. Following student teaching, all subjects were interviewed about their questionnaire responses and factors that influenced their teaching of NOS. Although all of the preservice teachers exhibited adequate understandings of NOS, they did not consistently integrate NOS into instruction in an explicit manner. NOS was not evident in these teachers' objectives, nor was any attempt made to assess students' understandings of NOS. The authors concluded that possessing an un-

derstanding of NOS is not automatically translated into a teacher's classroom practice. They further concluded that NOS must be planned for and included in instructional objectives, like any other subject matter content.

Akerson, Abd-El-Khalick, and Lederman (2000) were concerned solely with developing elementary teachers' understandings of NOS and not with the translation of this knowledge into classroom practice. The subjects were 25 undergraduate and 25 graduate preservice elementary teachers enrolled in two separate methods courses. Before and after the courses teachers' views about the empirical, tentative, subjective, creative, and social/cultural embeddedness of scientific knowledge were assessed. In addition, the preservice teachers' views on the distinction between observation/inference and between theories and laws were assessed. The courses explicitly addressed these aspects of NOS with a reflective, activity-based approach. The results indicated that explicit attention to NOS was an effective way to improve teachers' understandings of NOS. However, taken in the context of studies such as the previous one (Bell, Lederman, & Abd-El-Khalick, 2000), the authors were quick to point out that mere possession of adequate understandings will not automatically change classroom practice.

Abell, Martini, and George (2001) monitored the views of 11 elementary education majors during a science methods course. The particular context was a Moon investigation in which the authors targeted the following aspects of NOS: empirically based, involves invention and explanations, and is socially embedded. Students were asked to observe the Moon each night during the course and record their observations. An attempt was made by the instructors to be explicit as possible with respect to NOS. After the investigation, students realized that scientists make observations and generate patterns, but they did not realize that observations could precede or follow the development of a theory. Students were able to distinguish the processes of observing from creating explanations, but they could not discuss the role of invention in science. In various other instances, students were capable of articulating aspects of NOS, but were unable to see the connection between what they learned in the activity and the scientific community. The authors recognized the importance of being explicit in the teaching of NOS. They also recognized that their students' failure to apply what they learned beyond the learning activities themselves, to the scientific community in general, was a consequence of not making an explicit connection between what scientists do and the activities completed in class.

Abd-El-Khalick (2001) used an explicit, reflective approach to teach about NOS in a physics course designed for prospective elementary teachers at the American University of Beirut. Data were collected through pre- and posttests on open-ended surveys about NOS. The author reported significant improvement in the aspects of NOS providing focus for the investigation: tentative, empirically based, theory-laden, inferential, imaginative, and creative characteristics of scientific knowledge. In addition, the relationship between theory and law, and the distinction between observation and inference were investigated. The author definitely concluded that the explicit, reflective approach to instruction was successful. However, the conclusions were tempered by the author's concern that understandings of NOS are more easily applied to familiar contexts than to unfamiliar contexts within science.

The use of the history of science has long been advocated as a means to improve students' conceptions of science. Lin and Chen (2002) extended this logic to a program designed to improve preservice teachers' understanding of NOS. Sixty-three

prospective chemistry teachers in Taiwan were divided into experimental and control groups. The teachers in the experimental group were exposed to a series of historical cases followed by debates and discussions that highlighted how scientists developed knowledge. The historical cases were promoted as a way for these prospective teachers to teach science. Different from previous attempts to use the history of science to achieve outcomes related to NOS, the historical materials explicitly addressed NOS. The results clearly showed significant improvement in understandings of NOS by the experimental group relative to the control group. In particular, teachers in the experimental group showed significant improvement of their knowledge of creativity in science, the theory-bound nature of observations, and the functions of scientific theories. The authors claimed that helping teachers learn how to use the history of science in science instruction positively influenced the teachers' understandings of NOS.

Schwartz and Lederman (2002) looked at the improvement of two beginning teachers' understandings of the nature of science as well as their integration of such understandings into classroom practice. Two teachers were studied during their student teaching experience and throughout their first year of full-time teaching. These two teachers were part of a larger cohort, but the authors chose to focus more closely on these two teachers because of the differences in their subject matter knowledge. The results showed that the depth of NOS understanding, subject matter knowledge, and the perceived relationship between NOS and science subject matter affected the teachers' learning and teaching of NOS. The teacher with more extensive subject matter background, who also held a more well-developed understanding of NOS, was better able to address NOS throughout his teaching. This teacher's extensive subject matter background enabled him to address NOS throughout his teaching regardless of science topic. The teacher with less extensive subject matter knowledge was limited with respect to where she could integrate NOS. In addition, this teacher seemed more wedded to the examples of NOS integration provided in her preservice education program. This investigation illustrated for the first time that knowledge of subject matter was a mediating factor in the successful teaching of NOS. Prior to this study correlational studies on the relationship between NOS and subject matter knowledge showed little relationship. Of course, the relationship investigated here was with respect to the teaching of NOS.

Abd-El-Khalick and Akerson (2004) studied 28 preservice elementary teachers in a science methods course. In particular, they investigated the effectiveness of an explicit, reflective instructional approach related to NOS on these prospective teachers' views of various aspects of NOS. Data were collected from a combination of questionnaires, interviews, and reflection papers. As expected, participants initially held naïve views of NOS; however, over the course of the investigation substantial and favorable changes in the preservice teachers' views were evident.

Using a combination of authentic research experiences, seminars, and reflective journals, Schwartz, Lederman, and Crawford (2004) studied changes in secondary preservice teachers' conceptions of NOS. Prior research had indicated that providing teachers with authentic research experiences did not affect understandings of NOS. Consequently, the researchers supported such research experiences with explicit attention to NOS through seminars and a series of reflective journal assignments. The participants were 13 master of arts in teaching (MAT) students. Data

were collected via questionnaires and interviews. Most of the interns showed substantial changes in their views of NOS. Participants identified the reflective journal writing and seminars as having the greatest impact on their views, with the actual research internship just providing a context for reflection.

Abd-El-Khalick (2005) considered the perennial recommendation that teachers' should take courses in philosophy of science if we want to affect that knowledge of NOS. The sample was 56 undergraduate and graduate preservice secondary science teachers enrolled in a two-course sequence of science methods. Participants received explicit, reflective NOS instruction. Ten of the participants were also enrolled in a graduate philosophy of science course. The Views of Nature of Science—Form C (VNOS-C) was used to assess understandings of NOS at the beginning and end of the investigation. Participants were also interviewed about their written responses. Other data sources included lesson plans and NOS-specific reflection papers. Results indicated that the students who were enrolled in the philosophy of science course developed more in-depth understandings of NOS than those just enrolled in the science methods course. The author did not take the position that the philosophy of science course was more effective than the methods course for teaching NOS. Rather, the methods course, with explicit instruction about NOS, was seen as providing a framework that the 10 students enrolled in the philosophy of science course could use to significantly benefit from the philosophy course. In short, the methods course provided a lens with which learning of NOS could be maximized. Most recently, Scharmann, Smith, James, and Jensen (2005) used an explicit, reflective approach to teaching NOS within the context of a secondary teaching methods course. Nineteen preservice teachers were the subjects. Overall, the authors decided that the instructional approach was successful and supported the emerging literature on the value of an explicit approach to teaching NOS.

In addition to the typical studies investigating ways to change and improve teachers' conceptions of NOS, there is a slowly emerging attention to the rationales that have been used to justify the importance of teaching NOS to K–12 students. One justification for teaching NOS has been that an understanding of NOS will contribute to informed decisions on scientifically based societal and personal issues. Bell and Lederman (2003) tested this assumption, using a group of 21 highly educated individuals. These individuals were faculty members from various universities. Some were scientists and some were from areas outside of science. Individuals completed an open-ended questionnaire, followed by an interview, designed to assess decision-making on science and technology-related issues. A second questionnaire was used to assess participants' understandings of NOS, and an interview followed the completion of the questionnaire. Participants were separated into two groups based on the adequacy of their understanding of NOS. The two groups' decisions, decision-influencing factors, and decision-making strategies were compared. No differences were found between the two groups. Both groups used personal values, morals/ethics, and social concerns when making decisions, but NOS was not used. The authors concluded that decision-making is complex, and the data did not support the assumption that an understanding of NOS would contribute prominently to one's decisions. The authors also speculated that NOS may not have been considered because individuals need to have instruction on how NOS understandings could be used in aiding the decision-making process.

## Research on Students

It is safe to assume that teachers cannot possibly teach what they do not understand (Ball & McDiarmid, 1990; Shulman, 1987). Research on the translation of teachers' conceptions into classroom practice, however, indicates that even though teachers' conceptions of NOS can be thought of as a *necessary* condition, these conceptions, nevertheless, should not be considered *sufficient* (Lederman, 1992). At least one implication for research related to NOS is apparent. Research efforts, it is argued, should "extend well beyond teachers' understandings of nature of science, as the translation of these understandings into classroom practice is mediated by a complex set of situational variables" (Lederman, 1992, p. 351). Clearly, complex issues surround the possible influence of teachers' understandings of NOS on classroom practice and have yet to be resolved. It is safe to say, however, that there is general agreement among researchers concerning the strong influence of curriculum constraints, administrative policies, and teaching context on the translation of teachers' conceptions into classroom practice. Although there is a clear pattern in the research that compares teachers' conceptions with classroom practice, it is not uncommon to find a small minority of studies that continue to claim a direct relationship between teachers' conceptions and classroom practice (e.g., Kang & Wallace, 2005). In addition to investigations that assessed the relationship between teachers' conceptions and classroom practice, efforts to identify those factors that do influence students' conceptions have also been pursued.

In a comprehensive study of 18 high school biology teachers (Lederman, 1986a; Lederman & Druger, 1985), a set of 44 teacher behaviors and/or classroom climate variables was identified as being related to specific changes in students' understandings of NOS, as measured by the Nature of Scientific Knowledge Scale (Rubba & Andersen, 1978). In general, the classes of the most effective teachers were typified by frequent inquiry-oriented questioning, active participation by students in problem-solving activities, frequent teacher-student interactions, infrequent use of independent seat work, and little emphasis on rote memory/recall. With respect to classroom climate, classes of the more effective teachers were more supportive, pleasant, and "risk free," with students expected to think analytically about the subject matter presented. Although this investigation was correlational, the findings were supported by an experimental study conducted in junior college biology classes (Haukoos & Penick, 1983). A quasi-experimental design was used with two different instructional approaches (discovery-oriented and non-discovery-oriented) in general biology classes. Students in the discovery-oriented classes were found to make significant gains in the understanding of NOS as measured by the Science Process Inventory. The important point here is that the description of the discovery-oriented classes is consistent with the teaching approaches and classroom climate documented as "effective" in Lederman's correlational studies (Lederman, 1986a; Lederman & Druger, 1985). The significance of teacher-student interactions to conceptual changes in students' views of science motivated a follow-up study with 18 high school biology teachers and 409 students (Zeidler & Lederman, 1989). In this investigation, specific attention was focused on the nature of teacher-student interactions and the specific language used. In general, when teachers used "ordinary language" without qualification (e.g., discussing the structure of an atom without stressing that it is a model), students tended to adopt a realist conception of science.

Alternatively, when teachers were careful to use precise language with appropriate qualifications, students tended to adopt an instrumentalist conception. At the time, this investigation provided clear empirical support for Munby's thesis (1976) that implicit messages embedded in teachers' language provide for varied conceptions of NOS. Indeed, although the recent literature (past 10 years) predominantly indicates otherwise, some investigators (Craven, Hand, & Prain, 2002) still cling to the value of using implicit instruction for the teaching of NOS.

Inclusion of the history of science has often been touted as being a way to improve students' understandings of NOS. The value of history of science, however, has been held mostly as an intuitive assumption as opposed to being an idea having empirical support. Abd-El-Khalick and Lederman (2000b) assessed the influence of three history of science courses on college students' and preservice teachers' conceptions of NOS. The subjects were 166 undergraduate and graduate students and 15 preservice secondary science teachers at Oregon State University. All subjects were pre- and posttested with an open-ended questionnaire. A representative sample of students was also interviewed in an effort to establish face validity for the questionnaires. The results showed that most individuals entered the history of science courses with inadequate views of NOS, and there was little change after they completed the course. When change was noted, it was typically with respect to some explicit attention to NOS in one of the courses. In addition, there was some evidence that the preservice teachers learned more about NOS from the history of science courses than the other students. This was attributed to the possible benefits of having entered the course with a perceptual framework for NOS provided in their science methods course.

The use of "hands-on" activities has often been recommended as a way to improve students' understandings of NOS. Moss (2001) studied five volunteers from a class of 20 students. The volunteers were 11th- and 12th-grade students in a projects-based Conservation Biology class. Using a participant-observation approach, the author observed students, interviewed them six times during the academic year, and collected various artifacts of work. Over the course of the year, students' views did not change. They entered the course with adequate views on at least half of the eight tenet model of NOS used by the researcher, but little change was noted in any of the tenets. Although the author intuitively felt that students' views would change simply by exposure to a problem-based course, he did recognize that making NOS explicit was necessary. Several students made slight changes in response to implicit messages, which led to the conclusion that there is still a valuable place for implicit learning.

Liu and Lederman (2002) studied 29 gifted Taiwanese middle school students during a one-week summer science camp. The focus of the science instruction was scientific inquiry and NOS. A Chinese version of the Views of Nature of Science (VNOS) scale was developed to assess students in their native language. One question was added that was concerned with western medicine and eastern medicine to see if the students' cultural background influenced their views in any way. Instruction was provided in English, unless students clearly needed additional explanation. Liu presented all of the lessons. On the pretest, the students possessed good understandings of the tentative, subjective, empirical, and social/cultural embeddedness of science. Although all instruction was explicit, no changes were noted in students' understandings on the posttest. The authors explained the lack of change

in students' views as a possible consequence of a very short instructional period and a ceiling effect. After all, the authors argued, the students did fairly well on the pretest. No evidence was found to support the notion that cultural background may interact with students' understandings of NOS.

Few studies have studied the effectiveness of explicit, reflective approaches to teaching NOS relative to implicit approaches with K–12 students. One such study was completed by Khishfe and Abd-El-Khalick (2002) in Lebanon. A total of 62 6th-grade students in two intact groups ( $n = 29$  and  $32$ ) experienced inquiry-oriented instruction related to energy transformation and sedimentary rocks. One group was taught with an approach that explicitly addressed the tentative, empirical, inferential, imaginative, and creative aspects of scientific knowledge, whereas in the other class only implicit attention to NOS was included. The same teacher taught both classes. Students' knowledge of NOS was assessed through a combination of an open-ended questionnaire and semistructured interviews. The two groups entered the investigation with naïve, and equivalent, views on the various aspects of NOS. After instruction, the implicit group showed no changes in views of NOS, whereas students in the explicit group all exhibited improvement in their understandings of one or more aspects of NOS. Again, this particular study is important in that it demonstrated the relative effectiveness of explicit instructional approaches with a sample of K–12 students as opposed to preservice and inservice teachers.

Tao (2003) initially was interested in eliciting secondary students' understandings of NOS through a combination of peer collaboration and the use of science stories designed to illustrate aspects of NOS. The investigation showed that many students held empiricist views about scientific investigations and believed scientific theories to be absolute truths about reality. The author noticed that students' views were affected by group discussion about the stories. Instead of developing more informed understandings about NOS, however, the author noted that students moved from one inadequate view to another. In short, Tao felt that students simply looked for aspects of NOS that confirmed their views in the stories and ignored those aspects that ran contrary to their views.

Dhingra (2003) recognized that students learn about NOS through many sources, not just classroom instruction. The sample consisted of 63 female students from two single-sex high schools in New York City. Data were collected in response to a variety of television shows. The primary finding relative to NOS was that students reacted differently to shows that presented science as a collection of facts and those that presented science as more uncertain. Students had virtually no questions or comments about the science in shows that presented final-form science, but had numerous comments and questions in response to shows that presented science otherwise. A critical point here is that the television shows' depictions of science were explicit, and this explicitness appears to have had an impact on student learning.

Science apprenticeship programs have been a popular approach to engaging high-ability students in science, with an eye to promoting their interest in future careers in science. A commonly stated goal of such apprenticeship programs is that students will develop improved conceptions of NOS. Bell, Blair, Crawford, and Lederman (2003) systematically tested this assumed benefit of an apprenticeship program. The apprenticeship program was eight weeks long during the summer. Ten high-ability high school students (juniors and seniors) were pre- and posttested on their understandings of NOS and scientific inquiry before and after the apprentice-

ship. Both students and their mentor scientists were interviewed after the program. Although the scientists were of the opinion that their students had learned a lot about inquiry and NOS, student data (from interviews and questionnaires) indicated that changes occurred only in students' abilities to do inquiry. Of importance here is that students' conceptions of NOS on the pretest were not consistent with current reform efforts and, after the apprenticeship, with only one exception, remained the same. The authors ultimately concluded that students' conceptions of NOS (and knowledge about inquiry) remained unchanged because there was no explicit instruction about either associated with the apprenticeship. At least in practice, it appears to have been assumed that students would learn about NOS and inquiry simply by doing inquiry. As can be expected, not all studies involving explicit instruction related to NOS have met with success (Leach, Hind, & Ryder, 2003). In this particular investigation, the explicit instructional approach was not effective in promoting improved student views.

Among the volumes of research that focus on effecting change in conceptions of NOS, a small minority of studies focus on the impact that one's conceptions of NOS has on other variables of interest. Sadler, Chambers, and Zeidler (2004) focused on how students' conceptions of NOS affected how they interpreted and evaluated conflicting evidence on a socioscientific issue. Eighty-four high school students were asked to read contradictory reports related to global warming. A subsample of 30 students was interviewed in order to corroborate their written responses. The participants displayed a range of views on three aspects of NOS: empiricism, tentativeness, and social embeddedness. The authors claimed that how the students reacted to conflicting evidence was at least partially related to their views on NOS. This finding would appear to support the claim that an understanding of NOS is important because it contributes to an individual's decision-making.

## ASSESSING CONCEPTIONS OF NATURE OF SCIENCE

The development and assessment of students' and teachers' conceptions of nature of science have been concerns of science educators for over 40 years and, arguably, constitute a line of research in their own right. Although there have been numerous criticisms of the validity of various assessment instruments over the years, students' and teachers' understandings have consistently been found lacking. This consistent finding, regardless of assessment approach, supports the notion that student and teacher understandings are not at the desired levels. It is important to note, however, that during the early development of assessment instruments there was more of a focus on what we would currently describe as scientific inquiry as opposed to nature of science.

The history of the assessment of nature of science mirrors the changes that have occurred in both psychometrics and educational research design over the past few decades. The first formal assessments, beginning in the early 1960s, emphasized quantitative approaches, as was characteristic of the overwhelming majority of science education research investigations. Prior to the mid-1980s, with few exceptions, researchers were content to develop instruments that allowed for easily "graded" and quantified measures of individuals' understandings. In some cases, standard-

ized scores were derived. Within the context of the development of various instruments, some open-ended questioning was involved in the construction and validation of items. More recently, emphasis has been placed on providing an expanded view of an individual's beliefs regarding the nature of science. In short, in an attempt to gain more in-depth understandings of students' and teachers' thinking, educational researchers have resorted to the use of more open-ended probes and interviews. The same has been true with the more contemporary approaches to assessment related to the nature of science.

A critical evaluation of assessment instruments has recently been provided elsewhere (Lederman, Wade, & Bell, 1998). Therefore, the purpose here is to summarize the various instruments and identify trends in the assessment of NOS. Table 28.1 presents a comprehensive list of the more formal instruments constructed and validated to assess various aspects of NOS. Most of the instruments address only cer-

**TABLE 28.1**  
**Nature of Science Instruments**

<i>Date</i>	<i>Instrument</i>	<i>Author(s)</i>
1954	Science Attitude Questionnaire	Wilson
1958	Facts About Science Test (FAST)	Stice
1959	Science Attitude Scale	Allen
1961	Test on Understanding Science (TOUS)	Cooley & Klopfer
1962	Processes of Science Test	BSCS
1966	Inventory of Science Attitudes, Interests, and Appreciations	Swan
1967	Science Process Inventory (SPI)	Welch
1967	Wisconsin Inventory of Science Processess (WISP)	Scientific Literacy Research Center
1968	Science Support Scale	Schwirian
1968	Nature of Science Scale (NOSS)	Kimball
1969	Test on the Social Aspects of Science (TSAS)	Korth
1970	Science Attitude Inventory (SAI)	Moore & Sutman
1974	Science Inventory (SI)	Hungerford &Walding
1975	Nature of Science Test (NOST)	Billeh & Hasan
1975	Views of Science Test (VOST)	Hillis
1976	Nature of Scientific Knowledge Scale (NSKS)	Rubba
1978	Test of Science-Related Attitudes (TOSRA)	Fraser
1980	Test of Enquiry Skills (TOES)	Fraser
1981	Conception of Scientific Theories Test (COST)	Cotham & Smith
1982	Language of Science (LOS)	Ogunniyi

1995	Critical Incidents	Nott & Wellington
1998	Views of Nature of Science B (VNOS-B)	Abd-El-Khalick, Bell, & Lederman
2000	Views of Nature of Science C (VNOS-C)	Abd-El-Khalick & Lederman
2002	Views of Nature of Science D (VNOS-D)	Lederman & Khishfe
2004	Views of Nature of Science E (VNOS-E)	Lederman & Ko

tain aspects of NOS and often inappropriately confuse the issue by addressing areas other than NOS, including science process skills and attitudes toward science. Instruments considered to have poor validity have the following characteristics:

1. Most items concentrate on a student's ability and skill to engage in the process of science (e.g., to make a judgment and/or interpretation concerning data).
2. Emphasis is on the affective domain (the realm of values and feelings) rather than knowledge (i.e., over 50 percent of items deal with attitude toward or appreciation of science and scientists).
3. Primary emphasis is placed upon science as an institution, with little or no emphasis placed upon the epistemological characteristics of the development of scientific knowledge.

As mentioned before, the validity of many of these instruments is questionable because their primary focus is on areas beyond the scope of the nature of science. Those instruments with questionable validity (as measures of NOS) include the Science Attitude Questionnaire (Wilson, 1954), Facts About Science Test (Stice, 1958), Science Attitude Scale (Allen, 1959), Processes of Science Test (BSCS, 1962), Inventory of Science Attitudes, Interests, and Appreciations (Swan, 1966), Science Support Scale (Schwirian, 1968), Test on the Social Aspects of Science (Korth, 1969), Science Attitude Inventory (Moore & Sutman, 1970), Science Inventory (Hungerford & Walding, 1974), Test of Science-Related Attitudes (Fraser, 1978), the Test of Enquiry Skills (Fraser, 1980), and the Language of Science (Ogunniyi, 1982).

The remaining instruments have generally been considered to be valid and reliable measures of NOS by virtue of their focus on one or more ideas that have been traditionally considered under the label of "nature of science," as well as their reported validity and reliability data. These instruments have been used in numerous studies, and even the more traditional instruments (e.g., TOUS) continue to be used, even though there is a significant movement away from such types of paper-and-pencil assessments. The validity of some of the assessment instruments listed and briefly described below has been severely criticized (and justifiably so) in the past few years. However, they are presented here as being the most valid (in terms of assessment focus) attempts to assess understandings of NOS using a written response format. Following is a brief discussion of each instrument.

*Test on Understanding Science (TOUS)* (Cooley & Klopfer, 1961). This instrument has been, by far, the most widely used assessment tool in NOS research. It is a four-alternative, 60-item multiple-choice test. In addition to an "overall" or "general" score, three subscale scores can be calculated: (I) understanding about the scientific enterprise; (II) the scientist; (III) the methods and aims of science. During the past few decades, the content of the *TOUS* has been criticized and has fallen into disfavor (Aikenhead, 1973; Hukins, 1963; Welch, 1969; Wheeler, 1968).

*Wisconsin Inventory of Science Processes (WISP)* (Scientific Literacy Research Center, 1967). The *WISP* consists of 93 statements that the respondent evaluates as "accurate," "inaccurate," or "not understood." However, in scoring the exam, "inaccurate" and "not understood" responses are combined to represent the opposite of "accurate." With the exception of the *TOUS* exam, this instrument has been used more than any other assessment instrument. The *WISP* was developed and vali-

dated for high school students. Although this instrument has excellent validity and reliability data, a few concerns should be considered prior to its use. Of primary concern is its length. The 93-item test takes over an hour to administer, which precludes it from use in a single class period. In addition, this instrument does not possess discrete subscales, which means, unfortunately, that only unitary scores can be calculated.

*Science Process Inventory (SPI)* (Welch, 1967). This instrument is a 135-item forced-choice inventory (agree/disagree) purporting to assess an understanding of the methods and processes by which scientific knowledge evolves. The content of the SPI is almost identical to that of WISP and TOUS subscale III. The validation of SPI was achieved in the usual manner for such instruments: literature review, devising a model, employing the judgment of "experts," getting feedback from pilot studies, and testing the instrument's ability to distinguish among different groups of respondents. The length (135 items) is a concern, as is its forced choice format. Students are unable to express "neutral" or uncertain answers. Finally, like the WISP, the SPI does not possess subscales.

*Nature of Science Scale (NOSS)* (Kimball, 1968). This instrument was developed to determine whether science teachers have the same view of science as scientists. It consists of 29 items, which the respondent may answer with "agree" or "disagree" or register a "neutral" response. Kimball's model of NOS is based upon the literature of the nature and philosophy of science and is consistent with the views of Bronowski (1956) and Conant (1951). The specific content of NOSS was validated by nine science educators, who judged whether the items were related to the model. The development, validation, and reliability measures were carried out with college graduates. Thus, it lacks reliability and validity data with respect to high school populations. Another concern is that the instrument lacks subscales and is, therefore, subject to the same criticism as WISP or any other unitary measure of the nature of science.

*Nature of Science Test (NOST)* (Billeh & Hasan, 1975). This instrument consists of 60 multiple-choice items addressing the following components of NOS: Assumptions of science (8 items), Products of science (22 items), Processes of science (25 items), and Ethics of science (5 items). The test consists of two types of items. The first type measures the individual's knowledge of the assumptions and processes of science, and the characteristics of scientific knowledge. The second type of question presents situations that require the individual to make judgments in view of his/her understanding of the nature of science. The major shortcoming of this instrument is not its content, but rather, that no subscales exist. Thus, only a global or unitary score can be calculated.

*Views of Science Test (VOST)* (Hillis, 1975). This instrument was developed specifically to measure understanding of the tentativeness of science. It consists of 40 statements that are judged to imply that scientific knowledge is tentative or absolute. Respondents express their agreement with either view, using a five-option Likert scale response format. The instrument is considered too focused by some because it is restricted to a single attribute of scientific knowledge.

*Nature of Scientific Knowledge Scale (NSKS)* (Rubba, 1976). This instrument is a 48-item Likert scale response format consisting of five choices (*strongly agree, agree, neutral, disagree, strongly disagree*). The test is purported to be an objective measure of secondary students' understanding of NOS. The NSKS and its subscales are

based upon the nine factors of NOS specified by Showalter (1974). Rubba (1977) listed these nine factors as tentative, public, replicable, probabilistic, humanistic, historic, unique, holistic, and empirical. He noted a certain amount of shared overlap between the factors and proceeded to collapse them into a six-factor or six-subscale model of the nature of science. These six factors are: amoral, creative, developmental (tentative), parsimonious, testable, and unified. The instrument was developed, validated, and found to be reliable for high school-level students. The five-option Likert scale response format affords maximum freedom of expression to the respondent. The NSKS has generally been viewed positively by the research community; however, there is reason for some concern about its face validity. Many pairs of items within specific subscales are identical, except that one item is worded negatively. This redundancy could encourage respondents to refer back to their answers on previous, similarly worded items. This cross-checking would result in inflated reliability estimates, which could cause erroneous acceptance of the instrument's validity.

*Conceptions of Scientific Theories Test (COST)* (Cotham & Smith, 1981). The structure of this instrument was dictated by the developers' concern that previously existing instruments were based on single (supposedly enlightened) interpretations of NOS. Thus, the COST supposedly provides for nonjudgmental acceptance of alternative conceptions of science. The instrument is an attitude inventory consisting of 40 Likert scale items (with four options) and four subscales, each corresponding to a particular aspect of scientific theories. These include (I) ontological implications of theories; (II) testing of theories; (III) generation of theories; and (IV) choice among competing theories. The COST provides a theoretical context for four item-sets by prefacing each set with a brief description of a scientific theory and some episodes drawn from its history. The items following each theory description refer to that description. The four theoretical contexts are 1) Bohr's theory of the atom, 2) Darwin's theory of evolution, 3) Oparin's theory of abiogenesis, and 4) the theory of plate tectonics. A fifth context contains items that refer to general characteristics of scientific theories and is, therefore, not prefaced by a description. Two concerns must be addressed prior to the use of COST as an instrument to assess high school students' understandings of the nature of science. The first of these is the cognitive level of the instrument. It was designed for teachers and validated with undergraduate college students. The four theory descriptions used to provide context for the items are presented at a level that may be above the capabilities of many high school students.

A second concern with the COST instrument rests with the authors' claim that it, as opposed to all extant instruments, is sensitive to alternative conceptions of science. Cotham and Smith feel that it is extremely important for education to promote the view that scientific knowledge is tentative and revisionary. In their commitment to this concern, however, they actually specify which subscale viewpoints are consistent with the tentative and revisionary conception. Thus, although they claim to place no value judgments upon the various conceptions of science, Cotham and Smith actually do just that by linking certain viewpoints to the "highly prized" tentative and revisionary conception of scientific knowledge.

*Views on Science-Technology-Society (VOSTS)* (Aikenhead, Fleming, & Ryan 1989). The VOSTS was developed to assess students' understanding of the nature of science, technology, and their interactions with society. It consists of a "pool" of 114 multiple-

choice items that address a number of science-technology-society (STS) issues. These issues include Science and Technology, Influence of Society on Science/Technology, Influence of Science/Technology on Society, Influence of School Science on Society, Characteristics of Scientists, Social Construction of Scientific Knowledge, Social Construction of Technology, and Nature of Scientific Knowledge. The VOSTS was developed and validated for grade 11 and 12 students. A fundamental assumption underlying the development of this instrument was that students and researchers do not necessarily perceive the meanings of a particular concept in the same way. Aikenhead and Ryan (1992) recognized the importance of providing students with alternative viewpoints based upon student "self-generated" responses to avoid the "constructed" responses offered by most of the previous nature of science assessment instruments. Unlike most other instruments, the VOSTS does not provide numerical scores; instead it provides a series of alternative "student position" statements. These statements were obtained from extensive open-ended student "argumentative" paragraphs in which students defended their stated position on a STS issue or topic. The extensive work developing and validating the VOSTS instrument took approximately six years to complete and is reported in a series of research articles published in a special edition of the journal *Science Education* (Volume 71, 1987).

*Views of Nature of Science, Form A (VNOS-A)* (Lederman & O'Malley, 1990). In an attempt to ameliorate some of the problems noted by Aikenhead et al. (1987) during the development of the VOSTS and those noted in the use of the NSKS (Rubba, 1976) relative to the use of paper-and-pencil assessments, Lederman and O'Malley developed an open-ended survey consisting of seven items. This instrument was designed to be used in conjunction with follow-up interviews, and each of the seven items focuses on different aspects of tentativeness in science. Several problems were noted in the wording of some of the questions resulting in responses that did not necessarily provide information on students' views of "tentativeness." While these difficulties were alleviated by subsequent interviews, they served to reinforce the problems associated with attempting to interpret students' understandings solely from their written responses to researcher-generated questions.

*Modified Nature of Scientific Knowledge Scale (M-NSKS)* (Meichtry, 1992). This instrument is a modified NSKS instrument with 32 statements from four of the NSKS subscales. These subscales are: (I) creative, (II) developmental, (III) testable, and (IV) unified. M-NSKS was developed, with reliability and validity reported, for use with 6th-, 7th-, and 8th-graders.

*Critical Incidents* (Nott & Wellington, 1995). The use of "critical incidents" to assess teachers' conceptions of NOS was a significant departure from the usual paper-and-pencil assessment. In particular, Nott and Wellington are of the opinion that teachers do not effectively convey what they know about the nature of science in "direct response to abstract, context-free questions of the sort, 'What is science?'" (Nott & Wellington, 1995). Instead, they created a series of "critical incidents" that are descriptions/scenarios of actual classroom events. Teachers are expected to respond to the incidents by answering the following three questions: 1) What would you do? 2) What could you do? and 3) What should you do? So, for example, the teacher may be confronted with a situation in which a demonstration or laboratory activity does not yield the desired data. How the teacher responds to the aforementioned questions is believed to communicate what the teacher believes about NOS.

Although the use of critical incidents appears to be an excellent instructional tool to generate meaningful discussions in preservice and inservice courses, whether the teachers' responses are related to their views about NOS is still questionable. In short, the approach is based on the assumption that teachers' views of the nature of science automatically and necessarily influence classroom practice, an assumption that is simply not supported by the existing literature.

*Views of Nature of Science B,C,D (VNOS B,C,D,E).* This series or buffet of instruments has stemmed from the same research group and was meant to offer variations and improvements upon the original VNOS-A (Lederman & O'Malley, 1990). In particular, each instrument contains open-ended questions that focus on various aspects of NOS, with the differences being either the additional context-specific questions in forms B and C, or the developmental appropriateness and language of VNOS-D. From a practical standpoint, VNOS-B and VNOS-C are too lengthy to be administered easily during a regular class period. Teachers often take as long as 1.5 hours to complete VNOS-C. Consequently, VNOS-D and VNOS-E were created with the aid of focus groups of secondary ( $n = 10$ ) and elementary ( $n = 10$ ) teachers and their students. The resulting instruments are easily administered in less than one hour and yield the same results as the longer VNOS-B and VNOS-C. VNOS-E is the most recently developed instrument, and it has been designed for very young students (grades K–3). The items can also be used with students who cannot read or write (using a focus group format), and it represents the first measure of NOS designed for such a young audience. The particular authors credited for the development of each instrument are noted in the table of NOS instruments. A thorough description of the development of the VNOS A, B, and C instruments can be found in Lederman, Abd-El-Khalick, Bell, and Schwartz (2002).

## SOME THOUGHTS ABOUT ASSESSING NOS

The validity of instruments purporting to assess NOS has long been criticized on the grounds that each instrument assumes its interpretation of science to be the correct view (Cotham & Smith, 1981). This criticism is derived from the often discussed lack of consensus concerning NOS among scholars from various fields. As previously discussed, however, when one considers the developmental level of the target audience (K–12 students), the aspects of NOS stressed are at a level of generality that is not at all contentious. Nevertheless, if one is not willing to let go of the idea that the various aspects of NOS lack consensus and assessment of NOS is, therefore, problematic, the "problem" is easily handled. The issue lies not within the test, but rather in the interpretations of those scoring the test. If one interprets test scores simply as a measure of an individual's adherence to a particular conception of science, then no implicit value judgments are made. In short, the inherent bias in the scoring system of any assessment can be avoided if researchers simply use the scores to construct profiles of beliefs and knowledge.

Overall, there are two critical issues that have surrounded the "traditional" paper-and-pencil assessments of NOS: 1) assessment instruments are interpreted in a biased manner, and 2) some assessment instruments appear to be poorly constructed. These criticisms notwithstanding, it is interesting to note that research conclusions based on these instruments have been unusually uniform. That is, teachers and students generally score at levels considered to be less than adequate.

Thus, although the various instruments suffer from specific weaknesses, if these were significant, it would seem improbable that the research conclusions would be so consistent.

There is a more critical concern, however, about the “traditional” paper-and-pencil approach to the assessment of an individual’s understanding of NOS. Although not a new insight, Lederman and O’Malley’s (1990) investigation clearly highlighted the problem of paper-and-pencil assessments. They documented discrepancies between their own interpretations of students’ written responses and the interpretations that surfaced from actual interviews of the same students. This unexpected finding (i.e., the purpose of the interviews was to help validate the paper-and-pencil survey that was used) was quite timely, as it occurred when educational researchers were making a serious shift toward more qualitative, open-ended approaches to assess individuals’ understanding of any concept. Although the VNOS-A was created to avoid some of the concerns about “traditional” assessments (as were the subsequent series of VNOS forms), the problem of researchers interpreting responses differently than intended by the respondent remains to this day. The problem exists at all age levels (K–adult), with increasing levels of uncertainty as the age of the respondent decreases. It is for this reason that researchers should not abandon the interviewing of individuals about their written responses. Throughout the history of NOS assessment there has been a clear movement from traditional convergent assessments to more open-ended assessments. Most researchers realize how difficult it is to assess a construct as complex as NOS with multiple-choice and Likert scale items. Within all of us, however, is this “inherent” need to make our lives easier. Interviews and open-ended assessments are time-consuming to conduct and score. However, a quick perusal of the program from the Annual Meeting of the National Association for Research in Science Teaching in 2003–2005 indicates that attempts to create a “better” traditional assessment are alive and well. The desire to create an instrument that can be mass administered and scored in a short period of time continues. It is hoped that the need to collect valid data as opposed to large data sets will prevail.

Finally, there remains a small minority of individuals (e.g., Sandoval, 2005) who insist that students’ and teachers’ understandings of NOS are best assessed through observations of behavior during inquiry activities (i.e., knowledge in practice). Such a view is a remnant of the previously discussed assumption that a teacher’s understanding of NOS is necessarily reflected in his/her behavior. It is *déjà vu* all over again. The literature clearly documents the discrepancies that often exist between one’s beliefs/knowledge and behavior. More concretely, if an individual believes that scientific knowledge is tentative (subject to change) and another individual believes the knowledge to be absolute/static, how would this be evident in their behavior during a laboratory activity? If a student recognizes that scientific knowledge is partly subjective, how would this student behave differently during a laboratory investigation than a student with differing beliefs? Certainly, many similar questions could be asked in relation to other aspects of NOS. In short, this methodology of assessment adds an unnecessary layer of inference to one’s research design. Please do not misinterpret these comments about assessing through observation. Observations of behavior can be valuable if the behavior is what a student **says specifically** about NOS. Those supporting the “observation” approach also think that asking students to answer questions such as What is an experiment? is too abstract and unrelated to the student’s practical world. This view ignores the

fact that the nature of an experiment is included in most curricula, and it is related to the work that students do. The idea is far from being too much of an abstraction. However, if one insists that direct observations of student or teacher behaviors be pursued, then assessments of the subject's views of NOS should be made after observations and document analysis have been completed by the researcher, or the results of the assessments should be hidden until observations are completed. This is analogous to the "blind" studies often used in medical studies to reduce the impact of the researcher's and subject's bias on the results.

## FUTURE DIRECTIONS

After approximately 50 years of research related to students' and teachers' conceptions of NOS, a few generalizations can be justified:

- K–12 students do not typically possess "adequate" conceptions of NOS.
- K–12 teachers do not typically possess "adequate" conceptions of NOS
- Conceptions of NOS are best learned through explicit, reflective instruction as opposed to implicitly through experiences with simply "doing" science.
- Teachers' conceptions of NOS are not automatically and necessarily translated into classroom practice.
- Teachers do not regard NOS as an instructional outcome of equal status with that of "traditional" subject matter outcomes.

At this point in the history of research on the nature of science, the research has been relatively superficial in the sense of an "input-output" model with little known about the in-depth mechanisms that contribute to change in teachers' and students' views. Even the more recent efforts that have documented the efficacy of explicit, reflective approaches (Abd-El-Khalick & Lederman, 2000) to instruction are superficial in the sense that students and/or teachers are pretested and posttested relative to an instructional activity or set of activities. The specific mechanisms of change and/or the dynamics of change have yet to be explored in depth. We have simply discovered the situations under which change has occurred in the desired direction. Clearly, much more work is needed before we, as a research community, can feel confident in making large-scale recommendations to teachers and professional developers.

Regardless of the "holes" that one can find in the existing research literature, the past 50 or so years of research on NOS does provide us with some clear direction in terms of future research and teaching. What follows is just a few of the critical lines of research that need to be pursued.

*How do teachers' conceptions of NOS develop over time? What factors are important, and are certain factors more related to certain aspects of nature of science than others?*

We need more in-depth knowledge of how views on NOS change over time. Certainly, change in such views must be similar to the change that one sees with other science concepts. Shifts in viewpoints are most likely gradual, and certain aspects of NOS may be more easily altered than others. It is just as likely that those factors of importance have a differential influence on the various aspects of NOS. To date, the available research simply identifies whether an individual's views have changed from "naïve" to "adequate."

*What is the influence of one's worldview on conceptions of nature of science?*

Although much research on individuals' worldviews has been pursued, such research has rarely been directly and systematically related to views on NOS. One notable exception has been Cobern's work (2000). It seems that NOS may be a subset of one's worldview or is at least affected by one's worldview. Of primary importance is the relevance of this line of research for the teaching of NOS across cultures. What happens when there is a clash between one's cultural views and the views expressed in western-influenced depictions of science and NOS?

*What is the relative effectiveness of the various interventions designed to improve teachers' and students' conceptions? Is one better than another, or is a combination needed?*

Although there is strong emerging evidence that an explicit approach to the teaching of NOS is more effective than implicit approaches, there has been virtually no research that compares the relative effectiveness of the various explicit approaches. Are the various approaches equally effective? For example, is explicit instruction in the context of a laboratory investigation more or less effective than explicit reflection within the context of an historical case study? Is a combination of the two approaches more effective than either approach alone?

*Is the nature of science learned better by students and teachers if it is embedded within traditional subject matter or as a separate "pull-out" topic? Should the nature of science be addressed as both a separate "pull-out" as well as embedded?*

Similar to the issue of the relative effectiveness of various instructional approaches, is the issue of the curriculum context of NOS instruction. There is an existing assumption that when NOS is embedded within the context of lessons on other aspects of subject matter, student learning is enhanced. There is little published research specifically related to this issue. Even the most superficial perusal of the recent research on explicit instruction, however, shows that explicit teaching of NOS has supporters for embedded and non-embedded approaches. Systematic research that compares the relative effectiveness of these instructional approaches alone and in combination is needed.

*How do teachers develop PCK for the nature of science? Is it related to their knowledge structures for traditional science content?*

The relationship between one's views of NOS, subject matter, and pedagogy remains uncertain. If we are to assume that NOS is analogous to other aspects of subject matter that teachers teach and, it is hoped, students learn, it also stands to reason that teachers can and should develop PCK for NOS. Virtually no research has used the PCK perspective, which was so heavily researched during the 1990s, as a lens for research on the teaching of NOS. Such research would provide critical information for the planning and quality of professional development activities that focus on NOS. After all, it is one thing to teach teachers about NOS; it is a totally different endeavor to teach them how to teach NOS to their students.

*How are teachers' conceptions of the nature of science affected during translation into classroom practice? To what extent is the act of teaching an independent variable?*

Anyone who has ever attempted to enhance teachers' understandings of NOS is aware that the "newly developed" views resulting from a methods course or professional development workshop are fragile at best. Given what is known about how science is typically presented in various curriculum materials, there is the possibility that the curriculum may influence a teacher's views of NOS. Within the literature on PCK, there is some recognition that how one uses his/her subject matter

(e.g., teaching) can influence the individual's subject matter structure (Hauslein, Good, & Cummins, 1992). Consequently, it is quite possible that the teaching of science may have an impact on how a teacher views the epistemology of science.

*Does the difficulty of the subject matter within which the nature of science is embedded influence student learning?*

Unless NOS is taught independently of other science subject matter, it represents an additional outcome that students are expected to learn during science instruction. That is, for example, students would be expected to learn that scientific knowledge is tentative while at the same time learning the details of the model of the atom. It is quite possible that the difficulty level of the subject matter may interfere with the learning of NOS. Should NOS be withheld for situations in which relatively concrete science topics are being addressed?

*Does knowledge of the nature of science improve students' learning of other science subject matter?*

One of the original rationales for teaching NOS has been the belief that an understanding of NOS will enhance students' subsequent learning of science subject matter. This assumption, as is true with other assumptions related to the purported value of NOS as an instructional outcome, has yet to be systematically tested. Should students learn to view the subject matter they are being asked to learn through a lens of NOS? This line of research would inform the placement and role of NOS within the science curriculum

*Does understanding of the nature of science significantly influence the nature and quality of decisions students make regarding scientifically based personal and social issues?*

A second rationale for the teaching of NOS has been that such understandings would enhance decision-making on scientifically based personal and social issues. Other than Bell and Lederman's (2003) investigation of university faculty members (scientists and non-scientists), this assumption has remained untested. The results of that investigation did not support the long-held assumption about the value of NOS as an instructional outcome. In general, the assumptions that have been used as advocacies for the teaching of NOS need to be systematically tested. It may very well be that the only value in teaching NOS is that it gives students a better understanding of science as a discipline.

*Are the nature of science and scientific inquiry universal, or are conceptions influenced by the particular scientific discipline?*

Although NOS has been treated in the research literature as "generic" across all scientific disciplines, there appears to be a growing belief in the view that different disciplines may have different "definitions" of NOS. For example, is NOS in biology the same as it is in physics? Intuitively, it seems that there would be differences. Indeed, the phrase "natures of science" is starting to be heard in the halls of professional meetings. The published research literature, however, does not contain a test of this assumption. At this point, all that exists is the unpublished work of Schwartz (2005), and the results, as usual, do not support our intuitive assumptions. The implications this line of research has for teaching NOS in schools are clearly significant. Should NOS be characterized differently in the different science classes? Clearly, we need much more research that compares the views of nature of science (and scientific inquiry) of individuals viewed to have strong understandings of each. It cannot be overemphasized that researchers should carefully consider the developmental appropriateness of conceptions of inquiry and NOS they consider for use with K-12 students.

*How do teachers come to value NOS as having status equal to or greater than that of “traditional” subject matter?*

The last bulleted item at the beginning of this section noted that teachers do not value NOS at a level equal to that of “traditional” subject matter. The existing research clearly indicates that teachers can be taught NOS, and it clearly shows that teachers can be taught how to teach NOS to students. However, the research is lacking when it comes to providing guidance for how to develop teachers’ valuing of NOS as an important instructional outcome. Few would argue with the notion that teachers spend less time teaching what they don’t value or value less than other material. Even teachers who understand NOS and how to teach it may not actually attempt to teach NOS to students. This was illustrated in Lederman’s (1999) case study of five biology teachers quite knowledgeable about NOS. One reason teachers may not teach NOS, even though they are capable, is that NOS is typically not assessed on local, national, or international tests. However, if we hope to improve teachers’ instructional attention to NOS in a more creative way than just putting it on the test, a concerted effort must be made to unearth what it takes to get teachers to value NOS relative to other instructional outcomes.

At the beginning of this review, some attention was given to the question, Why teach NOS? A pessimistic answer might focus on the observation that each time one of the perennial reasons for teaching NOS is systematically studied, empirical support for our intuitive claims is nowhere to be found. Hence, all of the reasons we have always used for advocating NOS as an instructional outcome may be false. On a more positive note, it can always be argued that an understanding of NOS provides students with an understanding of science as a discipline, and it provides a meaningful context for the subject matter we expect students to learn. In this sense, NOS is advocated because of its inherent educational value in understanding science as a discipline, as opposed to its being anything of concrete instrumental value. Whether one ultimately decides to be an optimist or pessimist can only be derived from our continued research on teaching and learning of NOS. Although systematic research on NOS has existed for approximately 50 years, we are far from any definitive answers. And, of course, none of the answers we will eventually arrive at will be absolute, and they will always be subject to change!

## ACKNOWLEDGMENTS

I gratefully acknowledge Rola Khishfe, Byoung-Sug Kim, and Judith Lederman for their assistance in searching the literature and providing critical and productive feedback on earlier drafts of this chapter. Thanks also to Cathleen Loving and Lawrence Scharmann, who reviewed this chapter.

# CHAPTER 29

---

## Humanistic Perspectives in the Science Curriculum

Glen S. Aikenhead

*University of Saskatchewan*

Probably the most pervasive alternative to the traditional science curriculum has been a humanistic approach to school science that is intended to prepare future citizens to critically and rationally assess science and technology. This goal views science as a human endeavor embedded within a social milieu of society and carried out by various social communities of scientists. The purpose of this chapter is to synthesize the research that has investigated humanistic perspectives in the school science curriculum, perspectives that would significantly alter the tenor of school science.

Any perspective on the science curriculum, be it humanistic or solely scientific, expresses an ideological point of view explicitly or implicitly (Cross, 1997; Fensham, 2000b; Fourez, 1989). This chapter's ideology gives priority to a student-centered point of view and to citizens as consumers of science and technology in their everyday lives, as opposed to a scientist-centered view aimed at scientific or science-related careers. In the political arena defined by Spencer's (1859, p. 5) question, "What knowledge is [should be] of most worth?" the research literature expresses essentially two contrary positions, often in combination: educationally driven propositions about what is best for students and society, and politically driven realities supported by de facto arguments supporting the status quo. For instance, although empirical evidence overwhelmingly speaks to the *educational* failure of traditional school science (described below), the continuous survival and high status enjoyed by traditional school science attest to its *political* success. The research reviewed in this chapter reflects the tension between educational soundness and political reality.

We must not forget that curriculum decisions are first and foremost political decisions (Brickhouse & Bodner, 1992; Fensham, 1992; Roberts, 1988; Rudolph, 2003; Young, 1971). Research can *inform* curriculum decision making, but the rational, evidence-based findings of research tend to wilt in the presence of ideologies, as curriculum choices are made within specific school jurisdictions, most often favoring the status quo (Blades, 1997; Carlone, 2003; Cross & Price, 2002; Fensham, 1993, 1998; Gaskell, 1992, 2003; Hart, 2002; Hurd, 1991; Roberts, 1995).

Humanistic perspectives in the science curriculum have been described in various ways, including values, the nature of science, the social aspects of science, and the human character of science revealed through its sociology, history, and philosophy. Since the 1970s, a humanistic perspective has often been identified with science-technology-society (STS) curricula.

Humanistic perspectives have a long history, dating back to the early nineteenth century, when natural philosophy was sporadically taught in some schools. This history, particularly events following World War II, provides a context for appreciating both the educationally and politically driven agendas that motivate the research found in the science education literature and for understanding the literature's conceptualization of humanistic perspectives in the curriculum.

This chapter synthesizes pertinent research studies concerning the formulation of curriculum policy; clarifies different research methods employed; and draws conclusions concerning the strengths, weaknesses, and gaps in the research literature. The chapter unfolds in the following sequence: history of humanistic perspectives in science education, curriculum policy, and a discussion of the research with implications for future research studies.

A humanistic perspective is not the only innovation to challenge the status quo of school science. Other chapters in the *Handbook* are related to humanistic content in the science curriculum (e.g., Chapters 8, 10, 12, 24, and 28), and consequently their topics are not given much attention here, but are cross-referenced.

This chapter restricts itself to the intended school science curriculum that serves 11-year-old and older students. (For a review of research into the taught and the learned curricula of humanistic school science, see Aikenhead [2006].) This chapter excludes literature that simply offers a rationale for a humanistic science curriculum.

## A SHORT HISTORY OF HUMANISTIC PERSPECTIVES IN THE SCIENCE CURRICULUM

School subjects are grounded implicitly on the historical process through which they arose (Sáez & Carretero, 2002). The ideology of the traditional science curriculum is easily understood when placed in the historical context of its nineteenth century origin, an origin that emerged within the ongoing evolution of science itself.

Research into the history of the school curriculum provides a framework for the conceptualizations of humanistic perspectives in the science curriculum. Based on Chapter 26 (this volume), DeBoer (1991), Donnelly (2002), Fuller (1997), Hurd (1991), Kliebard (1979), Layton (1986, 1991), MacLeod (1981), Mendelsohn (1976), and Orange (1981), the following outline is offered: (1) The name *science* was chosen to replace *natural philosophy* during the birth of a new organization in 1831, the British Association for the Advancement of Science (BAAS). (2) In a speech to the third annual meeting in 1834, Whewell, the president of the BAAS and natural philosopher, coined the term *scientist* to refer to the cultivators of the new science. (3) The professionalization of natural philosophy into science was completed in England by 1850, by distancing itself from technology and ensconcing itself within the cloisters of university academia, where it could control access to its various disciplines. (4) English education reformers in 1867, directed by a BAAS committee, produced a science curriculum that marginalized practical utility and eschewed utilitarian issues and values related to everyday life. At the same time their "mental

training" argument helped squeeze the new science disciplines into an already crowded school curriculum. (5) Meanwhile in the United States, the BAAS served as a model for establishing the American Association for the Advancement of Science (AAAS) in 1848. (6) In 1894 critics of the U.S. National Education Committee of Ten erroneously accused it of imposing college entrance expectations on the high school curriculum, a criticism that college science faculty then embraced as an actual Committee recommendation. (7) By 1910, the American school science mirrored England's. (8) Many events, but particularly World War II, caused science and technology to form a new social institution called research and development (R&D), which is still called "science" today.

By contemplating the historical origins of today's traditional science curriculum, we recognize it as essentially a nineteenth century curriculum in its educational intent. As well, we can better appreciate the powerful ideologies that guide and sustain school science today (i.e., moving students through "the pipeline"; Frederick, 1991). These same ideologies cause most science teachers to teach in very similar ways toward very similar goals (Cross, 1997; Gallagher, 1998). The traditional ideologies of pre-professional scientific training, mental training, and screening for college entrance challenge any attempt to reform school science into a subject that embraces a humanistic perspective (Fensham, 1992).

There have always been educators who promoted school science as a subject that connects with everyday society. Different eras have brought different social, economic, political, and educational forces to bear on reforming the science curriculum into a humanistic type of curriculum (Hurd, 1991). Recent historical and case-study research shows how innovative humanistic proposals in the United Kingdom and Australia contravened the social privilege and power that benefited an elite student enrolled in a traditional science curriculum (Fensham, 1998; Hodson, 1994; Layton, 1991; Solomon, 1994a). Accordingly, attempts at reforming the traditional school curriculum into a humanistic one have largely been unsuccessful. This indicates that political and social power is involved in reaching curriculum decisions, an issue revisited throughout this chapter.

## **A Recent Humanistic Science Curriculum Movement**

The empirical research reviewed in this chapter is framed by several post-World War II humanistic conceptions of school science often associated with the STS movement (Ziman, 1980). Details of its particular history can be found elsewhere (Aikenhead, 2003; Bybee, 1993; Cheek, 1992; Fensham, 1992; Solomon, 2003b; Solomon & Aikenhead, 1994; Yager, 1996a) but can be summarized as follows.

Many proposals for a humanistic alternative to school science were inspired by university programs formally initiated in the late 1960s, in the United States, the United Kingdom, Australia, and the Netherlands. Some were highly academic history and philosophy of science programs that eschewed sociological perspectives on science. Others embraced sociology, economics, and politics and gave themselves the label STS. The university STS programs responded to perceived crises in responsibility related to, for instance, the environment and nuclear energy. Thus, social responsibility for both scientist and citizen formed one of the major conceptions on a humanistic perspective in school science (Aikenhead, 1980; Bybee, 1993; Cross & Price, 1992, 2002; Kortland, 2001). For instance, a societal issue-oriented science curriculum project

evolved from the integration of social studies and science at the University of Iowa (e.g., Cossman, 1969) and a decade later in Colorado (McConnell, 1982).

A second major conception to emerge from post-World War II academia was the poststructuralist analysis of science itself, often associated with Kuhn's *The Structure of Scientific Revolutions* in 1962. This analysis tended to challenge the positivism and realism inherent in traditional science courses (Abd-El-Khalick & Lederman, 2000; Kelly, Carlsen, & Cunningham, 1993).

Interest in humanistic content in the science curriculum enjoyed a renaissance at several university centers after World War II. At Harvard, for instance, President J. B. Conant (1947) encouraged his faculty to give serious attention to the history, philosophy, and sociology of science. He influenced Ph.D. student Leo Klopfer, who produced the *History of Science Cases* (Klopfer & Watson, 1957) and who critically researched their impact in schools (Klopfer & Cooley, 1963). Similarly influenced was Jim Gallagher (1971), who presciently articulated a blueprint for an STS science curriculum (echoed in Hurd's 1975 seminal publication). It rationalized teaching scientific concepts and processes embedded in the sociology, history, and philosophy of science; relevant technology; and social issues. Probably the most influential science education project to emerge from Harvard was Harvard Project Physics, a historical and philosophical perspective on physics aimed at increasing student enrolment in high school physics (Cheek, 2000; Walberg, 1991; Welch, 1973). It stimulated many other humanistic curriculum innovations worldwide (Aikenhead, 2003; Irwin, 2000).

The integration of two broad academic fields, (1) the interaction of science and scientists with social issues and institutions *external* to the scientific community and (2) the social interactions of scientists and their communal, epistemic, and ontological values *internal* to the scientific community, produced a major conceptual framework for STS (Aikenhead, 1994c; Ziman, 1984). In practice, however, some STS projects narrowly focused on just one of these domains. Other important conceptual frameworks for humanistic school science have been articulated in the research literature:

1. The degree to which a humanistic perspective supports or challenges a traditional positivist and realist view of science (Bingle & Gaskell, 1994).
2. Whether a humanistic perspective advocates being aware of an issue, or making a decision on the issue, or taking social action on the issue (Roth & Désautels, 2004; Rubba, 1987; Solomon, 1994b), a framework particularly salient to environmental education (Chapter 24, this volume) and to social responsibility (Cross & Price, 1992, 2002).
3. The degree to which humanistic content is combined with canonical science content (Aikenhead, 1994b; Bartholomew, Osborne, & Ratcliffe, 2002).
4. The degree to which the content and processes of technology are integrated into the humanistic perspective (Cheek, 2000; Fensham, 1988).
5. The degree to which school science is *integrated*—the integration of scientific disciplines, and the integration of school science with other school subjects (Chapter 19, this volume).
6. The degree to which schooling is expected to reproduce the status quo or be an agent of social change and social justice (Chapter 12, this volume; Apple, 1996; Cross & Price, 1999).

Slogans for a humanistic science curriculum, such as STS, can change from country to country and over time. In every era, slogans have rallied support for fundamental changes to school science (Chapter 25, this volume). Today, there are a number of slogans for humanistic science curricula worldwide, for instance: science-technology-citizenship, science for public understanding, citizen science, functional scientific literacy, public awareness of science, *Bildung*, cross-cultural school science, and variations on science-technology-society-environment. These humanistic science programs are often seen as vehicles for achieving science for all girls' participation in science (Chapter 10), scientific literacy (Chapter 25), and understanding the nature of science (Chapter 28).

Just as science had to compete in the 1860s with the classics and religion to get a foothold in the school curriculum, today a humanistic perspective must compete with the preprofessional training of elite students (moving through the pipeline) to earn a place in the school science curriculum. This reflects a competition between two ideologies: on the one hand, promoting practical utility, human values, and a connectedness with societal issues to achieve inclusiveness and a student-centered orientation, while on the other hand, promoting professional science associations, the rigors of mental training, and academic screening to achieve exclusiveness and a scientist-centered orientation.

Humanistic perspectives are represented by a variety of conceptual frameworks defined in the literature on research into the intended science curriculum, that is, curriculum policy.

## CURRICULUM POLICY

Four areas of research address an educationally sound curriculum policy for humanistic perspectives in the science curriculum: major failures of the traditional curriculum, successes of learning science in non-school contexts, the relevance of curriculum content, and the processes for formulating curriculum policy itself. Each area is discussed in turn.

### Major Failures of the Traditional Science Curriculum

Deficiencies in the traditional science curriculum have been the cornerstone of arguments supporting a humanistic perspective. At least three major failures are documented in research studies.

The first failure concerns the chronic declines in student enrollment (Dekkers & Delaeter, 2001; Hurd, 1991; Osborne & Collins, 2000; Welch & Walberg, 1967) due to students' disenchantment with school science (Hurd, 1989; SCC, 1984). This failure of school science threatens its primary goal: to produce knowledgeable people to go into careers in science, engineering, and related jobs; or at least to support those who do. It is instructive to examine the pipeline data from a 15-year longitudinal study (beginning in 1977 with grade 10 students) conducted by the U.S. Office of Technology Assessment (Frederick, 1991). Of the initial sample of four million grade 10 students, 18 percent expressed an interest to continue toward university science and engineering courses. Of these interested students, 19 percent lost interest during high school (i.e., they moved out of the pipeline), and then during uni-

versity undergraduate programs, 39 percent of first-year science and engineering students lost interest, *twice* the proportion than in high school. These quantitative data support in-depth qualitative research that concluded: the problem of qualified students moving out of the pipeline resides much more with universities than with high schools, especially for young women (Astin & Astin, 1992; Seymour, 1995; Tobias, 1990).

Another substantial reduction in the pipeline population occurred between high school graduation and first-year university, a transition that showed a 42 percent loss in the number of students interested in pursuing science and engineering courses (Frederick, 1991; Sadler & Tai, 2001). These data are partly explained by studies that discovered that highly capable A-level science students, particularly young women and minority students, switched out of science as soon as they received their school science credentials, because the curriculum *discouraged* them from studying science further (Gardner, 1998; Oxford University Department of Educational Studies, 1989).

Most research into the science curriculum concluded that school science transmits content that is socially sterile, impersonal, frustrating, intellectually boring, and/or dismissive of students' life-worlds (Hurd, 1989; Lee & Roth, 2002; Osborne & Collins, 2001; Osborne, Driver, & Simon, 1998; Reiss, 2000; SCC, 1984). This perception prevails even for science-proficient students who enroll in senior science courses in high school (Lyons, 2003). One major reason for advocating humanistic content in school science has been to reverse this chronic loss of talented students (Eijkelhof & Lijnse, 1988; Ziman, 1980). Evidence suggests that humanistic perspectives in the science curriculum can improve the recruitment of students (Solomon, 1994a; Welch, 1973; Welch & Rothman, 1968).

A second, and related, major educational failure of the traditional science curriculum concerns the dishonest and mythical images about science and scientists that it conveys (Chapter 28, this volume; Aikenhead, 1973; Gallagher, 1991; Gaskell, 1992; Larochelle & Désautels, 1991; Milne & Taylor, 1998). As a consequence, some strong science students lose interest in taking further science classes, some students become interested in science for the wrong reasons, and many students become citizens who are illiterate with respect to the nature and social aspects of the scientific enterprise. One major reason for offering humanistic content has been to correct these false ideas (Ziman, 1980).

A third documented major failure dates back to the 1970s research into student learning: *most students tend not to learn science content meaningfully* (Anderson & Helms, 2001; Gallagher, 1991; Hart, 2002; Osborne, Duschl, & Fairbrother, 2003; White & Tisher, 1986). Research suggests that the goal of learning canonical science meaningfully is simply not achievable for the majority of students in the context of traditional school science (Aikenhead, 1996; Cobern & Aikenhead, 1998; Costa, 1995; Hennessey, 1993; Layton, Jenkins, Macgill, & Davey, 1993; Osborne et al., 2003; Shapiro, 2004). As a result, alternative science curriculum policies have been proposed to radically change the meaning of school science, a controversial idea to be sure (e.g., Chapters 8 and 12, this volume; Aikenhead, 2000a; Fensham, 2000b, 2002; Jenkins, 2000; Millar, 2000; Roth & Désautels, 2002, 2004).

An important consequence of this third *educational* failure of the traditional science curriculum is the reaction of most students and many teachers to the *political* reality that science credentials must be obtained in high school or a student is

screened out of post-secondary opportunities. Empirical evidence demonstrates how students and many teachers react to being placed in the political position of having to play school games to make it appear as if significant science learning has occurred (Bartholomew et al., 2002; Costa, 1997; Loughran & Derry, 1997; Larson, 1995; Meyer, 1998; Roth, Boutonné, McRobbie, & Lucas, 1999). The many rules to these school games are captured by the term "Fatima's rules" (Larson, 1995). Playing Fatima's rules, rather than achieving meaningful learning, constitutes a highly significant *learned curriculum* of students and a ubiquitous *hidden curriculum* of school science (Aikenhead, 2000a). A curriculum policy that inadvertently but predictably leads students and teachers to play Fatima's rules is a policy that is difficult to defend educationally from a humanistic perspective, even though the policy flourishes for political reasons.

### Learning and Using Science in Other Contexts

Although the goal of meaningful learning of canonical science is largely unattainable for many students in the context of traditional school science, it seems to be attained in other contexts in which people are personally involved in a science-related everyday task (Davidson & Schibeci, 2000; Dori & Tal, 2000; Goshorn, 1996; Michael, 1992; Roth & Désautels, 2004; Tytler, Duggan, & Gott, 2001; Wynne, 1991). Thirty-one different case studies of this type of research were reviewed by Ryder (2001), who firmly concluded: *When people need to communicate with experts and/or take action, they usually learn the science content required.*

Even though people seem to learn science content in their everyday world as required, this learning is not often the "pure science" (canonical content) transmitted by a traditional science curriculum. Research has produced one clear and consistent finding: *most often, canonical science content is not directly usable in science-related everyday situations*, for various reasons (Furnham, 1992; Gee, 2001; Jenkins, 1992; Layton, 1991; Layton et al., 1993; Ryder, 2001; Solomon, 1984; Wynne, 1991). In other words, the empirical evidence contradicts scientists' and science teachers' hypothetical claims that science content is directly applicable to a citizen's everyday life. What scientists and science teachers probably mean is that scientific concepts can be used to abstract meaning from an everyday event. The fact that this type of intellectual abstraction is only relevant to those who enjoy explaining everyday experiences this way attests to the observation that most students perceive science as having no personal or social relevance.

How well do science teachers apply science content outside the classroom? When investigating an everyday event for which canonical science content was directly relevant, Lawrenz and Gray (1995) found that science teachers with science degrees did not use science content to make meaning out of the event, but instead used other content knowledge, such as values (i.e., humanistic content).

This research result, along with the 31 cases reviewed by Ryder (2001), can be explained by the discovery that canonical science content must be *transformed* (i.e., deconstructed and then reconstructed according to the idiosyncratic demands of the context) into knowledge that is very different in character from the "pure science" knowledge of the science curriculum, as one moves from pure science content for explaining or describing, to "practical science" content for action (Jenkins,

1992, 2002; Layton, 1991). "This reworking of scientific knowledge is demanding, but necessary as socio-scientific issues are complex. It typically involves science from different sub-disciplines, knowledge from other social domains, and of course value judgements and social elements" (Kolstø, 2000, p. 659). When the science curriculum does not include this reworking or transformation process, pure science remains unusable outside of school for most students (Layton et al., 1993). When students attempt to master unusable knowledge, most end up playing Fatima's rules instead. This empirical evidence supports the educational policy of incorporating everyday action-oriented science content (citizen science; Irwin, 1995); for instance, researchers Lawrence and Eisenhart (2002, p. 187) concluded, "science educators and science education researchers are misguided not to be interested in the kinds of science that ordinary people use to make meaning and take action in their lives."

Given these research conclusions that question the efficacy of teaching for meaningful learning in the context of the traditional science curriculum, there would seem to be little educational advantage for a teacher "to cover" the entire science curriculum but, instead, greater advantage to teaching fewer canonical science concepts chosen because of their relevance to a humanistic perspective (Eijkelfhof, 1990; Kortland, 2001; Häussler & Hoffmann, 2000; Walberg & Ahlgren, 1973). The latter approach is supported by a plethora of comparison studies, based on standardized achievement tests of canonical science, that showed no significant effect on students' scores when instruction time for the canonical content was reduced to make room for the history of science, the nature of science, or the social aspects of science (Aikenhead, 1994b, 2003b; Bybee, 1993; Eijkelfhof & Lijnse, 1988; Irwin, 2000; Klopfer & Cooley, 1963; Pedersen, 1992; Welch, 1973); and on occasion, students in a humanistic science course appeared to fair significantly better on achievement tests of canonical science (Häussler & Hoffmann, 2000; Mbajiorgu & Ali, 2003; Rubba & Wiesenmayer, 1991; Solomon, Duveen, Scot & McCarthy, 1992; Sutman & Bruce, 1992; Wang & Schmidt, 2001; Wiesenmayer & Rubba, 1999; Winther & Volk, 1994; Yager & Tamir, 1993).

In summary, a recurring evidence-based criticism of the traditional science curriculum has been its lack of relevance for the everyday world (Millar & Osborne, 1998; Osborne & Collins, 2000; Reiss, 2000), a problem dating back at least 150 years. The issue of relevance is at the heart of most humanistic science curricula.

## Research on Relevance

Humanistic approaches to school science represent many different views on relevance (Chapters 7, 8, & 28, this volume; Bybee, 1993; Cheek, 1992; Irwin, 1995; Kortland, 2001; Kumar & Chubin, 2000; Millar, 2000; Solomon & Aikenhead, 1994; Yager, 1996b). "Relevance" is certainly an ambiguous term. Mayoh and Knutton (1997) characterized relevance as having two dimensions: Relevant to whom? and Relevant to what? In this chapter, however, the multidimensional character of relevance is defined by a more political question (Häussler & Hoffmann, 2000; Roberts, 1988): *Who* decides? Research into humanistic curriculum policies is reviewed here according to seven types of relevance, a scheme developed in part from Fensham's (2000b) views about *who* decides what is relevant. These seven heuristic categories overlap to varying degrees.

***Wish-they-knew science.*** This type of relevance is typically embraced by academic scientists, education officials, and many science educators when asked: What would make school science relevant? (AAAS, 1989; Fensham, 1992; Walberg, 1991). The usual answer, canonical science content, moves students through the pipeline for success in university programs.

But how relevant is this wish-they-knew content for success by science-oriented students in first-year university courses? Research evidence suggests it is not as relevant as one might assume and, on occasion, not relevant at all (Champagne & Klopfer, 1982; McCammon, Golden, & Wuensch, 1988; Stuart, 1977; Tanaka & Taigen, 1986; Yager & Krajcik, 1989; Yager, Snider, & Krajcik, 1988). First-year university students who had not studied the prerequisite physical science course in high school achieved as well as their counterparts who did enroll in the prerequisite. Sadler and Tai's (2001, p. 111) more recent survey research claims, "Taking a high school physics course has a modestly positive relationship with the grade earned in introductory college physics." An endorsement of "modestly positive" would seem to be faint praise indeed. These research studies might rationally assuage science teachers' fear that time spent on humanistic content and citizen-science content will diminish students' chances of success at university. Although the *educational* arguments favoring wish-they-knew science are particularly weak, political realities favoring it are overwhelming (Fensham, 1993, 1998; Gaskell, 2003).

***Need-to-know science.*** This type of relevance is defined by people who have faced a real-life decision related to science and technology: for example, parents dealing with the birth of a Down's syndrome child, or town councilors dealing with the problem of methane generation at a landfill site (Layton, 1991; Layton et al., 1993). Curriculum policy researchers ask: What science content was helpful to the people when they were making decisions? Ryder (2001) in his analysis of 31 case studies of need-to-know science concluded, "Much of the science knowledge relevant to individuals in the case studies was *knowledge about science*, i.e. knowledge about the development and use of scientific knowledge rather than scientific knowledge itself" (p. 35, emphasis in the original). In other words, the curriculum must expand to include knowledge *about* science and scientists (humanistic content). One reason that people tend not to use canonical science content in their everyday world (in addition to it not being directly usable, as described above) is quite simple: canonical science content is the wrong type of content to use in most everyday action-oriented settings; instead need-to-know science (humanistic content) turns out to have greater practical value.

***Functional science.*** This is science content that is deemed relevant primarily by people with careers in science-based industries and professions. The category includes "workplace science" (Chin, Munby, Hutchinson, Taylor, & Clark, 2004).

Coles (1998) surveyed UK employers and higher education specialists in science who were asked to identify scientific content thought to be essential to school science. Unexpectedly, these respondents thought that students' understanding of science ideas was least important, compared with a myriad of other, more favored capabilities. Similar research findings emerged from broad studies into economic development within industrialized countries (e.g., Bishop, 1995; David, 1995; Drori, 1998). Consistently the research indicated that economic development depends on

factors other than a population literate in canonical science and on factors beyond the influence of school science, for example: emerging technologies, industrial restructuring, poor management decisions, and government policies that affect military development, monetary exchange rates, wages, and licensing agreements.

By conducting research *on the job* with science graduates, Duggan and Gott (2002) in the United Kingdom, Law (2002) in China, and Lottero-Perdue and Brickhouse (2002) in the United States discovered that the canonical science content used by science graduates was so context specific it had to be learned on the job, and that high school and university science content was rarely drawn upon. On the other hand, Duggan and Gott's findings suggested that procedural understanding (ideas about how to do science) was essential across most science-related careers. More specifically, they discovered one domain of concepts, "concepts of evidence," that was generally and directly applied by workers in science-rich occupations to critically evaluate scientific evidence, for instance, concepts related to the validity and reliability of data, and concepts of causation versus correlation. Similar findings arose in their research with an attentive public involved in a science-related societal issue. Duggan and Gott spoke for many researchers (e.g., Fensham, 2000a; Ryder, 2001) when they concluded, "Science curricula cannot expect to keep up to date with all aspects of science but can only aspire to teach students how to access and critically evaluate such knowledge" (p. 675).

The humanistic perspective germane here concerns a correct understanding of concepts of evidence when dealing with social implications, for instance: Is the scientific evidence credible enough to risk investing in a particular industrial process? or Is the scientific evidence good enough to warrant the social action proposed? In these contexts, it is useful for a person to understand the ways in which scientific evidence is technically and socially constructed (Bingle & Gaskell, 1994; Kelly et al., 1993; Cunningham, 1998; McGinn & Roth 1999), that is, humanistic content for the science curriculum. However, when "vocational science" courses are only concerned with vocational technology, they lose their humanistic perspective.

In a project that placed high school students in science-rich workplaces (e.g., veterinary and dental clinics), Chin and colleagues (2004) ethnographically investigated two issues: the relationship between school science and workplace science (a type of functional science) and the participants' perceptions of that relationship. The fact that students saw little or no connection between school science and workplace science was explained by the researchers this way: school science (canonical content) in the workplace was not central to the *purposes* of the workplace, and, therefore, school science was not overtly apparent in the workplace. In short, knowing canonical science content was not relevant to one's accountability in a science-rich workplace (a conclusion very similar to the results of research into need-to-know science, reviewed above).

Surveys and ethnographic research methods are not the only ways to substantiate functional science content. The Delphi research technique used by Häussler and Hoffmann (2000) in Germany was an educationally rational, in-depth method for establishing a physics curriculum policy by consensus among diverse stakeholders over "What should physics education look like so it is suitable for someone living in our society as it is today and as it will be tomorrow" (p. 691). Their 73 stakeholders represented people associated with wish-they-knew science (e.g., physicists and physics teachers) and with functional science (e.g., personnel officers in physics-

related industries and general educationalists). Häussler and Hoffmann did not initially group their stakeholders into these two categories, but instead used a hierarchical cluster analysis statistic to tease out like-minded stakeholders. This analysis produced two coherent groups: Group 1 generally favored “scientific knowledge and methods as mental tools” and “passing on scientific knowledge to the next generation” significantly more than Group 2, who favored “physics as a vehicle to promote practical competence” (p. 693). These statistical results lend credence to the two categories of relevance that distinguish between wish-they-knew and functional science. Interestingly, however, Häussler and Hoffmann found that both groups gave *highest* priority to topics related to “physics as a socio-economic enterprise” that show “physics more as a human enterprise and less as a body of knowledge and procedures” (p. 704).

*Enticed-to-know science.* By its very nature, enticed-to-know science excels at its motivational value. This is science content encountered in the mass media and on the internet, both positive and negative in its images of science and both sensational and sometimes dishonest in its quest to entice a reader or viewer to pay closer attention. Fensham (2000a, p. 75) reports that the OECD’s Performance Indicators of Student Achievement project is using enticed-to-know science “to see how well their science curricula are equipping [15-year old] students to discern, understand and critique the reporting of science in newspapers and the Internet.” Millar (2000) in the United Kingdom and Dimopoulos and Koulaidis (2003) in Greece described how a longitudinal analysis of the content of science-related articles in their respective national newspapers led to identifying the science and technology knowledge that would be most useful in making sense of these articles and the stories they presented. Millar’s analysis stimulated a revision of the AS-level syllabus in the United Kingdom and eventually culminated in Hunt and Millar’s (2000) high school textbook, *AS Science for Public Understanding*, which provides a humanistic perspective.

Moral issues and public risk are often associated with enticed-to-know science because the media normally attend to those aspects of events (Cross & Price, 1992, 2002; Eijkkelhof, 1990; Nelkin, 1995; Osborne et al., 2003). Moreover, the more important everyday events in which citizens encounter science involve risk and environmental threats (Chapter 24, this volume; Irwin, 1995).

*Have-cause-to-know science.* This is science content suggested by experts who interact with the general public on real-life matters pertaining to science and technology and who know the problems the public encounters when dealing with these experts (Law, Fensham, Li, & Wei, 2000). This empirical approach to developing curriculum policy is being tested in China, where the societal experts were drawn from the following domains: home and workplace safety; medical, health, and hygiene problems; nutrition and dietary habits; consumer savvy; and leisure and entertainment (Fensham, 2002; Law, 2002; Law et al., 2000). The approach assumes that societal experts are better situated than academic scientists to decide what knowledge is worth knowing in today’s changing scientific and technological world.

Have-cause-to-know science is a feature of the Science for the Public Understanding of Science Project (SEPUP) in the United States (Thier & Nagle, 1994,

1996). Societal experts in industry, the sciences, and education provided the curriculum developers with elements of a relevant issues-based curriculum that led to STS chemistry modules and three STS textbooks (SEPUP, 2003): *Science and Life Issues; Issues, Evidence and You*; and *Science and Sustainability*.

In the Netherlands, Eijkelhof (1990, 1994) used the Delphi research technique to gain a consensus among *societal experts* to establish the humanistic and canonical science content for an STS physics module, "Ionizing Radiation." The 35 Delphi participants in Eijkelhof's study were carefully selected to represent a variety of fields and opinions on the risks of ionizing radiation (a group purposefully more homogeneous than the stakeholders in Häussler and Hoffmann's [2000] study discussed above). After the normal three rounds in the Delphi procedure, Eijkelhof's radiation experts pointed to suitable societal contexts of application and concomitant scientific content that the public had cause to know. Eijkelhof (1990) warned, however, that policy research by itself should not *prescribe* the final curriculum. A curriculum development team must also consider educational issues, for example, learning difficulties of students, available instruction time, and pedagogical factors. He attended to those issues by drawing upon a decade or more of research by the PLON humanistic physics project (Eijkelhof & Lijnse, 1988; Ratcliffe et al., 2003).

In contrast, an Australian chemistry curriculum committee could not reach a consensus on a balance between societal contexts of application and scientific content, and as a result the committee's writers tended to promote the status quo wish-they-knew science rather than the intended have-cause-to-know science (Fensham & Corrigan, 1994).

The National Curriculum in the United Kingdom calls for humanistic content to be taught but does not specify the content. In a study focused entirely on humanistic content, Osborne and colleagues (2001) employed the Delphi technique to establish a consensus on what "ideas about science" should be taught in school science. During three rounds of the Delphi procedure, 23 experts (professional and academic people notable for their contributions to the clarification of science for the public) produced 18 ideas, nine of which showed sufficient stability and support (the top three were: "scientific methods and critical testing," "creativity," and "historical development of scientific knowledge"). These nine ideas about science informed the development of classroom teaching materials (Bartholomew et al., 2002). These materials were then embedded in a large-scale research project, "Evidence-Based Practice in Science Education" (IPSE). The have-cause-to-know science, elucidated by the IPSE project, addressed humanistic content; the canonical science content had been established by the National Curriculum's wish-they-knew science.

A disadvantage of the Delphi procedure is evident in the ambiguous or "motherhood" statements that sometimes emerge (e.g., creativity). This disadvantage likely results from participants not meeting face to face to clarify and articulate the meaning of each statement.

Curriculum policy research has also included surveys of experts to determine which social issues (and therefore, which have-cause-to-know science) they valued most in a humanistic science curriculum. The experts included (Bybee, 1993) scientists and engineers, citizens, science teachers, and science educators in the United States and around the world. The relevant contexts for have-cause-to-know science were identified, but their actual influence on curriculum policy has not been notice-

able (Cheek, 2000). This survey research was perhaps more politically successful at raising awareness of STS than developing specific curriculum policies.

*Personal-curiosity science.* When students themselves decide on the topics of interest for school science, relevance takes on a personal though perhaps idiosyncratic meaning, as students' hearts and minds are captured (Gardner, 1988; Osborne & Collins, 2000; Reiss, 2000). Based on a humanistic curriculum policy principle that one builds on the interests and experiences of the student, Sjøberg (2000) surveyed over 9,000 13-year-old students in 21 countries to discover (among other things) their past experiences related to science, their curiosity toward certain science topics, their attitude to science, their perception of scientists at work, and their self-identity as a future scientist. Based on the same curriculum policy principle, Häussler and Hoffmann (2000) surveyed over 6,000 German students, aged 11 to 16 years, to determine their interest in various physics topics. Sjøberg (2000) and Häussler and Hoffmann (2000) offer insights into students' differential interests; for instance, "music" was much more interesting than "acoustics and sounds," and "the rainbow and sunsets" much more than "light and optics." In other words, concrete themes embedded in student experiences were much more relevant than science discipline topics, a finding supported by three decades of research by the Dutch PLON project team (Kortland, 2001). In Sjøberg's study, students in non-Western countries had a significantly more positive image of scientists (heroic figures helping the poor and underprivileged) than their counterparts in Western countries, a finding that points to the importance of culture in a student's everyday world (a topic discussed below). In the Häussler and Hoffmann (2000) study, two outcomes are pertinent here: students' views were congruent with stakeholders who advocated a humanistic perspective in the physics curriculum, but discordant with the status quo. Häussler and Hoffmann pointed out that a curriculum policy founded on their Delphi research with stakeholders (reviewed above) would look very similar to a curriculum policy founded on student interests alone (i.e., personal-curiosity science).

## Science-As-Culture

A more holistic yet abstract concept of relevance in school science was advanced by Weinstein's (1998) research concerning the enculturation of students *into everyday society*, an approach to science education that stands in stark contrast to the enculturation of students *into scientific disciplines*. Culture decides, de facto, what is relevant for science-as-culture. For instance, in school culture, "Students constantly are being measured, sorted, and turned into objects of scrutiny. They learn science up close and personal but not as scientists; rather, they learn it as objects of science" (p. 493). Weinstein identified a network of communities in students' everyday lives: health systems, political systems, the media, environmental groups, and industry, to name a few. Each community interacts with communities of science professionals, resulting in a *cultural commonsense notion of science*.

Science-as-culture is more than just pop culture (Solomon, 1998). As a category of relevance, science-as-culture serves in part as a superordinate category to the

need-to-know, functional, enticed-to-know, have-cause-to-know, and personal-curiosity science categories. Its relevance resides in the student's community's culture (a commonsense notion of science) and in the student's home and peer cultures (Chapter 8, this volume; Costa, 1995; Solomon, 1994b, 1999, 2003a). Science's role in society is also embedded in science-as-culture, as evidenced by roles such as setting environmental standards, regulating commerce, providing legal evidence, announcing medical breakthroughs, creating novel ethical dilemmas, and requiring financial support for research and development (Dhingra, 2003; Jenkins, 2000; Stocklmayer, Gore, & Bryant, 2001).

Future research into students' science-as-culture may reveal useful ideas for a humanistic science policy, particularly for the enculturation of students into their local, national, and global communities. Prella and Solomon (1996), for instance, provide a rich account of the differences between students' orientation to an environmental issue and their scientific knowledge on the subject. The researchers explored students' science-as-culture by investigating those differences in three settings: the science classroom, students' homes, and on holidays. Nelkin's (1995) and Stocklmayer et al.'s (2001) seminal research into science and the media raises an important researchable policy question: What understandings of science and journalism are of critical value to consumers of the mass media?

Science-as-culture can also be captured by project-based learning in which local science-related real-life problems are addressed by students in an interdisciplinary way (e.g., Chapters 12 and 24, this volume; Dori & Tal, 2000; Jenkins, 2002; Lee & Roth, 2002; Roth & Désautels, 2004). This approach draws upon community resources and local culture to stimulate need-to-know, functional, and have-cause-to-know science, as well as science-as-culture, in short, citizen science. The presence of a humanistic perspective in a project-based curriculum depends, however, on the degree to which its humanistic content is made explicit in the instruction and assessment of students (Chapter 28, this volume; Aikenhead, 1973; Kortland, 2001; Ratcliffe, 1997).

## Conclusion

These seven heuristic categories of relevance, based on who decides what is relevant, can help describe the content and contexts found in a humanistic perspective of a particular science curriculum. More often than not, a curriculum will embrace several categories simultaneously (e.g., Aikenhead, 1994a; Eijkelhof & Kortland, 1988).

Ideologies inherent in any science curriculum can be explained in terms of two mutually exclusive presuppositions of school science (Aikenhead, 2000a; Rudolph, 2003; Weinstein, 1998): (1) the enculturation of students into their *local, national, and global communities*, communities increasingly influenced by advances in science and technology, and (2) the enculturation of students into the *disciplines of science*. These presuppositions represent two fundamentally different axiomatic views of relevance. Therefore, relevance precipitates a policy dilemma. Depending on the humanistic science curriculum, relevance will be fundamentally framed by an allegiance to scientific disciplines or to students' cultural communities. In an attempt to resolve the dilemma by integrating the two positions into the same curriculum, educators risk confusing and alienating students (Egan, 1996). The research reviewed in this chapter suggests that any science curriculum, humanistic or purely scientific, dedicated to the enculturation of all students into scientific ways of thinking will constantly be undermined by Fatima's rules.

## Processes of Formulating Curriculum Policy

Throughout this chapter's review of research, educationally driven research findings conflicted with political realities. These political realities intensify when we examine research into the processes by which people have formulated curriculum policy. For example, researchers have explored such questions as: Who has the sociopolitical power to set policy? and How do they assert and maintain that power? However, the paucity of research in this domain (Kortland, 2001; Roberts, 1988) may speak to the unease felt by research participants when political events come under public scrutiny, exposing the natural tension between maintaining the status quo of preprofessional training in the pipeline, and innovating a humanistic perspective for equity and social justice (Chapter 12, this volume; Apple, 1996; Fensham, 1998; Lee, 1997; Roth & McGinn, 1998).

Historical events, summarized earlier in the chapter, revealed the political context in which the first formal science curriculum policy emerged in 1867, a context characterized by the cultural values, conventions, expectations, and ideologies at that time, all of which determined what school science would be. Because context is paramount for policy inquiry, researchers have often employed qualitative methods such as case studies or vignettes to interpret and understand processes that led to a humanistic science curriculum policy. This was certainly the case for research into power conflicts over curriculum policy reported by Aikenhead (2002), Blades (1997), Fensham (1993, 1998), Gaskell (1989, 2003), Hart (2002), Roberts (1988, 1995), and Solomon (2002, 2003b). Each study revealed the various power dynamics adopted by different groups of stakeholders. When deciding what knowledge is of most worth, people usually negotiate by using both rational criteria and political power in an attempt to limit or enhance the influences of various stakeholders. Each educational jurisdiction has its own story to tell about how curriculum policy is formulated.

Two research studies are mentioned here to illustrate this type of research. In his book *Procedures of Power & Curriculum Change* (a research study into the temporary defeat of a humanistic science curriculum policy in Alberta, Canada), Blades (1997) allegorically described the intense clashes between newly aligned interest groups who organized a network of relationships (actor-networks; Carlone, 2003; Foucault, 1980; Gaskell & Hepburn, 1998) to serve their own self-interests, and who enacted "rigor" as a power ploy in their discourse. Blades discovered that one very powerful stakeholder-group altered its alliances, thereby reversing its original policy position. A second study by Gaskell (1989) in British Columbia, Canada, showed how science teachers' allegiances to different professional organizations and to their own professional self-identities undermined an emerging humanistic science curriculum policy (Rowell & Gaskell, 1987).

Although each case study and vignette found in the literature was unique, all reached the same conclusion (with some unique exceptions): local university science professors have a self-interest in maintaining their discipline and will boldly crush humanistic initiatives in school science policy (Aikenhead, 2002; Blades, 1997; Fensham, 1992, 1993, 1998; Fensham & Corrigan, 1994; Gaskell, 1989; Hart, 2002; Pandwar & Hoddinott, 1995; Roberts, 1988; Shymansky & Kyle, 1988), resulting in what Gaskell (2003, p. 140) called "the tyranny of the few." If local science professors become marginalized and lose their power to control policy decisions, they tend to re-

align their actor-networks into international alliances to defeat a local humanistic curriculum policy (Rafea, 1999).

Science curriculum policy is normally formulated more smoothly through consultation with different stakeholders (Orpwood, 1985), for instance: government officials, the scientific community, science teachers, university science educators, students, parents, business, labor groups, industry, and other groups and institutions. Government ministries of education generally rely on the advice of curriculum committees variously composed of some of these stakeholders. Because government committee meetings are almost always held out of the view of an inquisitive researcher, their confidentiality has prevented research into the early stages of formulation of government policy (De Vos & Reiding, 1999; Roberts, 1988).

Consultative research has also taken the form of research and development (R&D) studies that produced STS classroom materials (e.g., textbooks) as a means to influence or articulate a humanistic curriculum policy. Researchers have collaborated with ministries of education, selected teachers, students, and experts who furnished "functional" and "have-cause-to-know" science (among other types of relevance) for the science curriculum (Aikenhead, 1994a; Eijkelhof & Lijnse, 1988; Eijkelhof & Kapteijn, 2000; Kortland, 2001).

More rigorously systematic policy studies have used the Delphi research method to inform humanistic curriculum policy, for instance (as described above), the research by Eijkelhof (1990), Häussler and Hoffmann (2000), and Osborne and colleagues (2001). Their experts were able to reach a consensus, more or less, on the relevant contexts and associated knowledge for an educationally sound, humanistic science curriculum policy.

The most elaborate, theory-based, consultative methodology to produce curriculum policy is deliberative inquiry. Inspired by Schwab's (1974) "deliberative enquiry," it offers a combination of "top-down" central control by government bureaucrats and "grass-roots" populist control by other stakeholders. Deliberative inquiry is a structured and informed dialogic conversation among stakeholders who, face to face, help government officials reach a decision on curriculum policy by discussing and reexamining their own priorities (i.e., values) along with their reading of relevant research (Orpwood, 1985). Because science teachers will be central to implementing a humanistic science curriculum (Chapter 26, this volume; Roberts, 1988) and because curriculum evaluation research consistently shows that the teacher has more influence on student outcomes than the choice of curriculum taught (Aikenhead, 2006; Welch, 1995), the science teacher is a key stakeholder and usually holds a central role during deliberative inquiry meetings. The process of deliberation encompasses both educational and political dimensions to formulating curriculum policy.

The Science Council of Canada (SCC) used deliberative inquiry to produce a national science curriculum policy that embraced a humanistic perspective (Orpwood, 1985; SCC, 1984). The SCC study ensured that significant problems in science education were identified, that appropriate evidence was collected, and that the problems and evidence were considered by diverse stakeholders attending one of the 11 two-day deliberative conferences held across Canada. Stakeholders included high school students (science-proficient and science-shy students); teachers (elementary and secondary); parents; elected school officials; the scientific community; university science educators; and representatives of the business, industry, and la-

bor communities. The students' contributions were pivotal to recommendations related to student assessment. As Schwab (1978) predicted, "Deliberation is complex and arduous . . . . [it] must choose, not the *right* alternative, for there is no such thing, but the *best* one" (pp. 318–319, emphasis in the original). The "best" science curriculum policy for Canada was published as *Science for Every Citizen* (SCC, 1984). Inspired by the success of this deliberative inquiry, two other Canadian provinces conducted similar research, but on a smaller scale. Drawing upon the SCC's national study, Alberta resolved the problems identified by Blades (1997) (described above) by holding a series of deliberative conferences that gave science teachers a political voice (Roberts, 1995). Saskatchewan almost replicated the SCC study during the renewal of its science curriculum and yielded a strong teacher consensus on a humanistic perspective (Hart, 1989).

A different method of policy formulation, illustrated by the AAAS's (1989) *Project 2061* and the National Research Council's (NRC, 1996) *Standards* in the United States, utilizes consultation with stakeholders on a grand yet narrow scale. After conducting a complex series of inclusive national surveys and committee meetings, a "consensus panel of leading scientists" (Walberg, 1991, p. 57) determined the content of *Project 2061*, content critiqued as conveying a positivist, non-contemporary view of science by Bingle & Gaskell (1994) and Fourez (1989) and as ignoring student relevancy by Settlage and Meadows (2002). Thus the final say in the curriculum was greatly influenced by people who generally espouse the conventional wish-they-knew science. This exclusivity, plus the lack of published research on the consultation process itself, suggests that the national agencies may have prioritized political realism over educational soundness and have repeated their predecessors' 1867 policy decision. A humanistic perspective loses significance in the predominant wish-they-knew science of *Project 2061* and *Standards*.

## DISCUSSION OF THE RESEARCH

### Contexts of Research

Four themes can be identified in the research literature on curriculum policy: scale, the effect on classroom practice, school culture, and research paradigms. Each theme represents a different context related to the research reviewed in this chapter.

*Scale.* As plenary speaker at the 2003 NARST annual meeting, Richard Elmore, drew upon a great deal of research and experience with school innovation undertaken at Harvard University when he cryptically characterized a typical science education innovation study as follows: a gathering of "the faithful" (e.g., a few humanist science educators) to show that the innovation can work on a small scale and then leave "the virus" (i.e., the innovative idea) to populate the system on its own because the innovation is such a good idea (i.e., it is educationally sound). This approach to changing school science through new curricula has continually failed, mostly because of a scaling-up problem: moving from a small-scale preliminary study to a large-scale full implementation study. As an alternative, Elmore (2003) counseled researchers to treat a school jurisdiction as the unit of analysis through enacting larger scale projects.

However, the research synthesized in this chapter clearly indicates that a change to humanistic school science requires a broader context for research than a school system. Significant change demands a multidimensional context of scale that also includes teacher education programs, state curricula, and a host of diverse stakeholders of social privilege and power who provide support over a long period of time (Anderson & Helms, 2001; Fensham, 1992; Sjøberg, 2002). The most effective curriculum research would encompass a scale as broad as the interaction of research, political power, policy, and practice (Alsop, 2003).

*The effect of research on classroom practice.* As suggested by Elmore (2003) and Hurd (1991), noticeably absent from the research literature is evidence of a pervasive influence of science education research on practice. This was recently investigated by Ratcliffe and colleagues (2003, p. 21), who concluded: "Unless research evidence, including that from highly regarded studies, is seen to accord with experience and professional judgement [and ideology] it is unlikely to be acted on." However, research is more influential on the "development of national policy on science education." Again, the educationally sound defers to the political reality of teachers' knowledge, beliefs, self-identities, and ideologies (Section V, this volume; Aikenhead, 2006).

*School culture.* Elmore (2003) pointed out that school culture must be changed in order to nurture and sustain any significant innovation, a view broadly shared among researchers of humanistic school science (Aikenhead, 2000a; Brickhouse & Bodner, 1992; Carlone, 2003; Medvitz, 1996; Munby, Cunningham, & Lock, 2000; Solomon, 1994c, 2002; Tobin & McRobbie, 1996; Vesilind & Jones, 1998). If research into a humanistic curriculum is to be more than an academic exercise acted out on a small scale, it must reformulate itself into a framework of cultural change, because a humanistic perspective would significantly alter the culture of school science.

*Research paradigms.* It is convenient to discuss research in terms of three paradigms: quantitative, interpretive (qualitative), and critical-theoretic (Ryan, 1988). A science educator trained in the natural sciences may feel comfortable in the role of disinterested observer (quantitative paradigm), but most of the research reviewed in this chapter emphasizes the role of a curious empathetic collaborator (interpretive paradigm). Yet, if curriculum researchers expect to effect significant changes in school culture and classroom practice, they will also need to be seen as passionate liberators (critical-theoretic paradigm) generating emancipatory knowledge/practice in the face of seemingly unchangeable organizational structures, relationships, and social conditions.

Most of the research literature reviewed in this chapter reported on preliminary small-scale studies comprising a few volunteer science teachers to initiate or participate in a novel humanistic project, studies without sufficient resources to expand in scale or over time. One exception was the research on Harvard Project Physics (Welch, 1973), but it occurred in the 1960s at a time when a good science curriculum was deemed to be a teacher-proof curriculum (Solomon, 1999), when in-service programs simply transmitted the new curriculum's philosophy to passive teachers (White & Tisher, 1986), and when research strictly conformed to the quantitative research paradigm. This paradigm emphasized measurement of outcomes evaluated against expert judgments or against criteria from academic theoretical frameworks.

In contrast, research into humanistic science curricula has evolved dramatically since the 1960s. It is encouraging to see teachers and now students collaborate in the development of curriculum policy (e.g., Aikenhead, 1994a; Orpwood, 1985; Roberts, 1995), along with stakeholders other than university science professors and professional science organizations (e.g., Eijkelhof, 1990; Häussler & Hoffmann, 2000; Law, 2002). In-service programs now tend to be transactional (e.g., the Iowa Chautauqua Project; Yager & Tamir, 1993) and transformational (typically action research). Today research into humanistic science curricula most often follows the interpretive research paradigm, in which researchers attempt to clarify and understand the participants' views and convey them to others or incorporate them into a curriculum (e.g., Eijkelhof & Lijnse, 1988; Gallagher, 1991; Häussler & Hoffmann, 2000; Orpwood, 1985).

The four themes—scale, effect of research on classroom practice, school culture, and research paradigms—help clarify the contexts for past and future research agendas.

### Past Research Agendas

Since World War II, the renaissance of humanistic school science has led researchers to produce new knowledge in the attempt to establish the *credibility* of a humanistic perspective among science teachers and policy makers. Their educationally sound propositional knowledge, however, was almost insignificant in the arena of political reality. For the intended curriculum (this chapter) and for the taught and learned curricula (Aikenhead, 2006), strong evidence supports the educational soundness of a humanistic perspective. Hence, the issue of credibility need not monopolize research agendas in the future. We do not need more research to show that humanistic school science is educationally sound.

Other agendas have emerged to create classroom change, for instance, agendas associated with action research that combines educationally sound knowledge with politicization (Hodson, 1994; Keiny, 1993). Examples of action research include: Chapter 12, this volume; Bencze, Hodson, Nyhof-Young, and Pedretti (2002); Ogborn (2002); Pedretti and Hodson (1995); Solomon et al. (1992); and Tal, Dori, Keiny and Zoller (2001). However, Solomon (1999) recognized its limitation as only involving a tiny proportion of excellent teachers.

Research agendas associated with classroom change have explored the interaction between political power and practice at the school level (e.g., Carlone, 2003) and have extended this interaction into policy formulation (e.g., Gaskell, 2003; Gaskell & Hepburn, 1998) and into community practice (Calabrese Barton & Yang, 2000; Roth & Désautels, 2004). These studies penetrated the political core of curriculum policy and hold promise for future R&D and developmental research.

### Future Research Agendas

To investigate the interaction of research, political power, policy, and practice, with the expressed purpose of changing school culture, researchers must address the politics of school science currently encased in nineteenth-century ideologies. As they do so, one fundamental dilemma must be resolved explicitly and continuously within each research project: does the curriculum aim to enculturate students into

their local, national, and global communities (as other school subjects such as English do), or does it aim to enculturate students into a scientific discipline? The prospects of achieving the latter are extremely limited, according to the research synthesized in this chapter.

Politically motivated research in science education by itself may be necessary from time to time to reinvent the discovery that the traditional science curriculum fails most students, for various reasons (e.g., Reiss, 2000), or that humanistic school science can be credible. Of particular interest would be research into Fatima's rules played by various types of students and science teachers, and related to high-stakes testing, educational politics, and ideologies. Future research into humanistic science curricula will best be served by amalgamating the educational with the political, because educationally sound research by itself has had little impact in schools, although its influence is apparent in some official curriculum policies.

To achieve an amalgamation of the educational and political, research into consensus making on curriculum policy promises to be fruitful. Of all the studies into policy formulation reviewed in this chapter, the process of deliberative inquiry holds the greatest potential for devising an educationally sound, politically feasible, humanistic perspective in the science curriculum. Deliberative inquiry provides a political forum to hold negotiations among various stakeholders. During a deliberative inquiry meeting, research concerning major failures of the traditional curriculum can be scrutinized, research concerning successes at learning science in non-school settings can be debated, and research on relevance can help clarify the participants' values. For instance, new research on relevance might include: (1) studies of potential content for science-as-culture (e.g., Who is engaged with science and technology in the community? and How?); (2) studies of science-related knowledge/practice that local workers learn in science-related occupations (e.g., What knowledge do nurses actually use day to day on their job?); (3) studies of how science-proficient students use canonical science in their everyday lives (if at all), compared with how science-shy students cope with similar situations; and (4) studies of how professional scientists actually use canonical science in their everyday lives. An example of this last point is Bell and Lederman's (2003) work that showed how university scientists made decisions on everyday socio-scientific issues primarily on values rather than primarily on scientific ideas and evidence; thus creating a rational evidenced-based expectation for students' socio-scientific decision making in humanistic science courses (i.e., students should not be expected to use science content in situations where scientists do not). Future research projects will be more politically effective if they involve clusters of science teachers and other stakeholders. This research will gain politically potency according to the diversity of the research team and the social privilege of its members.

Deliberative inquiry (i.e., consensus-making R&D) will have greater impact on classroom practice: the larger the project's scale (e.g., SCC, 1984), the more culturally transformational it is (e.g., Chapter 12, this volume; Leblanc, 1989), and the more it embraces all three research paradigms appropriately (a feature of scale). Future research could investigate the influence of stakeholders involved in the consensus-making process: who they represent, their selection, their assigned versus their enacted roles (i.e., the dynamics of deliberative inquiry), and the actor-networks they bring into the deliberation and that develop as a result of the deliberation (e.g., Gaskell & Hepburn, 1998). R&D on actor-networks themselves could be a primary

focus of a deliberative inquiry, forging networks to enhance a clearer and more politically endorsed humanistic perspective.

In the future, preliminary small-scale research studies can still be worthwhile: “Rather than viewing the powerful sociohistorical legacy of science as an oppressive structure that limits the potential of reform, we can view the meanings of science in local settings as partially fluid entities, sometimes reproducing and sometimes contesting sociohistorical legacies” (Carlone, 2003, p. 326); but small-scale studies will lose significance unless they explicitly embed themselves in a larger, articulated, politico-educational agenda for humanistic school science (Fensham, 2002).

Future research programs will be strengthened by forging of alliances with researchers in other fields, such as educational cultural anthropology (Chapter 8, this volume), gender studies (Chapter 10), and transformative education studies (Chapters 12 and 24).

Caution is advised, however, against becoming sidetracked by some new research methods such as “design-based research” (Design-Based Research Collective, 2003) or “developmental research” (Lijnse, 1995), because their ultimate aim is to refine theories of learning and didactical structures, respectively. Rather than focus on the question, *How* do students learn best? the fundamental issues to be sorted out first are: *Why* would students want to learn it? and *Who* will allow them to learn it?

These two questions matter critically. The first (Why learn it?) speaks to educationally sound propositions, and the second (Who will allow it to happen?) speaks to the political reality in which all science education research resides.

## ACKNOWLEDGMENTS

# CHAPTER 30

---

## Systemic Reform: Research, Vision, and Politics

Jane Butler Kahle

*Miami University*

Systemic: of a system; specifically, in physiology, of or affecting the entire bodily system. (*Webster's New World Dictionary*, p. 1481)

Reform: v. to make better by removing faults and defects; n. an improvement; correction of faults or evils. (*Ibid.*, p. 1222)

Combining the above definitions provides a basic definition of systemic reform, that is, to make better an entire system by removing faults and defects. Although that basic definition applies to systemic reform of science education, it does not define what is a “system” in educational reform, nor does it address the issue of the time required for systemic reform. This chapter addresses that definition by limiting its discussion of systemic reform to large-scale reforms that affect multiple parts of the education system. In addition, it discusses reform in terms of time, that is, long-term reforms. Obviously these two parameters limit the contents of the chapter by eliminating many regional or local reforms, both in the United States and internationally.<sup>1</sup> But it can be argued that such limitations are necessary to both focus the discussion and to include a historical perspective.

It takes time to change any system, especially one as complex and entrenched as public education. Lee (2002) documented that changes in student achievement, the desired outcome of any educational reform, may require up to 30 years. When one

---

1. For the purposes of this chapter systemic reform has been defined as large-scale, long-term reforms that are intended to improve science education by affecting many parts of an educational system. Furthermore, an educational system is defined as one governed by the equivalent of a state or province. Therefore, although many larger (i.e., nations) or smaller (i.e., cities, districts, schools) entities have enacted reforms of science education and many reforms have focused only on one part of the educational system (i.e., curriculum only, assessment only, etc.), the chapter limits its discussion to research stemming from large-scale reforms affecting multiple parts of the educational system of a state, province, or territory. With these restrictions, a thorough search of the relevant and available literature using ERIC and Educational Abstracts located more than 300 document titles suggesting relevance to systemic science education reform internationally. However, only a handful of documents proved suitable and available, and most were descriptive, not research-oriented. Therefore, the decision was made to limit this chapter to U.S. reforms that fit the definitions above.

expands reform to include a whole system, the issue of time becomes paramount. Therefore, this chapter presents a historical overview of large-scale reform efforts in U.S. science education from the end of World War II to the present. Across the 60 years discussed, three themes have emerged in the United States: *Texts and Teaching*, *Courses and Competencies*, and *Excellence and Equity*. Those themes drove the systemic reforms that occurred in three waves: from Sputnik through *Man, A Course of Study (MACOS)*; from *A Nation at Risk* through national standards; and from the National Science Foundation's systemic initiative program to the No Child Left Behind legislation.

Although the launch of Sputnik in 1957 is commonly accepted as the catalyst for the first wave of systemic science education reform, both Dow (1991) and Jackson (1983) argue that it began earlier, and it focused on educating the scientific and technical workforce that was needed to out-compete the Russians in the race to space. The first wave of reform primarily addressed two parts of the educational system, *texts* and *teaching*. It involved federal support for the development of new curricula and Teacher Training Institutes focused on upgrading the content knowledge of teachers through graduate courses at colleges and universities across the nation. However, because of the public paranoia concerning a national curriculum, the Teacher Training Institutes were not ostensibly tied to the new curricula.

A second wave of reform was catalyzed by the publication of *A Nation at Risk* in 1983. This time the impetus was the need to improve the scientific literacy of all citizens in the new technological age. The U.S. Secretary of Education appointed a commission that had 18 months to report on the quality of America's education. The report focused on high schools and was devastating in its description of weaknesses (Goodlad, 2003; Sizer, 2003). Although it stopped short of calling for comprehensive, systemic reform, many states began to regulate education in ways intended to change the system. During the second wave of reform (approximately 1983 to 1991), another theme emerged, that is, *courses* and *competencies*. State policies were directed toward increasing scientific literacy and using science to improve the quality of life by ensuring that all students graduated from high school with adequate *courses* and *competencies*. The political context of the time involved issues of economic security within the emerging global economy.

The third wave of reform differed from the two previous ones, because it was based on theoretical insights. O'Day and Smith defined systemic reform as an effort "to upgrade significantly the quality of the curriculum and instruction delivered to all children . . . [requiring] major changes in the way states and local school systems make and implement policy" (1993, pp. 250–251). Their thinking and that of others<sup>2</sup> were taken up by the newly reorganized science education directorate at the National Science Foundation (NSF) and its director, Luther Williams. Indeed, the focus of the third wave of reform, as presented in this chapter, is reform of a state's educational system, and it was catalyzed by the NSF's Statewide Systemic Initiative (SSI) program. Although systemic reforms in the third wave addressed a variety of components in the educational system, the themes that focused activities and policies at several levels were *excellence* and *equity*.

It has been impossible to review the research on systemic reform without placing both the reforms and the studies of them in educational and political contexts;

---

2. In addition to O'Day and Smith (1993), Clune (1993), Fuhrman (1993, 1994), and Kirst (1984), among others, identified components and requirements for systemic reform.

for both contexts have affected the nature of the research. However, a comprehensive review of the literature revealed that the research base is uneven and most of it is evaluative in nature. The first three sections of the chapter address each wave of systemic reform and the research associated with it. A time line to guide the reader through the U.S. reforms is provided in Fig. 30-1. There is a common term used among those who participate in systemic reform, that is, *lessons learned*. The chapter concludes with a consideration of what lessons have been learned through research about systemic reform in science education.

### WAVE I: TEXTS AND TEACHING— (FROM SPUTNIK TO MACOS)

The three full decades after World War II are an intriguing period in the history of American education, for it was during those years—the 1950s through the 1970s, roughly speaking—that the federal government made an extraordinary effort, unprecedented in scale, to involve itself in educational affairs for the purpose of improving the quality of schooling for a significant portion, if not all, of our nation's youth. (Jackson, 1983, p. 143)

Although the launching of *Sputnik* in 1957 is credited with starting the first wave of systemic reform in the United States, Dow (1991) suggests that “Long before *Sputnik*, postwar criticism of American schooling had been gaining momentum both within and outside the education profession” (p. 1). For example, Vannevar Bush's 1945 report to President Truman, “Science—The Endless Frontier,” provided the basis for founding the National Science Foundation (NSF) in 1950 (Bush in Jackson, 1983).<sup>3</sup> The report articulated an urgent need to improve mathematics and science education. NSF responded by initiating Teacher Training Institutes and, in

3. The report was commissioned by President Roosevelt in 1944.

1954, funding the first curriculum project, the Physical Science Study Committee (PSSC) (Jackson, 1983). Both initiatives were accelerated and expanded after Sputnik, with Congress passing the National Defense Education Act in 1958, which provided funds for local districts to build laboratories and to sponsor teacher education in science, math, and foreign languages. Concurrently, Congress increased funding for education at the National Science Foundation to the point where education was apportioned about one-half of the NSF's budget (Office of Technology Assessment [OTA], 1988). In order to compare the extent of funding, those monies are translated into current dollars in Table 30.1.

## Teaching

The first wave of science education reform did not address all parts of the system, but it did address two aspects that were seen both educationally and politically as weaknesses, that is, the quality of the science teaching force and outdated science texts. From 1954 to 1974, NSF focused on *teaching* by funding Teacher Training Institutes at a total cost of \$500 million (OTA, 1988). Because the consensus at the time was that the teaching force was deficient in content knowledge about science, institutes focused on increasing content knowledge by developing graduate, degree-granting programs in the individual sciences.

If judged by the numbers of teachers reached, the institutes were very successful. At their peak in the early 1960s, about 1,000 institutes were offered annually, involving the participation of over 40,000 teachers each year (about 15 percent of the math and science teaching force). Although more supervisors (80 percent in mathematics and science) and upper secondary school teachers (37 percent in mathematics and 47 percent in science) attended, 5 percent of early elementary teachers also were involved (OTA, 1988). At the time, NSF judged that the program had reached about as many teachers as any voluntary program could. For example, in the late 1980s (second wave), all of NSF's programs reached only 2 to 3 percent of secondary math and science teachers (OTA, 1988), whereas in the third wave (the 1990s) the statewide systemic initiative program reached only 8 percent of the science and math teachers in the 25 states/territories involved (Zucker, Shields, Adelman, Corcoran, & Goertz, 1998).

**TABLE 30.1**  
NSF's Curriculum Development Funds

	<i>Actual dollars*</i>	<i>Equivalent 2003 dollars**</i>
1954	\$ 1,725	\$ 11,815
1955	\$ 5,000	\$ 34,247
1957	\$ 500,000	\$ 3,267,974
1959	\$ 5,500,000	\$34,810,127
1968	\$12,250,000	\$64,814,815

Although there is little research about the institutes or evaluation of their success, the Office of Technical Assistance reviewed their efficacy in the late 1980s. The OTA report is one of the few documents that include research and evaluation findings on the institute program. It reports, for example, that a General Accounting Office review of research on the NSF-funded institutes “found little or no evidence that such institutes had improved student achievement scores” (OTA, 1988, p. 120). However, the OTA review identified the following important effects of the Teacher Training Institute program.

- It brought teachers up to date with current scientific developments.
- It brought teachers closer to the actual processes of science, thereby improving their sense of competence in science.
- It provided a network of peers who provided professional support long after the institutes ended.
- It allowed teachers to do experimental work in science and encouraged them to replicate such experiences with their students.
- It helped define leaders for the science education community.
- It recognized the importance of the work of science teachers.
- It inspired and invigorated teachers to continue teaching.

In retrospect, many science educators agree that the two outcomes with the most lasting effects were the *development of a network of peers* and the *defining of leaders*. Both of these effects substantively changed the nature of the science teaching force through the next several decades (Helgeson, 1974).

Because NSF did not require evaluations of the institutes, little information other than the OTA (1988) report is available. However, in 1976, Willson and Garibaldi examined the results of a large-scale independent evaluation of five NSF Comprehensive Teacher Training Institutes to determine if there were evidence that the cognitive achievement of junior and senior high students increased because their teachers participated in an NSF-sponsored institute. According to Willson and Garibaldi, previous findings indicating that students benefited from their teachers attending NSF institutes were confounded by differences between institute and non-institute teachers. They also were compromised because the process of assigning students to teachers in schools was nonrandom.<sup>4</sup>

For their analysis, Willson and Garibaldi (1976) identified the most theoretically relevant factors affecting student achievement and examined each with respect to any observed differences in student achievement in classes of institute and non-institute teachers. For example, they examined the possible differential assignment of institute teachers to higher-ability classes and found that the distribution of teacher assignment by student ability was independent of NSF institute participation. As they sum-

---

4. A typical published study on teacher institute attendance and student achievement did not randomly assign teachers or students to experimental and control groups; did not provide the control group of teachers with any substantive professional development; did not control for differences in teacher characteristics such as type of degree, experience, etc.; and used student achievement tests that were oriented toward the content of the institute. Because of these problems, some research concerning institute effectiveness is not included in this review (for an example, see Thelen and Litsky, 1972).

marize, "Thus, it appears unlikely that students of institute attending teachers would do better than students of nonattending teachers because of differential ability" (Willson & Garibaldi, 1976, p. 433). They also examined the possibility that institute teachers might teach in larger cities but rejected this factor because urban representation in the study was small.<sup>5</sup> After controlling for student ability and school location, they found that institute participation was a positive and significant factor affecting student achievement. As they summarized, "[T]eacher attendance at institutes is associated with higher student achievement than no attendance, and . . . students of teachers with high institute attendance perform better than students of teachers who have attended only one or two institutes" (Willson & Garibaldi, 1976, p. 437).

## Texts

The second focal point of the first wave of reform was *texts*. Science textbooks in the 1950s were woefully out of date with current scientific advances. In 1954, Jerrold Zacharias and a group of physicists in Cambridge formed the Physical Science Study Committee (PSSC) and began to develop the first course in the NSF curriculum development program. It was soon followed by curricula in mathematics, chemistry, biology, and finally social science. Collectively, these curricula were known as the *alphabet soup* curricula (*BSCS*, *CHEM Study*, *CBA*, *SCIS*, *ESC*, etc.). By 1975, NSF had funded 53 curriculum projects at a cost of over \$117 million. In all cases, teams of scientists, science teachers, and science educators worked on the materials. According to Nelkin (1977), the materials were designed to be "teacher-proof" in that they presented current scientific knowledge and concepts regardless of local norms. The innovative curricula of the 1960s not only updated content; they also focused on the methods of inquiry and stressed individual judgment. Welch and Wahlberg's (1972) analysis of the differences between *Project Physics*, one of the NSF-funded curricula, and traditional physics texts provides insight into the education vision at that time:

The developers of *Project Physics* were originally concerned about the continuing drop in the proportion of students who take physics in high school. To attract students who are not bound for mathematical, scientific, or technical careers, and without compromising on the physics content, they attempted to develop an interest-awakening, module system of course components using a variety of media and methods for learning. . . . Perhaps the most distinctive aspect of *Project Physics* is its humanistic orientation. . . . (Welch & Wahlberg, 1972, pp. 373, 374)

Indeed, the texts developed in the first wave of reform differed from traditional texts in many ways. But all were directed toward improving and enlarging the scientific, mathematical, and technical workforce for the nation, the political necessity of the day.

Two curriculum projects merit discussion because they expanded the scope of the curricula efforts and illustrate how politics, not research findings, affect educational reform. In 1958, the Biological Sciences Curriculum Study (BSCS), initiated

---

5. They reported that "the majority of the schools sampled were in small towns and cities under 50,000 population (81 percent in science, 91 percent in mathematics)" (Willson & Garibaldi, 1976, p. 433).

by the American Institute of Biological Sciences, was the first group to address the needs of a diverse student body by developing three versions of an introductory high school biology text. The need was great. High school biology texts were at least 20 years behind developments in the discipline, hampering especially the teaching of evolution.

Considering the politics of the day, it was not surprising that field testing and marketing of the BSCS books ran into trouble. In 1961 a field test in Dade County, Florida, was stopped because the books contained diagrams of the human reproductive system. Although BSCS refused to remove the offending diagrams, Dade County school officials blackened out the offending ones before allowing the field test to continue (Nelkin, 1977). In addition, state boards of education in both Texas and New Mexico objected to the inclusion of evolution. BSCS stood its ground, and its books—with evolution—were included on their state adoption lists. However, the publicity generated ensured political conflicts in both states and local districts.

The second curriculum project affected by political reality was *Man: a Course of Study* (MACOS). Although NSF had approached curriculum development in the social sciences cautiously, in 1963 it funded a year-long program for fifth- and sixth-graders that used an ethnographic approach to studying human behavior. MACOS did not avoid controversial issues and urged students to cultivate independent attitudes and to raise questions. Although MACOS clearly was treading on sensitive ground, it was successfully field tested in over 300 classrooms before commercial publishers pulled out. After NSF provided a supplement to offset publishing and distribution costs, the books were finally published in 1970. In 1974 MACOS was used in over 1,700 schools in 47 states. However, a year later sales plummeted because of an epidemic of community disputes. The congressional hearings that followed not only put the death seal on MACOS but also on NSF's curriculum development efforts and, in 1981, on its education directorate. A quote from congressional hearings during that time illustrates the political environment: "You [MACOS] are not suggesting the philosophy . . . that is being taught. [That] is a local option of the school district" (Senator Talcott, 1976, in Nelkin, 1977, p. 24). Although generally the MACOS controversy is seen as ending the first wave of reform, Peter Dow, one of its authors, credits the Apollo moon walk in July of 1969 with its end. According to him, after that success in space, "the so-called 'education gap' seemed as ephemeral as the 'missile gap,' and federal support for curriculum reform began to wane" (1991, p. 7).

Although NSF was more or less comfortable with supporting projects to develop curricular materials, it approached the implementation of those materials with trepidation. Furthermore, NSF did not endorse or claim responsibility for the educational value of the curricula. It was hoped that by supporting several choices in different subject areas, the Foundation would not be accused of sponsoring a national curriculum. NSF was sensitive to any claims of "federal intervention" and was under constant congressional pressure to avoid such "interference." As Nelkin stated, "[NSF's] role was to make materials available but not to mandate their use" (1977, p. 27). However, Senator Allott put it more forcefully, saying, "I don't want these things rammed down the throat of educators" (Senator Allott, 1964, in Nelkin, 1977, p. 24).

Unlike the situation with the Teacher Training Institutes, there was considerable research on the efficacy of the NSF-supported curriculum materials. At the time,

one study summarized the situation in the following way: "After the urgency and excitement of the early years of this new curriculum movement had passed, many individuals and groups, including the Congress of the United States, demanded objective evidence of the value of the new courses" (Walker & Schaffarzick, 1974, p. 83). Research focused on student achievement and overall program impact is summarized next. However, it is important to note that student achievement research was clouded by controversy over the type of test used to obtain the data. Therefore, two studies that specifically addressed the issue of test bias are discussed in detail. The findings of other studies are included in major meta-analytical and qualitative syntheses from the 1970s, which are discussed also.

Some researchers attempted to overcome test content bias by using two achievement tests, one based on the innovative curriculum used and the other based on a comparable traditional curriculum (Heath, 1964; Heath & Stickell, 1963; Lisonbee & Fullerton, 1964; Rainey, 1964; Wallace, 1963). Others examined test content to determine if scores on subscales reflected patterns of emphasis present in the curricula (Herron, 1966; Wasik, 1971). However, findings were mixed, and the concern about test bias continued to cloud research done on student achievement and the NSF-supported curricula.

Two studies, one of *CHEM Study* and the other of *Project Physics*, were unique in that both controlled for test bias and one, *Project Physics*, used an experimental design. In 1966, Herron compared the cognitive ability of students who had a class using *CHEM Study* with those who used a conventional chemistry text.<sup>6</sup> He carefully constructed a chemistry test that measured cognitive ability—without regard to the actual content studied. He administered the test to chemistry students in four suburban schools and analyzed results by three student ability levels as measured by the *Iowa Tests of Educational Development*. Although there were differences in findings among the three ability groups, he found that at all ability levels *CHEM Study* students scored significantly higher on *Application* items than did students using conventional texts (Herron, 1966).

Welch and Wahlberg (1972) also addressed the need for controlled, experimental studies to assess student achievement with NSF-supported curricula. From a national list of 16,911 physics teachers, 136 were randomly selected to participate in this study. Of that number, 72 agreed to participate and were randomly assigned to either the experimental group (attended a six-week briefing session on *Project Physics*) or the control group (participated in a two-day physics workshop at Harvard University). Within the classes of both groups, students were randomly assigned to take one of two instruments that together assessed the following factors: cognitive, affective, learning environment, course reaction, semantic differential, and physics perception. Controlling for student ability, Welch and Wahlberg concluded that *Project Physics* students performed as well as students in other courses on cognitive measures and that they enjoyed their text and found physics less difficult than those in other physics courses. In addition, *Project Physics* had a special appeal to students in the middle-range IQ group (112 to 119), students who, they

---

6. Cognitive ability in Herron's (1966) study referred to any of the abilities described by the *Taxonomy of Educational Objectives* (knowledge, comprehension, application, analysis, synthesis, and evaluation) as well as to critical thinking as measured by the *Watson-Glaser Critical Thinking Appraisal*.

noted, had increasingly tended to elect not to take high school physics (Welch & Wahlberg, 1972).

In response to what many researchers, policy makers, and educators interpreted as a lack of substantive research on the quality of the curriculum and its influence on student learning, researchers began to use synthesis techniques, both qualitative and quantitative, to analyze findings across studies. One synthesis by Walker and Schaffarzick (1974) examined studies "in which an attempt was made to discriminate finer and more subtle differences between innovative and traditional curricula than a single score on an achievement test" (p. 94). They reviewed research since 1957 that compared the achievement of students using innovative curricula with the achievement of students using traditional curricula. The review included studies in science, mathematics, social studies, and English. Of the 23 studies that allowed for direct comparison of their results, a majority (12) were in science. Walker and Schaffarzick's (1974) review revealed an advantage for students using innovative curricula, compared with students using traditional curricula. They concluded that "[t]he innovative groups were superior about four times as often as the traditional groups in these comparisons" (p. 90). However, they continued to report that "innovative students do better when the criterion is well-matched to the innovative curriculum, and traditional students do better when the criterion is matched to the traditional curriculum" (p. 94). According to their synthesis, "different curricula produce different patterns of achievement, not necessarily greater overall achievement" (Walker & Schaffarzick, 1974, p. 97).

Boulanger (1981) synthesized research published between 1963 and 1978 that addressed science education for grades 6–12. The findings of over 50 studies were synthesized to determine the impact on student learning of certain aspects of instruction. Boulanger's synthesis "provides some insight into the effectiveness of systematic innovation in instruction" (p. 319). For example, the use of pre-instructional strategies (i.e., behavioral objectives, set induction, advanced organizers) was found to improve student conceptual learning. Training on scientific thinking, increased structure in the verbal content of materials, and increased realism or concreteness in adjunct materials also were aspects of science instruction found to improve cognitive outcomes. He also synthesized research on the quantity of time on topic, reporting that "simply expanding the amount of time spent on a given unit of material holds no special relationship to amount learned" (Boulanger, 1981, p. 321).

In order to provide a quantitative treatment of the research and reduce the potential for investigator bias, Shymansky, Kyle, and Alport (1983) synthesized 25 years (from 1955 to 1980) of experimental and quasi-experimental research regarding the effects of new science curricula on student performance. They used meta-analytic procedures to examine 105 studies, representing a total sample size of 45,626 students and 27 of the new science curricula. They measured the effect of 18 criteria on student performance individually, in combinations called criterion clusters (i.e., analytic skills, process skills, achievement, etc.), and by subject area.<sup>7</sup>

Shymansky and his colleagues found that the average student studying the new materials exceeded the performance of 63 percent of the students in traditional

---

7. Shymansky, Kyle, and Alport's (1983) study was part of a large meta-analysis project conducted by Anderson et al. (1982). The data were reanalyzed in 1990 and involved 81 studies (Shymansky, Hedges, & Woodworth, 1990).

science courses on the aggregate criterion variable (i.e., general achievement, process skills, analytic skills, and attitudes toward science).<sup>8</sup> The greatest gains were in process skills, attitudes, and achievement. They also reported that overall performance scores were more positive for mixed student samples than for samples that were predominantly male (less than 25 percent females) or for ones that were predominately female (more than 75 percent females). When analyzed by subject area, they found the biology curricula, developed in the BSCS, not only had the most positive impact on student performance but also had the most research supporting them. Furthermore, students using the new biology and physics programs showed the greatest gains across the 18 criteria measured, whereas students using the new chemistry and earth science materials showed the least gains.

As Shymansky and his colleagues note, their findings concerning overall improvements in achievement were especially important because much of the criticism of the new curricula assumed that improvements in process skills (a focus of all the new materials) could only be achieved at the expense of content knowledge (Shymansky, Kyle, & Alport, 1983).

Bredderman's (1983) meta-analysis of 57 controlled studies on three activity-based elementary science programs (*Elementary Science Study, ESS*; *Science—A Process Approach, S-APA*; and *Science Curriculum Improvement Study, SCIS*) found that 32 percent of the 400 comparisons favored the activity-based programs at least at the .05 level of significance. As he concluded,

The results of this meta-analysis of program effects help in estimating what the impact would be if activity-based programs were adopted across a wide variety of districts. Performance on tests of science process, creativity, and perhaps intelligence would show increases of 10 to 20 percentile units. Reading and math scores might be positively affected, and attitudes toward science and science classes would probably show a small improvement. Student performance on standardized achievement tests in science content, if affected at all, might go up slightly when averaged across all student populations. (p. 511)

On the other hand, Bredderman cautioned that gains from using the activity-based curricula were not sustained unless similar types of materials were used in subsequent grades.

In 1982, Weinstein and colleagues reported on a meta-analysis of 33 studies, involving over 19,000 junior and high school students in the United States, Britain, and Israel that was designed to assess the impact of the U.S. innovative secondary science curricula on achievement since 1960. They found a ratio of approximately 4:1 in favor of outcomes related to the use of the innovative materials (Weinstein, Boulanger, & Walberg, 1982). In 1986, Blosser synthesized many of these studies, concluding that "Data exist to support the idea that the science curriculum improvement project materials developed after 1955 were successful in promoting student

---

8. Shymansky and his colleagues defined traditional science curriculum and contrasted it with the new science curriculum. Traditional science curriculum emphasizes knowledge of scientific facts, laws, and theories. In it, laboratories are verification exercises. In contrast, the new science curricula, developed after 1954, were characterized by their emphasis on higher cognitive skills and the processes of science. In it, laboratories are integrated with the text and extend concepts introduced in the text (Shymansky, Kyle, & Alport, 1983).

**TABLE 30.2**  
**Estimates of Percentages of U.S. High School Physics Students Enrolled in PSSC**

Source	1962–63	1964–65
U.S. Office of Education	12.6 (50,300)**	20.6 (99,900)
National Science Foundation	25.0 (125,000)	50.0 (200,000)
College Entrance Examination Board	19.6	29.6

achievement in the use of science process skills, in creativity, in higher cognitive skills at both the elementary and secondary school levels” (Blosser, 1986, p. 517).

In summary, much of the research concerning the effectiveness of the NSF-supported curricula in improving student achievement was compromised by two issues: first, the problem of test bias, and second, the lack of random sampling. Most of the evidence for improved student achievement is based on secondary analyses, conducted after the period of funding. However, in general, the research indicates that many curriculum projects were successful in improving student achievement.

Another line of research involved the impact of the NSF-supported curricula. By 1970, approximately a quarter of all secondary students in the United States used NSF-funded materials in their science courses (Nelkin, 1977).<sup>9</sup> Together, the curricula spanned all levels of mathematics and science education, including the college level, and, at times, extended across levels and areas. According to Schlessinger and Helgeson (1969), the science curriculum projects were more numerous, but less comprehensive, than those in mathematics. However, both the science and the mathematics programs fell short in their attempts to reach the total school population. Schlessinger and Helgeson (1969) described the situation in the following way: “Varying with the new course content projects, we are reaching only from twenty to about fifty percent of the students within our classrooms. This is true even where the teachers have been given special institutes in preparation for teaching these courses” (pp. 639–640).

Using the Physical Science Study Committee (PSSC), the first NSF-supported project, as a case study, Welch (1968) described how three separate studies produced three different sets of percentages estimating the enrollment of students in PSSC courses (see Table 30.2). Welch concluded that discrepancy among the data sets “leads one to doubt the accuracy of any of the reported figures” (p. 231). As he wrote, “Thus it becomes apparent that an assessment of the impact of the course content improvement program, even at the gross level of counting heads, is not reliable” (p. 234).

In spite of varying estimates of the use of the NSF-supported curriculum, it was a massive effort that updated science content, changed instruction, and influenced

9. Use varied greatly across the projects, and type of data collected caused confusion and misunderstandings. For example, the OTA report (1988) states that BSCS materials were estimated to have been used in approximately half of all U.S. biology classes in the late 1980s, and one-quarter of those who graduated with a baccalaureate degree in physics in 1983–84 had studied PSSC physics in high school.

more traditional texts. For example, in biology, although only 50 percent of American secondary schools eventually used BSCS materials, the BSCS books influenced change in nearly 70 percent of the content of the most widely used text at that time, *Modern Biology* (Quick, in Jackson, 1983, p. 149). However, the success of the curricular reform in wave one also had a political pitfall. As Nelkin wrote, "By improving the public school curriculum, the NSF, despite its denial of responsibility, found itself involved not in an isolated neutral research endeavor but in a major social intervention filled with political implications" (1977, p. 27).

## Summary

Although the term *systemic reform* was not used in the 1960s and 1970s, the United States embarked on large-scale reform efforts that addressed two major parts of the educational system, *text* and *teaching*. Both efforts substantively changed science education, and the synergy between the two foci enhanced their separate effects. However, evaluation was not required of the various projects, and, particularly for the teacher training institutes, there are few research studies. Although more research exists for the curriculum projects, most studies were done after a project's completion. That is, results were not used to refine or continue the reform. The research usually used synthesis techniques, and findings generally supported the effectiveness of the new curricula to improve student attitudes, process skills, and achievement levels in science. The reforms of the 1960s and 1970s were national in scope; they reflected a shared vision of improved science education; but, in the end, they were limited by political issues and concerns.

## WAVE II: COURSES AND COMPETENCIES

The 1980s produced two distinct approaches to educational reform. One was a 'top-down' strategy that sought to change schools through state programs and regulatory activity. The other has been a 'bottom-up' reform movement in the form of school-based 'restructuring.' Both strategies have proved inadequate in substantial part because of the fragmentation of the current education system. (Smith, O'Day, & Fuhrman, 1992, p. 31)

The next wave of reform was signaled by the release of *A Nation at Risk* in 1983, which stated: "If an unfriendly foreign power had attempted to impose on America the mediocre educational performance that exists today, we might well have viewed it as an act of war" (National Commission on Excellence in Education, 1983, p. 5). Indeed, one researcher referred to reform efforts in the 1980s as "[attempts] to forcefully repair the sinking vessel" (Hawley, 1988, p. 418). Although the nation was aroused, the report did not address the dollars needed to change the educational system. However, in 1984, Congress passed the Education for Economic Security Act (EESA), which was designed to promote the teaching of mathematics, science, and foreign languages. Title II of that act directed the U.S. Department of Education to provide grants to school districts to address the shortfalls highlighted in *A Nation at Risk*. A second impetus for the reforms of the 1980s was the growing national awareness that the United States no longer dominated the global marketplace.

Although reform efforts occurred at both local and state levels, this section focuses on changes that were state, or top-down, efforts, because they were more sys-

temic in their approach and effect.<sup>10</sup> Two major changes occurred at the state level. First, states assumed the responsibility for determining high school graduation requirements; and, second, states mandated competency tests to ensure that graduating students had the skills and knowledge to be effective citizens in a global economy. The themes of the second wave of reform, therefore, are *courses* and *competencies*.

## Courses

In total, states enacted more rules and regulations affecting education in the three- to four-year period following the release of *A Nation at Risk* than at any time since the early 1960s (Timar & Kirp, 1989). Between 1983 and 1985, approximately 700 new policies were legislated (Darling-Hammond & Berry, 1988), and much of the activity focused on trying to ensure that all students reached high school graduation standards and, in many states, passed competency tests. In order to reach those goals, states increased the number of academic units or credits needed for graduation while concomitantly reducing the number and type of electives that would count toward graduation. In addition, states mandated passage of competency tests, added “pass to play” provisions (Texas), and developed grade-to-grade promotion standards (Wilson & Rossman, 1993).

The impetus for increasing course requirements was based on research, particularly in mathematics, indicating that student achievement as measured by standardized tests is improved by increased course taking (Alexander & Pallas, 1984; Schmidt, 1983a, b). Changes also were influenced by the National Commission on Excellence in Education’s (1983) delineation of minimum high school graduation requirements. Those requirements included four year-long courses in English, three in mathematics, three in science, three in social science, and a semester course in computer science. Furthermore, a foreign language was recommended for college-bound students. In 1980, 37 states defined minimal graduation requirements, but a decade later, 43 states had assumed that responsibility (Wilson & Rossman, 1993). Math or science requirements were increased in 32 of those states, and 25 raised graduation requirements in both math and science. One result of increased graduation requirements was a proliferation of science courses. Indeed, in the four years between 1982 and 1986, the largest enrollment increases were in science and foreign languages. Furthermore, to ensure that all students passed competency tests, schools offered more remedial courses.

Most of the research on course offerings relied on large national databases, providing profiles of course offerings, and/or state assessments of change. Researchers at the Educational Testing Service used the High School and Beyond database to analyze course-taking patterns across the nation, with the 1982–83 school year providing baseline data. According to Wilson and Rossman, “One topic of high interest in several of the studies was student enrollment in mathematics and science and

---

10. The school-based, “bottom up” reform that approached a systemic effort was *Success for All*, a comprehensive program designed to restructure elementary schools that served many students at risk of academic failure (Slavin, Madden, Karweit, Dolan, & Wasik, 1992). First piloted in Baltimore in 1987, by 1994 the program was implemented in approximately 200 schools in 59 districts in 20 states. Its expansion was primarily to high-poverty schools with substantial Chapter I resources, because schools/districts had to commit \$100,000 of their own funds to participate (Madden, Slavin, Dolan, & Wasik, 1993).

whether there was systemic variation by track, race, gender, socioeconomic status, or other demographic variables" (1993, pp. 36, 37). As expected, analyses found that enrollments differed by school characteristics.

Clune, White, and Patterson (1989) collected interview data in six states, 24 districts, and 32 high schools in order to analyze any effects of new graduation requirements. They found that slightly more than a quarter of students enrolled in an additional math class, and a third took an additional science class. They concluded that the increased graduation requirements both succeeded and failed, stating, "They succeeded in getting a lot more students into basic academic courses; . . . they failed in getting students into the most rigorous possible courses, in producing a reasonably uniform education for all students, and, probably, in conveying the higher-order skills necessary for a competitive economy" (p. 47).

Another study analyzed the effects of state policies on teachers' content decisions in elementary mathematics (Schwille et al., 1986, July). The seven states involved in the study ranged from ones with high direct state control (New York and South Carolina) to ones with a mix of direct and indirect control (Florida and California) to ones where control of school policies was at the district level or there was indirect control (Ohio, Indiana, and Michigan). Although differences were found between direct and indirect control states, the authors concluded that in both types of states, teachers had little autonomy over policies on instructional objectives, student testing, student placement, textbook selection, time allocation, and teacher qualifications. Indeed, the top-down component of the second wave of reform did not involve teachers in decision-making.

Retrospectively, Porter and his associates analyzed reforms during the 1980s from the perspective of opportunities to learn (Porter, 1994). The analysis focused on three aspects of the reform during the 1980s. First, did increased graduation requirements lead to higher dropout rates? Second, did schools accommodate students by offering more remedial courses? And, third, was instruction weakened in standard courses? Porter cites a study by the U.S. Department of Education that indicated that dropout rates, particularly among poor and/or minority students, did not increase (U.S. Department of Education, in Porter, 1994). The second question was answered by Clune and White's (1992) analysis of high school course-taking patterns. Using schools that enrolled mostly low-achieving students in four states, they concluded that course-taking patterns had not been affected by increased graduation requirements. That is, the additional academic credits were earned in courses of varying levels of difficulty, not only in basic or remedial courses. Porter focused on answering the third questions. As he wrote, "[N]o evidence was found that requiring more students to take more advanced mathematics and science resulted in compromising the curricula of the courses experiencing the increased enrollments. . . . The required Chemistry/Physics course looked as challenging in terms of topics covered as did the college prep Physical Science course, and the actual quality of instruction looked better" (Porter, 1994, p. 6).

The second wave of reform was characterized by a proliferation of graduation requirements by states that spawned new courses and varied types of instruction. However, the dire predictions that such top-down reform would lead to increased dropout rates or watered-down courses are not supported by the available research. The second characteristic of the second wave of systemic reform was an increase in state mandatory testing or *competencies*.

## Competencies

In addition to increasing academic course requirements, state reform policies addressed competencies by increasing the number and importance of state-mandated tests. Although state-mandated testing was intended to drive changes in the curriculum, it often resulted in narrowing the curriculum; thereby “[creating] adverse conditions for reform” (Fullan & Miles, 1992, p. 747). For example, a study by Corbett and Wilson (1990) found that new statewide testing requirements in Maryland and Pennsylvania resulted in narrowing of the curriculum by aligning subjects taught to a specific test. Similarly, a study of the impact of state-mandated assessments in mathematics in two states (Maine and Maryland) found that the new testing mandates resulted in teachers focusing their teaching activities on the tests, especially when testing was combined with high-stake conditions (Firestone, Mayrowetz, & Fairman, 1998).

Wilson and Rossman (1993) summarize the findings concerning the effects of competency testing on student enrollments stating, “What stands out, however, are the low levels of enrollment in mathematics and science courses relative to vocational courses and the suggestion that competency testing pushes students toward basic or remedial courses, at least in mathematics” (pp. 37, 38). Furthermore, they state that “one main effect of the reform of graduation requirements was . . . a redistribution of course offerings and staffing patterns across departments within schools” (p. 41). For example, although math enrollments remained fairly stable, there was a substantial redistribution of types of courses offered and enrollments in various courses.

Porter (1983, January-February) examined the research concerning testing and school effectiveness. He cites multiple studies that support testing as one of five factors contributing to effective schools, writing, “Within the context of the debate on testing, the effective schools literature must be seen as aligned squarely with the advocates of testing” (p. 25). Other analyses, such as the one discussed next, concurred that testing was effective in improving student achievement and in closing achievement gaps among subgroups of students.

A comprehensive analysis of three decades of math and reading scores from NAEP and SAT provides other evidence of the combined effects of increased graduation requirements (leading to diverse course offerings within a subject) and competency testing (Lee, 2002). Although the analyses do not include science, the results are pertinent. Using NAEP data, Lee reports that “During the period from 1978 to 1986, greater academic improvement of lower performing students across all racial and ethnic groups was observed” (p. 4). This change resulted in narrowing achievement gaps between Black/White and Hispanic/White students. Similar results were found with SAT scores. As Lee summarized, “It appears that low-performing students gained more than high-performing students when minimum competency was emphasized during the 1970s and early 1980s” (2002, p. 5).

## Summary

In looking back over the 1980s, two issues were paramount in affecting large-scale educational reforms. First, states increased graduation requirements while simultaneously restricting the types of elective courses that could be used to meet those re-

quirements. Second, states began to institute high-stakes tests, which defined the skills and knowledge students should have after successfully completing the courses required. However, many state policies were mandated without substantive input from teachers, resulting in the establishment of unrealistic timelines (Fullan & Miles, 1992; Schwille et al., 1986, July). Furthermore, states often reversed policies before achievement could be affected.<sup>11</sup> As noted in one report, "The 'top-down' mandates of the 1980s did little . . . to change the content of instruction (especially its focus on basic skills) or to alter the reigning notions of teaching and learning because, as some argued, fragmented and contradictory policies diverted teachers' attention and provided little or no support for the type of professional learning necessary" (Goertz, Floden, & O'Day, 1996, p. xi). As the decade drew to a close, the concept of a systemic approach to reforming science and mathematics education began to emerge in the literature (Horizon Research, 1994). Reform programs previously referred to as "comprehensive" were considered less extensive, and researchers and policy makers began to define the ways in which reform could address an entire educational system.

### WAVE III: EXCELLENCE AND EQUITY

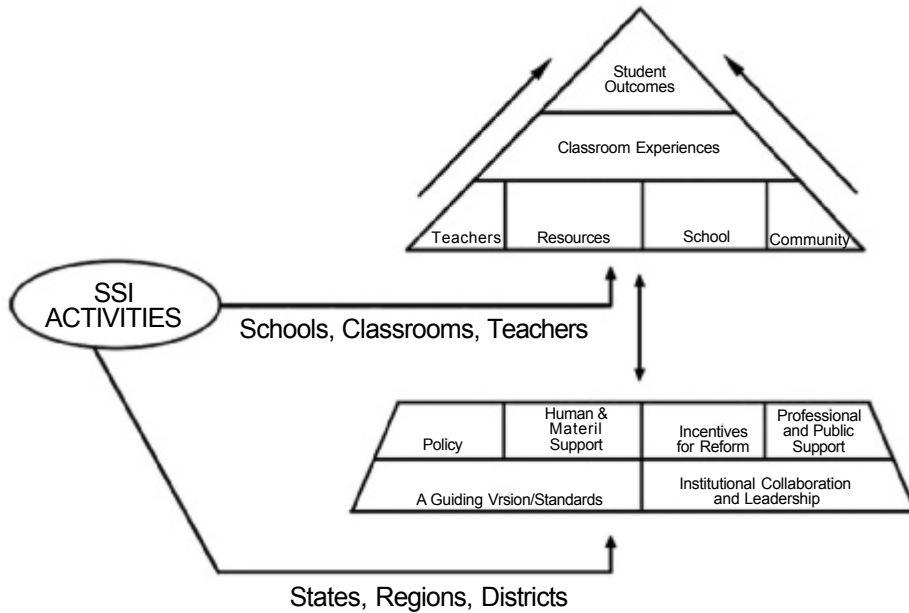

Systemic education reform, in theory and practice, is at its heart: (a) ambitious—in that it establishes new learning standards for all students, (b) comprehensive—in that it simultaneously targets many pieces of the educational system for change toward a common goal, and (c) coherent—in that it supports mutually reinforcing practices and policies that send a strong, consistent message to students, educators, and society about what is important in education. (Fuhrman, 1994, in Heck, 1998, p. 162)

In 1990, the National Science Foundation (NSF) acknowledged the need to address whole state educational systems by establishing the Statewide Systemic Initiative (SSI) program. The SSI program marked the beginning of the third wave of reform in science education. The program's goal was to improve classroom practice and, ultimately, student achievement through major systemic change in science and mathematics education (Fuhrman et al., 1995). As noted in one report, "In framing its solicitation for proposals, NSF emphasized the need for states to deal comprehensively with the key factors that shape instructional practice, the policies governing education, and the economic and political contexts in which science and mathematics education must operate" (Horizon Research, 1994, p. 3). Between 1991 and 1993, NSF entered into five-year cooperative agreements with 24 states and the Commonwealth of Puerto Rico to carry out standards-based systemic reform in mathematics and science education.

The path for systemic reform was paved by the publication of standards in mathematics (National Council of Teachers of Mathematics [NCTM], 1989) and in science by the American Association for the Advancement of Science's (AAAS)

---

11. Ohio, for example, developed a model curriculum in mathematics and provided a timeline for local districts to implement it. Failure to implement would affect district funding. However, after pressure from state legislators, the State Board of Education removed the penalty clause.

Note: From *A report on the evaluation of the National Science Foundation's Statewide Systemic Initiatives (SSI) Program*, by A. A. Zucker, P. M. Shields, N. E. Adelman, T. B. Corcoran, & M. E. Goertz, 1998, (Report No. NSF 98-147) p. viii. Arlington, VA: National Science Foundation.

FIGURE 30–2. A model of systemic reform.

*Benchmarks for Scientific Literacy* (AAAS, 1993). The *Benchmarks* were used by the state systemic initiatives as standards for science education until the publication of the *National Science Education Standards* (National Research Council [NRC], 1996). All three documents stress both *excellence* and *equity*. For example, the *National Science Education Standards* (1996) state, “[t]he intent of the Standards can be expressed in a single phrase: science standards for all students. The phrase embodies both excellence and equity” (p. 2). Furthermore, both the NCTM and the NRC standards are based on the premise that common, minimum standards do not promote equity; on the other hand, common, high standards of excellence do. NSF embraced that premise, and *excellence* and *equity* became cornerstones of systemic reform in science and mathematics in the 1990s.

Perhaps learning from the reforms of the 1960s and 1970s, NSF made comprehensive evaluations a cornerstone of its systemic initiative program. Several groups were contracted to evaluate the reforms through multiple studies that used both quantitative and qualitative methods.<sup>12</sup> In addition, a model of systemic reform was developed that helped focus evaluation and research questions (Zucker, Shields, Adelman, Corcoran, & Goetz, 1998). Figure 30–2 illustrates components of state

12. SRI International, Abt Associates Inc., and the Consortium for Policy Research (CPRE) were among the groups providing the NSF with evaluations of the SSIs.

educational systems in the United States. With the overall goal of improving student achievement in mathematics and science, the SSI reforms generally entered the system at two levels, as shown in Fig. 30–2. The majority of the reform activities entered in the middle and worked up through local classrooms, students, and teachers to improve student achievement. However, other activities began at the state, region, or district level to affect policies and public support for the reforms.

At the classroom level, the SSIs' primary focus was on teacher professional development (20 states), on developing instructional materials (initially 6 states but, by 1997, 13 states), and on supporting model schools (7 states). The states involved in systemic reform mainly used five strategies to affect state and district levels. Twenty-two states created an infrastructure to support systemic reform, 13 addressed teacher education, 14 mobilized public opinion, nine funded local systemic initiatives, and three attempted to align state policy as a primary target of the reform effort (Zucker, Shields, Adelman, Corcoran, & Goertz, 1998).<sup>13</sup>

Zucker and Shields (1995, 1998a, 1998b) conducted school-level case studies in 12 of the SSI states from 1992 through 1997 in order to assess the SSI program's impact on classroom practice and to identify characteristics of successful SSI strategies. Wherever possible, data from an SSI's internal evaluation were incorporated into the study. There was general agreement among the SSIs on what the problems were in mathematics and science classrooms and on the kinds of reforms needed to address the problems. The SSIs recognized the need for new, integrated forms of assessing student progress (e.g., portfolios, exhibitions) and the need for instructional strategies that focused more on active and interactive learning. Collectively, the SSIs called for new curriculum materials that placed increased emphasis on learning of all students, conceptual understanding of fundamental mathematical and scientific concepts, applications of mathematics and science to real-life situations, and interrelatedness across disciplines. Another study found that, overall, the SSIs' professional development stressed opportunities for teachers to enhance their content knowledge (Shields, Marsh, & Adelman, 1997).

Although the NSF-funded evaluations of the systemic initiatives are available, to date little research on the SSIs has been published. This is due partly to location of the initiatives within state departments of education (7), state higher education councils (3), or private groups (7), some of which were developed to run the initiatives. Only three SSIs were housed at universities. Much of the research focused on the two aspects of the third wave of reform that both the national standards and the NSF program addressed, *excellence* and *equity*. The review of research for the third wave of systemic reform traces both themes.

## Excellence

Because improved student achievement was the overall goal of the program, *excellence* and *equity* are addressed in relation to changes in student achievement. Although the ultimate goal of systemic reforms of the 1990s was to improve student learning, the SSIs varied in both the type and amount of student achievement data collected. Heck (1998) characterized the gathering of student achievement data by the SSIs as "problematic," because the measures of achievement did not fully reflect

---

13. Initiatives could select more than one category, so totals are more than 25.

the standards the initiative had adopted, were not given at the grade levels the initiative had targeted, did not aggregate and report scores at the level of the system the initiative primarily addressed, were given infrequently or changed too frequently to provide stable longitudinal data, or simply did not include science and/or mathematics.

A comprehensive review of the SSIs' impact on student achievement in science limited its findings to seven states "that were likely to generate the most credible evidence that student achievement has risen" (Laguarda, 1998, p. 1).<sup>14</sup> In spite of varying methodological and logistical problems, there was evidence of gains in achievement in science in Louisiana, Montana, Ohio, and Puerto Rico. In addition, findings in Ohio and Louisiana indicated that the reforms particularly benefited African American students. Laguarda (1998) concluded that student achievement gains were most likely to be found in states that focused their reform activities primarily at the school, classroom, and teacher level, as shown in Fig. 30–2. She stated:

Of the seven SSIs that were reviewed, the four with the most credible evidence of changes in student achievement—Louisiana, Montana, Ohio, and Puerto Rico—were those with the most intensive interventions aimed directly at classrooms. . . . [T]hose SSIs that invested most heavily in activities directed at state-level policy alignment (such as New Mexico and Vermont) or concentrated on building a state-level infrastructure to support change or on building local capacity to reform instruction (such as Kentucky and Vermont) . . . found it much more difficult to produce evidence of changes in student achievement that could be attributed directly to the SSI. (Laguarda, 1998, pp. 5, 6)

Laguarda's conclusion is supported by Zucker, Shields, Adelman, Corcoran, and Goertz's (1998) study. Although Zucker and his colleagues' evidence is based upon findings from four states, they concurred that improved student achievement in science occurred when a state-level reform focused at the school, classroom, and teacher levels.

Clune (1998) synthesized data across nine SSI states to test his theory of systemic reform; that is, *systemic reform* (SR) leads to *systemic policy* (SP) that leads to a *rigorous implemented curriculum* (SC) that results in *higher student achievement* (SA). He posited that those components could be represented as a *continuous causal sequence*:

$$\text{SR} \rightarrow \text{SP} \rightarrow \text{SC} \rightarrow \text{SA}$$

In testing his theory, he included several indicators of student achievement; such as overall achievement gains, gains in equity (closing any achievement gaps), gains in course enrollments, and achievement levels in subsequent courses. Using two dimensions to test his theory, breadth of change (number of students) and depth of change (size of change and quality of the data) and the nine case-study states, Clune found that, on a five-point scale, the nine states averaged 2.3 points on both breadth and depth of student achievement gain.<sup>15</sup> The results of his study suggest

14. The states and their initiatives were: Kentucky (PRISM), Louisiana (LaSIP), Montana (SIMMS), New Mexico (SIMSE), Ohio (*Discovery*), Puerto Rico (PR-SSI), and Vermont (VISMT).

15. Clune used the Case Studies, commissioned by NSF, as his data source (Zucker & Shields, 1995, 1998a, 1998b). The states included were: Connecticut, Maine, Montana, Louisiana, Michigan, California, Arkansas, Delaware, and New York.

that the goal of excellence, as indicated by overall achievement gains, was not reached in the five years of NSF support.

Near the end of the decade, NSF funded RAND to conduct a study of teaching practices and student achievement in six states and urban districts that had participated in the systemic initiative program (Klein, Hamilton, McCaffrey, Stecher, Robyn, & Burroughs, 2000). The research design included: (a) a measure of instructional practices, (b) an assessment of student achievement, and (c) an analysis of any relationship between them after controlling for student demographics. There are several concerns with the design. First, although large samples of teachers at each site responded to questionnaires, there was no effort to identify teachers who had participated with the SSI and those who had not. Second, there was no effort to link student responses with those of the teachers.<sup>16</sup> And, third, in order to reduce testing burden, scores from existing statewide or district-wide tests were used when available. The study included grades three through seven, and over 300 teachers and approximately 9000 students were included in the data analyses. Klein and his colleagues report, "After controlling for student background characteristics, we found a generally weak but positive relationship between the frequency with which a teacher used the reform practices and student achievement. This relationship was somewhat stronger when achievement was measured with open-ended response tests than with multiple-choice tests" (2000, p. xiv). They note that the findings may be compromised by inaccurate teacher reporting of frequency of use of various instructional practices, lack of alignment between tests and reform curricula, differences in student groups (unrelated to frequency of teacher use of reform practices), and length of time students were taught by teachers using reform practices. However, they suggest that the consistency of findings across sites, despite differences among the sites, is encouraging.

A carefully controlled, smaller study focused on student achievement in eight urban junior-high/middle schools in one SSI (Kahle, Meece, & Scantlebury, 2000). In this study, frequency of use of reform teaching practices was reported by both students and teachers, with student responses validating those of the teachers. Student and teacher data were linked, and teachers were identified as participating (or not) in the SSI's professional development. Furthermore, only one measure of achievement was used, and it was aligned with standards-based science content. However, results were reported only for African American students, because the number of European American students in the schools was too low to use in statistical analyses. Kahle and her colleagues reported that "students of teachers who participated in the SSI professional development, compared with students whose teachers had not participated, scored higher on the science achievement test. Second, students of SSI teachers rated their teachers as more frequently using standards-based teaching practices than did students in non-SSI teachers' classes" (Kahle, Meece, & Scantlebury, 2000, p. 1034). However, participation in the SSI's professional development was not a significant predictor of student achievement; rather the use of standards-based teaching practices was predictive.<sup>17</sup>

---

16. It is not clear if the student sample was limited to students with teachers in the teacher sample.

17. Fifteen percent of the variance in students' science achievement scores was due to teacher differences. Between-teacher variation was largely due to two factors: teacher gender and frequency of use of standards-based teaching practices, including inquiry and problem solving (Kahle, Meece, & Scantlebury, 2000).

Huffman and Lawrenz (2003) investigated the extent to which one state's systemic initiative reformed science education. Eighth-grade science teachers were involved in an *ex post facto* comparative study that assessed impacts on teachers' instructional practices, external relations, professional communities, school policies, and family involvement. They compared schools with high or low participation in the SSI, matching them on demographic characteristics, such as geographical location (urban/rural/etc.), size of school, and socioeconomic and ethnic characteristics of the students. In schools with high participation, they found that the use of standards-based instructional techniques increased and that external groups had more influence over science instruction. However, no differences were found for (1) teachers' influence on school policy (low in both types of schools), (2) teachers' involvement in professional communities (high in both), or (3) family involvement with the reform (low in both). From their findings, they concluded, "Perhaps comprehensive systemic reform is an unrealistic goal, but it does suggest we need to better understand systemic reform and use research to help design future reform efforts" (p. 376).

Although individual research studies identified successful components of the state systemic initiatives, Anderson, Brown, and Lopez-Ferrao (2003) synthesized official evaluation reports to analyze the effectiveness of the program. They concluded that the systemic initiative program contributed in three significant ways to the improvement of science and mathematics education. First, it led to the broad acceptance of a systemic approach in addressing education problems; second, it made improvement of mathematics and science education a priority nationally; and, third, the systemic reform efforts made serving all students a national mandate.

## Equity

Although NSF officially defined equity as the "reduction in attainment difference between those traditionally underserved and their peers" (Zucker, Shields, Adelman, Corcoran, & Goertz, 1998, p. 37), states approached equity in different ways. For example, most states focused on elementary and middle school science and mathematics, because all children would benefit from improvements in instruction and curriculum—improvements that might lead to more equitable enrollments in elective courses (Kahle, 1997). In addition, many states found that leadership both in the SSI and at the state and regional levels was not representative, and some took measures to expand the pool of effective leaders. Furthermore, states addressed the lack of minority teachers of science and mathematics. Overall states reported that 28 percent of teachers served by the SSIs' professional development activities were nonwhite—over double the proportion of minority science and math teachers in the workforce (Zucker, Shields, Adelman, & Powell, 1995).

However, most of the research on equity focused on reducing achievement gaps among identifiable subgroups of students. States varied in relation to the subgroups addressed. For example, ethnic/racial were the focus of 21 states, females of 19, and/or low-income students of four.<sup>18</sup> The different equity emphasis, in most cases, reflected population or achievement differences across the states; for example, Vermont, with few racial/ethnic minorities, did not have that focus, whereas

---

18. States could identify more than one group, so totals are more than 25.

Puerto Rico—with girls achieving higher than boys—did not focus on females. States also differed in the strategies used to improve equity, although the two most commonly identified ones were professional development and targeted funds. Professional development involved specific equity workshops (Georgia, Louisiana, and Ohio), whereas targeted funds were directed to low-performing schools (Connecticut, Michigan, New York, Louisiana, South Dakota, and Puerto Rico) (Zucker, Shields, Adelman, & Powell, 1995).

Much has been written about the “equity challenge” for the SSIs and for standards-based education in general (Boone, 1998; Kahle, 1998). For example, Massell, Kirst, and Hoppe (1997) conducted research on standards-based systemic reform in nine states. Their findings are based on in-depth interviews with policy makers and educators at state and district levels in California, Connecticut, Florida, Georgia, Kentucky, Minnesota (a non-SSI state), New Jersey, South Carolina, and Texas. They concluded, “[F]or the most part, attention to equity issues within the context of standards-based reform remained episodic and weak. With few notable exceptions [Kentucky], desegregation and school finance policies were pursued as separate, independent initiatives” (p. 9).

In 1996, the Office of Educational Research and Improvement (OERI) of the U.S. Department of Education funded 12 studies of different aspects of current education reform, including a study of the systemic reform movement (Goertz, Floden, & O’Day, 1996). The systemic reform study focused on math and reading and was conducted in three stages: first, a comprehensive review of the literature; second, intensive case studies of 12 reforming schools in six districts of three SSI states (California, Michigan, and Vermont); and, third, analyses of the findings in the context of state policies and sustainability. The study focused on all parts of the education system, analyzing capacity for change, governance structures, and teaching practices. It also included a section on equity, noting that both California and Michigan targeted some of their funds for schools and districts with large concentrations of low-performing and/or minority students. Incentives were offered to entice such schools to participate. Goertz and her colleagues reported that both districts and schools were restructured to be more responsive to diverse social, cultural, and educational needs of their students. Furthermore, they noted many examples of restructured curricula across the sites, particularly introducing curricula that embraced state and national standards and providing for bilingual education. Last, they reported that academic tracking declined.

Individual studies also addressed equity. Using Hierarchical Linear Modeling, Kahle, Meece, and Scantlebury (2000) concluded that the standards-based teaching, advocated by Ohio’s SSI and promulgated through its sustained professional development programs, improved the attitudes and achievement levels of urban, African American youth. Furthermore, the gender gap in achievement between African American girls and boys (favoring girls) was narrowed in SSI classes, compared with non-SSI classes in the same schools. Their findings are supported by Laguarda (1989), who states, “Special analyses conducted by both of these SSIs [Louisiana and Ohio] show that the gains demonstrated by students in SSI classrooms were greatest among African American students, students who received free or reduced-price lunches, and girls” (p. 3).

Fenster’s (1998) study of the New Jersey SSI probed three questions: (a) Do students learn more because of the SSI? (b) Are they better equipped to apply what

they learn to everyday problems? and (c) Have inequities in performance among different groups of students been reduced? Using scores on state-mandated assessments, he found that students in NJSSI schools did not learn more than their counterparts in schools without NJSSI affiliation, that the evidence for question (b) was too limited to draw conclusions, and that inequities in performance had widened between underserved school districts and the rest of the state on the required eighth-grade assessment.

Lee (2002) researched changes in racial and ethnic achievement gaps across 30 years. He assessed trends in both NAEP and SAT data for mathematics and reading. Although his study did not include science scores, other analyses suggest that his findings for NAEP mathematics are similar to those for science (Kahle, 2004). His synthesis did not separate SSI states from non-SSI states. His overall finding—that achievement gaps between Black/White as well as between Hispanic/White students widened in the 1990s—reinforces the importance of some systemic initiatives' success in narrowing similar gaps.

## Summary

The SSIs were designed to improve all parts of state educational systems; in so doing it was assumed that changes would enhance student achievement in science and mathematics (Weiss & Webb, 2003). The extensive NSF evaluations of the program as well as a smattering of research studies, however, suggest that the overall goal of excellence (as defined by improved student achievement) was not reached in the five years of NSF funding. Lee's (2002) comprehensive review of achievement changes indicates that 30 years are needed for widespread improvement in achievement. Individual research studies as well as case studies of selected SSI states, however, provide indications that the reforms of the 1990s strove for excellence and achieved it, albeit in small increments at various parts of the educational system.

In summary, Heck (1989) notes that *excellence* and *equity* were both mandated by NSF's systemic reforms of science and mathematics. He writes, "Equity, as NSF has conceived it and asserted it in the SSI program, is not a concept reserved for the traditionally underserved and underachieving groups" (p. 169). Rather, the SSIs were directed toward changing the entire system so that all children were able to reach their full potential. Heck recommended that research questions address both *excellence* and *equity* at all levels of the educational system, shown in Fig. 30-2. Clearly, in the third wave, evaluation and research concerning *excellence* and *equity* was needed to address changes in multiple parts of the system. However, the published literature primarily addresses improved student achievement, the ultimate goal of systemic reform.

## LESSONS LEARNED

Systemic reform is an extremely complex process, and it is not clear whether systemic reform is even possible. (Huffman and Lawrenz, 2003, p. 358)

So, across 50 years, what has been learned about systemic reform? In each wave of reform—from Sputnik to MACOS, from *A Nation at Risk* to the math standards

and science benchmarks, from the SSIs to *No Child Left Behind*—interactions between educational vision and political realities have shaped the reforms as well as the research about them. As research has documented, the vision of improved curricula in the first wave of reform was compromised by several political as well as educational realities. First, some of the new materials did not adhere to local norms concerning human behavior, evolution, and other topics; and, second, research concerning their effectiveness was seriously compromised by the lack of independent tests aligned with the goals of the curricula. Furthermore, although the first wave addressed two major components of the education system—*texts* and *teaching*—the politics of the day prevented articulation between those two massive efforts to improve science education, and each was weakened by that reality. In retrospect, there is a considerable body of research suggesting that the new curricula improved both student attitudes and achievement. However, there is little evidence of the effect of the Teacher Training Institutes on either classroom practice or on student achievement. Positive gains from that program were identified, on the other hand, by changes in the science teaching profession.

It is arguable whether the second wave of reform was systemic. However, authors have identified it as a time of major educational reform, and it involved both top-down strategies and bottom-up reforms (e.g., comprehensive school reform at the local level). The research reviewed focused on state-level, or top-down, reforms during the 1980s, assessing any effects of increased courses in science as well as competency testing on student skills and achievement. Lee (2002) found that the achievement gap between subgroups of students narrowed in the 1980s, a finding based on increases in minority scores while majority scores remained flat. Generally, a review of the research suggests that course proliferation was primarily at the basic level, and that competency testing, rather than raising the bar lowered it, pushing “students toward basic or remedial courses” (Wilson & Rossman, 1993, p. 38).

Indeed, the proliferation of science courses in the 1980s may have contributed to what was, in effect, tracking in science, the elimination of which was one of the goals of the NSF’s systemic initiative program. The third wave of large-scale reform, discussed here in relation to the statewide systemic initiatives, had a theoretical underpinning, was driven by an educational vision that excellence for all leads to equity, and was supported politically at the national and state levels. Although much can be learned from multiple and broad-scale evaluations of the SSIs, research concerning the third wave is somewhat elusive. The published literature is mixed concerning achievement of the dual goals of *excellence* and *equity*. There are several reasons for the lack of research concerning the third wave: first, there is the issue of time (the lag between collecting data and publishing results); second, there was more emphasis (at the state level) on doing the reforms than on studying their effectiveness; and, third, the driving vision of systemic reform as articulated through the SSIs was changed dramatically by the politics of the new century, and science education researchers may have shifted their focus before definitive studies were completed.

Across the three waves of reform, two basic lessons have been learned: first, large-scale reform of science education takes time; and, second, systemic reforms must include both top-down and bottom-up approaches. Research supports those lessons. McLaughlin (1990) reviewed a RAND study of 293 local projects in 18 states

from 1973 to 1978. All of the projects involved significant federal funds. McLaughlin drew the following conclusions:

- Adoption of a project consistent with federal goals does not ensure successful implementation.
- Successful implementation does not predict long-run continuation.
- Success depends primarily on local factors, not federal guidelines or funding levels.
- Local factors enhancing or distracting from success include commitment of district leadership, the project's scope, and the project's implementation strategy.

Likewise, a summary of research concerning systemic reform provides insights into prerequisites for success as well as for sustainability of systemic reform within and across schools (Carpenter et al., 2004, February). The authors identify the following factors:

- Learning communities through which teachers can articulate and examine new ideas about mathematics, science, student learning, and instructional practice.
- Professional development that enables and supports teachers' inquiry into subject matter, student learning, and teaching practice.
- Infusions of material and human resources from outside the school or the educational system, which are necessary to initiate and sustain reform

Synergy across various levels in the educational system, indeed, leads to sustained change. This synergy is articulated by the findings of the OERI review of research on systemic reform (Goertz, Floden, & O'Day, 1996). Those findings are summarized in Fig. 30–3. Systemic or large-scale reform across the last half-century has attempted changes at both local and state levels. Success has come (in terms of student outcomes) when it has been guided by vision and supported by politics of the day. Research across the past 50 years has probed to understand systemic reform, to develop models to guide it, and to provide findings to guide it. However, both the type of research as well as the type of questions asked have been affected by the politics of the day.<sup>19</sup>

## EPILOGUE

One reviewer of this chapter suggested that I include insights that I gained about systemic reform as a principal investigator of one of the initial Statewide Systemic Initiatives—one that continues with state funding. Although I studiously avoided personal thoughts in the chapter, the longer I thought about her suggestion, the more I liked it; for too few researchers are actively involved in systemic reform, and the field suffers from their absence. So, if my personal reflections can entice other scholars to the fray; then, I will modestly add them.

---

19. NSF, under political pressure, switched from qualitative to quantitative studies of SSIs in the mid-1990s.

- Coherence among state policies and a guiding vision is needed.
- Communication about the reform must reach parents, students, and teachers as well as policy makers.
- Reform takes time—time to learn new content and new skills, time to change instruction, time to enhance learning.
- Goals of the reform may have to strike a balance between current and desired practice.
- Deliberate, consistent, and pervasive strategies are needed to infuse equity into the reforms.
- Capacity building must include individual as well as organizational and systemic needs.
- Consistency, alignment, and coherence are needed across and throughout the system.
- Teachers and administrators need to be involved in multiple levels, not only at the school/classroom level.
- Capacity building strategies must pay attention to diversity at all levels of the system.
- Outside stakeholders and supporters must be involved if the reform is to be sustained.

*Note.* From *Systemic Reform. [Volume I: Findings and conclusions.] Studies of education reform*, by M. E. Goertz, R. E. Floden, and J. A. O'Day, 1996, (ERIC Document Reproduction Service No. ED397553). East Lansing, MI: National Center for Research on Teacher Learning.

FIGURE 30–3. Findings of OERI review on systemic reform.

As I wrote in a Performance Effectiveness Review for NSF, the basic problem we faced was trying to do systemic reform while simultaneously learning how to evaluate it, which included the development of the skills and strategies to do large-scale assessments across a period of time. Furthermore, the practicalities of working in multiple districts (in Ohio there were 614 independent school districts during the SSI) with limited budgets were a challenge. In fact, we constantly juggled research design against research practicalities. For those of us who collected student achievement data, the issue of attribution was continuous. In Ohio, we collected various types of achievement information and looked for patterns that supported the SSI. Politically—both in Ohio and at NSF—we could not conduct controlled experiments.

One of the most useful exercises I have ever undertaken was responding to a question, posed by Ohio's evaluator, Iris Weiss, president of Horizon Research Institute. She asked all members of the SSI Coordinating Council what each hoped the reform would look like five years after NSF funds ended—in Ohio's case in 2000. One aspect with which I had had little direct involvement—after its initial implementation—was a regional support system. Regional Councils largely controlled the way SSI funds were expended, public relations, teacher support, etc. I realized that it was critical that the regionalization be sustained to provide services to schools and teachers. Furthermore, I knew that the model of professional development that we had adapted from Reading Recovery was key to our success in changing teacher practice and improving student learning. I hoped that not only teachers and administrators but also parents and policy makers would support that model (sustained, content-based, rigorous, and expensive). I speculated that teacher licensure would change to ensure adequate preparation in math and science for middle school teachers.

Reflecting over the 15 years, there have been some wins and some almost-wins. Regionalization remains, although the Ohio Department of Education now funds and manages the regions. The regional centers support all disciplines, not only math and science, with much less funding. So, regionalization is only a partial win. The professional development model promulgated by the SSI continues, albeit enrolling many fewer teachers, but its basic strengths—content-based, sustained, and rigorous—remain. And, with few exceptions, the model is accepted and supported by administrators as well as by politicians and the public. Last, Ohio moved to middle school licensure (formerly it was K–8 or 7–12 certification) with specialties in math and science. Do I think programs leading to the new licenses have adequate math or science content for today’s teachers? No, but they are a giant leap forward.

At the state level, the systemics were to address all parts of the state’s educational system; yet, none of the SSIs were staffed by people with expertise in all of the areas needed. Most of us were either science or mathematics educators, so we focused on what we knew best—professional development. But we learned. We learned that appropriate texts were needed, so Montana and Nebraska developed curricula; we learned that the public needed to value what we were trying to do, so Ohio developed free booklets of science activities for each state park; we learned that state personnel were relatively fluid, so Connecticut and New Mexico formed independent agencies to guide their reform; we learned that visible units of change were important, so Maine and Michigan focused on model schools.

In spite of all that has been written about systemic reform, the research base is still shallow. Perhaps it is too soon after the last of the systemics, or, perhaps, we (the researchers) have lost interest in this grand experiment. In any case, two analyses of doctoral programs—one in mathematics education and one in science education—indicated that doctoral education has not changed in ways that will provide researchers with the tools and skills (including people skills) to do and to evaluate large-scale reform. In his recent book, Peter Fensham (2004) makes the distinction between research for its own sake and research to improve/change practice. He notes that for many of the science educators whom he interviewed, “the research process itself bound the purposes they saw as important for their research” (p. 163). Clearly, systemic reform is involved in change and improvement, and researchers with those interests are needed.

For me, the opportunity to be involved in the grand experiment—both as an educator and as a researcher—was the opportunity of a lifetime. To have the resources (both human and fiscal) to affect even some parts of a state’s educational system in order to make learning science and mathematics more equitable was important. It was worth all of the political skills that I painfully learned, all of the setbacks along the way, and all of the sleepless nights when I worried about logistics as well as about experimental design!

## ACKNOWLEDGMENTS

I would like to thank Dr. Mary Kay Kelly for her thoughtful suggestions and careful editing of this chapter. Her questions provided valuable insights and her suggestions improved it. Thanks also to Deborah Tomanek and Patricia Campbell, who reviewed this chapter.

# CHAPTER 31

---

## Review of Science Education Program Evaluation

**Frances Lawrenz**

*University of Minnesota*

The purpose of this chapter is to review the field of science education program evaluation. To accomplish that purpose the chapter begins by defining evaluation, outlining the broad types of evaluation that can be undertaken and the philosophies that underlie the different approaches, and distinguishing evaluation from research. The chapter goes on to explicate the relationships between science education program funding and science education program evaluation through a historical approach, where the history of science education is juxtaposed with the history of evaluation and examples of the types of science education program evaluation that were implemented. Following this historical examination of the development process, different models of evaluation are discussed, and examples of how these apply to science education program evaluation are provided. This discussion contrasts the strengths and limitations of the different approaches and specifies the types of questions that the different models are able to address. Within the discussion of models, different methodological approaches are also contrasted. Finally the chapter concludes with some thoughts about the future of science education program evaluation.

With the passage of the No Child Left Behind Act our nation is committed to accountability for its schools. Accountability, being held answerable for accomplishing goals, can be considered a subset of the larger concept of evaluation. Evaluation is based on the notion of valuing and includes a variety of perspectives in addition to accomplishing goals. The idea of evaluation is not a new one. Perhaps one of the first implementations of evaluation in the United States was Joseph Rice's 1897–1898 comparative study of student's spelling performance (Rice, 1900). The next landmark was "The Eight Year Study" by Tyler and Smith (1942). This longitudinal study of thirty high schools made use of a wide variety of tests, scales, inventory questionnaires, check lists, pupil logs, and other measures to gather information about the achievement of curricular objectives. The major impetus for science edu-

cation program evaluation, however, arose out of the National Science Foundation funding of large curriculum development projects and teacher institutes and the Elementary and Secondary Education Act of 1965. This was the first time legislated programs were required to have evaluations. This cemented the reciprocal arrangement between funding and evaluation and led to significant development of the field of educational evaluation.

Extensive literature searches were conducted to provide the background for this chapter. There is an enormous amount of material available, because science education program evaluation crosses discipline areas. For example, keyword searches for documents published between the years 1980 and 2003 on "Program Evaluation" produced 51,660 hits; "Science Education" produced 65,796 hits; and "Science Program Evaluation" 4,213 hits. The majority of articles are geared toward teacher assessment of content with a teacher and administrator audience in mind, not necessarily technical researchers or policy makers. Testing conducted within classrooms by teachers is only one component of science program evaluation, so the majority of the articles are not relevant to this review. The available materials about science education program evaluation are generally descriptions of the evaluation processes and the programs evaluated, again not directly useful for a review of science program evaluation. Also the range of programs is very wide, with references running the gambit from health science programs in universities to effects of using incubators in a fourth-grade classroom. Ultimately there is little direct research about how to conduct program evaluation. The references included in this chapter are meant to be exemplary of the range of material available, not an exhaustive set. Examples are drawn mainly from NSF-funded projects and programs.

## WHAT IS EVALUATION?

The Joint Committee on Standards for Educational Evaluation first presented standards for educational evaluation in 1981, and the second edition of the standards (1994) defined *evaluation* as the systematic investigation of the worth or merit of an object. Objects of evaluations include educational and training programs, projects, and materials and are sometimes described as *evaluands*. Michael Scriven in his *Evaluation Thesaurus* (1991) agreed with this definition and went on to say that the process normally involves "some identification of relevant standards of merit, worth, or value; some investigation of the performance of evaluands on these standards; and some integration or synthesis of the results to achieve an overall evaluation" (p. 139).

One of the first definitions of educational evaluation was provided by Daniel Stufflebeam and the Phi Delta Kappan National Study Committee on Evaluation in *Educational Evaluation and Decision-Making* (1971). In this book the authors say "the purpose of evaluation is not to prove but to improve" (p. v). They define *evaluation* as the systematic process of delineating, obtaining, and providing useful information for judging decision alternatives. This definition is particularly useful in that it highlights that evaluation includes determining what type of information should be gathered, how to gather the determined information, and how to present the information in usable formats. Evaluation is often divided into summative and formative aspects. A summative evaluation approach identifies how valuable an object is by demonstrating whether it is successful or not to various stakeholders. Formative evaluation is designed to help improve the object.

The field of evaluation and educational evaluation in particular has expanded quite a bit since the 1970s, although some of the original texts have kept pace through new editions and additional authors and continue to be the leading sources of evaluation information. The first edition of Weiss's *Evaluation Research* was published in 1972, the second, *Evaluation*, in 1998. Rossi and Freeman's *Evaluation: A Systematic Approach* (1979) is now in its sixth edition, with an additional author (Rossi, Freeman, & Lipsey, 1999). The original Worthen and Sanders text, *Educational Evaluation: Theory and Practice* (1973), is now in a fourth rendition with an additional author as *Program Evaluation: Alternative Approaches and Practical Guidelines* (Fitzpatrick, Sanders, & Worthen, 2003). The National Science Foundation has also provided an evolving set of User Friendly Handbooks to help principal investigators evaluate their projects. These began with the Stevens, Lawrenz, Ely, and Huberman (1993) text and culminated recently in the 2002 rendition by Frechtling.

As part of the expanding definitions of evaluation, Patton in his book *Utilization-Focused Evaluation* (1997) reiterates and extends usefulness by making it clear that the receivers of the evaluation information need to be substantively involved in the evaluation process so that the resulting information will be used effectively. Fetterman's empowerment evaluation was introduced in 1994 (Fetterman, 1994) and expanded in his text *Foundations of Empowerment Evaluation* (2001). Fetterman views empowerment evaluation as a shift from the previously exclusive focus on merit and worth alone to a commitment to self-determination and capacity building. In other words, empowerment evaluation is evaluation conducted by participants with the goal of continual improvement and self-actualization.

The different approaches to evaluation are grounded in different philosophies. House (1983) has categorized these differing philosophies along two continua: the objectivist-subjectivist epistemologies and the utilitarian-pluralist values. Objectivism requires evidence that is reproducible and verifiable. It is derived largely from empiricism and related to logical positivism. Subjectivism is based in experience and related to phenomenologist epistemology. The objectivists rely on reproducible facts, whereas the subjectivists depend upon accumulated experience. In the second continuum, utilitarians assess overall impact, whereas pluralists assess the impact on each individual. In other words, the greatest good for utilitarians is that which will benefit the most people, whereas pluralism requires attention to each individual's benefit. Often utilitarianism and objectivism operate together, and pluralism and subjectivism operate together, although other combinations are possible.

Collectively, approaches that engage the evaluand in the evaluation process are identified as participatory approaches to evaluation. Different approaches include stakeholder evaluation (Mark & Shotland, 1985), democratic evaluation McTaggart, (1991), or developmental evaluation (Patton, 1994). Cousins and Whitmore's (1998) framework categorizes participatory evaluation along three dimensions: control of the evaluation process, selection of participants, and the depth of participation. Positions along these different dimensions are indicative of different approaches to participatory evaluation.

Cousins and Whitmore (1998) suggest that there are two philosophies undergirding participatory evaluation. Practical participatory evaluation is one that is common in the United States and Canada and "has as its central function the fostering of evaluation use with the implicit assumption that evaluation is geared toward program, policy, or organizational decision making" (p. 6). Transformative participatory

evaluation “invokes participatory principles and actions in order to democratize social change” (p. 7).

Another underlying movement in evaluation is termed responsive evaluation. The legacy of the philosophy of responsiveness in evaluation is discussed by Greene and Abma (2001). This philosophical perspective informed Guba and Lincoln’s (1989) influential book, *Fourth Generation Evaluation*. This is an approach to evaluation that rests on a relativist rather than a realist ontology and on a monistic subjective, rather than dualistic objective, epistemology. It therefore recommends evaluations that are important and meaningful within the context and frames of references of the people involved. In terms of the discussion above, responsive evaluation is in the pluralism and subjectivism sphere.

Another way to help define something is to explain what it is not. Therefore it is important to point out that assessment can be considered a subset of evaluation and that although there are many similarities, evaluation and research are not the same. Generally assessment is considered the process of measuring an outcome, whereas evaluation employs assessment information in its determination of merit or worth.

Weiss (1998) suggests that what distinguishes evaluation from other research is not method or subject matter, but intent. In other words, evaluations are conducted for purposes than other research. Worthen, Sanders, and Fitzpatrick (1997) expand the distinction to point out that evaluation and research differ in the motivation of the inquirer, the objective of the inquiry, the outcome of the inquiry, the role played by explanation, and generalizability. In terms of motivation, evaluators are almost always asked to conduct their evaluations and therefore are constrained by the situation. On the other hand, although researchers may apply for grants to conduct their research, they are generally the ones who make the decisions about why and how to conduct it. The objectives and outcomes in the two types of inquiry are also slightly different. Research is generally conducted to determine generalizable laws governing behavior or to form conclusions. Evaluation, on the other hand, is more likely to be designed to provide descriptions and inform decision making. Finally, evaluation is purposefully tied to a specific object in time and space, whereas research is designed to span these dimensions.

These distinctions are important because they affect the type and appropriateness of evaluation designs. Because of their tie to specific situations, evaluations are both less and more constrained than research. They are less constrained because their results do not have to be universally generalizable, but they are more constrained because the results have to address a specific context.

## **THE RELATIONSHIP OF EVALUATION TO SCIENCE EDUCATION**

Evaluation is applied, disciplined inquiry. As suggested above, evaluations are generally commissioned in response to a specific need and operate across various power structures and in different contexts. In science education, evaluations have closely followed the funding priorities and requirements of the federal government. For example, as the government provided funds for science curriculum development, evaluations of science curricula were conducted. Naturally not all evaluation was directly tied to federal funding, but since the federal agendas reflect the priori-

ties of the citizens, the issues of interest to the general public and science educators were included. To help clarify this relationship, this section includes a look at the history of funding in science education with a parallel history of science education evaluation.

Many reviews have been provided on science education research (e.g., Welch, 1985; Finley, Heller, & Lawrenz, 1990); however, these reviews may include only one type of evaluation or may not include evaluations at all (Welch, 1977).

As explained earlier, assessment is a subset of evaluation; a comprehensive review of the history of assessment in science is provided by Doran, Lawrenz, and Helgeson (1994). That review highlights work in instrument development and validity. As they point out, the 1960s laid the groundwork for science education program evaluation with the beginning of the National Assessment of Educational Progress (NAEP) and the ESEA Act. The 1970s were a time of concern about fairness in testing and of advances in testing procedures, such as matrix sampling and item response theory. The first international science study was conducted during the 1969–70 school year by the International Association for the Evaluation of Educational Achievement. The 1980s showed consolidation and growing interest in gathering data on various indicators. Interest in international comparisons and authentic testing grew through the 1990s along with interest in trends analysis because longitudinal data were now becoming available. Currently the emphasis in assessment is on assessing student in-depth understanding of science content through authentic measures (Newman, 1996; Wiggins, 1998).

Status data provide a unique type of evaluation evidence. Generally status data are not tied to specific situations or stakeholders except in a very general way, so they are not evaluations in their own right. They are used, however, as comparison data for many individual programs and can be used to examine trends over time. NAEP, TIMSS, and the science and mathematics teaching surveys by Weiss at Horizon Research, Inc. are classic examples of status-type evaluation evidence. The Weiss reports began in 1977 and have continued at intervals through 2002. These reports contain information on the amount of time spent on science and mathematics, the objectives for science and mathematics, classroom activities, types of students in various types of classes, teachers' views of education, and their opinions about the environments in which they teach. NAEP and TIMSS show state, national, and international levels of student achievement in various areas of science, as well as some data on the teachers and classroom environments. These types of data have been synthesized into large reports outlining indicators of science education (Suter, 1993, 1996) as well as additional pieces such as comparing indicators with standards (Weiss, 1997).

Considering the history of the NAEP science tests provides some insight into the contextual and political changes that have worked to shape science education program evaluation. NAEP was born in a sea of controversy over whether or not the federal government should be collecting any national data. In response to the desire for local autonomy and privacy, the first NAEP reports provided information about only large regions of the country and were very careful to not suggest that any national standards or requirements were included in the data. Today, the pendulum has shifted to acceptance of national standards and openness in reporting, so not only are individual state data reported, but they are expected. Furthermore, they are tied to standards, and the collection of ever more data is being required

(No Child Left Behind Act, 2001). These types of status data are also being collected internationally; the TIMSS-R (U.S. National Research Center, 2003) is but the latest step in this process.

Another historical example is the evolution of the Joint Dissemination and Review Panel of the Department of Education, which was established in 1972. It began as a group of research experts who judged the quality of educational programs requesting dissemination funds based on evidence the program provided. The panel was strict in its assessment of causality, and very few programs were designated as “programs that work.” In 1987 the panel was reconstituted and renamed the Program Effectiveness Panel (Cook, 1991). This panel was instructed to include a variety of evidence in its deliberations, including qualitative data and implementation costs. Educational programs were expected to provide proof that their claims were met, and these claims were judged based on the data provided. In 1994 the Educational Research, Development, Dissemination and Improvement Act directed the establishment of panels of appropriately qualified experts and practitioners to evaluate educational programs and designate them as promising or exemplary. Multiple panels were created (e.g., the Math and Science Education Expert Panel), with several different criteria and several subpanels. Subject matter experts and users determined the quality of the materials. Evaluation experts commented on only one of the criteria—the extent to which the program made a measurable difference in student learning. Programs received overall ratings as promising as well as effective. These panels were phased out recently, but new panels for determining quality programs are being formed.

As an exemplar of evolution at the federal level, Table 31.1 outlines the major activities of the Science Education Directorate at the National Science Foundation, along with evaluation emphases. The accompanying Fig. 31–1 shows the history of funding at the National Science Foundation by directorate. Figure 31–1 clearly shows the changing levels of funding supporting the Education Directorate activities described in Table 31.1 and the proportion of the funding that was allotted to education.

In the 1960s, with the advent of Sputnik, the National Science Foundation began to focus on curriculum development. People believed that the United States would win the race for space if our children had better science and mathematics curricula. Many different curricular projects were undertaken. Evaluation concentrated on the effectiveness of these curricula in helping students learn science.

In the 1970s curriculum development continued, but the emphasis shifted toward how to get these new curricula implemented in the schools. Evaluation was focused on delivery systems and accomplishing change within classrooms, schools, and districts. There was also an emphasis on enhancing teachers’ science knowledge so that they would be better prepared to deliver the new curricula. Evaluations of these teacher institutes focused on perceived quality. The “Man: A Course of Study” curriculum caused a great furor across the country. Many people did not believe their children should be studying about different cultural practices, such as Eskimo elders going out on the ice to die. As shown in Fig. 31–1, funding for the Science Education Directorate was essentially wiped out by the political aftermath. It was rebuilt, however, through funding of smaller local programs, often summer institutes, designed to enhance teacher understanding of science and mathematics and teacher pedagogical skills. The small local nature of the programs guaranteed local acceptance. Evaluation of these programs was individualized to the needs of

**TABLE 31.1**  
**History of NSF Education Directorate Funding Initiatives**  
**and Science Education Program Evaluation**

<i>Date</i>	<i>Major NSF Education Directorate Funding Initiatives</i>	<i>Science Education Program Evaluation</i>
60s	Curriculum development	Focused on improving the individual curricula being developed. National Assessment of Education Progress begins.
70s	Comprehensive curriculum implementation and teacher institutes	Extent of implementation and gains in teacher content knowledge in individual projects. An Office of Program Integration related to evaluation of programs was established. First international science study and first status survey of science teaching.
80s	Precipitous drop in funding and then rebuilding. Funding of small and varied projects in graduate and undergraduate education and K–12 teacher inservice	Evaluation tied to individual projects. Focus on science teacher perceptions of professional development. Status studies continue.
90s	Systemic initiatives	Comprehensive evaluations of many aspects of projects. Centralized requirements for projects to meet program evaluation needs. An office of evaluation was formed and expanded into the Division of Research, Evaluation and Dissemination. Government Performance and Results Act required agency accountability.
00s	Partnerships	Evaluations focusing on K–12 student achievement and institutional climate. RFPs to conduct program evaluations, provide expert assistance to large project evaluators, expand evaluation capacity, and conduct research about evaluation.

the program and their stakeholders. This time also witnessed a growth in commitment to diversity in the pool of science and mathematics professionals. Evaluation of these programs focused more on social activism and facilitation of movement across power barriers.

The 1990s were characterized by systemic initiatives. The idea was that all parts of a system needed to be focused on the same goals in order to achieve success. The systemics included statewide programs, urban programs, and local programs. Evaluation was much more complex and assessed how to change cultures as well as interactions and what results those changes might produce. This produced the beginnings of national data bases to track the status information, centralized or pooled approaches to conducting evaluations, and the realization that this sort of evaluation takes a good deal of time and money. The systemics met with mixed success, and in particular it was difficult for the larger initiatives to “go to scale.” The systemics

FIGURE 31-1. Funding levels for the NSF directorates over time (in millions of constant FY 2003 dollars).

were successful in some ways or at some locations, but that success did not seem to spread across the entire system.

The present emphasis in funding is partnerships. These focus on changing various institutions so that they will better interact with others. Evaluation of partnerships is complex, like it was for the systemics, but the approaches are more restricted in some ways. There is a heavy emphasis on accountability and direct ties to state-based testing systems. In contrast, how to measure organizational change and promote interaction is viewed as complex, and several technical assistance evaluation projects are being funded to assist the partnerships with their evaluations.

Today science education evaluation is quite complex. It functions at both the individual project and the state or national program level. The terms *project* and *program* are often used by federal or state funding agencies and their evaluators in a distinct way. The term *program* is used to mean the overall funding initiative across the state or nation, and the term *project* is used to mean the sites that were funded. Therefore program evaluation would be of all of the projects related to or funded under a particular plan or funding initiative. Project evaluation is a smaller and more coherent endeavor with fewer categories of stakeholders. Take, for example, the NSF materials development program, which funds several individual curriculum development projects. Each project would be responsible for conducting an evaluation of itself. The program evaluation would examine the value of all of the projects as a set. Projects can range in size from a single school's attempts to improve its science curriculum to a large math science partnership working with several school districts and multiple institutions, including higher education, informal science settings, and business and industry. With these sorts of large projects the distinctions between program and project evaluations blur somewhat. Sometimes smaller types of project evaluations can be combined in a technique called cluster evaluation, where a cluster of

projects work together to obtain evaluation help and comparable data that might be used in a program evaluation (Barley & Jenness, 1993).

Project evaluations are generally quite varied and unique to the specific project. They can follow diverse philosophies and use the full range of evaluation methods, so they are difficult to characterize. The following examples help to illustrate the range of project evaluations. One example is the evaluation of the teaching and learning of Hispanic students in a solar energy science curriculum which showed that the approach increased the student retention rate (Hadi-Tabassum, 1999). Another example is a school district that was concerned about the quality of its K–12 science curriculum. The evaluation consisted of a series of focus group sessions with parents; elementary; middle and high school teachers; and middle school, high school, and recently graduated students. The focus groups discussed visions for excellence and strengths and limitations of the existing curriculum, which revealed a need for stronger communication about goals and closer articulation across schools and grade levels (Huffman & Lawrenz, 2003). Another example is the Desimone, Porter, Garet, Yoon, and Birman (2002) evaluation of the effects of science and mathematics teacher professional development. That evaluation showed that professional development focused on specific instructional practices increases teachers' use of those practices in the classroom. Furthermore, specific features, such as active learning opportunities, increased the effect. It is clear from these examples that the range of issues, styles, and goals is very broad.

The Science Education Directorate at the National Science Foundation provides an exemplar of the current state of affairs in program evaluation. Evaluations being funded can be categorized along a continuum based on the level of participation of the projects: exterior evaluation, centrally prescribed evaluation, consensus evaluation, and pooled evaluation (Lawrenz & Huffman, 2003). At one end of the continuum are evaluations conducted by an entity separate from the projects, with the external entity collecting the data and making the decisions to address the needs of NSF. This type of evaluation is exemplified by the evaluation of the Advanced Technician Education program. The evaluation is funded through a different division of NSF than the program and employs its own instruments and collects its own data independently from the funded projects and centers. It is directly tied to the needs and questions of NSF through matching of survey and site visit instruments to a logic model. This evaluation project produces yearly reports, which are posted on the program evaluation web site (Hanssen, Gullickson, & Lawrenz, 2003). The results have shown that the projects engage in a wide variety of activities related to technician education, that significant amounts of cost sharing have been provided to the projects, that a random subset of the materials developed by the projects is perceived by external experts as of good quality, and that the number of technicians produced has increased.

Another example of an external program evaluation is COSMOS Corporation's evaluation of the statewide systemic reform initiative (SSI) (Yin, 2002). This evaluation examines the status of statewide reform in seven states and one territory through intensive case studies that provide an inventory of district policies and curriculum practices, and an analysis of student achievement trends over time. The interim findings suggest that across the eight sites much reform progress only occurred in the late 1990s and is still occurring. Interestingly, it appears that school finance rulings by state supreme courts may be an important reform influence. Successful reform

processes do not necessarily follow a top-down format. The case studies show that successful states may need to make a sustained commitment to the reform process. Finally it appears that SSIs can pursue both catalytic and direct service roles in support of reform.

Moving on toward the middle of the continuum are program evaluations with mandated procedures that each of the sites must follow but which allow the sites to collect their own data and turn it in to the central external evaluator. These are exemplified by the Local Systemic Change (LSC) program evaluation. In that program each funded project is required to gather specific information with the use of pre-designed evaluation instruments. Each project may also add its own evaluation components. The data from all of the different projects are synthesized into program evaluation reports. An extension of this type of evaluation is the status data collection required of projects in several NSF education programs. This status information includes information such as numbers and characteristics of participants.

The LSC evaluation reports are provided yearly (Weiss, Banilower, Crawford, & Overstreet, 2003). The outcomes for 2003, like those for other years, show mixed results. Thirty-five percent of the teachers participating nationally rated the LSC professional development they received as excellent or very good. Professional development sessions show high ratings on appropriateness of the mathematics/science content, the climate of respect for and collegial interactions among participants, and for encouraging active participation. Weaknesses include questioning about conceptual understanding and providing adequate wrap-up. Survey data show significant positive impact on teacher attitudes and beliefs about mathematics/science education. In addition, participants are becoming more confident in their content knowledge and more likely to use standards-based instructional strategies. Classroom observations show that the quality of the lessons taught improved, with increased participation in LSC activities.

Toward the participatory end of the continuum are evaluations where the projects determine the evaluation procedures and what data to collect. The Collaboratives for Excellence in Teacher Preparation (CETP) program evaluation is an example. The CETP program evaluation is one where sites collect some similar data, using centrally developed instruments. The procedures and instruments were developed by the projects, and projects decide which data they wish to provide. The program evaluation or core team provides leadership, a communication hub, instruments, data analysis, and incentives for collecting core data. Evaluation reports are provided yearly (Lawrenz, Michlin, Appeldoorn, & Hwang, 2003). The results show that the CETP projects have had a positive impact on the establishment and institutionalization of reformed courses and on interactions within and among STEM and education schools and K–12 schools. Over time, it appears that all higher education classes used more standards-based instructional strategies. Results from the K–12 classrooms show that CETP and non-CETP teachers were reporting the same frequencies of use of instructional strategies in their classrooms. Students, however, reported that their CETP teachers more frequently used real-world problems, technology, and more complicated problems in their teaching. Students of non-CETP teachers, on the other hand, were more likely to report doing activities involving writing, making presentations, and using portfolios. Moreover, external observers rated CETP classes higher.

## MODELS FOR SCIENCE EDUCATION PROGRAM EVALUATION

Stufflebeam (2001) provides a descriptive and evaluative review of the different evaluation models that have been used over the past 40 years. He describes 22 different approaches and then recommends nine for continued use. He bases this recommendation on how well these approaches meet the Program Evaluation Standards of utility, feasibility, propriety, and accuracy. These nine include three improvement or accountability-oriented approaches, four social agenda or advocacy-oriented approaches, and two method-oriented approaches. The models are defined below and listed in Table 31.2, along with an example of how each could be operationalized in science education.

The three accountability-oriented approaches are Decision/Accountability, Consumer Orientation, and Accreditation. Decision/Accountability evaluation provides information that can be used to help improve a program as well as to judge its merit and worth (Stufflebeam, 1971). Consumer Orientation evaluation provides conclusions about the various aspects of the quality of the objects being evaluated, so that the consumers will know what will be of use in their situations (Scriven, 1974). Accreditation evaluation studies institutions, institutional programs, and personnel to determine the fit with requirements of a given area and what needs to be changed in order to meet these requirements.

**TABLE 31.2**  
**Science Education Examples of Evaluation Models**

<i>Model of Evaluation</i>	<i>Science Education Example</i>
Decision/accountability	Determining the strengths and weaknesses of a science teacher training program to make decisions about what to do in the coming year
Consumer-oriented	Rating all of the existing high school science curricula using a specific set of criteria
Accreditation Utilization-focused	Certifying that a middle school's science program was acceptable Providing a timely report to a school district contrasting the two science curricula they were considering using criteria they felt were important
Client-centered/responsive	Working with a school district as they develop a new science curricula gathering different data about different questions as needs evolve
Deliberative democratic	Having all of the science teachers in the school district debate and vote on the evaluation questions, the data and the interpretation
Constructivist	Providing descriptions of the different perspectives different groups of science teachers have of a new assessment procedure
Case study	Providing a school board with an in depth description of the AP chemistry class
Outcome/value added assessment	Looking at school level student science assessment results over time and examining the change of slope in schools using a new science program.

The four social agenda approaches are Utilization-Focused, Client-centered/Responsive, Deliberative Democratic, and Constructivist. Utilization-Focused evaluation is a process for making choices about an evaluation study in collaboration with a targeted group of priority users, in order to focus effectively on their intended uses of the evaluation (Patton, 2000). Client-centered evaluation requires that the evaluator interact continuously with the various stakeholders or clients and be responsive to their needs (Stake, 1983). Deliberative Democratic evaluation operates within a framework where democratic principles are used to reach conclusions (House & Howe, 2000). Constructivist evaluation works within a subjectivist framework and requires that the evaluators advocate for all participants, particularly the disenfranchised, to help emancipate and empower everyone (Guba & Lincoln, 1989; Fetterman, 2001).

The two method-oriented approaches are Case Study and Outcome/Value Added Assessment. Case study evaluations are in-depth, holistic descriptions and analyses of evaluands (Merriam, 1998). Outcome/Value Added Assessment evaluation involves determining what changes have occurred in the patterns of data collected over time as the result of program or policy changes (Sanders & Horn, 1994).

Stufflebeam's categorization of evaluation models is in addition to other models that have been proposed for the evaluation of science education. Early models were provided by Welch (1979a,b), Welch (1985), and Knapp, Shields, St. John, Zucker, and Stearns (1988). A more recent model was provided by Altschuld and Kumar in the 1995 issue of *New Directions for Program Evaluation* edited by Rita O'Sullivan. Their model is a synthesis of models of evaluation applied to science programs before 1994. They review several different types of science evaluation at what they call the micro developmental or formative level and the macro system or contextual level. They then provide a model with the main stages of program or product development, defined as Need, Conceptualization, Development, Tryout, Formal Use, and Long-Term Use and Impact. These stages are informed by contextual and supportive factors and intermediate outcomes. Their intent is that the main stages are embedded in specific contexts and that the contexts will have profound effects on the implementation and results of the stages. Synthesis of the stages and factors results in an evaluation of overall effectiveness. They say, "Carefully evaluating development, studying process variables, evaluating outcomes along the way rather than just at the end of product development, and analyzing supportive and contextual variables generates a comprehensive understanding of the overall effectiveness of science education programs and to a degree, the interface between levels" (p. 13).

In 2001 the National Research Council's Committee on Understanding the Influence of Standards in K-12 Science, Mathematics and Technology Education presented *A Framework for Research in Mathematics, Science and Technology Education* (NRC, 2001). The committee's Framework used two main questions: How has the system responded to the introduction of nationally developed mathematics, science, and technology standards? and What are the consequences for student learning? The Framework "provides conceptual guideposts for those attempting to trace the influence of nationally developed mathematics, science, and technology standards and to gauge the magnitude or direction of that influence on the education system, on teachers and teaching practice and on student learning" (p. 3). Undergirding the

first question are contextual forces such as politicians and policy makers, the public, business and industry members, and professional organizations. These forces are viewed as operating through channels of influence, including curriculum, teacher development, and assessment and accountability. The context funneled through the channels results in teachers and teaching practice in the classroom and the school context, which ultimately leads to student learning. The Framework goes on to provide examples of hypothetical studies that could address the evaluation questions. In conjunction with this, the Council of Chief State School Officers (1997) has a Tool Kit for evaluating the development and implementation of standards.

## METHODS FOR SCIENCE EDUCATION PROGRAM EVALUATION

Despite the differences between research and evaluation, they use similar methodologies and are subject to the considerations of rigor applied to all forms of disciplined inquiry. There is an ongoing debate about what constitutes rigor, which was highlighted by the National Research Council (2003) report *Scientific research in education*. The report articulates the nature of scientific research in education and offers a framework for the future of a federal educational research agency charged with supporting high-quality scientific work. The report considers several different methodological approaches to research, and consequently evaluation, with an emphasis on rigor and matching the methods to the questions. Many of the research questions in education are evaluation-oriented, such as, is this curriculum better than the one we have, or what is happening or how is it happening? A special class of questions is questions of causality, which the NRC report suggests are best answered by randomized experiments. Various researchers have raised several issues, such as how to have a culture of rigor and how to educate professionals to operate within such a culture (Pellegrino and Goldman, 2002). Additionally, issues such as random assignment, the uniqueness of each site, and the potential endorsement of an evidence-based social engineering approach to educational improvement need to be considered (Berliner, 2002; Erickson & Gutierrez, 2002).

There is a good deal of information available on what constitutes rigor in quantitative evaluations. There are fairly clear guidelines on how to calculate appropriate sample sizes, which statistical tests are appropriate for what types of data, and what constitutes a meaningful result. The guidelines for rigor in more interpretive or qualitative evaluation are no less strong, but they are different. Lincoln and Guba (1985) provide an informative contrast of terms related to rigor from the quantitative and qualitative perspectives. They say that in quantitative work there is validity as determined by an evaluation's internal validity, external validity, reliability, and objectivity. In contrast, in qualitative work there is trustworthiness, as determined by an evaluation's credibility, transferability, dependability, and confirmability. Anfara, Brown, and Mangione (2002) suggest making the qualitative research process more public to help ensure rigor. They discuss different techniques that would help to increase trustworthiness (e.g., triangulation, member checks, prolonged field work) and go on to suggest that all qualitative research (or evaluation) should include documentation tables that show how the different techniques were used. Suggest-

tions include specifically linking interview questions to research questions, providing tables of how individual codings of narratives were synthesized, and having matrices of triangulation showing findings and sources.

Another rich methodological source for science education program evaluation is design experiments. This type of evaluation attempts to support arguments constructed around the results of active innovation and intervention in classrooms (Kelly, 2003). It is aimed at understanding learning and teaching processes when the researcher or evaluator is active as an educator. This approach ties into the participatory evaluation literature as well as the evaluation capacity-building literature, because the people involved in the innovation are the evaluators, and through the experience they gain expertise, which will enhance the educational enterprise (Stockdill, Baizerman, & Compton, 2002). It also dovetails with the action research or teacher-as-researcher movements.

Most science education evaluations employ mixed methods. In other words, a variety of data-gathering and interpretation techniques are incorporated into a single evaluation. The issues involved in mixing methods are complex because the methods are often embedded in an overarching philosophy that informs how the method should be interpreted. For example, Greene and Caracelli (1997) suggest three stances to mixing methods: purist, pragmatic, and dialectical. The purist stance uses methods embedded within a philosophical paradigm. The pragmatic stance puts methods together in ways that produce an evaluation result that is the most useful to the stakeholders in the evaluation. The dialectical stance is synergistic in that it plays the different methodologies off against each other to produce an evaluation that transcends any of the individual methods. Caracelli and Greene (1997) go on to discuss how these different stances can be formulated into different mixed method evaluation designs. These include component designs where different methods could be used to triangulate findings, to complement findings from another more dominant method, or to address different aspects of the science education program being evaluated. There are also integrated, mixed-method designs where the use of different methods could be iterative, nested, holistic, or transformative (giving primacy to the value and action oriented aspects of the program). Lawrenz and Huffman (2003) combined these ideas into another mixed-method model they termed the archipelago approach.

The mixed approaches to evaluation are grounded in methodological advances across the qualitative and quantitative continuum. There have been significant advances in quantitative analyses, especially in the area of modeling, such as linear models (Moore, 2002), hierarchical models (Byrk & Radenbush, 1992), longitudinal models (Moskowitz & Hershberger, 2002), and structural equation modeling (Maruyama, 1998). There has also been significant work in measurement and sampling theory, including matrix sampling and Rasch modeling (Wright, 1979). In the middle of the quantitative-qualitative continuum there have been advances in survey design to encompass the new capabilities inherent in web-based settings (Dillman, 2002). On the qualitative side there have been new approaches and new insights, including, for example, interpretive interactionism (Denzin, 2001) and interpreting the unsayable (Budick, 1989).

Table 31.3 lists some science education areas, selected methods that could be used, and the evaluation questions each method would allow the evaluator to answer. The intent is to show the direct tie between the evaluation questions and the

**TABLE 31.3**  
**Science Education Area by Evaluation Method and Questions**

<i>Science Education Area</i>	<i>Evaluation Method</i>	<i>Questions the Method Addresses</i>
A science education program focused on institutional culture	Case study Opinion surveys of institutional members and persons from other institutions who interact with the primary institution with retrospective items Pre and post observations by external experts or participant observers Artifact analysis of policies, procedures and public statements during the course of the program Pre and post testing of content knowledge, attitudes, teaching philosophies. Phenomenological study	How can the nature of the institution be described? What do people within the institution think the culture is? How do they think it has changed? What do people who interact with the institution think the culture is? How do they think it has changed? How do observers characterize the culture of the institution before and after the program? What changes have occurred in the policies, procedures and expressed public image during the program? What immediate changes have occurred in teacher content knowledge, attitudes and teaching philosophies? How do the teachers perceive the lived experience of the workshop?
A teacher development workshop on participating teachers	Observations of the workshop by external experts or participant observers Ethnography	What are observers' opinions of the quality of the workshop? What is the culture of the classroom and how is it evolving?
A new curriculum on science classroom environment	Pre and post assessment of student perception of the classroom environment Observations of the classroom by experts Discourse analysis	How do students perceive the classroom environment before and after using the curriculum? What are observers' opinions of the characteristics of the classroom environment What verbal interaction patterns are heard within the classroom and how do these reflect on the classroom environment? How do selected students view the lived experience of participating in standards based instruction?
Effect of standards based science instruction on students throughout a district	Phenomenological studies Assessment of student knowledge and attitude and application of HLM analyses Value added analysis of student scores over time	Which student variables are predictive of student achievement and attitude and how much do classrooms and schools contribute to this relationship? What changes have occurred in the longitudinal patterns of student achievement and attitudes across the district since the implementation of the new science instruction?

methods. Methods are not good or bad (assuming they are implemented proficiently), but they can only be used to answer specific types of questions.

## CONCLUSION

This review has documented the significant growth experienced by the field of science program evaluation since its solidification in the early 1960s. Science program evaluation is also shown as closely tied to political agendas through public and private funding initiatives. The literature reveals that most published work has focused on practical applications and descriptions of approaches. Philosophical underpinnings have become more clearly articulated, and diverse models and approaches have been developed and implemented. The variety of methods available to use has expanded, and connections between methods and questions have become more explicit. Despite this growth there has been very little research on science program evaluation practices per se. The work has been mainly theoretical. The literature provides extensive examples of procedures and approaches and suggestions of when to use them, but little direct research about which of these might be more effective.

Research comparing the strengths and weaknesses of different science program evaluation approaches and methods would be beneficial to the field. This type of research, however, would be expensive because more than one evaluation would have to be funded for any project. Also research comparing different approaches would have to be carried out in multiple settings, such as different grade levels, different content areas, or different types of students. Also as is clear from the existing theoretical and practical work, different types of evaluation provide different types of information. This information might be differentially valuable to different stakeholders in determining the merit or worth of a science education program. Therefore the value of science program evaluation approaches would have to be determined in terms of the needs and opinions of different stakeholders. One possible cost-effective manner of addressing some of the issues would be through consideration of the evaluation results of similar programs obtained through different methods. This idea is similar to the one suggested by the National Research Committee to assess standards-based reform. However, those recommendations are related to using evaluation results to understand standards-based reform, not to answering questions about how to conduct evaluation. The distinction between researching the value of evaluation and researching the value of the programs being evaluated needs to be kept in mind.

Experience and expertise in science education program evaluation is growing but is still scarce. Educational programs designed to provide qualified science education program evaluators should be continued and perhaps expanded. Increasing the capacity of the evaluation field to deal with science program evaluation has pursued several avenues, such as direct grants, indirect training programs, graduate-level programs, short courses, and intensive workshops. Additionally, although there has been work identifying the essential competencies required of an evaluator, there is no clear indication of what skills might be expressly needed for science program evaluation (King, Stevahn, Ghere, & Minnema, 2001). Furthermore, there is little evidence available about which sort of educational programs would produce

the best science program evaluators. Capacity building then is another fruitful area for research. Currently the Research Evaluation and Communication division of NSF has a yearly competition for proposals to increase the capacity of science program evaluators. Coordinating and pooling evidence from these projects might provide valuable information about improving capacity.

The field of science education program evaluation continues to mature and expand. At present evaluations encompass a variety of methodologies, underlying social values, and philosophies. Recent emphases in funding tend toward large projects that require complex evaluations. It is likely that new techniques and devices designed to evaluate system-wide reforms, partnerships, and collaborations will be developed to meet this need. The diversity within science program evaluation contributes to a rich literature and the opportunity for the field to debate and discuss issues and perspectives. These interactions provide fertile ground for the field of science education evaluation to grow and evolve. Without the various perspectives the field could easily become sterile and barren.

The new federal emphasis on accountability, specifically student assessment, may significantly narrow the diversity of methods and perspectives existing in science education evaluation. Currently evaluations use a variety of information to judge program value. Student achievement, as defined by a score on a particular test, is only one of many valuable outcomes hoped for in science education. Science education evaluations are designed to serve the many stakeholders involved in the object being evaluated. This responsiveness to evaluating a program to address the needs and ideals of all people concerned about or affected by it, appears to be the process most likely to produce the most valid indication of the value of the science education programs. Science educators should advocate for diversity of perspectives and methods, as well as high quality and rigor, in evaluations of science education projects.

# CHAPTER 32

---

## Classroom Assessment of Science Learning

**Beverley Bell**

*University of Waikato, New Zealand*

In this chapter, classroom assessment of science learning is taken as that assessment done by the teacher of science, in the classroom, for formative and summative purposes, for use by the teacher and student. Other chapters are reviewing the research on assessment in science education for the purposes of accountability and international comparisons, for summative assessment for reporting to others outside the classroom and for external qualifications, and for program evaluation. In other words, classroom assessment is viewed as teacher assessment for the participants of the classroom—the teacher and students.

Classroom assessment is an important part of science teaching and learning. Its importance is indicated by the extensive and valuable reviews of classroom assessment of science learning in two previous handbooks of science education (Black, 1998a; Doran, Lawrenz, & Helgeson, 1993; Gitomer & Duschl, 1998; Parker & Rennie, 1998; Tamir, 1998). This review builds on these and other seminal reviews of classroom assessment research in education generally (Black & Wiliam, 1998a; Crooks, 1988; Natriello, 1987) to highlight the continuing as well as new trends in research on classroom assessment of science learning.

The importance of classroom assessment is also indicated in that classroom assessment is viewed as a highly skilled and complex task that is a major component of classroom teacher practice (Bell & Cowie, 2001b; Doran et al., 1993). Hattie and Jaeger (1998) assert that the factors that are most effective at improving student learning are clearly in the hands of teachers and include the giving of feedback during some assessment tasks. Most assessments of science learning are carried out by teachers of science in classrooms, it is the teacher who is responsible for either initiating or implementing changes in assessment in the classroom, and it is the teacher who has to ultimately judge the educational worth, significance, and use of different assessment practices.

This chapter reviews the literature in classroom assessment of learning in general, as well as that in science education, science education being a subset of educa-

tion. The two bodies of literature form the structure of this integrative review, as does the work in early childhood, primary, secondary, and tertiary science education.

By way of an overview, the two main trends in assessment of science learning (as well as assessment of learning in general) are the following:

1. Assessment in education is moving from being viewed as using only traditional psychometric testing and psychological measurement based on a unitary trait view of intelligence and true score theory (Black, 2001), to *educational assessment*, that is, from assessment to prove learning to assessment to improve learning (Gipps, 1994a, 1994b). This move requires a different view of the learner; a different relationship between the pupil and assessor; an acknowledgment that context, pupil motivation, and the characteristics of the task will affect the performance (the demonstration of the competence on a particular occasion or under particular circumstances) as distinct from the competence (the basic ability to perform); and different notions of quality (Gipps, 1994b).

2. Educational assessment is being “perceived less [as] a technical matter of measurement and more a human act of judgment, albeit based on sound evidence” (Broadfoot, 2002; Harlen & James, 1997, p. 378). This concurs with Eisner’s notion of “connoisseurship” (Eisner, 1985). Hence, assessment in classrooms is being seen as a *teacher and student practice embedded in political, historical, social, and cultural contexts* (Broadfoot, 2002).

It is acknowledged that psychometric testing and measurement and their associated technical considerations still have a place in assessment (Black, 2001; Hattie & Jaeger, 1998), and as Black (2001) stated, “the apparatus of psychometric statistics will still be needed, but in the service of new endeavours, not as keeper and promoter of the old traditions” (p. 80).

Hence, this review specifically focuses on these two new more recent and developing trends of educational assessment and assessment as a sociocultural practice of teachers and students. These two trends are evident in the political contexts of assessment, the multiple purposes for assessment, the assessment of multiple goals, assessment for formative and summative purposes, the notion of quality in assessment, and theorizing of assessment. Each of these aspects of assessment of science learning is discussed in this review.

## ASSESSMENT AND ITS POLITICAL CONTEXTS

One trend evident in assessment in science classrooms (as in other classrooms) is that it continues to be determined as much by politics as it is by educational theorizing (linking assessment with learning) or psychometrics (the measuring of individual differences) (Donnelly & Jenkins, 2001; Tamir, 1998; Torrance, 2000). Assessment is a part of the political enterprise that is education (Apple, 1982, 1996; Delpit, 1995; Gipps, 1998). In other words, a researcher’s findings indicating a need for change will not automatically be accepted by politicians, teachers, students, or the community. Research of itself does not necessarily instigate change. All shareholders in the practice called assessment need to be convinced of the necessity for change. What a researcher values in assessment may not be what is valued by other shareholders.

In the last 20 years, an increasing number of political views are being given voice and demanding attention in educational developments. An increasing number of different stakeholders/shareholders with legitimate interests in the purposes for which the assessments are carried out seek to influence the assessment purposes, practices, and reporting of assessment in classrooms. Shareholders may be government officials seeking to develop and implement government policy, teachers, parents, employers, and discipline authorities. Their influence is particularly visible when the assessments are high stakes; that is, there is much riding on the outcomes, such as teacher appraisals, curriculum evaluations, school funding based on the outcomes, student career paths, or student entry to further education. Accounts are given in the literature of the context of national or local requirements for certification and accountability exerting a powerful influence on the practice of assessment in classrooms in the New Zealand context (Bell, Jones, & Carr, 1995; Codd, McAlpine, & Poskitt, 1995; Crooks, 2002b; Gilmore, 2002; Hill, 1999), English context (Black, 1995a, 1995d, 1998b, 2000; Donnelly & Jenkins, 2001; Reay & Wiliam, 1999), Scottish context (Harlen, 1995a), Canadian context (Doran et al., 1993; Mawhinney, 1998; Orphwood, 1995), Korean context (Han, 1995), Australian context (Butler, 1995), and U.S. context (Atkin, Black, Coffey, & National Research Council [U.S.], Committee on Classroom Assessment and the National Science Education Standards, 2001; Berlak, 2000; Collins, 1995, 1998; Doran et al., 1993; Johnston, Guice, Baker, Malone, & Michelson, 1995).

Increasingly, teachers' professional voice and assessment judgment making, if they are included at all, are negotiated with other shareholders, in the political process that is education (Atkin, 2002). The importance of the values held by the politicians cannot be underrated. An example would be politicians' view of the professionalism of teachers—is this to be fostered to improve the quality of education or a barrier to be removed if quality is to be increased (Atkin et al., 2001; Atkin, 2002; Donnelly & Jenkins, 2001)? Politics can also be viewed in the post-structural sense as the discourses and grand narratives of a society or culture, and the micro-politics of the classroom (Bell, 2000; Torrance, 2000; Torrance & Pryor, 1998). In this view, all human practices and actions can be seen to have a dimension of power and hence a political aspect.

Hence, assessment policies, practices, and issues will vary from country to country or state to state, in accordance with the social, political, and historical contexts in which the assessments are done (for examples see Doran et al., 1993). Therefore, this review discusses the larger trends evident in the research literature, with the details of the debates specific to an individual country or state given in the cited references. Some or all of these trends may or may not be relevant in the country of each reader.

## ASSESSMENT OF SCIENCE LEARNING FOR MULTIPLE PURPOSES

The second broad trend, derived from the first, is that the research confirms what science teachers (and other teachers) already know: that they are increasingly being asked to do assessment in their classrooms for multiple purposes. And the number of these purposes has increased with the number of different shareholders wishing to use the assessment information generated by teachers and students in

classrooms for different purposes. These purposes are linked not only to the goals of education, but also to the political nature of assessment.

This international trend, of multiple purposes for classroom assessment, was brought into sharp focus in the 1990s, when politicians and others wanting to hold educationalists accountable looked to assessment to provide the information required for the accountability process, for example, to audit teacher effectiveness (Bell & Cowie, 2001b). This added to the existing demands for assessment information by people who operate outside the classroom, for example, care-givers, principals, school governing bodies, local or national government officials, awarders of national qualifications, selection panels for tertiary education programs, and employers. These multiple purposes can include auditing of schools, national monitoring, school leaver documentation, awarding of national qualifications, appraisal of teachers, curriculum evaluation, and the improvement of teaching and learning. While these purposes are often mandated by people who operate outside the classroom, the assessments themselves are often done by teachers on their behalf. There are three cornerstones of this education accountability process—a prescribed set of standards, an auditing and monitoring process to ascertain if the standards have been attained, and a way of raising standards if low standards have been indicated in the audits (Bell & Cowie, 2001b). Classroom assessment of (science) learning is seen as a way of raising standards (Atkin et al., 2001; Ministry of Education, 1993).

This more recent addition of assessment for accountability purposes is reflected in this statement of the three main purposes for assessment in education:

Assessment has multiple purposes. One purpose is to monitor educational progress or improvement. Educators, policymakers, parents and the public want to know how much students are learning compared to the standards of performance or to their peers. This purpose, often called *summative assessment*, is becoming more significant as states and school districts invest more resources in educational reform.

A second purpose is to provide teachers and students with feedback. The teachers can use the feedback to revise their classroom practices, and the students can use the feedback to monitor their own learning. This purpose, often called *formative assessment*, is also receiving greater attention with the spread of new teaching methods.

A third purpose of assessment is to drive changes in practice and policy by holding people accountable for achieving the desired reforms. This purpose, called *accountability assessment*, is very much in the forefront as states and school districts design systems that attach strong incentives and sanctions to performance on state and local assessments. (National Research Council, 1999)

The multiple purposes for which classroom assessment is done give rise to several issues of interest to the science education research community:

1. There can be confusion about the use of terms *formative* and *summative* assessment (Black & Wiliam, 1998a; Brookhart, 2001; Harlen & James, 1997). The terms *formative* and *summative* were first used by Scriven (1967, 1990) to distinguish between the two roles that evaluation may play in education, but the current use of these terms is as adjectives to describe the different *purposes* of assessment, not evaluation or assessment tasks. There is often a confusion reported in the literature over the

terms *formative*, *summative*, and *continuous summative assessment* (Bell & Cowie, 2001b; Glover & Thomas, 1999; Harlen & James, 1997; Scriven, 1990). For example, teacher assessments, which are collected mainly for summative purposes, usually over the course of the year, are often aggregated into a single score or grade for reporting purposes. This assessment practice is called "continuous assessment" (Nitko, 1995), and although the assessments may have a weak formative role, the main purpose for the assessment information being generated is summative. In the same way, assessment for accountability purposes may have a weak formative purpose informing future teaching and learning, but the time delay is extended when compared with classroom assessments undertaken primarily for formative purposes. Harlen (1998) suggested the use of a continuum from procedures and purposes of assessment that are strongly formative through to those that have a strong summative focus.

2. The terms *summative*, *formative*, and *accountability* describe the purpose for which the assessment is done, not the task itself, as one assessment task might be used for both formative and summative purposes. For example, a concept-mapping task may be used for formative purposes during the teaching unit, or summatively after the teaching (Francisco, Nakhleh, Nurrenbern, & Miller, 2002; Toth, Suthers, & Lesgold, 2002), as can portfolios (Childers & Lowry, 1997; Treagust, 1995; Tripp, Murphy, Stafford, & Childers, 1997) and demonstration assessments (Deese, Ramsey, Walczyk, & Eddy, 2000). Although it is acknowledged that teachers do assessment for both formative and summative purposes (Biggs, 1998; Black, 1993, 1995b, 2002) and that the two purposes overlap, the issue arises as to whether the information collected by a teacher for formative purposes (that is, to inform the learning and teaching) can be used at a later time for summative purposes (that is, at the end of the teaching and learning) or accountability purposes. Similarly, can assessment information collected for summative purposes be used by others for accountability purposes, given concerns of ethics; quality such as reliability, validity, fairness; manageability; and the tensions between the dual roles of the teacher of advisor and adjudicator? Harlen (1998) highlighted these problems in that "assessment for formative purposes is pupil-referenced and judgments are made by pupils and teachers about next steps, whilst assessment for summative purposes requires judgments to be made by teachers against public standards or criteria" (p. 9). In the United Kingdom, as in New Zealand, the teacher judgments are often used to allocate students' achievement to a curriculum "level." Harlen saw no problem in using the raw information, but not the judgments, collected for formative purposes for later summative purposes. Hence, she advocated using the *evidence* of pupil learning but not the *results* (emphasis in original). A growing number of authors are arguing that the interaction of all three purposes is both possible and desirable, given the burdens of assessment on teachers and students (Biggs, 1998; Black, 1993; Gilmore, 2002; Harlen & James, 1997). A note of caution was given by Bell & Cowie (1997, 2001b), who presented research findings to indicate that the students in research science classrooms were able to determine the purpose of the assessment as being formative or summative, even if the teacher had not been explicit. Moreover, their performance was influenced by the level of disclosure they felt comfortable with, given the level of trust that existed, thereby influencing the quality of the assessment.

3. In the classroom, the practices of curriculum, pedagogy, learning, and assessment are connected, interdependent, and in tension (Carr et al., 2000), as are the purposes for doing assessment. Changes to the assessment practices in a classroom will affect the other practices and vice versa. For example:

- curriculum change can influence assessment practices (Black & Wiliam, 1998b; Gitomer & Duschl, 1995; Orpwood, 2001);
- assessment practices will affect curriculum, learning, and pedagogy (Buchan & Welford, 1994; Carr et al., 2000; Crooks, 2002a; Hill, 2001; Mavrommatis, 1997; Smith, Hounshell, Copolo, & Wilkerson, 1992), for example, the impact of high-stakes, standardized national testing on school learning (Black & Wiliam, 1998a);
- for assessment practices to change, curricula and pedagogy must change also (Black & Wiliam, 1998b; Cheng & Cheung, 2001; Dori, 2003; Treagust, Jacobowitz, Gallagher, & Parker, 2001).

In the same way, the three key purposes of assessment, formative, summative, and accountability, are interdependent and interactive:

- Some classroom assessments for school summative purposes may be used for accountability purposes if schools are required to produce evidence that they are making a difference to audit agencies (Hill, 1999). This strong emphasis on assessment for summative and accountability purposes, and especially the high-stakes assessment, may decrease the assessment for formative purposes that teachers feel able to do (Cowie & Bell, 1999).
- There is a tension between classroom assessments (for formative and summative purposes) and national assessment for accountability and monitoring purposes, with opportunities for doing assessment for formative purposes declining with the straitjacket of national assessment (Black & Harrison, 2001a, 2001b; Black & Wiliam, 1998a; Broadfoot, 1996; Daws & Singh, 1996; Eley & Caygill, 2001, 2002; Gipps, Brown, McCallum, & McAlister, 1995; Keiler & Woolnough, 2002; Preece & Skinner, 1999; Smith et al., 1992; Swain, 1996, 1997). A strong emphasis on national or state assessment for accountability purposes may lead to teaching to the test or increased teaching time on the school work assessed by such tests (Gipps et al., 1995) or even less teaching time available (Gipps et al., 1995). However, the primary teachers (of science) in the Gipps et al. (1995) study on the impact of national testing became more knowledgeable in assessment; redirected the focus of their teaching, with resulting improvements in national assessments of basic skills; undertook more detailed planning; made more use of a systematic approach to collecting evidence from the students and written records than intuition; gained a better understanding of an individual's progress; and developed increased levels of discussion and collegiality with other staff.
- Multiple purposes for assessment means that there are multiple audiences, and it raises the issue of whether one assessment task can provide information for several assessment purposes and audiences (Black, 1998a).

Research on assessment for accountability purposes is reviewed in Chapters 31 and 33. The multiple purposes of classroom assessment of science learning are seen as giving rise to two broad categories of assessment: assessment for formative (including diagnostic) and summative purposes. These two purposes are discussed in the fourth and fifth sections.

## ASSESSMENT AND MULTIPLE GOALS OF SCIENCE LEARNING

What is assessed? is an important question, as it links assessment strategies, learning goals, and curriculum together and is part of what is called “validity inquiry in the psychometric literature” (Messick, 1989, 1994). In the 1993 review of assessment of science learning, the list of what is assessed was given as knowledge of facts and concepts, science process skills, higher order science thinking skills, problem-solving skills, skills needed to manipulate laboratory equipment, and attitudes of science (Doran et al., 1993). A strong criticism of assessment in the past has been that only learning goals that could be readily assessed, say by use of recall to answer multiple-choice tests, were assessed with a subsequent negative impact of the curriculum, pedagogy, learning, and learners in the classroom (Crooks, 1988). There is now the recognition that all learning goals need to be assessed, and not just recall and understanding of science concepts because they are easy to test for (Osborne & Ratcliffe, 2002). The additional science learning goals to be assessed include:

- the nature of science views held by students (Aikenhead, 1987; Lederman, Abd-El-Khalick, Bell, & Schwartz, 2002);
- what matters in the discipline of science (Gitomer & Duschl, 1995): knowledge and skills that are deemed important within the discipline, that is, knowledge and science experiences through investigation procedures similar to those scientists employ; the changing nature of scientific knowledge being acquired from an investigation; the accepted rules of practice that guide scientific practice; meanings and background knowledge of the scientific discipline;
- knowing that science is culturally and historically embedded, and contextualized (Fusco & Barton, 2001);
- the ideas and evidence—the processes and practices—of science, that is, *how* we know as well as *what* we know (Osborne & Ratcliffe, 2002);
- learning dispositions (habits of mind), such as resilience, playfulness, reciprocity, curiosity, friendliness, being bossy; confidence, curiosity, intentionality, self-control, relatedness, communication, cooperation, courage, playfulness, perseverance, responsibility, selectivity, experimentation, reflection, opportunism, and conviviality (Allal, 2002; Carr, 2001; Carr & Claxton, 2002), as well as effective learning skills in the learning-to-learn literature (Baird & Northfield, 1992).

In the next section, the research on assessment of science learning for formative purposes is reviewed.

## ASSESSMENT OF SCIENCE LEARNING FOR FORMATIVE PURPOSES

Another trend in the research on classroom assessment is the increasing emphasis on assessment for formative purposes. This trend has arisen because of recent political demands for increased accountability of teachers for learning outcomes, the research on the role of feedback in learning and teaching, and the research on teaching and assessment for conceptual development in science education (Bell & Cowie, 2001b; Treagust et al., 2001).

### Definitions and Characteristics

Formative assessment is increasingly being used to refer only to assessment that provides feedback to students (and teachers) about the learning that is occurring, during the teaching and learning, and not after (Cowie, 1997). The feedback or dialogue is seen as an essential component of formative assessment interaction, where the intention is to support learning (Black, 1995b; Black & Wiliam, 1998a; Gipps, 1994a; Hattie, 1999; Hattie & Jaeger, 1998; Perrenoud, 1998; Ramaprasad, 1983; Sadler, 1989). And assessment can be considered formative only if it results in action by the teacher and students to enhance student learning (Black, 1993). These components are reflected in various definitions of formative assessment, for example, "The process used by teachers and students to recognise and respond to student learning in order to enhance that learning, during the learning" (Bell & Cowie, 2001b, p. 8). It is through the teacher-student interactions during learning activities (Newmann, Griffin, & Cole, 1989) that formative assessment is done and that students receive feedback on what they know, understand, and can do and receive teaching to learn further. Formative assessment is at the intersection of teaching and learning (Gipps, 1994a), and, in this way, teaching, learning, and assessment are integrated in the curriculum (Hattie & Jaeger, 1998). The term *formative interaction* (Jones, Cowie, & Moreland, 2003; Moreland, Jones, & Northover, 2001) may be used instead of *formative assessment* to highlight this interactive nature of formative assessment—that teacher-student interactions are the core of formative assessments. Assessment for diagnostic purposes, for example (Barker & Carr, 1989; Feltham & Downs, 2002; Simpson, 1993), is therefore included, as is embedded assessment (Treagust et al., 2001; Volkmann & Abell, 2003). Harlen and James (1997), in a review of literature, summarized that the characteristics of formative assessment, to distinguish it from summative assessment, are that it is positive, is a part of teaching, takes into account the progress of students, can elicit inconsistencies that can provide diagnostic information, places more value on validity and usefulness than reliability, and requires the students to be actively involved in monitoring their own progress and improving their learning. Harlen (1998) describes assessment for formative purposes as that which is "embedded in a pedagogy of which it is an essential part; shares learning goals with students; involves students in self-assessment; provides feedback which leads to students recognizing 'the gap' and closing it; underpinned by confidence that every student can improve; and involves reviewing and reflecting on assessment data" (p. 3).

Bell and Cowie (1997, 2001b), in reporting the findings of a major research project, summarized the characteristics of formative assessment on the basis of the qualitative data generated by the 10 teachers of year 7–8 students (aged 10–14) in a two-year research project into classroom assessment and science education. Over the two years, the teachers were asked to describe what it was that they were doing, when they were doing assessment for formative purposes. Their ability to articulate and make explicit this often tacit practice increased over the two years as a shared understanding and use of a shared language also grew. The nine characteristics of formative assessment discussed by the teachers were that it was responsive (that is, dynamic and progressive, informal, interactive, unplanned as well as planned, proactive as well as reactive, responding with individuals and with the whole class, involves uncertainty and risk taking, and has degrees of responsiveness); uses written, oral, and nonverbal sources of evidence; is a tacit process; uses professional knowledge and experiences; is an integral part of teaching and learning; is done by both teachers and students to improve teaching as well as learning; is highly contextualized; and involves managing dilemmas (Bell & Cowie, 1997, 2001a, 2001b).

A descriptive and interpretive account of some characteristics of formative assessment was also given by Treagust et al. (2001). In this study, the classroom practices of an acknowledged exemplary U.S. middle-school teacher of 23 grade 8 students studying sound were researched with an interpretive research methodology over a period of 3 weeks. The researchers explored and documented how the teacher incorporated assessment tasks as an integral component of her teaching about the topic sound. They reported that the teacher used “the information to inform her teaching, nearly every activity had an assessment component integrated into it, that students had a wide range of opportunities to express their knowledge and understanding through writing tasks and oral questioning, and that individual students responded to and benefited from the different assessment techniques in various ways” (p. 137).

## Importance of Formative Assessment

Formative assessment, like assessment in general, does influence learning (Crooks, 2002a; Gipps & James, 1998). The case for formative assessment was made in a report commissioned by the British Educational Research Association to argue the case for raising achievement through the use of assessment for formative purposes, rather than through large-scale testing for accountability purposes. This seminal review of the research reported in 578 articles, by Black and Wiliam (1998a, 1998b), states the importance of formative assessment for learning as “The research reported here shows conclusively that formative assessment does improve learning. The gains in achievement appear to be quite considerable, and as noted earlier, amongst the largest ever reported for educational interventions” (p. 61).

The science education research included in the Black and Wiliam review, along with others to provide evidence to back up this knowledge claim, was that of Frederiksen and White (1997). Likewise, Hattie (1999) concluded his meta-analysis to evaluate the relative effects of different teaching approaches and different components of teaching by stating that the single most powerful moderator that enhances achievement is feedback.

Having reviewed the literature to document the evidence that formative assessment can indeed raise standards Black and Wiliam (1998a) then addressed the question, "is there evidence that there is room for improvement?" They concluded that there is research evidence "that formative assessment is not well understood by teachers and is weak in practice; that the context of national or local requirements for certification and accountability will exert a powerful influence on its practice; and that its implementation calls for rather deep changes both in teachers' perceptions of their own role in relation to their students and in their classroom practice" (Black & Wiliam, 1998a, p. 20). The science education literature to support this knowledge claim is found in a number of studies (Black, 1993; Bol & Strage, 1996; Daws & Singh, 1996; Duschl & Gitomer, 1997; Lorsbach, Tobin, Briscoe, & LaMaster, 1992).

Although there has been much advocacy by science educators on the importance of formative assessment to improve learning and standards of achievement (for example, Atkin et al., 2001; Black, 1995b, 1995c, 1998a; Black & Wiliam, 1998a, 1998b; Harlen, 1995b; Harlen & James, 1997; Hunt & Pellegrino, 2002), there have been only a few actual research studies on the process of formative assessment of science learning. These are now reviewed.

## Models of Formative Assessment

In addition to the empirical research on formative assessment in the general assessment research literature, for example (Torrance & Pryor, 1998, 2001) with their work on formative assessment in UK primary classrooms (of students aged 4–7), there are three major research studies in science education: Bell and Cowie (2001b), Cowie (2000), and Treagust et al. (2001). The first study sought to research the nature of assessment for formative purposes so as to make the often tacit knowledge of teachers explicit. In this way, the research could help teachers to share their knowledge of this highly skilled pedagogy during teacher development situations. The findings are summarized in a model of formative assessment (Bell, 2000; Bell & Cowie, 2001b; Cowie & Bell, 1999). This model is notable in that it was developed by the teachers involved in the research project (Bell & Cowie, 1999). The 10 teachers were asked to develop a model that would communicate to teachers not involved in the research what it was that they were doing when they were doing formative assessment. The primary teachers in the research by Torrance and Pryor (2001) similarly developed a "practical classroom model." The teachers within the Bell and Cowie study reported that they undertook two forms of formative assessment: planned formative assessment and interactive formative assessment.

The process of *planned formative assessment* was characterized by the teachers eliciting, interpreting, and acting on assessment information. The main purpose for which the teachers said they used planned formative assessment was to obtain information from the whole class about progress in learning science as specified in the curriculum. This assessment was planned in that the teacher had planned to undertake a specific activity (for example, a survey or brainstorming) to obtain assessment information on which some action would be taken. The teachers considered the information collected as a part of the planned formative assessment was "general," "blunt," and concerned their "big" purposes. It gave them information that was valuable in informing their interactions with the class as a whole with respect

to “getting through the curriculum.” This form of formative assessment was planned by the teacher mainly to obtain feedback to inform her or his teaching. The purpose for doing the assessment strongly influenced the other three aspects of the planned formative assessment process of eliciting information, interpreting, and taking action to enhance the students’ learning. Acting on the interpreted information is the essential aspect of formative assessment that distinguishes it from continuous summative assessment. To do this, the teacher needed to plan to have a flexible program and to allow for ways in which she or he could act in response to the information gathered. It also helped to be able to act in a variety of ways in response to that gathered information.

The second form of formative assessment identified by the teachers was *interactive formative assessment*, which can be characterized as the teachers’ noticing, recognizing, and responding. Interactive formative assessment was what took place during student-teacher interactions. It differed from the first form—planned formative assessment—in that a specific assessment activity was not planned. The interactive assessment arose out of a learning activity. Hence, the details of this kind of formative assessment were not planned and could not be anticipated. Although the teachers often planned or prepared to do interactive formative assessment, they could not plan for or predict what exactly they and the students would be doing, or when it would occur. As interactive formative assessment occurred during student-teacher interaction, it had the potential to occur any time students and teachers interacted. The teachers and students within the project interacted in whole-class, small-group, and one-to-one situations. The main purpose for which the teachers said they did interactive formative assessment was to mediate in the learning of individual students with respect to the intended learning. The teachers’ specific purposes for interactive formative assessment emerged in response to what sense they found the students were making. Interactive formative assessment was therefore embedded in and strongly linked to learning and teaching activities. The teachers indicated that through their interactive formative assessment, they refined their short-term goals for the students’ learning within the framework of their long-term goals. The teachers indicated that their purposes for learning could be delayed and negotiated between the teacher and the students through formative assessment feedback. The teachers described interactive formative assessment as teacher and student driven rather than curriculum driven. The response to what the teacher had noticed and recognized was the essential aspect of interactive formative assessment. The response by the teachers was similar to the acting in planned formative assessment, except that the time frame was different—it was more immediate. Within the process of interactive formative assessment, the teachers often had to make quick decisions in circumstances in which they did not have all the necessary information, using “teacher wisdom” rather than intuition or instinct (Jaworski, 1994).

The teachers in the study commented that the two kinds of formative assessment were linked through the purposes for formative assessment; that some teachers used interactive formative assessment more than other teachers; and that a teacher moved from planned to interactive and back. The link between the two parts of the model was seen to be centered around the purposes for doing formative assessment. It is of interest to note that the teachers in the Torrance and Pryor (2001) study placed the “making task and quality criteria explicit” in the center of their classroom practice model, which is linked to purpose. The teachers in the new Zealand study indi-

cated that their assessment for formative purposes tended to be decreased if there was too much emphasis on assessment for summative and accountability purposes (Bell & Cowie, 2001b), reflecting the views of Black (1995c), Harlen and James (1997), and Hill (1999).

The key features of the model are now discussed, in association with other research on formative assessment. First, the model of formative assessment developed by the teachers included the notion of *planning*, which has also been highlighted by other researchers (Fairbrother, Black, & Gill, 1995; Harlen, 1995b; Torrance & Pryor, 1995).

A second key feature of the model is that formative assessment is described as a *complex, highly skilled task*, and as it is in other research (Torrance & Pryor, 1998), which relied on the following knowledge bases (Shulman, 1987): content knowledge (for example, knowing the scientific understanding of the concepts being taught); general pedagogical knowledge (for example, of classroom management); curriculum knowledge (for example, of the learning objectives in the curriculum being taught); pedagogical content knowledge (for example, knowing how best to teach atomic theory to a class of 14-year-olds); a knowledge about learners in general and the students in the class; knowledge of educational contexts (for example, the assessment practices in the school); and a knowledge of educational aims and purposes (for example, a possible "science-for-all" emphasis in a national curriculum). To this list, the teachers' knowledge of progression in students' learning of specific concepts can be added (Bell & Cowie, 2001c; Jones et al., 2003). The formative assessment also relied upon the processes of pedagogical reasoning and action (Shulman, 1987), including the transformation of content knowledge into pedagogical knowledge, through preparation, representation, selection, and adaptation. The teachers felt the use of both forms of formative assessment, and switching between them was the hallmark of a competent teacher.

A third key feature of the model is teachers' *interaction skills, and the nature of the relationships* they had established with the students was also seen as important. It was felt that the teachers needed a disposition to carry out interactive formative assessment; that is, the teachers needed to value and want to interact with the students to find out what they were thinking about. Cowie (2000) also commented on the relationships that developed between the teachers and students as individuals, groups, and a class. Mutual trust and respect were identified as the key factors mediating student willingness to disclose their ideas to teachers and peers, and hence enable formative assessment interactions to occur. Hence the findings support the contention by Tittle (1994) that the views and beliefs of the interpreters and users of assessment information (here teachers and students) are an important dimension of any theory of educational assessment.

A fourth key feature of the model is the central role given to *purpose* in both forms of formative assessment by the teachers.

A fifth key feature of the model is the *action* taken as part of both planned and interactive formative assessment, for it distinguishes assessment for formative purposes from that for summative and accountability. The action means that formative assessment can be described as an integral part of teaching and learning and that it is responsive to students. Much of the current literature, for example, Driver, Squires, Rushworth, and Wood-Robinson (1994), on conceptual development in science education involves a consideration of the teacher being responsive to the thinking of students, often phrased as "taking into account students' thinking." To respond to

and mediate students' thinking involves the teacher finding out what the thinking is, evaluating the thinking, and responding to it. These are the three components in both planned and interactive formative assessment. The teachers in the research made the claim that they did not think they could promote learning in science unless they were doing formative assessment (Bell & Cowie, 1997). The role of the teacher included *providing* opportunities for formative assessment to be done (for example, having the students discuss in small groups their and scientists' meanings of "electric current," rather than listening only to a lecture by the teacher) and using the opportunity to do formative assessment (for example, interacting with the students while they are doing small-group discussion work about their conceptual understandings of electric currents). In addition, the action taken as part of both planned and interactive formative assessment was seen by the teachers as a part of teaching and by the students as a part of learning. The teachers acted and responded on the assessment information they obtained in science (criterion-referenced), student (ipsative), and care-referenced ways. In the care-referenced actions, the teachers took action to sustain and enhance the quality of interactions and relationships between the students and between themselves and the students. Other research has also noted the dual ipsative and criterion-referenced nature of formative assessment (Harlen & James, 1997) and the care aspect of formative assessment (Treagust et al., 2001). A single action or response might have one or more of these aspects in it. It was the action part of planned and interactive formative assessment that the teachers felt they needed more help with in future teacher development.

One important aspect of the "taking action" is the feedback to the student from the teacher or another student. The feedback is more effective in improving learning outcomes if it is about the substance of the work, not superficial aspects (Crooks, 1988; Harlen, 1999); linked with goal setting (Black & Wiliam, 1998a; Gipps & Tunstall, 1996b; Hattie, 1999; Hattie & Jaeger, 1998); and linked to the students' strengths and weaknesses of the task, rather than to just the self, as in praise (Black & Wiliam, 1998a; Hattie, Biggs, & Purdie, 1996). The quality of the feedback may involve a comparison between the students' achievement or performance and other students' (norm-referenced), standards or learning goals (critierion-referenced), or the student's previous achievements (ipsative). In assessment for formative purposes the ipsative frame of references for feedback is important. Another important aspect of the taking action part of the formative assessment process has become known as "feedforward," to distinguish it from feedback (Bell & Cowie, 2001b). Whereas "feedback" was used to refer to the response given to the student by the teacher (Sadler, 1989) or another student about the correctness of their learning, the term "feedforward" was used to refer to those aspects of formative assessment in which the teacher was helping students to close the gap between what they know and can do, and what is required of them as indicated in the standards or curriculum objectives (Sadler, 1989). Hence, to provide both feedback and feedforward a teacher must know the curriculum content and standards or curriculum objectives, the progression of students' learning, and the scaffolding required for learning in the Zone of Proximal development, after Vygotsky (Allal & Ducrey, 2000; Torrance & Pryor, 1998).

A sixth key feature of the teachers' model of formative assessment was the central role of *self-assessment and self-monitoring*. This is distinct from feedback, which is given by another person (Sadler, 1989). Research on this aspect of assessment for formative purposes was also reviewed in the meta-analysis by Hattie et al. (1996), who concluded that interventions, which are integrated to suit the individual's self-

assessment, orchestrated to the demands of the particular task and context, and self-regulated with discretion, were “highly effective in all domains (performance, study skills and affect) over all ages and abilities, but were particularly useful with high-ability and older students” (p. 128). And they were more effective than the typical study skills training packages. To be able to give effective feedback and feed-forward, the research by Jones et al. (2003), Moreland and Jones (2000), and Moreland et al. (2001) with teachers of technology indicated that the pedagogical content knowledge as well as pedagogical approaches of teachers had to be enhanced. This is so the teachers could make a judgment about where the student’s learning is in relation to the intended curriculum learning goals, communicate this to the student, and suggest steps for the student to improve his or her learning, based on their knowledge of progression in learning a specific skill or concept.

The following have been suggested for teachers and students, on the basis of the review of the research evidence, as interventions to improve the use of assessment for formative purposes: “feedback to any pupil should be about the particular quality of his or her work, with advice on what he or she can do to improve, and should avoid comparisons with other pupils”; “for formative assessment to be productive, pupils should be trained in self-assessment so that they can understand the main purposes of their learning and thereby grasp what they need to achieve”; “opportunities for pupils to express their understanding should be designed into any piece of teaching, for this will initiate the interaction whereby formative assessment aids learning”; “the dialogue between pupils and a teacher should be thoughtful, reflective, focused to evoke and explore understandings, and conducted so that all pupils have an opportunity to think and to express their ideas”; “tests and homework exercises can be an invaluable guide to learning, but the exercises must be clear and relevant to learning aims. The feedback on them should give each pupil guidance on how to improve, and each must be given opportunity and help to work at the improvement” (Black & Wiliam, 1998b, pp. 9–13). This was later summarized to the following:

The research indicates that improving learning through assessment depends on five, deceptively simple key factors: the provision of effective feedback to pupils; the active involvement of students in their own learning; adjusting teaching to take account of the results of assessment; a recognition of the profound influence assessment has on the motivation and self-esteem of pupils, both of which are crucial influences on learning; and the need for pupils to be able to assess themselves and understand how to improve. (Assessment Reform Group, 1999) (p. 4), and;

sharing learning goals with pupils; involving pupils in self-assessment; providing feedback which leads to pupils recognizing their next steps and how to take them; underpinned by confidence that every pupil can improve. (Assessment Reform Group, 1999, p. 7)

Publications for teachers, based on the above research reviews, to help them improve the assessment for formative purposes in the classroom, have been produced (Atkin et al., 2001; Clarke, 1998; Clarke, Timperley, & Hattie, 2003). For example, the latter publication has a chapter on each of the components of formative assessment as:

clarifying learning intentions at the planning stage, as a condition for formative assessment to take place in the classroom; sharing learning intentions at the beginning of

lessons; involving children in self-evaluation against learning intentions; focusing oral and written feedback around the learning intentions of lessons and tasks; organizing individual target setting so that children's achievement is based on previous achievement as well as aiming for the next level up; appropriate questioning; and raising children's self-esteem via the language of the classroom and the ways achievement is celebrated. (Clarke et al., 2003, p. 14)

The last key feature of the model is the *teacher development* that occurred in its development by the teachers (Bell & Cowie, 1997; Bell & Cowie, 2001c), providing some information to answer Black and Wiliam's question, "Is there evidence about how to improve formative assessment?" Information has also been provided by other researchers, using collaborative action-research (Torrance & Pryor, 2001), reflective surveys (Black & Harrison, 2001a, 2001b), and reflection on teachers' knowledge bases (Jones et al., 2003). A notable feature of the literature is that teacher development for assessment for formative purposes also involves changing one's overall pedagogy, not just the assessment aspects (Ash & Levitt, 2003; Bell & Cowie, 2001c; Black & Wiliam, 1998a, 1998b; Treagust et al., 2001).

## Research on Students and Assessment for Formative Purposes

Students have considerable agency in the practice of formative assessment. But although feedback, feedforward, and self-assessment position both the teacher and student as taking action during formative assessment, the core activity of formative assessment lies in "the sequence of two actions. The first is the perception *by the learner* of a gap between the desired goal and his or her present state (of knowledge, and/or understanding, and/or skill). The second is the action taken *by the learner* to close that gap in order to attain the desired goal (Ramaprasad, 1983; Sadler, 1989)" (Black & Wiliam, 1998a) (emphases added).

There is a growing interest in the wider education research literature in the views of students on teaching, learning, and assessment (as distinguished from their views on the subject matter content), for example, Heady (2001) and Morgan and Morris (1999). Although there have been reviews on the impact of assessment on students (Crooks, 1988; Hattie & Jaeger, 1998; Natriello, 1987), there has been little research until recently on students' views of assessment (Brookhart, 2001; Gipps & Tunstall, 1996a; Jones et al., 2003). Two studies are worthy of discussion here. In the primary school, Pollard, Triggs, Broadfoot, McNess, and Osborn (2000) reported on the findings of the Primary Assessment, Curriculum and Experience (PACE) project in the United Kingdom, stating that "the picture of children's experience of classroom assessment that emerges from different sections of the pupil interviews is remarkably consistent. They are aware of assessment only as a summative activity and use criteria of neatness, correctness, quantity and effort when commenting on their own and others work" (p. 152). In the research by Brookhart (2001) the able students did not keep distinct the formative and summative purposes of assessment, but rather these successful students integrated the two. However, there has been research where students have been interviewed on their views of science assessment for formative purposes (Cowie, 2000). In this doctoral research, 75 students (years 7 to 10, or ages 11 to 14) were interviewed in either individual or group situations about their views on classroom assessment. The findings indicate that the students constructed

themselves as active and intentional participants in learning, its assessment, and their self-assessment of it. The criteria for judging the success of their learning, reported by students, included the ability to perform a task, gaining good marks or grades, the teacher confirming their ideas were correct, and feelings of completeness and coherence. Another finding was that students viewed formative assessment as embedded in and accomplished through interaction with teachers, peers, and parents. Disclosure was another aspect of students' views of formative assessment. The students were very aware that their questions, actions, and book work had the potential to disclose not only what they knew but also what they did not know, to peers and teachers, who may or may not make positive judgments and actions on the basis of these disclosures. Students indicated that they withheld disclosure if the classroom was not safe, doing so only in a trusting relationship with the teacher and peers. This would influence not just the validity but the essence of formative assessment. Student disclosure is central to formative assessment, and participation in assessment interactions could lead to both benefit and harm in learning, social, and relationship constructions. Torrance and Pryor (1998) described the teacher during formative assessment as using power-with and power-for students in their learning.

Cowie (2000) also detailed the ways in which student perspectives of formative assessment in the classroom contributed to the mutual construction of what it means to be a student and a teacher in that classroom, that is, notions of identity. For example, "student perceptions that time and attention were limited and teachers assessed what was important to them, meant that teacher assessment served to communicate to the students who and what was important to the teacher" (p. 260); "for students, the key feature of formative assessment as a meaning making activity was that it contributed to their identity in the classroom . . . the students contended that disclosing their ideas in an attempt to enhance their understanding could lead their peers and the teacher to perceive them as 'try hards', 'bright' or 'dumb' and to their learning being enhanced or them being embarrassed and feeling stupid. They indicated that for them, assessment and learning were intimately connected and inherently linked with who they were and how they felt" (p. 261). The students and teachers in Cowie's study were seen as actors (that is, taking action) in formative assessment. The students were actors in formative assessment in three ways: their academic and social goals and interests mediated their interactions; they sought to manage the disclosure of their learning by choosing (or not choosing) to ask questions and by acting to restrict teachers' incidental access to their book work; and they assessed the teacher to ascertain how the teacher reacted to their questions and therefore to find out what was seen as important by the teacher. In summary, Cowie (2000) stated that the students were both active in the formative assessment process and profoundly affected by it, as did Reay and Wiliam (1999). The students in the Cowie (2000) study insisted that

their teachers could only assess their learning through face-to-face interaction with them. Face-to-face interaction was considered to enhance the fidelity (Wiliam, 1992) of teacher formative assessment, because students could negotiate the meaning of teacher questions and because students were more prepared to ask questions, thereby disclosing their views. Teachers were said to provide more useful feedback during one-to-one and small group interactions. (p. 267)

Students' views of assessment are also embedded in use of the questions generated by students as assessment information for diagnostic and formative purposes (Biddulph, 1989; Rop, 2002; Zeegers, 2003).

## ASSESSMENT OF SCIENCE LEARNING FOR SUMMATIVE PURPOSES

A fifth trend in classroom assessment of science learning is the ongoing research and development of assessment for summative purposes. Classroom assessment of science learning for summative purposes is that which summarizes the learning achieved after teaching is completed and includes end-of-unit tests, teacher assessments for qualifications, and teacher assessments for reporting to parents, caregivers, and others outside the classroom. Whereas assessment for formative purposes is to improve learning, assessment for summative purposes is assessment of learning (Crooks, 2001). Included in this section is ongoing or continuous summative assessments, in which a series of short summative assessments is aggregated in some way, usually to reduce the assessment information into a single score or grade (Harlen, 1998).

In the past decade, the bulk of the *development* on classroom assessment of science learning has been largely about assessment for summative purposes and has been concerned with developing the summative assessment of both a wider range of science learning outcomes and the use of a wider range of assessment tasks or formats, in order to increase the quality of the summative assessments, especially validity. This trend is noticeable in the handbook-type publications for teachers on classroom assessment (for example, Phye, 1997) and on assessment of science learning (Enger & Yager, 1998; Mintzes, Wandersee, & Novak, 2001, 1999; Shepardson, 2001); exemplars of assessment as curriculum support (Ministry of Education, downloaded 2003); released assessment items and information from assessment for national and international accountability (for example, Crooks & Flockton, 1996; Eley & Caygill, 2001); resource banks (Gilmore & Hattie, 2001; Marston & Croft, 1999); pre-post-assessment items used in research into science learning (Barker & Carr, 1989); and released national/state examinations papers.

The last decade of *research* of science learning for summative purposes has included researching the assessment of a wider range of learning outcomes using performance assessment and researching the use of a wider range of assessment formats, including performance assessment, concept maps, portfolios, interviews, prediction tasks, learning stories, observations, dynamic assessments, experimental and customized challenges, group assessment, and computer-based assessment. These are now discussed.

## THE ASSESSMENT OF A WIDER RANGE OF LEARNING OUTCOMES USING PERFORMANCE ASSESSMENT

Performance assessment to assess a wider range of learning goals, in diverse learning situations (Solano-Flores & Shavelson, 1997; Stoddart, Abrams, Gasper, & Cana-

day, 2000), has been a focus of research on classroom assessment of science learning. It was felt that traditional pen-paper tests, requiring recall and recognition of knowledge "about," did not validly assess the learning of some goals of science education (Fusco & Barton, 2001). Performance assessments were developed to assess production or performance and hence enable the assessment of all the curricula goals, not just those that were readily assessed by multiple choice or short answers. Performance-based assessment has been defined as "the execution of some task or process which has to be assessed through actual demonstration, that is, a productive activity (Wiggins, 1993)" (Cumming & Maxwell, 1999, p. 180). It is the assessment of actual performance showing what a student can do, rather than what a student can skillfully recall. The term may also include an emphasis on the integration of knowledge, practices, holistic applications (that is, to the whole and not just separate parts); multiple opportunities for teaching and learning (Wolfe, Bixby, Glenn, & Gardner, 1991); assessment in contexts that mirror real-life science or science in everyday life (Lubben & Ramsden, 1998); collaborative inquiry, problem solving, co-construction of understandings, and knowledge-building communities (Fusco & Barton, 2001; Rogoff, 1990); and many different kinds of performance, rather than just one kind (Eisner, 1993; McGinn & Roth, 1998). The literature indicates that performance assessments are highly sensitive, not only to the tasks and the occasions sampled, but also to the method (Ruiz-Primo & Shavelson, 1996b) and the kinds of knowledges that students need to access to complete a performance task (Erickson & Meyer, 1998).

The use of performance assessment has been most notable in the assessment for summative purposes of laboratory or "practical" work, not by the use of pencil-and-paper assessment of knowledge-about and knowledge-how-to, but by assessment of performance (Bednarski, 2003; DeTure, Fraser, Giddings, & Doran, 1995; Doran et al., 1993; Erickson & Meyer, 1998; Fairbrother, 1993; Gott, Welford, & Foulds, 1998; Harlen, 1999; Stefani & Tariq, 1996; Tariq, Stefani, Butcher, & Heylings, 1998). Critiques in the research of the use of performance assessments to assess investigative work include the influence of the always-present content and context in the assessment task (Harlen, 1999); the use of the visiting examiner when the classroom performance assessments are being done for national qualifications (Kennedy & Bennett, 2001); the need to select an investigation that could satisfy the assessment criteria, the perceived tension between the assessment and teaching roles of the teacher and the allocation of marks (Lubben & Ramsden, 1998); calls for caution when using performance-based assessments concerning the establishment of their validity and reliability (for example, Hattie & Jaeger, 1998; Shaw, 1997); the need to address "the psychometric findings that have highlighted the importance of effective scoring protocols, the judgments used in setting cut-offs and standards, and the importance of ensuring the construct representation of performance tests particularly given the costs and the hazards of construct under-representation of these tests" (Hattie & Jaeger, 1998); and a need to expand the current visions of performance assessment (Fusco & Barton, 2001) to include three ideals encompassed in critical, inclusive, feminist, and multicultural views of science education: that "performance/assessment addresses the value-laden decisions about what and whose science is learned and assessed and include multiple world-views, that performance assessment in science simultaneously emerges in response to local needs, and that the performance/assessment is a method as well as an ongoing search for method" (Fusco & Barton, 2001, p. 339).

## RESEARCHING A WIDER RANGE OF ASSESSMENT FORMATS

A second aspect of research on classroom assessment of science learning for summative purposes is research on the use of a wider range of assessment task formats, often called alternative assessments, including performance assessments, concept maps, portfolios, interviews including think-aloud protocols, learning stories, observational methods, dynamic assessment, self-assessment, and self-reports (Dori, 2003). The main rationale for widening the range of assessment tasks has been to match the means of generating assessment information with the learning outcomes, or standards, thereby increasing the validity; the wider range of learning goals being assessed requires different assessment tasks to maintain validity and to develop authentic assessments in that they are embedded in the teaching and learning and not disconnected with it. Hence, there has been an increased use of the terms "school-based," "alternative," "embedded," and "authentic" assessments (Dori, 2003), as well as "performance assessments," "problem-based assessments," and "competence-based assessments" under the general umbrella of "authentic assessments" (Cumming & Maxwell, 1999) to describe this wider range of assessment task formats. Their use has not been limited to the classroom; they are also included in nationwide assessments (Dori, 2003). Examples of the research on this wider range of assessment task formats are now discussed.

### Concept Maps

Previous reviews of concept mapping as an assessment tool provide a valuable introduction to their use in the classroom assessment of science learning (Edmondson, 1999; Fisher, Wandersee, & Moody, 2000; White & Gunstone, 1992). Concept maps have been researched for use for assessment for diagnostic and formative purposes (for example, Treagust, 1995; Childers & Lowry, 1997; Tripp et al., 1997); as a research tool (for example, Wallace & Mintzes, 1990); and as a tool for assessment for summative purposes (for example, Barenholz & Tamir, 1992; Childers & Lowry, 1997; Kinchin, 2001; Liu & Hinchey, 1996; McClure, Sonak, & Suen, 1999; Mintzes et al., 1999; Rice, Ryan, & Samson, 1998; Roth & Roychoudhury, 1993; Ruiz-Primo & Shavelson, 1996a; Stoddart et al., 2000; Wilson, 1996). Ruiz-Primo and Shavelson (1996a) reviewed the literature on the use of concept maps in science assessment and described a concept map used as an assessment tool as: "(a) a task that elicits evidence bearing on a student's knowledge structure in a domain, (b) a format for the student's response, and (c) a scoring system by which the student's concept map can be evaluated accurately and consistently" (p. 569).

A concern raised in these studies is about the validity and reliability of the concept maps as assessment tools, and in particular the use of a scoring rubric and/or the comparison/correlation between concept map scores and those on conventional tests (Kinchin, 2001; Liu & Hinchey, 1996; McClure et al., 1999; Rye & Rubba, 2002; White & Gunstone, 1992). For example, Stoddart et al. (2000) documented the development and evaluation of concept mapping as an assessment tool for summative purposes. They document in some detail the development of a concept-mapping method for a specific learning activity, using a scoring rubric, which extracts quanti-

tative information about the quality of understanding from each map in three stages: vocabulary review, content scoring, and a content validity check. Hence, they did not use measures of the elaborateness of the maps or the number of links and map components. The core of the rubric was based on three prepositional variables (accuracy, level of explanation, and complexity). Inter-rater agreement and inter-rater reliability found this concept-map scoring rubric to be reliable, valid, and practical.

## Portfolios

Portfolios are another assessment task format in the trend toward more authentic assessment and are described as: "a container of collected evidence with a purpose. Evidence is documentation that can be used by one person or groups of persons to infer another person's knowledge, skill, and/or disposition" (Collins, 1992, p. 453). Other descriptions of portfolios may include that they contain a sample of student work, evidence of reflection and self-evaluation as this represents the students' understanding of the assessment criteria and where their achievements are in relation to these, the students' incremental development in their learning of science, and a rich and broad array of evidence of learning (Anderson & Bachor, 1998).

The issues for the teacher are what multiple goals for science learning are being assessed; what counts as evidence of learning—both the progress toward the goals and the achievement of the goals. What might the portfolios be used for? Weekly or yearly assessments? Reporting to parents, the school, or next year's teacher? (Collins, 1992). Other issues include the method of scoring, which needs to be commensurate with the degree of complexity and multifaceted nature of the assessment tasks and the learning. Although a score may not be appropriate to maintain this complexity, the school of state/national assessment system may require a single score or grade. Other ways of "scoring" need to be developed, such as holistic expert judgment.

Anderson and Bachor (1998), when reviewing the Canadian research on the use of portfolios, list the issues with the use of portfolios for assessment as the consistency of portfolio contents between students; the validity of the contents with respect to learning goals; the level of agreement between judges; the stability of estimates of student achievements; the rigor of standards; the reliability of scoring criteria and rubrics used in evaluating the contents of portfolios; the costs and feasibility of portfolio use; and the extent to which students are involved in making judgments, for example, in co-constructing the criteria, selection of the samples of work, and the application criteria in the marking process, in so-called learner-centered pedagogies and curricula. They also explain the fall in usage as students shift to higher grades on the increased subject specialization, larger student loads per teacher, and an increased focus on obtaining marks and grades for reporting student achievement to those outside the classroom. They report that rubrics are being used in two ways: the teacher selects, perhaps in conjunction with his or her students, the criteria to be used in evaluating the portfolio; and the students use the criteria to help them decide what to include in their portfolios. The notions of validity and reliability in the context of the use of portfolios for assessment of student achievement have been reexamined, and the questions asked about the meaning of these terms, once used

for large-scale pen-and-paper testing and measurement, are still appropriate here. Are classroom validity and reliability different from those of large-scale testing?

The reported benefits of using portfolios in the literature include: "students taking more responsibility for their own learning by assessing their own work, learning and its assessment being viewed as a developmental process that occurs over extended time periods, and the encouragement of learning activities that are consistent with current notions of how people learn and what is worth learning" (Gitomer & Duschl, 1995, p. 299); a tool for changing instructional practice in fundamental ways (Duschl & Gitomer, 1997); "students . . . engaging in learning activities consistent with current psychological, historical, and sociological conceptions of growth of scientific knowledge . . . teaching is organized to encourage conceptual change, learners are active constructors of meaning . . . and assessment is an invaluable tool that teachers as well as students use to make instructional decisions" (Gitomer & Duschl, 1995); learners successfully organize and integrate newly acquired scientific knowledge; feel less anxious about learning physics; devote considerable time to reading and studying outside class; internalize and personalize the content material and enjoy the learning experience, although there may be no significant difference in learner achievement (Slater, Ryan, & Samson, 1997; Slater, 1997); there is more of a match with learner-centered curricula and pedagogies (Anderson & Bachor, 1998), especially when the learner is involved in the decision making about the identification of relevant learning outcomes, samples of student work and the marking; and portfolios have been used to document from the critical science perspective, a public story of science for community change with homeless youths (Fusco & Barton, 2001).

There is, however, little empirical evidence to support the use of portfolios (Gitomer & Duschl, 1998), and reliability and validity results may be disappointing (Cizek, 1997; Shapley & Bush, 1999). The questions being asked are, Can portfolios show evidence of complex scientific thinking in several domains? Is there any consistency of high performance over all pieces of work, that is, homogeneity?

## Interviews and Conversations

Another assessment format is that of interview and conversations. Interviews have been used to assess for summative purposes (Bell, 1995) to elicit student thinking as to whether they have learned the intended science learning outcomes or to elicit what they have learned, whether intended or not. The interview-about-instances and interview-about-events format, initially developed for research purposes (Osborne & Gilbert, 1980), has been adapted for use in classrooms (Bell, Osborne, & Tasker, 1985). Likewise, (Griffard & Wandersee, 2001) used a think-aloud task to diagnose alternative conceptions of photosynthesis, in conjunction with a traditional pen-and-paper test. Lederman et al. (2002) documented research findings on the use of an open-ended instrument, the views of the Nature of Science Questionnaire, which in conjunction with individual interviews aims to provide meaningful assessments of students' nature of science views. They argued against mass assessments of large samples, aimed at describing or evaluating student beliefs using standardized forced-choice pencil-and-paper assessment instruments. Instead they

argue for individual classroom interventions aimed at enhancing learners nature of science views and hence assessment for formative purposes.

### **Predict-and-Explain Situations**

Another assessment task format is that of providing the students with a situation or phenomeona, about which they have to make a prediction, and give an explanation for what actually does happen (Lawrence & Pallrand, 2000; White & Gunstone, 1992). The prediction and explanation can provide information for assessment for summative purposes.

### **Learning Stories**

Learning stories (Carr, 2001) have been developed for assessment for summative (as well as formative) purposes in an early childhood setting. Learning stories are described as

structured observations in everyday or “authentic” settings, designed to provide a cumulative series of qualitative “snapshots” or written vignettes of individual children displaying one or more of the target learning dispositions. . . . Practitioners collect “critical incidents” that highlight one or more of these dispositions and a series of learning stories over time, for a particular child, can be put together and scanned for what Carr has called “learning narratives”: what we might call in the present context, “developmental trajectories” of learning dispositions. Children’s stories are kept in a portfolio; often they include photographs or photocopies of children’s work and children’s comments (Carr & Claxton, 2002, p. 22).

### **Observational Methods**

Observations may be used in the classroom teaching and learning situation as a source of assessment information for formative and summative purposes. For example, (Leat & Nichols, 2000) used “mysteries” as an assessment tool for formative and diagnostic purposes with 13- and 14-year-old UK pupils.

### **Dynamic Assessments**

Dynamic assessments (as distinct from static intelligence tests) have been used as assessment formats for summative purposes (Lidz, 1987). For example, the study of (Grigorenko & Sternberg, 1998) involved “the assessor setting ‘examinees’ a task too hard for them and observing how they respond and how they make use of standardised prompts and hints they are offered” (Carr & Claxton, 2002, p. 19). Dynamic assessments are linked theoretically to Vygotsky’s notion of the Zone of Proximal Development and reportedly measure the “learning power” of the student, what the student is capable of generating through scaffolded interaction with the assessor. Dynamic assessments were also used to investigate students’ mental models of chemical equilibrium and the resulting positive influence of tutoring in cognitive

apprenticeship, such as coaching, modeling, scaffolding, articulation, reflection, and exploration (Chiu, Chou, & Liu, 2002).

## **Experimental and Customized Challenges**

Experimental and customized challenges (e.g., jig-saws, problem situations; Norris, 1992) are also another way of eliciting assessment information for summative purposes.

## **Self and Peer Assessments**

Self and peer assessments (Claxton, 1995; Gale, Martin, & McQueen, 2002; Stefani & Tariq, 1996; Taras, 2002; Wiediger & Hutchinson, 2002; Zoller, Fastow, Lubezky, & Tsaparlis, 1999) have also been used for assessment of science learning summative purposes and are often an integral component of other assessment task formats, for example, self-reports, journals, questionnaires, interviews, portfolios.

## **Group Assessment**

Group assessment is the assessment of a group's collective learning rather than that of an individual. The use of group work in science education is increasing as the ability to work cooperatively as part of a team (research and development teams) to achieve a common goal is highly valued by employers in the science and technology sector, and is therefore included in the goals of some science curricula. It is also being advocated by the research into learning science from a sociocultural view point (Rogoff, 1990). Lowe and Fisher (2000), as part of doctoral research, studied the effect of year 9 and year 10 New Zealand students being in small cooperative groups, in which the students performed all their assignments, tests, laboratory work and fieldwork, on their motivation and attitudes toward science. "All members of the group received the same mark for any given assessment exercise and students were encouraged to communicate and work co-operatively during these activities" (p. 131). The protocol for group organization regarding assessment was as follows: "For written tests, students were arranged in their groups at the laboratory benches to allow them to work together with a minimum of contact with other groups. Talk within the group was permissible but talk between groups was not. Answers were by consensus and one group member had the task of writing the script, which was handled in and marked. All members received the same grade" (p. 133). The study reported that the students interviewed stated that "they preferred working in groups, especially during tests where they reported they felt they were learning from their peers even as they completed tests. The students stated that they felt less nervous when doing their tests since they were doing it with their friends" (p. 141). The teachers expressed some initial concern about group work mostly in relation to assessment; they reported positively on the formative purposes of the tests in groups; and they spent significantly less time carrying out assessment, particularly marking. No correlation data between group assessments and the

usual individual assessments were reported, nor were any measures of the quality of the assessments.

## Computer-Based Assessment

The use of computer technology to assess for summative purposes has been documented (Fisher et al., 2000). Sewell, Stevens, and Lewis (1995) used multimedia computer technology as a tool for teaching and assessing biological science with university students. They found a high rank correlation (0.96, Spearman's correlation) between the computer-based assessment of the knowledge base gained from the teaching program and the marks obtained in the sessional written examination.

In summary, alternatives to paper-and-pen testing formats have been developed and researched in science education. However, concerns about the use of a wider range of assessment tasks have been raised and include time constraints, financial constraints, teacher and student knowledge of assessment, the difficulty in creating authentic tasks, the quality of the wider range of tasks, especially validity and reliability (Lester, Lambdim, & Preston, 1997), and the need for professional development (Gitomer & Duschl, 1998; Ruiz-Primo & Shavelson, 1996b).

A parallel aspect of this trend to use alternative assessment tasks has been the trend to move from using norm-referenced and standardized, commercially made (by people external to the classroom) tests, to criterion-referenced, construct-referenced, or ipsative-referenced teacher-made assessments. Norm-referenced assessment is where individuals are compared with the norm of a group, indicating whether they can do something better or less well than others, and not what an individual can or cannot do. Criterion-referenced assessment compares a student's learning with a well-defined objective, that is, the desired learning goals. Ipsative assessment compares a student's performance with her or his previous performance, and construct-referenced assessment is that made within the context of the school and marked by teachers, of a particular idea or construct (William, 1992). Others have also noted that criterion-referenced assessment has tended to move away from overspecification toward a more holistic approach (Gipps, 1994a; Moss, 1992; Popham, 1987, 2003), allowing for the assessment of more complex skills and processes than can detailed ones. A disadvantage is that it can result in less reliability, but this can be addressed by the use of exemplars of student work at particular levels and group moderation (Gipps et al., 1995).

## INCREASING THE QUALITY OF ASSESSMENTS

The sixth of the trends in assessment in science classrooms (and in other classrooms) has been research on the development of high-quality assessment procedures and is based in the debates of the shift from a paradigm of measurement and psychometric approaches based on true score theory (Black, 2001; Cumming & Maxwell, 1999) to a "new paradigm of assessment" (Gipps, 1994a). In educational assessment, quality is just not a technical issue, as assessment involves making and acting on choices and judgments, which are underpinned by social values (Messick, 1994; Berlak et al., 1992; (Gitomer & Duschl, 1998) and discourses of power (Cherryholmes, 1988). As-

assessment can be seen as a social practice determined by the specific social, historical, and political contexts in which they are undertaken (Gipps, 1999). Given today's social values, for example, on equity, and given the move from psychometric testing and measurement toward educational assessment, quality is no longer thought of in terms of the initial use of the terms *validity* and *reliability* as previously. The notion of quality in educational assessment has been developed to reflect the notions of assessment for educational purposes, that is, formative assessment (Cowie & Bell, 1996), embedded assessment (Treagust et al., 2001), authentic assessment (Cumming & Maxwell, 1999), holistic assessment (Wiliam, 1994), and the use of quality assessment terms such as *validity*, *equity*, *trustworthiness*, *fairness* (Gipps, 1998; Gipps & Murphy, 1994); *inference*, *generalizability*, *consequences*, *social values* (Gitomer & Duschl, 1998); *manageability*, *facility*, *discrimination* (Osborne & Ratcliffe, 2002); *reliability*, *dependability*, *validity*, *disclosure*, *fidelity* (Wiliam, 1992), *confidence* (Black, 1993), and *equity*, *trustworthiness*, and *appropriateness* (Cowie & Bell, 1996).

Reliability is only a small aspect of the dependability of a test, and therefore traditional statistical techniques of estimating reliability (test-retest, mark-remark, and parallel forms reliability and split-half reliability) are not relevant to classroom assessment of learning. Therefore other indicators of quality are of more use to classroom assessment (Wiliam, 1992).

A key indication of quality of educational assessments is that of validity. In the 1970s and 1980s, there was much criticism of the low validity of summative assessments used by teachers in classroom-based assessment (Doran et al., 1993) and in external testing and examinations, for example, for national qualifications (Gauld, 1980; Keeves & Alagumalai, 1998). The meaning of validity expanded as alternatives to pen-and-paper testing were developed (Crooks, Kane, & Cohen, 1996). Whereas reliability is affirmed by statistical means, validity relies "heavily on human judgment and is therefore harder to carry out, report and defend" (Crooks et al., 1996, p. 266). The initial meaning of validity as "measuring what it purports to measure" in relation to traditional multiple choice and pen-and-paper tests has been expanded as the notion of validity has been developed with respect to the quality of alternative assessments, such as performance assessment (Moss, 1992). Crooks et al. (1996) indicate the breadth of current understandings of validity and threats to the validity in their account of eight different stages of the assessment "chain" and the associated threats to validity. For Crooks et al. (1996) the validity of the entire assessment procedure is constrained by the strength of the weakest of the eight links in the validity chain.

Whereas some view an independence of validity and reliability in some circumstances (Moss, 1994), others see the two notions as interdependent (Crooks et al., 1996; Gitomer & Duschl, 1998), viewing some degree of generalizability (reliability) as essential for validity. For assessment for formative purposes, the validity of the assessments is more important than the reliability (Harlen & James, 1997; Moss, 1994). There is a tension, in devising assessment procedures, between local validity and beyond-local reliability (Carr, 2001; Carr & Claxton, 2002). Cumming & Maxwell (1999) argued for more attention to be given to authentic learning goals or objectives, teaching practices, and assessment tasks as interdependencies. Then "the validity of an assessment can be evaluated in terms of the extent to which the assessment relates to the ascribed educational values, learning theories and teaching theories as well as to the realisation of the desired assessment theory" (p. 193).

Recent studies on the reliability and validity of newly developed assessments of science learning include researching multiple-choice diagnostic instruments to assess high school students' understanding of inorganic chemistry qualitative analysis (Tan, Goh, Chia, & Treagust, 2002); student competence in conducting scientific inquiry (Zachos, Hick, Doane, & Sargent, 2000); ascertaining whether students have attained specific ideas in benchmarks and standards (Stern & Ahlgren, 2002); the sensitivity of close and proximal assessments to the changes in students' pre- and post-test performances (Ruiz-Primo, Shavelson, Hamilton, & Klein, 2002); multiple-choice and open-ended formats to assess students' understanding of protein synthesis (Pittman, 1999); alternative methods of answering and scoring multiple-choice tests (Taylor & Gardner, 1999); nature of science views (Lederman et al., 2002; Aikenhead, 1987; Taylor & Gardner, 1999); concept mapping (Stoddart et al., 2000; Liu & Hinchey, 1996; Ruiz-Primo & Shavelson, 1996a); time-series design in assessments (Lin & Frances, 1999); inconsistency in test grading by teachers of science (Klein, 2002); the use of distractor-driven multiple choice tests to assess children's conceptions (Sadler, 1998); the use of examinations to elicit "misconceptions" in college chemistry (Zoller, 1996); an assessment scheme for practical science in Hong Kong (Cheung, Hattie, Bucat, & Douglas, 1996); assessment tasks to assess the ideas and evidence—the processes and practices—of science, that is, how we know as well as what we know (Osborne & Ratcliffe, 2002); the use of rubrics (Osborne & Ratcliffe, 2002; Toth et al., 2002); the science achievement outcomes for different subgroups of students using different assessment formats (Lawrenz, Huffman, & Welch, 2001); and the quality of interviews as an assessment tool, in the classroom and in research (Welzel & Roth, 1998).

Researchers have argued that new forms of educational assessment (often called alternative assessments) cannot be fairly appraised unless the older definition of validity is broadened (Linn, Baker, & Dunbar, 1991). Research on the broader notion of quality of assessments of science learning includes those addressing consequences, equity, fairness, cultural validity, trustworthiness, appropriateness, manageability, fidelity, and authenticity. Each of these newer notions of quality is now discussed.

## Consequences

Gitomer and Duschl (1998) argued that typically, the validity of assessments has been considered only in terms of *construct validity*—how well the evidence supports the interpretations made on the basis of the assessment. However, Messick (1989) raised the prominence of a second consideration of validity, the consequences of an assessment, that is, consequential validity, which is centrally important to assessment of formative purposes, given that the definition of formative assessment is based on the taking of action to improve learning (Black, 1993; Cowie & Bell, 1996; Crooks, 2001) and given that the appraisal is made in relation to its effectiveness in improving learning. In considering the concept of consequences, Cowie (2000) asserted that the consequences of formative assessment—cognitive, social, and emotional—cannot be separated out, and "therefore adequate and appropriate (valid) ways of generating, interpreting and responding to information gained from students and their learning, are those that benefit and not harm student learning, identity, feelings and relationships with others" (Cowie, 2000, p. 281).

## Equity and Fairness

Equity is an important factor in considering the quality of an assessment and is associated with issues of moral and social justice (Darling-Hammond, 1994) and the equitable and inclusive practice and production of science, multiple worldviews, and science assessment across diversity (Fusco & Barton, 2001; Roth & McGinn, 1998). It implies practices and interpretation of results that are fair and just to all groups, and a definition of achievement which applies to all students, not just a subgroup (Gipps & Murphy, 1994); equal opportunity to sit and achieve within an exam (William, 1994); and providing opportunities for all students to participate in communication and particularly in the classroom interactions that are the heart of assessment for formative purposes (Cowie & Bell, 1996; Torrance, 1993; Crooks, 1988), even if different modes of communication and task formats have to be used (Kent, 1996; Lawrenz et al., 2001).

Fairness is an aspect of equity and validity. Students do not come to school with identical experiences, nor do they have identical experiences at school. Therefore, multiple opportunities for assessment might be needed to provide fairness and comparable treatment for all students in a class—students who will have differing educational experiences—to demonstrate their achievement if they are disadvantaged by any one assessment in a program (Gipps, 1998). The notion of fairness can be viewed as having three aspects: in the sense of assessing students on a fair basis, in the sense of not jeopardizing students' chances to learn the subject matter while they were being assessed, and in the sense of not depriving students of opportunities of receiving an all-around education (Yung, 2001). Equity and fairness may be in terms of gender (Gipps, 1998; Gipps & Murphy, 1994) or ethnicity (Darling-Hammond, 1994; Gipps, 1998; Lawrenz et al., 2001; Lee, 1999, 2001). The two main messages here are that where differences in performance are ignored and not monitored, patterns of inequality will increase, and that to ensure assessments are as fair as possible, we need to address the curriculum content (the constructs) being taught and assessed, teacher attitudes toward different groups of students, and the assessment mode and item format (Gipps, 1998).

## Cultural Validity

Cultural validity has been suggested as an indication of quality in science assessment (Klein et al., 1997; Lokan, Adams, & Doig, 1999; Solano-Flores & Nelson-Barber, 2001). To attain cultural validity, development of the assessments must consider how the sociocultural context in which students live influences the ways in which they make sense of science items and the ways in which they solve them. These sociocultural influences include the values, beliefs, experiences, communication patterns, teaching and learning styles, and epistemologies inherent in the students' cultural backgrounds, as well as the socioeconomic conditions prevailing in their cultural groups. They contend that current approaches to handling student diversity in assessment (e.g., adapting or translating tests, providing assessment accommodations, estimating test cultural bias) are considered to be limited and lacking a sociocultural perspective. Solano-Flores and Nelson-Barber (2001) asserted that there are five aspects to cultural validity: "student epistemology, student language proficiency, cultural world views, cultural communication and socialization styles and student life context and values" (Solano-Flores & Nelson-Barber, 2001, p. 566).

## Trustworthiness

Trustworthiness relates to whether something or someone can be trusted in the classroom setting and is based on the perceptions of both teachers and students and is an essential element of teaching, learning, and assessment, particularly formative assessment (Bell & Cowie, 1997; Cowie & Bell, 1996). Teachers must trust students to provide them with reasonably honest and representative information about their understandings and misunderstandings. Students must trust teachers to provide them with learning opportunities, to show interest in and support for their ideas and questions, to act on what they find out in good faith, and have faith and trust in the assessment practices. Trust in the relationship between a student and teacher in the practice of formative assessment also effects the disclosure by the students of what they know and can do (Cowie, 2000). Cowie stated that from a student perspective, a valid formative assessment is trustworthy, one in which students can have trust in the process as well as the person, where both support and the process do not undermine student understanding, affect, and relationships; give all students access to opportunities to participate in formative assessment; and encourage them to participate in and respond to formative feedback.

## Appropriateness

To be judged appropriate by teachers and students, assessment must be beneficial and not harmful to student learning (Crooks, 1988). Hence, appropriate formative assessment, for example, is that which is first equitable and trustworthy but also supportive of learning (Black, 1995c), is indicative of what counts as learning (Crooks, 1988), is matching of the views of teaching and learning used in the classroom (Gipps, 1994a; Torrance, 1993), and addresses the importance of students' views and the on-going interactive nature of the practice of assessment for formative purposes (Bell & Cowie, 1997; Cowie & Bell, 1996). Validity concerns are raised when students do not give the fullest responses they are capable of (Eley & Caygill, 2001, 2002; Gauld, 1980; Kent, 1996; Shaw, 1997).

## Manageability

An aspect of quality that is of great concern for teachers is that of manageability, that the assessment can be managed within the busy classroom life of teachers and students, and not take time away from teaching and learning the set curriculum (McClure et al., 1999; Stoddart et al., 2000).

## Fidelity and Disclosure

Wiliam (1992) identified two issues, disclosure and fidelity, which may limit the information teachers have to notice and recognize in interactive formative assessment. The disclosure of an assessment strategy is the extent to which it produces evidence of attainment (or nonattainment) from an individual in the area being assessed (Cowie & Bell, 1996). Wiliam (1992) defined *fidelity* as the extent to which evidence of attainment, which has been disclosed, is observed faithfully. He claimed that fidelity is undermined if evidence of attainment is disclosed but not observed.

For example, the teacher may not hear a small-group discussion in which the students demonstrate they understand a concept. Fidelity is also undermined if the evidence is observed but incorrectly interpreted. For example, if the teacher did not understand the student's thinking, it is possible that there is insufficient commonality in the teacher and the students' thinking.

## **Authenticity**

Another aspect of quality is that of authentic assessment (a term used mostly in the United States), for example (Brown, 1992; Kamen, 1996). It includes a construct of the teaching, learning, and assessment that is contextualized and meaningful for students; holistic rather than extremely specific (Erickson & Meyer, 1998); representative of activities actually done in out-of-school settings (Atkin et al., 2001); interacting with/in the world in informed, reflective, critical, and agentic ways (Fusco & Barton, 2001; Rodriguez, 1998); and includes authentic learning goals and including of performance assessments of complex tasks, problem-based assessments, and competence-based assessments (Cumming & Maxwell, 1999; Darling-Hammond, 1995; Darling-Hammond & Snyder, 2000; Doran et al., 1993). An assessment is authentic (and of sufficient quality) if the form and criteria for success are explicit and public; it involves collaboration (which is not seen as cheating); it is contextualized; it represents realistic and fair practices in the discipline; it uses scoring commensurate with the complexity and multifaceted nature of the assessments; it identifies strengths; it is multipurpose; it enables the integration of knowledge and skills learned from different sources; it is dynamic, as evidence can be added or removed during its development; and it encourages metacognition and reflection along with peer and self-evaluation (Collins, 1992; Wiggins, 1989). Concerns about authentic assessment include "camouflage," which Cumming and Maxwell (1999) describe as occurring "when a traditional form of assessment is 'dressed up' to appear authentic, often by the introduction of 'real world' elements or tokenism" (p. 188). The extra reading demands of the camouflage may not facilitate a solution and in fact may even add to the literacy demands of the task for some students. Another concern is that the assessment task will invariably be in a context, as will the teaching. If the context is familiar, it may be measuring only recall and comprehension, not higher order cognitive skills such as argumentation, that examine evidence critically. If the context is too unfamiliar and demands too high a level of literacy, the wording of the contextual information may be a distraction for students answering the question, add a reading comprehension problem, or confuse the students' interpretation of the demands of the assessment (Osborne & Ratcliffe, 2002; Eley & Caygill, 2001).

## **THEORIZING ASSESSMENT**

A seventh trend in research and development in assessment of science classrooms (as of other classrooms) has been to consider pedagogy, learning, assessment, and curriculum together, rather than individually in an analytical, reductionist approach. Hence, a discussion on assessment cannot be divorced from a discussion of teaching and learning, or from its curriculum and political contexts (Carr et al., 2000). If teaching, learning, assessment, and curriculum are considered in an integrated and interdependent way, one might theorize them in similar ways, and therefore assess-

ments should create a “learning environment in which students are engaging in learning activities consistent with current psychological, philosophical historical, and sociological conceptions of the growth of scientific knowledge” (Gitomer & Duschl, 1995, p. 300). This match/mismatch between theorizing, and between practices and theorizing is discussed by Bol and Strage (1996) and Hickey and Zuiker (2003).

As theorizing about learning and teaching has developed from a behaviorist to cognitive science to sociocultural views (Bell & Gilbert, 1996; Duit & Treagust, 1998), so too has theorizing of assessment.

For example, there has been the development of views of assessment to match the constructivist views of learning (Berlak et al., 1992; Gipps, 1994a; Wiliam, 1994), and a growing number of studies theorize assessment as a sociocultural practice (Bell & Cowie, 2001b; Broadfoot, 1996; Carr, 2001; Chiu et al., 2002; Filer, 1995; Filer, 2000; Filer & Pollard, 2000; Gipps, 1999; Keys, 1995; McGinn & Roth, 1998; Roth & McGinn, 1997; Welzel & Roth, 1998; Cowie, 2000; Fusco & Barton, 2001; Hickey & Zuiker, 2003; Pryor & Torrance, 2000; Solano-Flores & Nelson-Barber, 2001; Torrance & Pryor, 1998), and with discursive, post-structuralist theorizing (Bell, 2000; Fusco & Barton, 2001; Gipps, 1999; Sarf, 1998; Torrance, 2000). As Berlak (2000) stated, “there is an overwhelming body of research conducted over the last two decades documenting that, beyond a shadow of a doubt, that the school context, the particularities of its history, the immediate and wider socio-economic context, the language, the race and social class of the students and their families, and the culture of the school itself have an enormous bearing students’ interest in and performance on all school tasks, including taking standardised test, and examinations” (p. 193). To view assessment as a sociocultural practice is to view it as value laden, socially constructed, and historically, socially, and politically situated. That is, one can never do assessment separate from one’s own history (individual or social) or outside of its contexts. As Gipps (1999) said, “to see assessment as a scientific, objective activity is mistaken; assessment is not an exact science” (p. 370). Assessment may be viewed as a purposeful, intentional, responsive activity involving meaning making and giving feedback to students and teachers, to improve learning; an integral part of teaching and learning; a situated and contextualized activity; a partnership between teacher and students; and involving the use of language to communicate meaning (Bell, 2000; Bell & Cowie, 2001b).

Theorizing assessment as a sociocultural practice raises several issues for researchers. One is the issue of whose theorizing and the purpose of the theorizing (Bell, 2000; Bell & Cowie, 2001b, 2001c; Torrance & Pryor, 1998, 2001). In both of these major research studies, the teachers and university researchers involved have been encouraged to theorize their own assessment practices and to develop classroom practice models, using their own shared vocabulary. This theorizing was identified by the teachers as an important aspect of their teacher development practices. Another is the unit of analysis, which is “the *event*, rather than the individual is the primary unit of analysis for evaluating learning environments from a socio-cultural perspective. . . . The key issue in studying innovative curricula is the knowledge practices in which learners collectively participate” (Hickey & Zuiker, 2003, p. 548). This is evident in the use of cameos (Bell & Cowie, 1997, 2001b) and “incidents” (Torrance & Pryor, 1998) in research on formative assessment.

If assessment is theorized in terms of a sociocultural view of mind, the implications (Gipps, 1999) include that assessment can only be fully understood if the social, cultural, and political contexts in the classroom are taken into account; the practices

of assessment reflect the values, culture of the classroom, and, in particular, those of the teacher; assessment is a social practice, constructed within social and cultural norms of the classroom; what is assessed is what is socially and culturally valued; the cultural and social knowledge of the teacher and students will mediate their responses to assessment; assessments are value-laden and socially constructed; a distinction needs to be made between what a student can typically do (without mediational tools) and best performance (with the use of mediational tools); assessments need to give feedback to students on the assessment process itself to enable them to do self and peer formative assessment; and teachers and students need to negotiate the process of assessment to be used, the criteria for achievement, and what counts as acceptable knowledge.

## FURTHER RESEARCH ON CLASSROOM ASSESSMENT OF SCIENCE LEARNING

Despite the wealth of research reviewed in this chapter, there are many opportunities for further research, including professional development, pre- and inservice, higher education for teachers of science on classroom assessment of science learning (Bell & Cowie, 2001c; Campbell & Evans, 2000; Higgins, Hartley, & Skelton, 2002; Yorke, 2003); online teaching and assessment, especially that using web-based sites (Buchanan, 2000; Peat & Franklin, 2002), where feedback and feedforward are given to students without face-to-face contact; group assessment (Black, 2001); students' views of assessment practices, as well as teaching practices; and a critique of the research paradigms and methods used to date, including action research, case studies, cameos, incidents, classroom observations, interviews, pre- and post-testing; the progression in students' learning and how this research findings might be used in assessment for formative and summative purposes (Osborne & Ratcliffe, 2002); the quality of assessment for summative purposes, given the trend from normative to criterion, construct and ipsative referenced assessment; and the interaction between classroom assessments for formative and summative purposes.

Further research on the quality of assessments will continue as new assessment task formats are developed, particularly on the effect of context on performance and construct validity (Gipps, 1998).

## ACKNOWLEDGMENTS

Thanks to Audrey Champagne and John Pryor, who reviewed this chapter.

# CHAPTER 33

---

## Large-Scale Assessments in Science Education

**Edward D. Britton**  
**Steven A. Schneider**

*WestEd Mathematics, Science and Technology Program*  
*Redwood City, California*

This chapter focuses on changes in large-scale assessments in science education, at the international, national, and state levels. Historically, these assessments are for purposes such as international comparisons, accountability, summative assessment for reporting to others outside the classroom, qualification for entry to college, and evaluation of programs. Thus, the term “large-scale assessments” encompasses quite a variety of assessments that differ in their purposes, formats, and other features. It is important to consider the specifics of those features to avoid inappropriate generalizations—ones that imply all large-scale assessments have the same characteristics (Kifer, 2000).

The number and types of large-scale science assessments have grown substantially in recent years at every level of education system, as illustrated by the following facts, which are discussed in this chapter. Since 2000, there have been two international organizations sponsoring international science comparisons on a regular basis, and the number of countries that participate in such studies is growing. At the national level in the United States, the nature of the National Assessment of Education Progress (NAEP) will undergo significant changes beginning in 2009. This chapter includes the just-released framework that will guide the future of NAEP science assessments. The No Child Left Behind (NCLB) legislation is dramatically increasing the number of state science assessments, including increased use of Advanced Placement exams and creation of high school exit examinations (Center on Education Policy, 2005). Many countries have had the latter for some time, but such examinations have been relatively rare in the United States until this decade.

An indicator of how much science assessment has increased is the fact that this Handbook needs to split its treatment of assessment into two chapters. Chapter 32 in this Handbook describes research on classroom assessments—those by teachers for direct use for and with students. The current chapter on large-scale assessment does not revisit classroom assessments, but mentions emerging models for enhanc-

ing the relationship between large-scale and classroom assessment. In prior handbooks for science education, only a single chapter had to be devoted to all large-scale assessments. Both Doran, Lawrenz, and Helgeson (1994) and Tamir (1998) provide broad portraits of science assessment that span both classroom assessment and large-scale external assessments. The former review includes considerably more discussion of large-scale assessments than the latter. The current chapter builds on these prior reviews by focusing more on recent developments rather than also recounting the considerable history of science assessment already provided, particularly by Doran, Lawrenz, and Helgeson (1994).

We must further delimit the large body of work that could be in the purview of a chapter on large-scale assessment. Research in large-scale assessment cuts across many subject-area disciplines and resides in several fields of educational research. Although such literatures are as relevant to science education as any other subject area, we generally emphasize literature that is targeted at science education, while still noting some seminal publications that address a broader context. Also, a rendering in detail of the results from each major large-scale assessment is beyond the scope of the following discussion, as are the psychometric or other technical issues involved, even those specific to science assessments (e.g., Quellmalz et al., 2005; Welch, Huffman, & Lawrenz, 1998).

This chapter elaborates the following recent trends and prospects for the future of large-scale assessment of science:

- The increased potential benefits as well as risks of large-scale assessments in science education, should the increasingly prevalent assessments become more of the same.
- Both the frequency and types of international comparisons of student understanding in science, which are increasing.
- Aspects of national science assessment in upcoming administrations of NAEP are about to change.
- The number if not the nature of state science assessments is changing because of requirements of the No Child Left Behind (NCLB) legislation for implementation beginning in 2007. The chapter ends by reporting a model for creating coherent systems of large-scale and classroom assessments.

## **OVERVIEW OF ISSUES IN LARGE-SCALE SCIENCE ASSESSMENT**

Certain prevailing characteristics of large-scale assessments present significant benefits and risks to science education. This section gives an overview of four issues that will grow if the upcoming, increased number of assessments continue mostly to have the same characteristics as ones currently in use. First, attaching increasingly high stakes to assessments can increase the amount of science instruction occurring in classrooms and provide some policy guidance, but the policy implications drawn and resulting science instruction can be at odds with research on some aspects of how students learn. This section begins by framing and elaborating on such tensions.

Second, this barrier to congruence stems from emphasizing use of multiple-choice and short open-ended items (also referred to as constructed or free response items), because the former type of item cannot adequately interrogate the whole spectrum of science standards held by the science education community. For example, multiple-choice items are limited for assessing students' ability to conduct scientific investigations, particularly through the use of inquiry approaches. This section describes research on alternative types of items for science assessment.

Third, just as the science education community continues its quest to reach all students, large-scale assessments need to be designed in ways such that all kinds of students have equivalent opportunities to succeed at taking them. This section briefly notes research on accommodating students with disabilities and addressing problems in creating and translating tests for students of different languages and cultures.

Fourth, using assessments that are not adequately aligned with standards for science education cannot provide adequate guidance to teachers on what to do differently. This section discusses the alignment of state science assessments with state science standards, which would be a significant incremental enhancement of the state of large-scale assessment.

## **Benefits and Risks of More of the Same**

Increased large-scale science assessment offers both great opportunity and substantial risk for science education. Requiring science assessment helps ensure that science gets attention in school. This is particularly true for the elementary grades, where teachers must balance and choose the amount of attention to all subjects, but it also has implications for secondary levels of schooling.

In the United States, the initial NCLB requirement of assessment in mathematics and reading but not in science has had a dampening effect on elementary teachers' inclusion of science instruction. This is common knowledge in the science education community, and the first author has encountered examples of analogous effects at the middle and even high school levels during field work in recent years. He encountered more than one high school where students who, because they were failing at mathematics, were required to double up their number of mathematics courses. The concern is that this was being accomplished by dropping their formerly required general science classes. By requiring that science join reading and mathematics as annual subjects of states' standards-based assessment by the year 2007, NCLB pushes science to the center stage of public attention and helps to ensure that it gets the priority it deserves in the school curriculum.

Particular kinds of assessment can help to promote more effective teaching and learning of science for all students. But there is also the danger of assessment pushing teaching and learning in undesirable directions that are counterproductive to the goals of scientific literacy. There is danger too of missed opportunities to push the current state of the art to the new levels required to have assessment systems that truly support accountability and classroom assessment purposes.

Ample research suggests that accountability systems can be powerful in communicating expectations and stimulating teachers and schools to modify their teaching and work to attain established performance goals. Studies conducted in numer-

ous states using a variety of quantitative and qualitative methodologies have shown quite consistent results, described below [Arizona (Smith & Rottenberg, 1991), California (McDonnell & Choisser, 1997; Herman & Klein, 1996), Kentucky (Koretz, Barron, Mitchell, & Stecher, 1996; Stecher, Barron, Kaganoff, & Goodwin, 1998; Borko & Elliott, 1998; Wolf & McIver, 1999), Maine (Firestone, Mayrowetz, & Fairman, 1998), Maryland (Lane, Stone, Parke, Hansen, & Cerrillo, 2000; Firestone et al., 1998; Goldberg & Rosewell, 2000), New Jersey (Firestone, Camilli, Yurecko, Monfils, & Mayrowetz, 2000), North Carolina (McDonnell & Choisser, 1997), Vermont (Koretz, McCaffrey, Klein, Bell, & Stecher, 1993), and Washington (Stecher, Barron, Chun, & Ross, 2000; Borko & Stecher, 2001)]:

1. Accountability tests serve to focus instruction. Teachers and principals indeed pay attention to what is tested and adapt their curriculum and teaching accordingly.
2. Teachers model what is assessed. They tend to model the pedagogical approach reflected on high-visibility tests. When a state or district assessment is composed of multiple-choice tests, teachers tend to rely heavily on multiple-choice worksheets in their classroom instruction. However, when the assessments use open-ended items and/or extended writing and rubrics to judge the quality of student work, teachers prepare students for the test by incorporating these same types of activities into their classroom practice.
3. Test scores show initial increases. In state after state, when new assessments and accountability provisions are put into place, student scores show an increase, at least for the first few years. Such sustained attention to test content and format tends to show up in test performance.

Although these first points demonstrate some of the benefits of assessment, other research showed unintended consequences:

4. Schools focus on the test rather than the standards. With sanctions and incentives riding on test performance, educators appear to give their primary attention to what is tested and how it is tested, rather than to the standards underlying the test. Teachers shift how much classroom instruction time is accorded to core curriculum subjects, depending on whether or not a particular subject is tested at their grade levels (Stecher & Barron, 1999).
5. What is not tested becomes invisible. As a corollary, focusing on the test rather than the standards also means that that which is not tested tends to get less attention or may be ignored altogether. Both the broader domain of the tested disciplines and important subjects that are not tested may get short shrift. That a number of studies have found that state tests tend to give relatively little attention to complex thinking and problem solving and instead tend to focus on lower levels of student performance thus has strong implications for what is likely to be taught. Moreover, when tests and standards are not well aligned, it seems clear that the test and not the standards will be the focus of attention.
6. Test score increases appear to be inflated. If teachers teach only to the test and not to the larger domain that the test is intended to represent, the test score

results may represent just that—higher scores on a specific test and not genuine learning that generalizes to other domains of science instruction. Research findings showing disparities between student performance on state accountability tests and that on other achievement measures that are intended to measure similar areas of learning raise questions about the meaning of increasing test scores. For example, Bob Linn (1998) has shown dramatic drops in performance when school districts or states change from one standardized test to another. Dan Koretz and colleagues (Koretz & Barron, 1998) have found limited correspondence between gains on state tests and those on the National Assessment of Educational Progress.

### Use of More Varied Types of Assessment Items

Multiple-choice and short-answer-type items tend to dominate in large-scale accountability tests for several reasons. Many of them can be included within the testing time available, permitting assessment of as many domains of science content as possible. Furthermore, this type of item can be more inexpensively scored than open-ended items. However, large-scale assessments certainly have employed other types of items, for example: several international comparisons have included performance-based science assessments as an option for participating countries; and NAEP science examinations have included practical skills tests for subsets of the sample—even as far back as 1972 (NAEP, 1975). Israel and some regional examination boards in England and Wales have historically used laboratory practicals as part of large-scale high school exit examinations (Britton & Raizen, 1996; Tamir, 1974).

Multiple-choice and short-answer items can be different or more complex than the routine fare. Sadler (1998) is developing science assessments where the distractors in multiple-choice items are based on research about students' misconceptions rather than mostly being based on the psychometric analysis of whether they adequately discriminate between high- and low-performing students. Figure 33.1 is a Japanese multiple-choice item in biology for students who are applying for college. The item requires applicants to make two sequential choices from among 13 response options instead of the more typical four or five choices. Figure 33.2 presents a short-answer item in biology from an Israeli matriculation examination. It provides students with a multiple-choice item and identifies the correct answer, but then asks students to explain why that response is the correct one. Other, similar items require students to identify the correct answer first, before asking them to explain their answer.

However, the multiple-choice and short-answer items that most commonly are employed in large-scale assessments can go only so far in tapping the complex thinking, communication, and problem-solving skills that students will need for future success. Rather, multiple measures are needed to address the full depth and breadth of our expectations for student learning (Herman, 1997).

In addition to multiple-choice and short open-ended items, large-scale assessments can include such item types as more extended constructed-response items (varying from responses involving sentences or paragraphs to full essays), concept maps, and performance-based science tasks, involving hands-on problems with ma-

Read the following descriptions, and select one correct answer from Group A and *two* correct answers from Group B. Write your answer from Group A first. List your answers from Group B in the order of the photosynthesis process, such as "1,4,5."

Group A:

- 1) Oxygen is discharged during photosynthesis in chlorophytes or during photosynthesis by photosynthetic bacteria.
- 2) Oxygen is discharged during photosynthesis in chlorophytes but not during photosynthesis by photosynthetic bacteria.
- 3) Oxygen is discharged during photosynthesis by photosynthetic bacteria but not during photosynthesis in chlorophytes.

Group B:

- 4) Oxygen, which is discharged during photosynthesis in chlorophytes or photosynthesis by photosynthetic bacteria, derives from the water.
- 5) Oxygen, which is discharged during photosynthesis by photosynthetic bacteria, derives from the water.
- 6) Oxygen, which is discharged during photosynthesis in chlorophytes, derives from the water.
- 7) Oxygen, which is discharged during photosynthesis in chlorophytes or photosynthesis by photosynthetic bacteria, derives from the carbon dioxide.
- 8) Oxygen, which is discharged during photosynthesis by the photosynthetic bacteria, derives from the carbon dioxide.
- 9) Oxygen, which is discharged during photosynthesis in chlorophytes, derives from the carbon dioxide.
- 10) Glucose is produced from a reaction between water and carbon in carbon dioxide.
- 11) Glucose is produced from a reduction of carbon dioxide by hydrogen in the water.
- 12) Glucose is produced through oxidation of the carbon dioxide by oxygen in the water.
- 13) Glucose is produced from a reaction between hydroxide ions in water and carbon dioxide.

FIGURE 33-1. Japanese multiple-choice item in biology for students who are applying for college.

terials or computer-based simulations of phenomena or data. Berg and Smith (1994) examined differences in multiple-choice items and free-response items in assessing graphing abilities.

Science performance assessments can address aspects of knowledge that multiple-choice items cannot, but they bring their own challenges, such as not always tapping higher-order thinking, and they are expensive to develop, administer, and score (Collins, 1993; Ruiz-Primo & Shavelson, 1996a; Solano-Flores & Shavelson, 1997). Doran et al. (1993) tried a large-scale, performance-based assessment of science laboratory skills in Ohio and found that more refinements would be needed. It is challenging to devise performance tasks that adequately probe cognitive complexities (Baxter & Glaser, 1997; Sugrue, 1994). Science items involving concept maps pre-

In the next question, the correct answer is noted. Copy the answer into your notebook and explain briefly why it is correct.

2. An accurate measurement was made between the amounts of dry substance in corn plants at two different times: at noon on a hot summer day and at night after that day. It is reasonable to assume that the amount of dry substance is

1. larger at noon.
2. larger at midnight.
3. identical at the two times.
4. in some of the plants, larger at noon, whereas larger at midnight in others.

FIGURE 33–2. Short answer item in biology from an Israeli matriculation examination.

sent problems as well as advantages (Ruiz-Primo & Shavelson, 1996b). Computer-simulated and hands-on science performance assessments are not interchangeable, and several possible sources of variation can explain this (Huff & Sireci, 2001; Rosenquist, Shavelson, & Ruiz-Primo, 2000).

## Assessment for All

The science education community has for some time adopted the goal of reaching all students with science instruction. There are related issues in devising and administering large-scale assessments for which all kinds of students have equivalent opportunities to demonstrate their learning. Researchers have investigated gender differences in large-scale science assessments (e.g., Lee & Burkam, 1996; Walding et al., 1994). Assessments historically have not accommodated well the needs of students with disabilities. Korenz and Hamilton (1999) conducted an analysis of the effects of accommodations and test formats in science and other subjects for students with disabilities taking the Kentucky state assessment. Abedi et al. (2001) looked at NAEP math test accommodations for students with limited English proficiency, and similar studies are envisioned for NAEP in science and other school subjects.

Research is revealing more challenges than were recognized in the recent past for producing tests originally developed in English for use by students of other languages and from different cultures. This issue is of critical importance in international U.S. assessments. Research has shown that test translation for science and other subjects does not guarantee full test equivalence (e.g., Sireci, 1997). International and some national assessments now employ a process of back-translation to reveal differences in meaning. Developers of large-scale assessments have for some time been on the lookout for cultural bias during item development. However, studies of how cultural differences as well as language differences generate variation between translated and untranslated versions of science tests in both Spanish-speaking and Native American communities reveal more complexity to the issue (Solano-Flores & Nelson-Barber, 2001; Solano-Flores, Trumbull, & Nelson-Barber, 2002). Assumptions about

the experiences and cultures of English learners, combined with test developers' limited experiential knowledge about students' home and community lives, led to greater than anticipated inadequacies in test development. These emerging results suggest that different test development methods may need to be considered in the future if such sources of variation are to be fully addressed.

### **Alignment of Large-Scale Assessments with Standards**

Alignment is the lynchpin of standards-based reform. If assessment results are to be used to provide feedback that helps schools and the teachers and students within them attain understanding described in state standards, then it is essential that the standards and assessments be aligned. Although the vagueness and lack of specificity of standards in many states can make any determination difficult, available evidence suggests that the alignment of current tests is problematic.

Studies have been conducted by several research teams on the alignment of state or local assessments with corresponding curriculum frameworks, for science and several other subjects. Results from more than 10 states by each of the teams led by the Achieve organization, Norm Webb (Webb model), and Andrew Porter and John Smithson (Surveys of Enacted Curriculum or SEC model) reach similar overarching conclusions. Existing state tests do not fully cover intended science standards. A common omission in state assessments is attention to scientific inquiry. Furthermore, state assessments tend to emphasize levels of knowledge and skills that are lower than those exhorted by the state standards (Porter, 2002; Rothman et al., 2002; Webb, 1997, 2002). What is tested instead seems to be at least as much a function of the items that particular item writers are most adept at producing and those that survive psychometric field-testing—such as items that are at appropriate levels of item difficulty and that relate in empirically coherent ways to other items—as it is a function of what sets of items will provide the most comprehensive and balanced view of how students are achieving relative to standards (Herman, Webb, & Zuniga, 2003).

## **MORE AND DIFFERENT INTERNATIONAL SCIENCE ASSESSMENTS**

The frequency of cross-national assessments in science has escalated over time to the point where it is now hard to keep track of them all. Table 33.1 provides a chronology of the major assessments conducted or planned through 2007. The biggest jump occurs in 2000. Until then, the Netherlands-based International Association for the Evaluation of Educational Achievement (IEA) had been the only main sponsor of cross-national comparisons. The Educational Testing Service (ETS) briefly entered the terrain during a time period between two administrations by the IEA. That is, the International Assessment of Educational Progress (IAEP), which borrows its name and some concepts from the ETS administration of the U.S. NAEP, occurred between IEA's first and second international studies of science (LaPointe, Mead, & Phillips, 1989; LaPointe, Askew, & Mead, 1992).

In 2000, the Paris-based Organisation for Economic Co-Operation and Development (OECD) launched a line of cross-national comparisons that has important differences from the IEA studies, which are discussed in a following section. Both IEA

2007	IEA	TEDS <sup>9</sup>	Teachers, math	TBA	—	IEA, 2005

*Notes:*

- (1) Sponsoring organizations: International Associations for the Evaluation of Educational Achievement (IEA); Educational Testing Service (ETS); Organisation for Economic Co-Operation and Development (OECD)
- (2) Short names of acronyms stand for the following full names of the studies: First International Science Study (FISS); Second International Science Study (SISS); International Assessment of Educational Progress (IAEP); Third International Mathematics and Science Study (TIMSS); Programme for International Student Assessment (PISA).
- (3) The naming of the TIMSS evolved after the original TIMSS in 1995. The 1999 version became TIMSS-repeat, or TIMSS-R for short. Beginning in 2003, the full name was changed to *Trends in Mathematics and Science Study*, which still has the short name of TIMSS.
- (4) PISA assesses three subjects each time (reading, mathematics, science). In a given year, however, one subject is fully tested while only partial tests are given for the other two subjects. The lead subject has been rotated, and the first main administration of science will be in 2006.
- (5) International Assessments have used two similar means of setting the target populations of students to be assessed. Some studies target students of a particular age, while others target students in a particular grade. These two strategies lead to different sampling strategies and have implications for study studies.
- (6) End Sec stands for End of Secondary. Since the last year of schooling varies among countries (e.g., some end at grade 12, others at 13), the international study does not set a uniform age or grade level for the targeted secondary population.
- (7) Size refers to number of participating countries. The number provided here is for the number of countries that participated in at least one test population (age/grade). Typically, a number of countries elect to participate in some rather than all populations.
- (8) These sample reports are limited to those reporting international comparisons for international audiences, versus U.S. or any other nation's perspective on its performance relative to other countries (e.g., Schmidt, McKnight & Raizen, 1997). The reports selected also are limited to results of student achievement in science. Many studies report on other aspects of the study, such as accompanying analyses of the countries' science curricula (Schmidt et al., 1997).
- (9) The Teachers Education and Development Study (TEDS) will be the first IEA study with a principal focus on data collection about teachers rather than students. The 2007 administration will be for mathematics teachers, and study organizers hope to conduct a similar investigation about science teachers in the future.

and OECD studies occur every three years now. The two studies occurred in the same year recently (2003), and a number of countries participated in both of them.

Notice the following characteristics that can help distinguish among studies:

1. All of the listed studies assessed science, but some studies assessed science only (FISS, SISS), whereas others assessed both mathematics and science fairly equally (the TIMSS and IEAP series); and the PISA series emphasizes one of three subjects (reading, mathematics, or science) in any given year, limiting the assessment of the other two subjects in that year.
2. The studies use either ages or grades to identify target populations of students to be assessed. Studies vary in the number of target populations they include. See notes 5 and 6 in Table 33.1.
3. There is wide variation in the number of countries that participated, and a participating country may decide to assess only some of the target populations. See note 7 in Table 33.1.
4. This table lists only international publications of cross-national results for science achievement. All studies measure students' science achievement, which is the original focus and a continuing hallmark of such studies. The table does not list U.S. or other countries' reports that give a national perspective on cross-national achievement results. See note 8 of Table 33.1.

However, all studies, in addition to achievement tests, include to varying extents some data collection from other sources, such as national, school, teacher, or student questionnaires. Furthermore, many tests offer additional student assessment options; for example, study organizations offer a performance-based science assessment that countries can elect to add to their administration. Some assessments go further and include an optional or required analysis of participating countries' science curriculum, accompanying qualitative case studies of nations' science education, or video studies of classroom teaching in select countries. Using the above characteristics, the largest international science assessment to date remains the first TIMSS study (1995), as explained below.

Notice that IEA has recently authorized a quite different kind of international large-scale study during 2005–2009—a comparison of how different countries prepare and induct beginning teachers for mathematics at both the elementary and secondary levels (Teacher Education and Development Study, TEDS). Study organizers are interested in a similar, future study of science teachers. These studies are the first systematic, extensive investigations for IEA where the principal study focus is on teacher rather than student information.

The following sections further discuss the IEA and OECD series of studies in science. As mentioned in the chapter introduction, the authors describe the characteristics of each study and point readers to the published results. However, it is beyond the confines of this chapter to provide the actual results from each study.

## **IEA Studies**

The International Association for the Evaluation of Student Achievement (IEA), with administrative offices in Amsterdam and a technical data-processing center

in Hamburg, is an independent research organization comprising members from national and government research institutions and agencies. It began in 1958 at the UNESCO Institute for Education at Hamburg as a discussion and consultation among psychologists, sociologists, and psychometricians around issues of schools and student achievement and what constituted the proper evaluation of these. A Pilot Twelve-Country Study, conducted in 1959–1962, evaluated five areas: science, mathematics, reading comprehension, geography, and nonverbal ability. IEA studies are most widely known for assessing science content (including the nature of science), but they also are designed to assess students' performance expectations in science and perspectives toward science. As an example of the latter, the study framework for science in the TIMSS called for investigation of students' understanding; theorizing, analyzing, and solving problems; use of tools, routine procedures, and science processes (performance expectations); and attitudes, careers, and participation by underrepresented groups (perspectives) (Robitaille et al., 1993).

A hallmark of IEA studies has been their emphasis on students' opportunity to learn the subject matter. Opportunity to Learn (OTL) has had a pragmatic focus on what is actually done in classrooms with respect to the subject assessed as opposed to what may be intended to occur in classrooms according to official standards or textbooks. This emphasis may also be seen as a natural development from the goal shared by all IEA studies to illuminate the factors that explain or cause differences in educational achievement (Postlethwaite, 1995). The IEA tripartite curriculum model defines curriculum at three different levels: the *Intended*—what a system intends students to study and learn; the *Implemented*—what is taught in classrooms; and the *Attained*—what students are able to demonstrate that they know (Travers & Westbury, 1989).

The First International Science Study (FISS) was conducted by the IEA from 1966 through 1973, part of a larger Six Subject Survey that was designed to apply what had been learned in the First International Mathematics Study to other subjects. IEA studies routinely target one or more of three student populations: 10-year-olds, 14-year-olds, and those in the last year of secondary education. For FISS, only 10-year-olds were assessed in earth science, whereas only the older two student populations were assessed in the areas of the nature and methods of science and understanding science. All three student populations were assessed in the areas of biology, chemistry, and physics. Nineteen national education systems participated in the assessments of the older two student populations; 17 participated in the study of 10-year-olds (Comber & Keeves, 1973).

The Second International Science Study (SISS), conducted in 1983–1986, sought to apply what had been learned from FISS as well as from the Second International Mathematics Study (SIMS), which had recently been conducted. There was an interest in examining achievement differences between countries and gathering some information that could suggest explanations for these differences, as well as in making an attempt to explain the source of achievement differences *within* any one country. The number of countries that participated in SISS again varied according to the student population of interest. Fifteen national systems participated in the assessment of 10-year-olds (grade 5 in the United States); 17 systems in the assessment of 14-year-olds (U.S. grade 9); and 14 systems in the assessment of students in their last year of secondary education (U.S. grade 12) (Jacobsen & Doran, 1988). For assessment purposes, four groups of students were defined for the oldest group: those

who were studying biology, those studying chemistry, those studying physics, and those not studying any science at the time of assessment (IEA, 1998; Postlethwaite & Wiley, 1992). A report by Keeves (1992) discusses changes in achievement among the 10 countries that participated in both FISS and SISS over the 14 years between the two studies.

### Third International Mathematics and Science Study

“[T]he Third International Mathematics and Science Study [1995] is the largest, most comprehensive, and most rigorous study of schools and students ever.” These remarks by Pascal Forgione, the Commissioner of Education Statistics, were the opening words in the first U.S. report coming from the U.S. participation in the TIMSS (National Center for Education Statistics, 1996, p. 3). Subsequent versions of the TIMSS have enlisted comparable or greater numbers of countries than the 1995 TIMSS, and PISA studies by the OECD have attracted similar country participation (see Table 33.1). Table 33.2 shows the varying numbers of countries participating in versions of the TIMSS over the years and, within a given year, the large differences in numbers of countries participating at the various target populations (ages/grades).

What remains unprecedented today is the scope and depth of the information gathered in the first TIMSS. One of the goals of the original Third International Mathematics and Science Study (TIMSS), conducted in 1993–95, was to collect data on mathematics and science education at the *same time* and with the *same students*, so that relationships between these two school subjects might be more easily explored. In addition to assessments in both mathematics and science, students completed a background survey. The teachers of the students participating in the assessments were also asked to complete an extensive survey, as was the principal (or other school official) in the schools where students were assessed.

A pioneering in-depth analysis of curriculum standards and textbooks contributed a unique facet to the study and is likely to be one of the main reasons it will remain unparalleled for years to come. Most of countries were trained to analyze the science topics and student performance expectations found in their science textbooks, line by line, page by page (McKnight & Britton, 1992; Schmidt, Jakwerth, & McKnight, 1998). Some prior IEA studies included curriculum analyses; for example, Rosier and Keeves (1991) reported the curriculum analysis in SISS. However, none of them employed such extensive data collection and analyses.

While the TIMSS 1995 collected data from the three standard IEA student populations, a more complex and demanding means of doing so was utilized: the two adjacent grade levels in which the most nine-year-olds were enrolled (grades 3 and 4 in the United States); the two adjacent grade levels in which the most 13-year-olds were enrolled (U.S. grades 7 and 8); and students in their last year of secondary school (U.S. grade 12). Subsequent editions of TIMSS and PISA assessments have not assessed all of these student populations. One of the challenges in interpreting international comparative research is the differences between countries in when students begin formal schooling. Differences among countries in this educational policy create difficulties in defining a consistent population of students to study. Does one want to study and compare students who are of a particular age but will have had varying numbers of years of formal schooling from one country to another,

or does one want to study and compare students who have all had the same number of years of formal schooling but may differ in age by a year or more, thus confounding developmental maturity with educational exposure? In an attempt to proceed down a middle path, TIMSS defined the two younger student populations as the combination of both age and years of schooling: the two adjacent grades in which the majority of 9-year-olds (population 1) or 13-year-olds (population 2) were

enrolled. Wiley and Wolfe (1992) discuss the additional kinds of analyses that such methods permit.

Twenty-seven national systems participated in the assessment of 9-year-olds (grade 3 for the lower grade and grade 4 for the upper grade in the United States and many other systems) and 43 systems in the assessment of 13-year-olds (grade 7 for the lower grade and grade 8 for the upper grade in the United States and many other countries). All but two countries (Israel and Kuwait) that assessed students in the upper of the two adjacent grades for 9- and 13-year-old students also assessed students in the lower grades (see Martin et al., 1997; Beaton et al., 1996). Two student populations were defined for assessment of the end-of-secondary student population: all students who were completing the last year of secondary education in their program and those students who were in their last year of secondary education and had specialized in science. The general population was administered a science literacy assessment designed to measure what experts considered to be the level of scientific knowledge required to function as a science-literate citizen of the twenty-first century. Science specialists were given an assessment in physics. Twenty-two countries participated in the assessment of mathematics and science literacy, and only 16 countries participated in the physics assessment (Mullis et al., 1998).

Another aspect of TIMSS unique to the original 1995 study was the inclusion of an optional performance assessment component for both mathematics and science for students in the fourth and eighth grades (Harmon et al., 1997). Far fewer countries participated in this aspect of the study (10 at fourth grade; 21 at eighth grade). These performance tasks required students to use materials and apparatus to solve a multistep practical problem such as designing and constructing a box to hold four plastic balls.

In conjunction with the U.S. participation in TIMSS 1995, the U.S. government, through the National Center for Education Statistics, funded two supplementary international projects: the videotape classroom study and three case studies (Stigler et al., 1999; Stevenson, 1998). Both studies focused on mathematics at the eighth-grade level in Germany, Japan, and the United States. For TIMSS 1999, a more extensive video study included science, and results were released early in 2006 (National Center for Education Statistics, 2006).

**Results.** In addition to an overall score for science, the TIMSS international science report included the average percentage correct in five broad science areas: earth science, life science, physics, chemistry, and environmental issues and the nature of science (Beaton et al., 1996). A later analysis of TIMSS grade 8 data identified a group of A+ countries as those countries significantly outperforming the majority of TIMSS countries (Valverde & Schmidt, 2000). These A+ or highest performing countries for science were Singapore, the Czech Republic, Japan, and Korea. There was great consistency in the relative rankings of these four countries—and indeed for nearly all countries—across the five broad content areas in the international report. Singapore was the top-ranked country in all five areas, and Korea was in the top four ranked countries in all areas.

Overall science rankings by country can mask significant differences within particular science areas. For example, even the highest overall performers had areas of science in which their performance was not as strong. One of the books published by the U.S. National Research Center for TIMSS contained a more detailed analysis of student achievement that reflected greater variation (Schmidt et al., 1999). The

authors argued that this greater variation was a reflection of the variation in the science curriculum found across the participating countries. Considering the 17 eighth-grade curricular areas of science presented, one can see that each of the highest performing countries ranked first in at least one of these categories. However, among these four countries, Singapore had the lowest rank in any one area (21st in the area of Life Cycles and Genetics), and each country had ranks of 10th or lower in four of the 17 curricular areas.

The extensive curriculum analysis, which was a unique aspect of TIMSS 1995, provided an in-depth analysis of these issues through an examination of official curriculum standards and textbooks (Schmidt et al., 1997). An examination of the curriculum in the highest performing countries found that across these four countries (Singapore, the Czech Republic, Japan, and Korea) the five most emphasized science topics accounted for about 80 percent of the eighth-grade science textbook. These five most emphasized topics were electricity; the chemical properties of matter; chemical changes; energy, types, sources, and conversions; and organs and tissues. This represents one biology topic, two physics topics, and two chemistry topics.

The Teacher Questionnaire in TIMSS provided two more indicators of the science curriculum in countries: the percentage of teachers who taught specific topics during the school year in which the student assessment was conducted and the relative proportion of instructional time devoted to specific topics. Several reports have combined these two curricular indicators from teachers with the two curricular indicators of content standards and textbooks to provide a multifaceted perspective on what constitutes eighth-grade science across the world from the perspective of the TIMSS countries (Cogan, Wang, & Schmidt, 2001; Schmidt et al., 2001). Comparing the five most emphasized eighth-grade science topics according to each of the indicators—content standards, textbooks, percentage of teachers teaching a topic, and relative amount of instruction time devoted to a topic—the topic of “human biology” is the only topic present in all four. Aspects of energy (“electricity,” “energy processes,” and “energy types, sources, conversions”) were also well represented.

Not all countries intended to begin science instruction as soon as children entered school. In fact, three of the four top-performing countries at eighth grade—Singapore, Japan, and the Czech Republic—did not intend science instruction to begin until grade 3 (see Schmidt et al., 1997, pp. 83–84). The number of topics intended to be taught and learned at each grade, the emphasis afforded topics within a year, and the pattern of sequencing topics across the years of schooling have been identified as important indicators of the coherence, focus, and rigor of any country’s curriculum (Schmidt, McKnight, & Raizen, 1997). Nonetheless, two of the highest achieving countries at eighth grade were also the top performers on the fourth-grade student assessment: Korea and Japan; Singapore ranked 10th and the Czech Republic ranked 6th (Martin et al., 1997).

The Czech Republic was the only highest achieving country at eighth grade that also participated in the end-of-secondary student assessments but did not demonstrate comparable outstanding performance, ranking only 13th out of 21 participating countries on the science literacy assessment and 14th out of 16 on physics (Mullis et al., 1998). Students in Sweden ranked first in science literacy and second in physics. Norway ranked first on the physics assessment and fourth on the science literacy assessment.

Many participating countries generate national reports that show how their students performed in TIMSS and discuss implications for national issues in science

education. Researchers also have done analyses to compare science performance between particular countries (e.g., Wang, 1998). In the United States, TIMSS garnered so much attention that states and consortia of school districts have done special, more intensive sampling in order to relate their local student science or mathematics performance to international results (e.g., Kimmelman, 1999).

### **TIMSS 1999 and 2003**

Although items from each of these assessments were released into the public domain, similar items were written and included in the subsequent assessments to maintain a very similar emphasis in the broad areas of science. Across the three eighth-grade student assessment times—TIMSS (1995), TIMSS-R (1999), and TIMSS 2003—the emphasis on earth science was 16 percent, 15 percent, and 16 percent, respectively. Life science emphasis was 30 percent, 27 percent, and 29 percent; physics was 30 percent, 27 percent, and 24 percent; chemistry was 14 percent, 14 percent, and 16 percent. Environmental issues and the nature of science was the focus of 10 percent, 17 percent, and 14 percent of the items on the respective assessments.

The number of countries involved in each assessment and the differences in the items comprising each assessment preclude drawing any conclusions from direct comparisons. Furthermore, because the scaled scores are formed each time on the basis of the participating students, the scaled scores for any two assessments, such as TIMSS 1995 and TIMSS 2003, are not directly comparable. One report uses revised scale scores for each of the assessments to enable more appropriate comparisons (Gonzales et al., 2004). Only seven countries have participated in all assessments at each of the three TIMSS time points: Australia, Cyprus, Hungary, the Netherlands, New Zealand, Slovenia, and the United States. Although the report does note some statistically significant differences in the performance of some countries from one assessment to another, the magnitudes of these differences do not suggest major shifts in student performance (see Gonzales et al., p. 17, Table 11).

### **OECD-PISA**

The Organisation for Economic Co-operation and Development (OECD) launched a new cross-national assessment of science in 2000. The OECD is a Paris-based organization of industrialized countries that historically is most widely known for its cross-national reports on economics, such as comparisons of per capita spending on education. Within OECD, the Center for Education Research and Innovation (CERI) has since 1968 organized occasional studies of the educational aspects of education, including science education (e.g., Black & Atkin, 1996; Raizen & Britton, 1997).

The new regularly scheduled assessment by OECD is known as the Programme for International Student Achievement (PISA). This assessment emphasized science for the first time in 2006. It focuses only on 15-year-olds and includes assessment of three subject areas every year it is offered—literacy, mathematics, and science. In each cycle, however, one subject receives dominant attention: literacy in 2000 (OECD 2001), mathematics in 2003 (OECD 2004a), and science in 2006. The IEA's TIMSS series occurs every four years, and the PISA cycle is three years. PISA has attracted strong international interest, as indicated by the participation of over 40 countries in the first two administrations. The TIMSS and PISA test specifications give compar-

ble emphasis to life sciences, whereas PISA has emphasized earth sciences more than TIMSS, and TIMSS has more strongly emphasized physical science.

The characteristic of PISA that distinguishes it from TIMSS is the nature of science that it seeks to evaluate, and this affects the nature of the test items in PISA versus TIMSS. Whereas TIMSS primarily focuses on the formal content of the scientific disciplines, PISA emphasizes students' application of science in real-life contexts. Gauging these multifaceted aspects of science requires more open-ended than defined-response items (Nohara, 2001). Neidorf et al. (2004) reports that typical PISA items make more complex cognitive demands on students. Scott and Owen (2005) contrast the purposes, construction, and uses of NAEP, PISA, and TIMSS.

The PISA 2006 specification of scientific literacy has four interconnected aspects. *Context* involves recognizing life situations involving science and technology. *Knowledge* is understanding the natural world, including technology, on the basis of scientific knowledge that includes both knowledge of the natural world as well as knowledge *about* science itself. The latter includes interactions among science and technology and the material, intellectual, and cultural environments. The first criterion for choosing knowledge to be assessed is its relevance to real-life situations. The second criterion is that the selected knowledge should represent important scientific concepts. The TIMSS design typically reverses these priorities. The *attitude* aspect includes interest in science, support for scientific inquiry, and motivation to act responsibly (e.g., toward natural resources and the environment).

The PISA framework gives priority to a fourth related aspect, *competencies*: identifying scientific questions; describing, predicting, or explaining phenomena based on scientific knowledge; interpreting evidence and conclusions; and using scientific evidence to make and communicate decisions. In other words, solving science-based problems is a central student activity in PISA assessments (OECD, 2004b).

The PISA 2006 science framework gives significant attention to technology education. A number of countries have for more than 10 years included technology as an additional school subject, separate in the school day from science (Britton, De Long-Cotty, & Levenson, 2005), but technology education does not have as strong a foothold to date in the United States (Meade & Dugger, 2004). The National Academy of Engineering and the National Research Council describe technology as follows:

In its broadest sense, technology is the process by which humans modify nature to meet their needs and wants. However, most people think of technology only in terms of its artifacts: computers, aircraft, . . . , to name a few. But technology also is the knowledge and processes necessary to create and operate those products, such as engineering know-how and design, manufacturing expertise, various technical skills, and so on. (NAE & NRC, 2002, pp. 2–3)

Both the AAAS and NRC standards documents clearly include attention to technology (AAAS, 1993; NRC, 1996). Additionally, the technology education community has its own national curriculum standards (International Technology Education Association, ITEA, 2000). Development of the technology standards was funded by both the NSF and the National Aeronautics and Space Agency (NASA), and they were vetted by NAE and NRC.

The PISA results to date have received significantly less attention than TIMSS results in the United States, perhaps because of the current policymaker emphasis on the formal disciplinary knowledge that is more strongly assessed by TIMSS.

## CHANGES IN NAEP SCIENCE

More than 35 years ago, NAEP began gathering information on student achievement in selected academic subjects (Johnson, 1975). That first administration included practical skills tests in science (NAEP, 1975). It has grown in scope several times over the years. The third assessment added items to assess student attitudes toward science (NEAP 1978). The 1986 NAEP science investigated students' home environments and the kinds of science instruction they received in school (Mullis & Jenkins, 1998). Also in 1986, an experimental assessment was developed to test higher order thinking skills, and students interacted with a computer simulation for an item (NAEP, 1987). Originally, assessments were of students 9, 13, and 17 years old; beginning in 1983, the assessment has sampled students in grades 4, 8, and 12. During the late 1980s, the Educational Testing Service (ETS), the contractor that conducts NAEP, made a brief, analogous foray into international assessments (LaPointe, Mead, & Phillips, 1989; LaPointe, Askew, & Mead, 1992).

Each administration of NAEP has become an important and continuing source of information on what U.S. students know and are able to do at that time. In addition, NAEP provides information on how student performance has changed over time in reading, mathematics, science, U.S. history, writing, and other subjects (e.g., NAEP, 1992; Campbell, Voelkl, & Donahue, 1998). NAEP data are publicly available, so that researchers can conduct secondary analysis of the science assessment (e.g., Linn et al., 1987; Welch, Walberg, & Fraser, 1986).

Since the mid-1990s, in addition to the national-level assessments, NAEP has conducted and reported state-level assessments at grades 4 and 8 in reading, mathematics, writing, and science (Hudson, 1990). State-level science assessments were conducted in 1996, 2000, and 2005. The resulting data on student knowledge and performance have been accompanied by background information that allows analyses of a number of student demographic and instructional factors related to achievement. The assessments have been designed to allow comparisons of student performance over time and among subgroups of students according to region, parental education, gender, and race/ethnicity. In 2002, NAEP began a Trial Urban District Assessment (TUDA) in districts that volunteered to participate. The TUDA continued through 2005, when 10 districts took part in NAEP assessments that produce district-level results.

The National Assessment Governing Board (NAGB) is responsible for the NAEP program. This included the development in 1993 of three levels of achievement—basic, proficient, and advanced. *Basic* denotes partial mastery of prerequisite knowledge and skills that are fundamental for proficient work at each grade. *Proficient* represents solid academic performance for each grade assessed. Students reaching this level have demonstrated competency over challenging subject matter, including subject-matter knowledge, application of such knowledge to real-world situations, and analytical skills appropriate to the subject matter. *Advanced* signifies superior performance. These levels are the primary means of reporting NAEP results to the general public and policymakers regarding what students should know and be able to do on NAEP assessments.

The framework that guided the last three NAEP science assessments was developed 15 years ago. The NAGB in late 2005 approved the next framework that will guide administrations of NAEP science from 2009 through 2021.

## Science Content

The 2009 NAEP science content domain is defined by a series of content statements that describe key principles, concepts, and facts in three broad content areas: physical science, life science, and earth and space science (see Table 33.3).

As measured by student response time, the distribution of items by content area should be as follows: roughly equal across physical, life, and earth and space science at grade 4; more emphasis on earth and space science at grade 8; a shift to more emphasis on physical and life science at grade 12.

Some content cuts across the areas of physical, life, and earth and space science. Some instances of cross-cutting content are identified and described below.

*Uses and transformations of energy and energy conservation.* To demonstrate an understanding of energy uses, transformations, and conservation, students must be able to do so in the context of different types of systems. These systems include biological organisms, earth systems, ecosystems (combining both life forms and

    - Biogeochemical Cycles
-

their physical environment), the solar system and other systems in the universe, and human-designed systems.

**Biogeochemical cycles.** To demonstrate an understanding of biogeochemical cycles, students must draw on their knowledge of matter and energy (physical science), structures and functions of living systems (life science), and Earth systems (earth and space science). Fixed amounts of chemical atoms or elements cycle within the Earth system; energy drives this movement of matter, which includes water and nutrient cycles; and human use of Earth's finite resources affects the land, oceans, and atmosphere, as well as plant and animal populations.

## Science Practices

The second dimension of the framework is defined by four practices: identifying science principles, using science principles, scientific inquiry, and technological design. By crossing any science content statement above with the four practices, it is possible to generate specific performance expectations on which assessment items can be based. Therefore, neither content statements nor practice statements will be assessed in isolation; all assessment items will be derived from a combination of the two. Observed student responses to these items can then be compared with expected student responses in order to make inferences about what students know and can do.

Table 33.4 summarizes general performance expectations for each of the four practices. Certain ways of knowing and thinking—cognitive demands—underpin the four science practices. Four such cognitive demands are as follows: *knowing what*, *knowing how*, *knowing why*, and *knowing when and where to apply knowledge*. The set of four cognitive demands can be used as a lens to analyze student responses, thereby checking expectations regarding what content and practice(s) are being tapped by a given assessment item.

## Item Formats

Item formats for the 2009 NAEP science assessment fall into two broad categories: 1) selected-response items comprise individual multiple-choice items, cluster multiple-choice items, and Predict-Observe-Explain (POE) multiple-choice items; 2) constructed-response items comprise short constructed-response items, extended constructed-response items, concept maps, hands-on performance tasks, and interactive computer tasks. As measured by student response time, roughly no more than 50 percent of the assessment items at each grade level should be selected-response items; the remainder should be made up of constructed-response items. In order to further probe students' abilities to combine their understandings with the investigative skills reflective of practices, a subsample of students should receive an additional 20–30 minutes of response time to complete hands-on performance and interactive computer tasks. There should be at least a total of four of these tasks at each grade; of these four tasks, there should be at least one hands-on *and* one interactive computer task per grade; the number of hands-on tasks should not exceed the number of interactive computer tasks.

**TABLE 33.4**  
**General Performance Expectations for Practices, NAEP Science 2009–2021**

<i>Identifying Science Principles</i>	<i>Using Science Principles</i>	<i>Scientific Inquiry</i>	<i>Technological Design</i>
State correct science principles	Explain specific observations or phenomena	Design and critique scientific investigations	Design and critique technological solutions to given problems
Connect different representations of science principles and patterns in data	Predict specific observations or phenomena	Conduct scientific investigations using appropriate tools and techniques	Identify scientific tradeoffs in design decisions and choose among alternative solutions
Make connections among closely related content statements	Propose, analyze, and evaluate alternative predictions or explanations	Find patterns in data. Relate patterns in data to theoretical models	Apply science principles or data to anticipate effects of technological design decisions
Describe, measure, or classify observations	Suggest examples of observations that illustrate a science principle	Use empirical evidence to draw valid conclusions about explanations and predictions	
← Communicate accurately and effectively →			

In hands-on performance tasks, students manipulate selected physical objects and try to solve a scientific problem involving the objects. NAEP hands-on performance tasks should provide students with a concrete, well-contextualized task (problem) along with “laboratory” equipment and materials. However, the response format should give students the freedom to determine scientifically justifiable procedures for addressing the problem and arriving at a solution. Students’ scores should be based on both the solution and the procedures created for carrying out the investigation and the solution.

Interactive computer tasks should be of four types: 1) information search and analysis, 2) empirical investigation, 3) simulation, and 4) concept maps. Information search and analysis items pose a scientific problem and ask students to query an information database to bring conceptual and empirical information to bear, through analysis, on the problem. Empirical investigation items put hands-on performance tasks on the computer and invite students to design and conduct a study to draw inferences and conclusions about a problem. Simulation items model systems (e.g., food chains), pose problems of prediction and explanation about changes in the system, and permit students to collect data and solve problems in the system. Concept-map items probe aspects of the structure or organization of students’ scientific knowledge by providing concept terms and having students build concept maps on the computer. A concept map is a network whose nodes are concept terms (e.g., *density*, *buoyancy*, *mass*). The nodes are connected by directed, labeled lines. A directed line shows the relationship between a pair of concept terms; the label on the line describes the relationship.

## COHERENT STATE SYSTEMS OF LARGE-SCALE AND CLASSROOM ASSESSMENT

Better alignment between large-scale science assessments and science standards, discussed earlier, enhances the assessment enterprise in educational systems. Shepard (1993) discusses the difficulties in making large-scale assessments relevant to student learning. However, experts in assessment now argue for more substantial changes in both classroom assessment and large-scale assessments to forge them into coherent, articulated assessment systems. The National Research Council has released a model for doing this, *Systems for State Science Assessment* (Wilson & Bertenthal, 2005). Although few if any states currently or will soon be able to have systems that are mostly consistent with this model, the NRC publication at a minimum is a good lens for examining the explosion of state science assessments being driven by the NCLB requirement that states must be assessing science no later than 2007.

The NRC model particularly draws upon some prior NRC work, for example: Committee on Assessment in Support of Instruction on Learning (2003) led by Atkin, the Committee on the Foundations of Assessment (*Knowing What Students Know: Science and Design of Educational Assessment*, NRC, 2001) led by Pellegrino, and *How People Learn* (Bransford, Brown, & Cocking, 1999). Another prominent influence on the 2005 NRC model is ongoing work at the NSF-funded Center for the Assessment and Evaluation of Student Learning (CAESL), which includes work at the Berkeley Evaluation and Assessment Research Center (BEAR).

Three kinds of coherence are envisioned (Wilson & Bertenthal, 2005, p. 4). Horizontal coherence is where curriculum, instruction, and assessment are all aligned with the standards, as described previously. Vertical coherence exists when all levels of the educational system—classroom, school, district, state—are based on a shared vision of the goals for science education, the purposes of assessment, and a definition of competent performance. The system is developmentally coherent when it attends to how students' science understanding develops over time.

The CAESL model, shown in Fig. 33.3, proposes a systems view of assessment that serves top-down policy needs for sound assessment information for accountability purposes, but is also built bottom up so that it is responsive to teachers' needs for ongoing, formative information to support their students' learning. As designed, the system also would support needs at intermediate levels (e.g., school/department, district) for periodic monitoring and evaluation of student performance.

The CAESL model starts with specified standards and uses a theory-based model of student cognition to derive a coordinated set of large-scale and classroom-based assessment tools. The large-scale assessments incorporate on-demand, multiple-choice, open-ended, concept-map, performance, and explanation items, which are intended to provide comparable and generalizable information on the status of students' attainment. Such information is appropriate for determining whether learning goals have been achieved—at the individual, classroom, school, or district levels—and is a source of needs assessment information for program and instructional planning at an annual or semiannual interval, depending on when such results are available.

Historically, most external assessments in the United States have been administered at the end of the school year, timed to capture what students have mastered

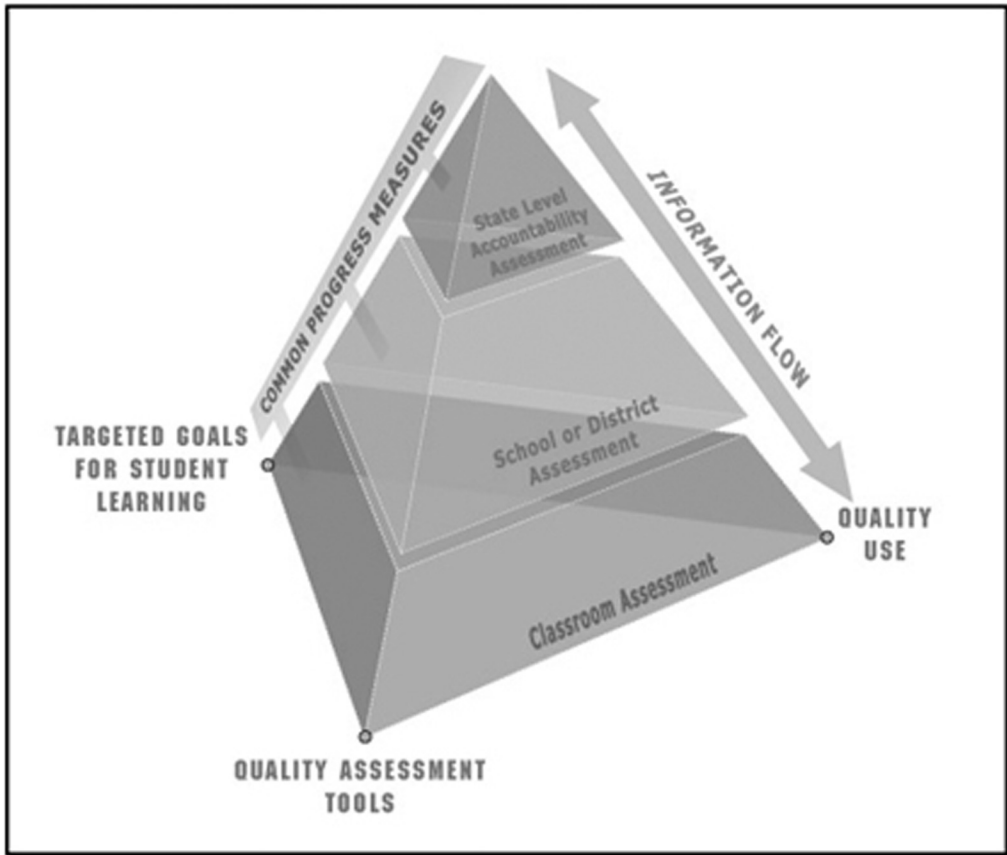

FIGURE 33-3 Assessment model, Center for Assessment and Evaluation of Student Learning (CAESL, [www.caesl.org](http://www.caesl.org)).

during the school year. Teachers can only use such information to inform what they might do differently next school year, so the tested students do not get a direct benefit from the time that they had to spend on the assessments. As a result, today we find that although students are tested in the spring for national or state purposes, districts may also be testing them at the beginning of the year to produce data to guide teachers' instruction. During the 1980s, France instituted an assessment system where national examinations were administered in grades 3 and 6 at the beginning of the school year and quickly scored so that teachers could have the results. Policy makers accepted that for external purposes, they had to make different inferences about what the results could mean. However, many teachers became enthusiastic about the examinations because they served as a diagnostic that could immediately inform their instruction (Black & Atkin, 1996, pp. 103–107).

In the CAESL model, the classroom or curriculum-embedded tools are more ongoing and performance-oriented and provide the smaller grain size and instructionally sensitive information needed to diagnose whether and how students are making progress on key science content. Results from these classroom tools are intended to

be the basis for immediate instructional action for individuals, subgroups, and/or the class as a whole, drawing on strengths and addressing learning needs that may be revealed by the assessments.

Both the large-scale and classroom measures reflect common continuums of expected learning progress relative to core areas of scientific knowledge and skills that are subject to assessment—for example, fundamental ideas, core principles, and/or key aspects of inquiry. Based in a model of cognition (Shavelson, 2003; Li & Shavelson, 2001; Shavelson & Ruiz-Primo, 1999), each of these progress continuums forms a “progress variable” in the CAESL model and are the basis for the consistent measurement system linking all educational levels (Masters, Wilson, & Adams, 1992; Wilson, 2005).

That all measures are developed to reveal students’ progress relative to a consistent, cognitively based measurement scale means that the *classroom assessments have potential to be aggregated beyond the classroom level*. Such aggregated data have potential for monitoring student progress at the school and/or district levels and may even serve accountability purposes, possibly reducing or eliminating the need for traditional, on-demand assessments (Wilson, 1992, 2004).

The emphasis on student progress has other implications as well. It connotes CAESL’s commitment to measures that assess and support the development of students’ depth of understanding, as progress implies movement from naïve to sophisticated understanding and applications. Because dealing with science content in depth necessarily limits the range of science content that can be taught and because coordinating classroom and large-scale assessment requires advance planning, the model thus advocates assessment of a limited but powerful set of science understandings and applications. To derive the most power from a limited but rich set of assessments, the CAESL model focuses its assessment targets on key unifying ideas and inquiry skills of science.

Note that the CAESL model also includes explicit attention to the *use* of assessment information. Having sound tools integrated into a coordinated system of assessment provides essential precursors but does not ensure that the results of such a system will be used to promote students’ learning. In fact, there is considerable evidence that most teachers do not currently have the capacity to use assessment for such purposes well.

While laying out these multiple pathways through which assessment can enhance teaching and learning, recent research also acknowledges the sophisticated content and pedagogical knowledge required to implement this vision: knowledge of standards and their conceptual underpinnings, knowledge of the instructional content and sequences that are most likely to achieve aims, knowledge of optimal and varied ways to support student progress, knowledge of ways to capitalize on students’ background knowledge and provide access for all students, and knowledge of likely stumbling blocks and misconceptions, etc.

Moreover, the model recognizes that its view of assessment implies a dramatic shift in how teachers see themselves as teachers and as professionals who truly are responsible for their students’ learning progress and for their attainment of standards. Substantial professional development and support are needed to build teachers’ capacity and guiding perspectives in this domain (Atkin, Black, & Coffey, 2001). The CAESL model is mindful of the role and challenges in building teacher capacity to use assessment well, including teachers’ knowledge of science, their knowledge of assessment, and their teaching and assessment practices.

All stakeholders in a coherent assessment system will have to make significant efforts in forging an assessment system from the fractured collection of assessments that is typical today. A substantial investment is needed in professional development to help practitioners understand the relationships possible between large-scale and classroom assessment, and to empower them to incorporate classroom assessment strategies that will produce versions of the former that can be aggregated into or articulated with external assessments. State policy makers, assessment experts, scientists, and educators who oversee development of state science tests along with practitioners will need to collaborate very much more than typically is the case.

## Sample State Assessment Systems

The NCLB legislation requires all states to test the progress of all students in science once during grades 3–5, 6–9, and 10–12, beginning in 2007. To meet the NCLB requirement, states only need to report student scores and not necessarily establish a comprehensive assessment system that meets the current recommendations of the National Academy of Science’s Board on Testing and Assessment (BOTA). These recommendations encompass a broad range of ideas for a systems approach to assessment that stresses ideas of *vertical coherence* and *horizontal coherence* (Wilson & Bertenthal, 2005). Vertical coherence indicates the importance of having shared goals for assessments at the classroom, district, and state levels. Horizontal coherence emphasizes the need for consistency between standards, assessments, curricula, and instructional practice.

The implications of science literacy on assessment are also discussed, as states are encouraged to align their assessment systems to accurately measure the following components: knowledge of science content, understanding science as a way of knowing, and understanding and conducting scientific inquiry. States are urged to develop detailed content standards, generate guidelines for all users, allow for independent reviewers, and maintain regular cycles of revision of the standards. The report also advises states to consult research and professionals in the design of their assessments to ensure that test items bring to light student progress and understanding.

Many suggestions for both the implementation and support of assessments are elaborated. States should form advisory committees, develop plans and strategies for the entire assessment system, align assessment plans with science standards, ensure analysis and usability of score reports, provide staff development in the use of the assessments, and certify teachers who are competent in their subject and assessing student understanding of it. States must also be conscious of issues of equity and adequacy. Assessments systems should collect information on opportunities for a wide range of students to learn the necessary material. At the same time, systems should include alternative assessments for those with significant cognitive disabilities. States should set aside resources for the revision of these assessments. Finally, it is recommended that states rigorously monitor and evaluate their science assessment systems to ensure that all parts of their systems are aligned with corresponding goals.

There are a number of states moving beyond NCLB compliance toward the kinds of assessment systems envisioned by the NRC. We provide here four examples of current state systems that have incorporated components of the recommendations.

The state of Connecticut has established a statewide testing program that includes both the Connecticut Mastery Test (CMT) and the Connecticut Academic Performance

Test (CAPT), the latter of which includes a science assessment (Connecticut State Board of Education, 2001, 2005). Connecticut has also developed a CAPT Skills Checklist for students identified with cognitive disabilities. The state has been building this assessment system for almost two decades. English language learners are provided with accommodations as needed, ensuring equality in testing. The CAPT goes beyond traditional multiple-choice testing to include a variety of assessment techniques, such as performance tests, which not only indicate what students know, but what they can do. The tests were designed to assess not only knowledge of scientific facts, but also the application of concepts, the use of experimentation, and the understanding of scientific reasoning. The science portion of CAPT includes a hands-on laboratory activity that is to be completed in the weeks prior to the written portion of the test.

The CAPT produces vertical coherence, as educational priorities from the classroom level to the state level are set and reinforced by the content of the assessment. Results of the test provide feedback to educators at all levels of the system for the reevaluation of their work and priorities. Results of the CAPT are provided to students and educators, along with an interpretive guide and software for data analysis. In the development of CAPT, advisory committees are utilized, as are testing companies and curriculum and assessment specialists. Aware of the need for staff development and training, Connecticut provides various initiatives to enhance the use of assessment results and subsequent instructional change, including annual test coordinator workshops, instructional workshops with curriculum consultants, and alternative assessment workshops for the CAPT Skills Checklist. The state has also set long-term plans for its assessments, as the testing program is viewed in terms of "generations," allowing for periodic and systematic review and revision of assessments.

The Delaware Student Testing Program (DSTP) employs a systems approach to assessment (see Delaware Department of Education, 2005, n.d.). Assessments are linked to the state content standards and are intended to measure student progress. Assessment results are reported at the state, district, school, and individual student levels. Delaware teachers are involved in the entire process of developing the DSTP, from writing, reviewing, and editing test questions to recommending cutoff points for performance levels. This encourages horizontal coherence by giving guidance for instructional change and provides vertical coherence in serving as the state's overarching accountability system.

Delaware has content standards that reflect current thinking in the scientific community, regarding science literacy as not only knowledge of content but also as a way of understanding the world. Delaware's science assessment employs both multiple-choice and constructed-response items. Students identified as having cognitive disabilities are given the Delaware Alternate Portfolio Assessment. A Bias Committee, a Content Advisory Committee, and several other specialists and advisors ensure the reliability, validity, and unbiased nature of the test. Delaware also uses test results to form Individual Improvement Plans for students who may need extra support, advising, extra tutoring, extra classes, or summer school. Results of the DSTP are also used to inform districts and schools of specific content areas that may need improvement.

Maine's approach to assessment is quite systematic (see Maine Department of Education, n.d.). Each component of the system has its specific purpose and process

for enhancing teaching and learning, monitoring and holding educators accountable to state standards, and ensuring student achievement of standards. Maine has established a Comprehensive Assessment System comprising an interconnected web of state and local components. The Maine Educational Assessment is the state-wide assessment aligned to Maine's "Learning Results" or standards. Maine also has a Local Assessment System, which is perhaps the most important component of Maine's larger Comprehensive Assessment System.

This Local Assessment System allows individual districts to develop their own comprehensive systems of assessment that can be tailored to the needs of their students. However, districts are also expected to ensure that assessments are aligned to state standards and are valid, reliable, and equitable. Going beyond traditional multiple-choice tests, Maine has developed the Maine Assessment Portfolio Project, which provides another option for local assessments whereby students are able to demonstrate proficiency on standards and performance indicators. Maine's Comprehensive Assessment System is vertically coherent in its structure of including everything from NAEP to classroom assessments developed by individual teachers. The system is also horizontally coherent in its focus on local assessments that have been developed and scored by individual districts and teachers.

This structure provides educators with detailed knowledge of the material being assessed and may result in corresponding instructional changes. The state recognizes its responsibilities in maintaining such a system of assessment and therefore provides assistance to districts in clarifying their system standards, in monitoring and evaluating performance tasks and student portfolios, in disseminating information to and from individual districts regarding best practices, and providing alternative assessment frameworks to ensure equality.

The Washington State Assessment System (WSAS) has three components: state-wide standardized testing, classroom-based assessments, and professional development for teachers about assessment (see Washington Department of Education, n.d.). Washington has developed its own content standards (Essential Academic Learning Requirements, or EALRs), which provide vertical coherence in having achievement indicators for the state, the districts, schools, and individual students. Additionally, curriculum specialists are consulted in the design of assessments that are distributed to districts. Horizontal coherence is incorporated into the state's use of classroom-based assessments that are linked to the content standards and which affect instructional practice. Washington also has a staff development assessment program in which teams of trainers provide instruction and materials to classroom teachers and principals to aid the improvement of reliable assessment practices. The state has developed its own assessment, the Washington Assessment of Student Learning (WASL), a criterion-reference test incorporating multiple-choice questions, short constructed response items, and extended constructed response items. Each item is individually aligned to a state content standard, as well as to a component of science literacy.

The entire statewide testing program includes three components: the WASL, the Iowa Tests of Basic Skills (ITBS) or the Iowa Tests of Education Development (ITED), and the National Assessment of Educational Progress (NAEP). The performance standards for the WASL are based on research from an outside professional testing service, the Iowa tests provide data on basic skills, and NAEP acts as a national base of comparison as well as an indicator of the validity of the WASL.

An assessment system that provides feedback to all major stakeholders in the educational system is very demanding and costly. This type of system has to clearly demonstrate the “value added” to the educational enterprise to justify effort and cost. The state systems described above illustrate how best practice in the field can address the National Academy’s guidance. However, a number of states that previously had complex assessment systems had to scale them back when they were perceived as creating unacceptable burdens at various levels of the educational system.

## HIGH SCHOOL EXIT EXAMS

The chapter concludes by briefly mentioning a kind of exam that historically was rare in the United States but has spread quickly in recent years—the high school exit exam. For years in many other countries, there have been examinations in science and other subjects given at the end of secondary school, either as part of matriculation, or for college-bound students to gain entry to college. In a companion study to the TIMSS, the National Center for Improving Science Education (NCISE) conducted an item-by-item content analysis of such science examinations (Britton & Raizen, 1996). In collaboration with the American Federal of Teachers (AFT), the exams themselves were published to make U.S. audiences more aware of them (AFT & NCISE, 1994, 1995, 1996).

In the United States, 26 states now have exit exams or are preparing to implement them, including 19 states that currently require students to pass exit exams and 7 states that plan to phase in mandatory exit exams during the next 7 years (Center on Education Policy, 2005). Historically, only a few states, such as California and New York, had such examinations (Golden State Exams and New York Regents Exams, respectively). Although only a bare majority of the states even now have exams, this is not an accurate representation of the number of students affected. By 2012, about 72 percent of all American public school students will attend school in states with required exit exams. An estimated 82 percent of minority students, 71 percent of special education students, and 87 percent of English language learners will have to pass exit exams in coming years.

There are three kinds of exams: minimum competency exams, standards-based exams, and end-of-course exams (such as Advanced Placement). States are moving away from the reputedly easier minimum competency tests toward the more challenging standards-based and end-of-course exams. Only three of the 25 states that are now using or plan to implement exit exams will use minimum competency exams, 17 will be using standards-based, and five will use end-of-course exams.

Currently, 10 states have exit exams in science: Alabama, Georgia, Louisiana, Mississippi, New Mexico, New York, Ohio, Tennessee, Texas, and Virginia. By 2010, the states of Maryland, Nevada, New Jersey, and Washington also will have science examinations. By 2007, 11 states plan to use the same science exam to award diplomas and meet the NCLB requirement for testing high school science.

## ACKNOWLEDGMENTS

Lee Cogan at Michigan State University provided substantial text for the section on the TIMSS. The NAEP section draws upon work by the NAEP framework develop-

ment committee, co-chaired by Richard Shavelson and Senta Raizen. Joan Herman at CRESST, Mike Timms at WestEd, and others provided substantial text for the section on CAESL. Stephen Zuniga at CRESST contributed to the literature review for several sections, and Cindy Lee contributed to the section on exemplar state science examinations. Thanks to Audrey Champagne and Angelo Collins, who reviewed this chapter.

## Science Teacher Education

# CHAPTER 34

---

## Science Teacher as Learner

**J. John Loughran**

*Monash University, Australia*

Research into learning to teach was initially based on ideas associated with a developmental model of teacher learning (Fuller, 1969; Fuller & Bown, 1975), a model that could be construed as portraying student teachers progressing along a predetermined path in the development of their competence as teachers. Over time, however, this interpretation has been challenged. For example, teacher thinking (Clark & Peterson, 1986) brought new ways of researching practice to the fore as it focused on the complexity of teachers' knowledge and expertise. Likewise, the resurgence of Dewey's (1933) articulation of reflection through the work of Schön (1983, 1987) led to views of good teaching being aligned with the notion of reflective practice (Clarke, 1995; Clift, Houston & Pugach, 1990; Grimmett & Erickson, 1988; Loughran, 1996; Russell & Munby, 1991). And, reflective practice became an entrée into studies of teachers learning about teaching through researching their own practice (Cochran-Smith & Lytle, 1993).

Hand in hand with these developments was the growth in understanding of constructivism (e.g., Cobb, 1994; Gunstone, 2000), which, as Clarke and Erickson (2004) have noted, reflected a shift in views of the nature of learning from a predominantly behaviorist model to more cognitive and phenomenological models. Thus, through developments in approaches to examining teachers' practice and a sharper focus on the need for greater congruence between the purposes and practices of teaching and learning, the limitations of transmissive teaching approaches (Barnes, 1975) were called into question. Not surprisingly, then, the notion of teacher as learner has emerged as an important construct in extending perceptions of quality in (science) teaching and learning.

Science teacher as learner is a seductive descriptor, as it captures the essence of the necessary challenge to the long tradition of science teaching as telling that has been so pervasive in schools, characterized by the stereotypical view of the transmission of science as propositional knowledge. Science teacher as learner suggests that practice carries an ongoing commitment to teaching science for understanding. Hence, science teacher as learner offers one way of exploring the uneasy tensions of

practice that emerge as science teachers attempt to better align their teaching with their expectations for their students' science learning, partly derived from understandings of constructivism. So, just as views about the nature of learning have changed over time, so too have views of, and the subsequent expectations for, teaching. In reviewing research literature within these two fields, this chapter attempts to build a case for the centrality of the notion of science teacher as learner in the quest to better align science teaching with science learning.

## STRUCTURE AND PURPOSE OF THE CHAPTER

In this chapter, four general areas (preservice science teacher as learner, elementary science teacher as learner, secondary science teacher as learner, and science teacher educator as learner) have been designated in order to highlight some of the distinguishing features of science teachers as learners. Interestingly, much of the teacher as learner literature tends to focus on the development of understanding and knowledge of teaching generally, rather than being content specific. Hence, a literature search with the science designation offers diminished returns. Yet, this result can be viewed as a challenge for science teaching and learning researchers, as it highlights the need for a more concentrated effort in this area. Another positive aspect to this outcome is that the studies that inform the field are generally richly descriptive and offer interesting insights into the work of science teachers as learners. Furthermore, the personal perspective germane to much of this work also highlights a clear bifurcation between studies *on* science teachers as learners as opposed to studies *of* science teachers as learners.

In this chapter, studies of science teachers as learners, or studies that at least carry the voice of science teachers as learners, were selected for review so that a concentration on what had been learned and why was considered in concert with how it was learned from the participants' perspective. Inevitably, then, the particular exemplars cited in this chapter are examined in more detail than is common in a Handbook. This strong attention to exemplars is also important in drawing attention to that which research efforts have perhaps overlooked in the past and to therefore help set an agenda for the future so that science teaching and learning research might push the boundaries of that which is understood to be meaningful, applicable, and useful in the world of practice.

## PRESERVICE SCIENCE TEACHER AS LEARNER

Student-teachers' experiences of school science influence their understanding of science teaching (per Lortie's (1975) apprenticeship of observation), and, as successful graduates of the "system," they often teach in ways similar to how they were taught (Sarason, 1990). Not surprisingly, many student teachers expect to learn the "script" for science teaching and can be quite resistant to alternative perspectives (Britzman, 1991; Hayward, 1997; Richardson, 1996). This issue is important in shaping what it means to challenge student teachers' prior experiences in order to influence their own practice of science teaching.

Research into teachers' beliefs (Pajares, 1992) and the relationship between beliefs and practice has drawn much attention (Bandura, 1986; Brickhouse, 1990; Bryan &

Abell, 1999; Hashweh, 1996), largely because challenging an individual's beliefs may be a powerful way of encouraging a restructuring of understanding of both learning and teaching. Hence, by challenging beliefs, one's prior experiences may be questioned rather than remain as taken-for-granted assumptions for practice (Brookfield, 1995).

Challenging beliefs has been a common beginning point for reshaping student teachers' views of, and approaches to, practice (Gunstone, Slattery, Baird, & Northfield, 1993). However, strong examples of preservice science teachers as learners are not easy to find, because many studies focus on the big picture of the intent of such a challenge, rather than highlighting specific instances of participants' personal shifts in understanding. With this in mind, the studies selected in this section of the chapter illustrate that, in science teacher preparation programs, clear examples of student teacher as learner exist, but the field itself is one that begs more involvement of the participants themselves—as co-authors and authors of their own experiences of teaching and learning science. This then is a major challenge for the science teacher education research community, so that new ways of accessing understandings of what student teachers are confronted by might be more readily identified—so that responses to learning outcomes might be appropriately implemented.

## Challenging Conceptions and Beliefs

The children's science and conceptual change literature (e.g., Driver, Guesne, & Tiberghien, 1985; Gunstone, 1990; Hewson, Beeth, & Thorley, 1998; Osborne & Freyburg, 1985; West & Pines, 1985) has illustrated how important it can be for students to experience cognitive dissonance, so that their existing conceptions might not only be personally recognized, but also restructured as a result of the experience. Dana, McLoughlin, and Freeman (1998) reported on a long-term project that studied changes in conceptions and beliefs of prospective teachers while learning to teach science in a preservice teacher education program based around the use of dissonance. Their study paid particular attention to the ways in which prospective science teachers made sense of teaching science for understanding and the program features that helped them to do so.

By focusing on the student teachers themselves, the authors built on Borko and Putnam's (1996) view that what and how student teachers learn in their teacher preparation program is strongly influenced by their existing knowledge and beliefs; therefore, challenging these through *creating* dissonance as one way of *generating* opportunities for new learning. They outlined how the program was purposely designed to "support the prospective teachers' conceptual development around ideas connected to teaching science for understanding" and how "certain aspects of the course appeared to be especially helpful in creating dissonance, challenging beliefs, and fostering the reconstruction of science pedagogies, stimulating professional growth" (p. 7).

Dana et al. (1998) also illustrated how they created a *need to know* for student teachers that encouraged a reconsideration of the teacher as teller role so strong in many student teachers. They also highlighted how the recognition of an unanticipated classroom problem was the catalyst for change. A strength of the data they offered was in student teachers' voices and how participants personally detailed situations with which they were confronted, and how their ensuing sense of dissonance

caused them to learn about aspects of teaching and learning science that they had not explicitly questioned previously.

These authors described the principles that guided their program and offered ways of conceptualizing how to create opportunities for student teachers to be learners by confronting their taken-for-granted assumptions of teaching as telling and learning as memorization. They also noted that the "learning to teach process is generative" (p. 14). Lederman, Gess-Newsome, and Latz (1994) also illustrated evidence of student teachers as learners in their study of secondary preservice science teachers' content and pedagogical knowledge structures, whereby pedagogical knowledge stood out as a primary influence on instructional decisions.

These studies are illustrative of student-teachers as learners, because an overt focus on their experiences was adopted as a guiding principle in teacher preparation. Furthermore, van Driel and de Jong's (1999) investigation of preservice chemistry teachers' pedagogical content knowledge (PCK) (Shulman, 1986, 1987) highlighted the importance of listening to students as an impetus for recognizing and responding to differences between beliefs and practices. While van Driel and de Jong focused on the question, "Is a development in the preservice teachers' PCK observable, and if so, what is the influence of specific factors on this development?" their study illustrated how these student teachers recognized that "their usual way of reasoning cause[d] problems for [their] students, who . . . became confused . . . [as] the different activities and events during [their] classroom teaching affected their knowledge of specific learning difficulties of students" (p. 5). Thus the primacy of experience emerged as an important factor in the promotion of a preservice science teacher as learner stance.

Veal (1999), another researcher interested in the PCK of preservice science teachers, also paid careful attention to student teachers' voices. Veal's participants questioned the use of language as an important shaping force in the implicit messages of teaching about science in ways that they had not previously recognized in their own learning of science. They also responded to their own sense of dissonance when confronted by difficulties in (re)learning chemistry and physics and began to make meaningful links to the ways in which they might then teach those concepts themselves. For example, one student teacher (Randi), in responding to a consideration of the abstract nature of chemistry, focused attention on the importance of concrete representations—a learning breakthrough that affected Randi's view of teaching. However, Veal made clear that just because student teachers recognized the need for particular approaches to practice, it did not necessarily follow that changes were automatically implemented. This point is a reminder of the interplay between beliefs and practice and the role of dissonance as a catalyst for meaningful learning from experience for student teachers.

Like many others (e.g., Cochran & Jones, 1998; Gunstone & Northfield, 1994; Hoban, 2003; Northfield, 1998; Vander Borgh, 2003), Veal (1999) also noted how the influence of classroom teaching experience and participants' interactions with students tended to raise new issues for teaching and learning that could only really be apprehended through the experiences of student teachers. Therefore, Veal further supported the view that, to encourage student teachers as learners, their existing belief structures need to be sufficiently (and consistently) challenged in ways that will cause them to reconsider their taken-for-granted assumptions of science teaching and learning.

## Learning from Experience

Munby and Russell (1994) offered an analysis of detailed feedback from physics methods students enrolled in a preservice education program at Queen's University, Canada, and used these messages to develop the notion of the "authority of experience" to explain the unease many student teachers felt about their transition from being "under authority" to being "in authority" as they moved through student teaching. The development of "authority of experience" was a salutary reminder of the ongoing conflict between teaching as telling and teaching for understanding as it highlighted how some student teachers wanted to be *told* how to teach while others wanted to *learn* how to teach. Through a desire to explicitly develop student teachers' authority of experience, Russell (1997) sought new ways of empowering his student teachers as learners through a sustained concentration on, and analysis of, *their* teaching experiences (see Featherstone, Munby, & Russell, 1997; Russell & Bullock, 1999). Russell therefore worked with his student teachers (Featherstone and Bullock) to help them reflect upon, and research, their own experiences of learning to teach.

Featherstone documented how his views of teaching and learning changed as he gathered feedback from his students about their learning, and how he listened to his students to *really* hear what they were saying. In so doing, he better aligned both his teaching and learning intents in explicit and meaningful ways. Following a series of lessons on "natural succession" and his purposeful attention to his students' views, he noted that, "I have been reminded just how important it is that one does not underestimate the value of creating a forum for listening to students' voices . . . there is something special about being able to say that my decision [about how to further develop his teaching] is based on what I have learned from my students" (Featherstone et al., p. 136).

In a similar way, Bullock highlighted his learning through experience by documenting his practice. Having spent some time thinking about the differences between his views of science learning and his actual science teaching, Bullock was encouraged to take risks in his practice. Eventually, even though his instincts told him to act differently, he came to see value in allowing his students to explore science for themselves, not unlike the way he was learning to explore teaching himself, by discovery and risk, not through "being told." His big-picture breakthrough highlighted how his learning about teaching was based on valuing experience:

I would argue that the nature of science is to construct your own reality of how the world works. . . . We as educators should remember that although it is apparent to us that, say, all objects undergo the same acceleration due to gravity near the Earth's surface, it remains a mystery to most high school students. "Experience first" allows people to discover science rather than be information sponges. (Bullock in Russell & Bullock, 1999, p. 137)

Featherstone and Bullock's reports lend further weight to the call (see Lederman et al., 1994) for more importance to be placed on better integration of subject-specific pedagogy courses in preservice teacher preparation programs. If subject-specific pedagogy is to be recognized and developed by preservice science teachers as learners, then they need opportunities to pursue their learning about practice in

more meaningful ways (per Geddis's [1993] study of student teachers' learning about isotopes), rather than simply as task-driven activities. In so doing, the possibilities for preservice science teachers as learners would be enhanced through the creation of possibilities for effective reflective practice (Loughran, 2002), whereby their own experiences are the basis for personally identifying the value in framing practice in intelligible, plausible, and fruitful ways (Posner, Strike, Hewson, & Gertzog, 1982) for their own conceptual development. If this were the case, then de Jong, Korthagen, and Wubbels' (1998) concern for better linking of student teachers' conceptions and actions in classroom practice might be realized.

### **ELEMENTARY SCIENCE TEACHER AS LEARNER**

Elementary science teachers' need for a strong science knowledge base has been raised many times in the literature (Appleton, 1992; Appleton & Symington, 1996; Carr & Symington, 1991; DEET, 1989; Harlen, Holroyd, & Byrne, 1995; Skamp, 1991; Welch, 1981) and is often interpreted as simply meaning that more science content knowledge equates with better science teaching. This interpretation, though, has been challenged (Bennett, Summers, & Askew, 1994). In fact, Schibeci and Hickey (2000) noted that "there is no place, in our view, for a 'cognitive deficit' model in providing assistance to elementary teachers to improve their content backgrounds" (p. 1168). They stated this as a result of their experience in organizing and conducting a professional development program<sup>1</sup> designed to help elementary science teachers become meaningful learners of science. However, what they came to learn was that such development was dependent on three salient dimensions: a scientific dimension—to promote change in teachers' concepts and support development of more sophisticated ideas, theories, and principles; a professional dimension—based on content to be taught in elementary classes thus having high relevance and purpose to teachers; and a personal dimension—related to everyday life and providing a motivation for teachers to learn and understand (p. 1168).

Schibeci and Hickey (2000) conceptualized these three dimensions because their involvement with elementary teachers highlighted for them that content alone did not necessarily lead to more effective teaching. What this suggests is that the general predominance of the scientific dimension as a focus for the development of elementary science teachers' practice has perhaps masked the importance of the other two dimensions in learning about science teaching and learning. However, finding real examples in the literature of the professional and personal dimensions of science teachers as learners (in the teachers' voice) is difficult; perhaps it could also be argued that a strong science knowledge base itself is important in encouraging the necessary risk-taking to publicly explore the professional and personal dimensions of science teacher as learner in research reports.

### **Confidence in Science Teaching**

Appleton and Kindt (1999) offered another way of viewing the development of these three dimensions through a consideration of "science activities that work."

---

1. Similar learning through organizing professional development for elementary teachers is also reported by Pearson and Wallace (1997).

They noted how science content was sometimes perceived as being well taught if the “activities” for the students were fun, hands-on, and/or thematically developed. They also highlighted how some elementary teachers’ lack of confidence in science led them to avoid teaching science.

The need to place more emphasis on elementary science teachers as learners has been apparent for some time but is perhaps a part of the science education research agenda that has not garnered sufficient attention in the mainstream research literature. Yet, the seeds for such development have long been planted. For example, Smith and Neale (1989) offered strong indicators of the value of concentrating on personally and professionally meaningful shifts in perspectives and practices in science teaching as an invitation for science education researchers to work *with* rather than *on* teachers.

Geddis (1996), working with teachers, and exploring two experienced elementary teachers’ efforts to make science a more significant part of their teaching, drew attention to the fact that a concentration on teaching science disrupted elementary teachers’ views of themselves as teachers. In Geddis’ case studies, the participating teachers appeared to have developed new perspectives on science teaching and learning. For these elementary science teachers as learners, their actions created a sense of unease in “intervening in [their] students’ learning” (p. 263). Yet, in many instances, intervention was necessary if science teaching was to begin to address students’ alternative conceptions. What Geddis’s work highlighted was how elementary teachers’ “professional identities have often been associated with a variety of slogans whose central message is essentially, I teach *children*, not *subjects*” (p. 264). Adopting a science teaching and learning frame for practice may well cause a sense of unease among teachers because it challenges their traditional view of themselves as teachers. Addressing this unease is congruent with Schibeci and Hickey’s (2000) suggestions about the need for personal and professional change as opposed to that of science knowledge alone. But how might this be done in ways that are responsive to the real needs and expectations of elementary teachers?

## Science Learning Through a Community of Practice

Summers and Kruger (1994), through a two-year longitudinal study of the development of elementary teachers’ subject matter knowledge in science, illustrated that through well-designed in-service education, participants’ understanding of science concepts could be substantially enhanced. Yet despite the best intentions, education systems and providers often fail to develop and implement ongoing, well-organized, and conceptually coherent science education programs.

Fleer and Grace (2003) responded to this situation in their study of the professional commitment to teacher as learner through the development of a community of practice (Wenger, 1998). In their account, the voice of the teachers and students was particularly strong and illustrated how the professional and personal dimensions of learning about practice, and the subsequent changes in actions, blossomed through collegial leadership. They paid attention to their community of practice through full participation and the collective (rather than individual) accumulation of experiences. Their study illustrated how children’s science experiences were deliberately broadened as more teachers joined their quest for learning. It also made clear how, by centering on children and their learning, classroom teachers could be drawn into an evolving community of science practice. This work challenges some

of the barriers to teaching and learning science raised in many previous studies by addressing the situation holistically—in the typical elementary approach of an integrated curriculum—rather than focusing solely on the science itself.

Grace offered a series of case studies that illustrated the development of the community of practice in which the involvement of others in the students' study of the Enhanced Greenhouse Effect positively influenced approaches to science teaching and learning. The teachers themselves were genuinely involved in the children's learning journey and were activated to join the growing community of learners.

The development of a community of science practice created a context in which the boundaries for learning were not defined by a single classroom, but were deliberately broad. The evolving community of practice included the staff in the school, the families of the children, community members, and local, regional, and international contexts (Fleer & Grace, 2003, p. 132).

The majority of research into elementary teachers' practice of science adopts an individualistic approach whereby the unit of study is the teacher. In such situations, the community in which the teacher exists is perhaps less likely to be accorded sufficient importance as a research focus. The framing of the research may simply overlook aspects of science teaching and learning that are embedded in the community rather than the individual. Fleer and Grace's overt focus on the community illustrated how teaching and learning in science can respond to many of the concerns and issues raised in much of the literature. However, such responses require researchers to be active participants within the elementary school environment itself, and such practice no doubt challenges more "traditional" research practices. Perhaps the unease felt by elementary teachers (as noted by Geddis, 1996) is equally apparent in the "practice" of researchers (in that traditional research is seen as distinct from the work of practice) and helps to account for the small number of strong alternative perspectives on elementary science teacher as learner available in the mainstream science education literature. Fleer and Grace clearly offer one way of challenging such a situation.

## SECONDARY SCIENCE TEACHER AS LEARNER

The literature shows a clear distinction between beginning and experienced secondary science teachers as learners. Obviously, beginning and experienced science teachers are two ends of a continuum. However, the distinction between them can be somewhat blurry. For example, White, Russell, and Gunstone (2002) and Lockard (1993) illustrated how, when experienced science teachers changed schools or taught unfamiliar content, they became beginning science teachers again. In this case, for ease of distinction and analysis, I define a beginning science teacher as someone in the first five years of teaching.

### Beginning Science Teachers as Learners

Adams and Krockover (1997) studied science teachers moving from preservice into the early years of teaching. They found that the initial shifts from didactic teaching practices toward conceptual/constructivist teaching and learning practices were encouraged through reflection, and that seeds for the development of PCK were incorporated into the schema of beginning teachers. Loughran (1994), following a co-

hort in a similar fashion, outlined a model to account for beginning science teachers' search for a better alignment of their teaching and learning intents. Carlsen (1991), in his year-long study of four new high school biology teachers, attempted to quantify subject matter knowledge and how that knowledge affected novices' teaching. However, what he recognized was what McNeil (1986) described as a "contradiction of control" whereby the "social and institutional concerns act as cross-purposes with goals like promoting inquiry through discourse" (Carlsen, 1991, p. 646), affecting these beginning science teachers' approach to teaching. This contradiction of control was also noted by Munby, Cunningham, and Locke (2000) in their detailed case study of a year 9 science teacher, highlighting how the nature of the school in which she worked set up barriers to the development of her professional knowledge.

Through this period of transition from student teacher to beginning teacher, much learning occurs as the search for time to reflect on practice as well as the need to develop professionally satisfying approaches to practice are continually buffeted by the day-to-day concerns and expectations of the role. Trumbull's (1999) longitudinal study of six beginning biology teachers in her book, *The New Science Teacher*, is one study that strongly illustrated this transition through the participants' own voices.

Trumbull (1999) followed six of her student teachers through their teacher preparation program and out into their first three years of teaching science. Through insightful interview data, she allowed each participant to tell the story of his or her development and learning over time. The first participant, Fred, learned about the contradiction between teaching for understanding and teaching to pass examinations; his learning was about his realization of the ongoing dilemma associated with choosing to teach for understanding by trying to help his students get "excited" about the topics they were investigating.

Pat Green learned about the importance of a personal connection to content by responding to the serendipitous nature of learning and, in so doing, came to see how central that was to her growth in understanding of science teaching and learning. Sylvie Andrews learned about how taking risks in her teaching required a confidence to pursue teaching approaches that were initially discomfiting for both the teacher and the learners. Yet, Elaine Spring grew in confidence sufficiently to be more responsive to the need to modify her existing teaching materials and to develop a more coherent view of the courses she was teaching. In so doing, she learned how to "react more immediately when her students brought up important topics spontaneously" (p. 76).

Being involved in the research with Trumbull was helpful in Maggie Deering's development, as she came to see aspects of her practice that she needed to adjust in order to capitalize on her teaching and learning intents in practical ways. She noted the need for explicit instruction in higher level thinking and explanatory writing for her students to become more independent and responsible learners. This was also mirrored in her recognition of the same thing occurring in her learning through the research project. "As I read your [Trumbull's] case study about me, I wondered if my involvement in the project helped me be more reflective in my practice" (p. 91).

The final participant, George Frage, was interested in "biology for its own sake and for the complex reasoning involved in research and experimentation" (p. 103). However, his learning was centered on the frustration he felt about the perceived need to cover the content as opposed to learning some concepts in depth. This frus-

tration was something with which he struggled. His level of concern was more closely linked to his developing notions of PCK; his strength of content knowledge appeared to influence his concern for teaching in ways that enhanced his understanding of practice. It could well be argued that George was beginning to learn that content knowledge alone was not sufficient for good teaching, and that the development of his students' learning in ways that would satisfy him professionally would be the teaching and learning challenge he might come to name for his future development.

Anderson and Mitchener (1994) described the transition from pre-service to in-service education as an induction phase whereby the beginning teacher is confronted by: "(1) the isolated nature of teaching, (2) the abrupt nature of the transition into teaching, (3) the documented attrition rate of beginning teachers, and (4) the personal and professional well-being of the beginning teachers" (pp. 31–32). What the beginning science teacher as learner literature illustrates is that, in this induction phase, there is a need for genuine support and guidance so that these science teachers can learn to frame and name the nature of their concerns in order to actively decide what they personally need to pursue to enhance their own learning about teaching and learning in science. It seems that when personal and professional well-being is well managed, the beginning science teacher as learner begins to emerge as a result of a growth in confidence through the associated risk-taking and experimenting with practice necessary in addressing the differences between teaching intents and learning outcomes (see Trumbull's cases).

The challenge, though, is to manage this induction phase in such a way as to encourage the sharing of learning so that the sometimes contradictory messages of socialization do not reinforce the very teaching behaviors that have so shaped many beginning teachers' views of science teaching. Professionalization rather than socialization for the beginning science teacher is encouraged most through the modeling of a science teacher as learner approach by the experienced science teachers who comprise the community in which the beginning teachers work.

## **Experienced Science Teachers as Learners**

Klopfer's (1991) *summary of science education to 1989* highlights not only the approach to research in science education to that point in time (largely instrumental and generally work on teachers rather than with teachers), but also that "some researchers found that teachers had difficulty translating their knowledge into practice or that teachers believed that they had implemented more good practice into their classroom than observations supported" (p. 352). This point about translating knowledge into practice highlights an issue indicative of science teacher as learner—making the tacit explicit.

## **Articulation**

One common external mechanism that encourages science teachers to see a need to make the tacit explicit is involvement with science education researchers (often through enrolment in postgraduate programs) and the subsequent development of a language for sharing understandings of the complex nature of science teaching and learning. Geelan (1996) illustrated this point when his "newfound" need to

read about educational theories and practices offered him tools to reflect on his own teaching and to grow and develop as a science teacher. Geelan's study showed how, when a teacher is placed in the position of learner, the need to articulate understandings of teaching and learning is catalyzed.

Maor (1999) described such a situation through a professional development program designed to place teachers in the role of learners in an attempt to challenge their use of multimedia and to influence their use of constructivist teaching approaches in their classrooms. The need for a vocabulary to share their knowledge of practice was an important issue and has been central to much of the debate about teaching as a profession—it is seen as crucial to teachers valuing the knowledge that underpins their practice.

As a high school chemistry teacher, Ian Mitchell became well aware of the value of a language for discussing teaching and learning. The cofounder of PEEL (Project for the Enhancement of Effective Learning; see Baird & Mitchell, 1986; Baird & Northfield, 1992; Loughran, 1999), Mitchell was responsible for an ongoing, largely unfunded professional development project that hinged on teachers' using a language for learning and the extensive development of teaching procedures to enhance students' metacognition. Yet, when he found himself facing an impending absence from his science class, the crucial information that he needed to pass on to the teacher who was going to cover for him did not carry the understanding necessary for that teacher to perform her function in the way Mitchell had intended. Mitchell soon discovered that,

I had no idea that I had omitted in my advice [to the other teacher] such a huge part of what I did. I was astounded to discover this. Identifying the frame of "maintain a sense of progress" was very important for lesson sequences that have a focus on restructuring or constructing understanding of key ideas rather than completing tasks . . . however, part of the crucial wisdom that I had also developed about how to maximize the prospect by overtly maintaining a sense of progress of success was only revealed [to me] by the sequence of events just reported. (Mitchell, 1999, pp. 60–61)

What Mitchell came to recognize was that, despite his exemplary teaching practice and overt focus on developing students' metacognitive skills through teaching for understanding, he did not explicitly recognize the key features of the information he needed to pass on to another teacher to continue with his class commensurate with the ideas and approaches he was using. Only by being confronted by the situation in which he found himself did he learn how "seriously [he] underestimated the highly tacit nature of so many crucial aspects of teacher knowledge" (p. 63).

Drawing further on PEEL, Zwolanski (1997) and McMaster (1997) highlighted how their focus on students' learning gave them a powerful language for discussing issues of teaching and learning that directly related to changes in their science teaching practice. Zwolanski noted, "I am more aware of my teaching style and am constantly evaluating the lessons and content taught . . . the students have a say in the direction of the lesson" (p. 133). For Zwolanski, this was quite a shift in her approach to teaching, something that she had to learn about in order to do, not something she could just simply employ. Similarly, McMaster described how he began to learn how to bring his practices more into line with his beliefs about teaching and learning: "It is of no use to admit that children have prior views of topics if you don't let them approach the 'scientist's view' by their own learning skills. The

method of acknowledging their views only to systematically knock them down would not shift them as much as by letting them review their own ideas or check their own understanding" (McMaster, 1997, p. 143).

The PEEL project is replete with examples of science teachers as learners whereby the need to articulate features of practice drives a learning about practice in very real and tangible ways. However, change itself is invariably problematic.

## **Science Teaching and Learning: A Problematic Adventure**

Viewing teaching and learning as problematic is important, for were it not problematic, it would surely be a simple task to apply the correct approach to resolving any prescribed learning difficulty. If one accepts that teaching is problematic, then one way of understanding this perspective is through the notion of dilemmas. A dilemma by definition is something that is managed, not resolved; hence, a teacher who is learning to manage a dilemma is learning about practice rather than solving a problem with practice. This is not to suggest that there is a lack of progress or development in the knowledge and skills of teaching. Rather, that which is being better understood is itself an indication of development and progress and is a sign of a professional approach to understanding the ongoing tensions, frustrations, and concerns associated with better linking of teaching and learning.

In the edited book *Dilemmas of Science Teaching: Perspectives on Problems in Practice* (Wallace & Loudon, 2002) this very point of practice being problematic is the basis for insights into science teachers as learners. The understandings that emerged through the careful examination of teachers' dilemmas led to a questioning of the taken-for-granted assumptions of practice that guided these teachers' development in new understandings of teaching and learning in science. For example, when McGuiness, Roth, and Gilmer (2002) reconsidered laboratory work and questioned what it did, how it was performed, and the value of the associated tasks, assessing practical work emerged as an issue that had not seriously been considered in the past. In a similar way, the Krueger, Barton, and Rennie (2002) examination of group work led to a confrontation with the exclusionary approaches of some students that limited the learning possibilities for others. Furthermore, Gribble, Briggs, Black, and Abell (2002) reconsidered the use of questioning and began to see things in classroom discourse that had not been so apparent (if at all) in the past. Overall, the examination of dilemmas highlights how attempting to teach, not tell, continually emerges as a challenge for those who perceive practice as being problematic.

Northfield, in *Opening the Classroom Door: Teacher, Researcher, Learner* (Loughran & Northfield, 1996), his year-long examination of his teaching of a year 7 class of high school students, left no doubt about his learning as a science teacher. Through extensive accounts of classroom situations and his reflections on practice through conversations with others and his journal entries, he came to a point whereby he was able to synthesize and categorize his learning.

Northfield's categories highlighted principles that shaped his approach to practice; however, the differences he articulated between his expectations for teaching and learning and his students were disconcerting. Northfield explored these differences by contrasting his teacher view, "Learning requires learner consent," and his students' view, that "Learning is done to students and teachers have a major respon-

sibility for achieving learning" (p. 137). Northfield's account offered interesting insights into the world of the teacher as learner and raised issues about the theory-practice gap. And it is through appropriate explorations of the theory-practice gap that the science education community's knowledge and understanding of practice might be enhanced. However, in some cases, neither world pays sufficient attention to the other, despite the efforts of those who try to bridge this gap in thoughtful ways.

### **Theory-Practice Gap: Practice-Theory Bridge**

Pekarek, Krockover, and Shepardson (1996) drew attention to the oft-cited theory-practice gap as an issue in terms of addressing concerns about changes in the pedagogy of science. McGoey and Ross (1999), in response to the lament about "the lack of teachers' application of research in informing their day-to-day practice" (p. 117), discussed their use of conceptual change pedagogy and offered a "report to the research community [about] where advances in research ha[d] taken [them], and where [they] would appreciate future research to be directed" (p. 117).

In an interesting slant on the theory-practice gap (so often reported from the research perspective), McGoey and Ross (1999) outlined what they saw as the important difference between technical information (the "how to" of teacher journals) and theoretical frameworks (the "how come" and "what if" of research journals) that influences what is sought and what is useful in the worlds of theory and practice. In so doing, they approached the theory-practice gap from a teaching perspective. Although they stated that they represented a minority of teachers, they offered a bridge into theory from practice by making clear what had been helpful to them and, therefore, what they looked for in their learning about science teaching and learning. Their approach illustrated the difference between what many researchers might pursue and make available to practitioners and what they, as teachers, do pursue. They rightly expected that the explication of their perspective might encourage a shift in research focus as they "look[ed] forward to a day when collaboration between the academy and the classroom teacher [would be] a commonplace of [the] profession [of] science teaching" (p. 120). The hope was that the two would work together so that research and practice might inform one another in meaningful ways.

There has been a great deal of research into aspects of the nature of teachers' beliefs, knowledge, and practice (see chapters by Lederman, Abell, Jones, & Carter) designed to elucidate factors that might genuinely help to improve the quality of science teaching (in ways commensurate with the hopes of Goodrum & Hackling, 1997). Many of these efforts have been professional development projects (Johanna, Lavonen, Koponen, & Kurki-Suonio, 2002; Radford, 1998; Shymansky et al., 1993; van Driel, Verloop, & de Vos, 1998) aimed at addressing many of the research findings (noted above). However, the difficulty has often been that although these projects are sympathetic to the work of science teachers, and the researchers are concerned for the development of quality in science teaching and learning,<sup>2</sup> the teachers

---

2. Particularly evident in the work of Clark (2003) in his study of a South African teacher attempting to teach for understanding while struggling with a major lack of resources and support. Clark's account is one that reflects, in a very powerful way, the concerns, issues and difficulties of teaching science for understanding when the lack of expectations and conditions for such practice are overwhelming.

themselves have not necessarily been the initiators or sustainers of the research effort. When teachers are the initiators and sustainers of the work (as reported by Hoban, 2003), the focus and results are considerably different.

Briscoe (1991), for example, followed an experienced secondary science teacher considered exemplary by his peers, for a year. The teacher wanted to make changes to his teaching practice, but the paper illustrated how such a purpose was continually under attack because of the conflict between his goals for learning and his actions as a teacher. The study illustrated how difficult it can be for a teacher to actually make the changes being sought, even though the expectation is clear. Nelson (2001) also followed an experienced teacher with an extensive understanding of oceanography as she transformed her teaching from a more traditional form into an inquiry-based approach. She found that changes in the teacher's practice occurred, and were encouraged, as a result of her strong content knowledge in conjunction with reflection on her students' learning.

Both of these studies are examples of research into science teaching and learning from the practice perspective and illustrate the shift in research focus, data, and results that accompany such a shift. Both researchers appeared sympathetic to the teachers' world; what they uncovered was no doubt helpful to other teachers in similar situations. However, the work of Fitzpatrick (1996), a science teacher and head of his school's science department, took this process one step further. He described what happened when he and his colleagues decided to "throw away" the existing year 8 curriculum and replace it with a new course structure and new teaching and learning approaches because, "after years of stagnation . . . [he was] very quickly convinced of the benefits of adopting a constructivist philosophy" (p. 1). Fitzpatrick (1996) gave reasons for deciding to change and described how their work led to the development of new pedagogical skills.

However, few studies responded to the McGoey and Ross (1999) agenda to the extent of that described by Berry and Milroy (2002). Having decided to pay careful attention to their students' learning about atomic theory, Berry and Milroy were confronted by a realization:

We asked students to expose their thinking and did not know how to help them . . . when we turned to the research literature to find a context for teaching about atomic structure, or practical classroom assistance for dealing with the particular conceptions we had uncovered and wanted to challenge, we found little . . . We needed a user-friendly guide (where the users were teachers like us) for dealing with the variety of individual conceptions—how to challenge; what to do with those students who already had a coherent view of the phenomenon. (Berry & Milroy, 2002, pp. 200–201)

Because they were unable to find the research knowledge and help they required for the task they had set themselves, they became active science teacher learners, collaborating in a learning about science teaching experience that was certainly much more demanding and challenging than they had anticipated. The nature of their work, the daily demands of teaching, and the need to make real progress (for their students and themselves) created a research agenda (and a report) very different from that generally found in the literature, especially when such work is portrayed from a traditional research perspective. Their account was constructed around 10 powerful "snapshots" of their learning about science teaching and presented is-

sues and concerns that were developed and analyzed in ways that other teachers would readily identify with and likely find helpful and informative in their own practice. Their study was one that has helped to set a new agenda for what research into science teaching and learning might pursue in seriously challenging the theory-practice gap. These science teachers as learners illustrated that there are real ways of responding to McGoey and Ross's (1999) call as they began to build a bridge from practice into theory that invited travelers to traverse from both sides.

## SCIENCE TEACHER EDUCATOR AS LEARNER

Over the past decade, self-study of teacher education practices (Hamilton, 1998) has become increasingly influential in shaping approaches to teaching and research in teacher education, partly as a result of a shift in focus toward teacher educators' desire to learn more about their own practice (Adler, 1993; Korthagen & Russell, 1995; Mueller, 2003; Munby, 1996; Nicol, 1997; Pereira, 2000) and partly in response to teacher educators' growing interest in the knowledge base of teaching and learning about teaching (e.g., Berry & Loughran, 2002; Loughran & Russell, 1997; Mayer-Smith & Mitchell, 1997; Trumbull, 1996; Trumbull & Cobb, 2000).

Science methods teaching in teacher preparation programs is the context in which much of the science teacher educator as learner studies are located. For example, Russell (1997), through his physics methods teaching, considered his learning about science teaching specifically in terms of how his knowledge of practice could be made more accessible to his student teachers, so that their learning of science teaching would encourage them to challenge the status quo of science teaching as the delivery of facts. Chin (1997) similarly pursued an understanding of his teaching about chemistry teaching as he "articulate[d] some significant experiences that informed [his] beliefs about teaching and learning within the teacher education context" (p. 117). In so doing he made clear how, as a science teacher educator, he was also a learner. Both of these teacher educators illustrated how their learning about their own science teaching substantially informed their practice in teaching about science teaching and that their learning was continually being challenged as they sought honest and constructive feedback about the impact of their practice on their student teachers' learning.

Segal (1999) pursued her learning about teaching science by taking the risk of placing herself in the learner's position as she struggled with how to teach in a three-part learning and teaching model (cooperative groups, learners' questions, and a techno-science context). Her paper examined the differences between being a learner of science teaching and a learner of science learning and showed how she came to better understand the dilemmas of practice that were important in shaping the situations through which the teaching approach (the three-part model above) affected the learning of her students:

I did not realize until I was a full participant in their [student-teachers'] explorations that my own understanding was tenuous. . . . In genuinely seeking to understand how they were learning, I was involved in the appropriation process myself. . . . After a positive boost to my confidence, I was probably keen that students should experience this type of inner satisfaction through the learners' questions part of the learning model. (Segal, 1999, pp. 17–18)

Segal's efforts were extended by collaboration with a colleague, following their student teachers through teacher preparation and into their first year of teaching (see Schuck & Segal, 2002). They learned a great deal about their teacher education practices and how their own assumptions about student teachers' learning of science were challenged when they sought evidence of meaningful change. Having specifically taught science in ways designed to create student-centered, activity-based, small-group learning, Segal came to see that she needed to "employ multiple strategies in class to challenge the assumption . . . that as long as the children are having fun, they are developing conceptual science understanding" (p. 95). She found using first-hand experiences with student teachers did not lead to student teachers using the same practices when they were full-time teachers.

Schuck and Segal (2002) found that, although they could create powerful learning experiences for their student teachers at the university, in many cases these experiences created an impression for their student teachers that such approaches were "seamless and unproblematic" (p. 96). Hence, when their student teachers were challenged by the reality of teaching in those ways themselves, many retreated to the very teaching approaches they had experienced and been dissatisfied with as school students.

Hoban's (1997) investigation of his teaching about elementary science focused on helping his student teachers understand their own learning of science in order to counter the transmissive model of teaching about teaching so predominant in teacher preparation programs. His study showed that, although many elementary student teachers lacked "a solid knowledge base about science and many ha[d] negative attitudes about the subject, . . . providing them with large amounts of science content in courses [was] not the way to address this difficulty" (p. 146). His study illustrated how enhancing student teachers' self-awareness of their own beliefs and practices led them to make meaningful shifts in their own practice. In his teaching about teaching, modeling was important to him: "This is risky business; you are exposing yourself to criticism from your own students. But [how can] trainee teachers take seriously your recommendations about being a reflective teacher [if] you do not do it yourself?" (p. 147).

Modeling what one expects of one's students is a crucial feature of science teacher educator as learner. Tobin (2003) accepted this challenge when he found his previous science education knowledge and experiences less than helpful in a new and demanding situation. In his study, not only did he reconceptualize what it meant to be a science teacher educator, but he also placed the same expectations on himself as a teacher as he had for his student teachers by student-teaching in a local urban high school:

I regarded myself as a strong teacher and never considered that the knowledge gleaned from a long career of teaching, research, and teacher education would fail to carry me through even the stiffest of challenges. . . . I moved to the University of Pennsylvania where I taught a science education course for prospective science teachers . . . all of the new teachers were assigned to urban high schools for a year-long field experience. The problems they were experiencing were profound and my suggestions, though grounded in research and theory, were of little use to them. Most of what I knew seemed inapplicable to their problems and the contexts in which they taught . . . [I took a teaching position in an urban high school similar to that which my student-teachers were experiencing] . . . I was to realize all too quickly that I needed to re-learn to teach in urban schools . . . I failed to understand teaching as praxis. For too long I had regarded teaching as

knowledge that could be spoken, written, and thought. But words could not be turned into teaching to mediate the learning of students. (Tobin, 2003, p. 34)

Tobin's learning experiences could not help but dramatically affect his teaching about science teaching. The sense of dissonance, the inability to convey meaning to his student teachers, and then being confronted by the same problems as his student teachers were experiencing helped him understand and know about practice in new and different ways, ways that he did not understand before genuinely adopting a science teacher and science teacher educator as learner stance.

## CONCLUSION

Clarke and Erickson (2004) noted how the literature on student as learner and that on teacher as learner have converged through common links to constructivism and how the search for "universal type laws" of learning that apply equally well to all contexts have been abandoned because of the inherent situated and contextually bound nature of learning. Following from this, the notion of science teacher as learner is then clearly bound up in understandings of contemporary theoretical perspectives on learning and concerns for the improvement of teaching practices—especially so from a teacher's perspective. Wallace (2003) extended this view through his articulation of three conceptual themes: (a) that learning about teaching is situated, and as a consequence, the development of teachers' understanding and knowledge requires a focus on authentic activities; (b) that learning about teaching is social and that "creating rich opportunities for diverse groups of teachers to participate in, and to shape, discourse communities" is critical (p. 10); and (c) that learning about teaching is distributed, and, hence, collaboration is central to change.

I suggest that a major unaddressed challenge facing the science education community is to purposefully pursue research that is meaningful, applicable, and appropriate for teachers in the development of *their* pedagogy of science, so that ultimately students' learning of science is enhanced. As I trust this review illustrates, addressing such a challenge demands a concentration on the science teacher as learner in conjunction with that of science teacher educator as learner—the two cannot be divorced. A science teacher as learner stance must be taken seriously at all levels of teaching about science, and doing so requires an understanding of teaching as being problematic.

Fundamental to responding appropriately to this challenge is the need for science teachers to consistently: (a) challenge the taken-for-granted in their practice; (b) examine, articulate, and disseminate their learning through experience; and (c) seek to continually ensure that practice and theory inform one another. To do this requires a conceptualization of professional practice that explicitly values a science teacher as learner stance. The science education community can no longer excuse (science) teachers or teacher educators who espouse constructivist views of learning while continuing to practice transmissive approaches to teaching. For the expectations of the science education community in general to shift, individuals must respond. This chapter has offered insights into some of the approaches to, and experiences of, science teachers as learners who have approached their research and practice in ways that have helped to genuinely rejuvenate and shape the world of science teaching and learning. More than ever, your personal response matters.

## ACKNOWLEDGMENTS

# CHAPTER 35

---

## Science Teacher Attitudes and Beliefs

**M. Gail Jones**  
**Glenda Carter**

*North Carolina State University*

When Janice, a biology teacher, enters the classroom each day, her beliefs and attitudes about science, science learning, and science teaching influence virtually every aspect of her job, including lesson planning; teaching; assessment; interactions with peers, parents, and students; as well as her professional development and the ways she will implement reform. Although this influence is not necessarily linear or obvious, attitudes and beliefs play significant roles in shaping teachers' instructional practices.

This chapter examines the complex constructs of science teacher beliefs and attitudes and how beliefs and attitudes influence instructional practices. According to Keys and Bryan (2001), virtually every aspect of teaching is influenced by the complex web of attitudes and beliefs that teachers hold, including knowledge acquisition and interpretation, defining and selecting instructional tasks, interpreting course content, and choices of assessment. Advances in cognitive psychology have integrated attitudes and beliefs into conceptual change models as significant influences on conceptual growth and change. Putnam and Borko (1997) suggested that teachers learn as they "construct new knowledge and understandings based on what they already know and believe" (p. 1125). Although teacher attitudes and beliefs are key to understanding and reforming science education, these areas are poorly understood. Research that can unravel the complexities of teacher attitudes and belief systems is needed.

In this chapter, we summarize the historical perspectives and early research on science teacher attitudes and beliefs and present a sociocultural model. Using this model, we describe recent research studies on beliefs and attitudes. One of the consistent research findings discussed is the link between science teachers' epistemological beliefs and their instruction. Pajares (1992) maintains that "beliefs teachers hold influence their perceptions and judgments, which, in turn affect their behavior in classrooms" (p. 307). These beliefs have been called theories of action; Kane, San-

dretto, and Heath (2002) maintained that teachers' "espoused theories of action impacts their theories-in-use" (p.188). In the sections that follow, we describe teachers' epistemologies about science, science teaching, and science learning. This is accompanied by a discussion of the relationships of these to prior experiences, other beliefs, self-efficacy, expectancies, perceived environmental constraints, motivation, and, ultimately, instructional behaviors. In addition, we include new advances in research that document the role of the larger culture in shaping science teachers' beliefs systems.

## WHAT ARE ATTITUDES AND BELIEFS?

### Emerging Constructs

Although social psychology and the study of attitudes first emerged as an investigative area in the early 1900s, theory in this area lacked cohesiveness until the 1930s. It was during the 1930s that L. L. Thurstone and G. W. Allport laid the groundwork for the emergence of this branch of psychology that focused on attitudes (Kiesler, Collins, & Miller, 1969). Allport, in his 1935 *Handbook of Social Psychology*, synthesized the definitions and theories of attitude into a relatively cohesive construct. Thurstone provided a rationale as well as a method for measuring attitudes; thus attitudinal studies became a way to predict and understand social change (Ostrum, 1968).

Despite Allport's attempt to unite the definitions of attitude, a universal definition was never adopted. Throughout the research literature there reside multiple definitions for the construct of attitude and several theories of attitude construction. This makes interpreting the body of literature related to teacher attitudes problematic, and the issue is compounded by the interchangeable use of the term *belief* with *attitude*.

### Defining Attitudes and Beliefs

Attitude as a construct has been defined in a myriad of ways by philosophers, psychologists, researchers, and practitioners. Simpson, Koballa, Oliver, and Crawley (1994) defined an attitude as "a predisposition to respond positively or negatively to things, people, places, events, or ideas" (p. 212). In a similar fashion, Jaccard, Litardo, and Wan (1999) stated, "[A]n attitude is traditionally viewed as how favorable or unfavorable an individual feels about performing a behavior" (p. 103).

Ernest (1989) included not only positive and negative affect, but also added other characteristics, "attitudes include liking, enjoyment and interest . . . or their opposites . . . teacher's confidence . . . the teachers' self-concept . . . valuing" (p. 24).

As researchers moved from identifying attitudes to examining beliefs as a separate construct, the distinctions became problematic. Table 35.1 shows the wide range of definitions and attributes that are used throughout the literature. Fishbein (1967) delineated *attitudes* from *beliefs* by identifying attitudes as affective constructs and beliefs as cognitive constructs. While this distinction seems to be generally accepted, the relationship between knowledge and beliefs is viewed from multiple perspectives. Smith and Siegel (2004) identified five distinct relationships of beliefs

**TABLE 35.1**  
**Definitions of Belief**

<i>Definition</i>	<i>Source</i>
"Individuals' thoughts are equated with belief." (p. 331)	Southerland, Sinatra, & Mathews, 2001
"lay theories . . . images . . . metaphors, and webs" (p. 254)	Bird, Anderson, Sullivan, & Swidler, 1993
"both evidential and nonevidential, static, emotionally-bound, organized into systems, and develop(ed) episodically" (p. 55)	Gess-Newsome, 1999
"affective and subjective" (p. 335)	Southerland, Sinatra, & Mathews, 2001
"deeply personal, stable, lie beyond individual control or knowledge, and are usually unaffected by persuasion." (p. 786)	Haney & McArthur, 2002
"attitudes, judgments, axioms, opinions, ideology, perceptions, conceptions, conceptual systems, preconceptions, dispositions, implicit theories, explicit theories, personal theories, internal mental processes, action theories, rules of practice, practical principles, perspectives, repertoires of understanding, and social strategy" (p. 309)	Pajares, 1992
"personal constructs" (p. 1) "propositions considered to be true by the individual . . . non-evidential as they are based on personal judgment and evaluation" (p. 2)	Luft, Roehrig, Brooks, & Austin, 2003
"espoused theories of action" (p. 178)	Kane, Sandretto, & Heath, 2002
"person's understanding of himself and his environment" (p. 131)	Fishbein & Ajzen, 1975
"psychologically held understandings, premises or propositions about the world that are felt to be true" (p. 103)	Richardson, 1996
"subjective, private opinion" (p. 227)	Coburn, 2000

and knowledge by research communities and described them as follows. One, knowledge and beliefs are separate constructs with reciprocal impact. Two, beliefs are viewed as an integral part of schema and beliefs are subsumed in the knowledge construct. Three, knowledge and beliefs are inseparable, as they do not represent separate entities and therefore no attempt is made to distinguish between them. Four, the term *belief* is used to identify naïve conceptions, and the term *knowledge* implies the presence of scientifically accepted constructs. Five, the terms are used interchangeably with the tacit assumption that the difference will be interpreted within context of the research.

Regardless of the knowledge/belief perspective adopted, the cognitive and developmental views of beliefs precipitated a shift in the research focus in teacher education from attitudes to beliefs. This shift, beginning in the 1980s, is attributed to the shift in social psychology from an affective orientation to a developmental and cognitive orientation (Kane et al., 2002; Richardson, 1996). Until this time, attitude

research studies were more prevalent in the science education literature than studies that focused on beliefs.

In this chapter, we situate attitudes as a component of an individual's belief system. As Fishbein (1967) noted, attitudes have an affective dimension. Beliefs, however, are integral to larger belief systems that include self-efficacy, epistemologies, attitudes, and expectations. These are all intertwined and embedded in the sociocultural context. For example, a teacher's beliefs about using cooperative learning in the science classroom cannot be separated from her beliefs about science, science teaching, science learning, her motivation, her self-efficacy, her knowledge of constraints, her knowledge of cooperative learning, her skills using cooperative learning, prior experiences, the class and school context, as well as the larger cultural contexts. Thus beliefs are part of belief systems and attitudes are components of this larger system.

## HISTORICAL PERSPECTIVES

### Early Research on Attitudes and Beliefs

The initial interest in researching teachers' attitudes was based on the underlying premise that attitudes could be used to predict teaching behavior, and that changes in attitude would result in changes in behavior. A review of the science education research literature from the 1940s through the 1970s reveals three bodies of literature related to science teacher attitudes. One body of attitude literature reported prevailing teacher attitudes about science and teaching science, and science curriculum. Elementary teachers were the focus of most of the research on teacher attitudes toward science and teaching science. Although Dutton and Stephens (1963) reported that preservice elementary teachers' attitudes toward science were generally positive, many other surveys concluded that elementary teachers generally did not feel positive about teaching science. The sources of elementary teachers' negative attitudes were identified as a lack of interest in science, perceived difficulty of science, lack of content and/or pedagogical content knowledge, and lack of time (Lammers, 1949; Soy, 1967; Victor, 1962; Washton, 1961; Wytias, 1962). Needs surveys during the early years revealed that elementary school teachers were also concerned about management of materials and how to excite students about science, whereas secondary school teachers reported needing to know how scientists work and the latest advances in the field (Stronk, 1974). Both elementary and secondary school teachers reported negative attitudes about having students memorize information as the emphasis of science teaching (Stronk, 1974). Other informational needs reported by secondary science teachers included where to get materials, how to motivate students, and how to select appropriate pedagogy for science teaching (Moore, 1978).

### Sputnik Reform: Testing Variables

The pre-Sputnik/post-Sputnik years provide the line of demarcation in studies of teachers' attitudes toward science curricula. Though comparably few in number, attitudes toward using "innovative practices" during the pre-Sputnik years revealed

underlying concerns similar to those espoused toward the post-Sputnik curricula. Teachers cited lack of equipment and time as well as a preference for traditional curricula as reasons for negative attitudes toward change in practice (Lampkin, 1944; Sadler, 1967).

The onslaught of the National Science Foundation alphabet curricula of the late 1960s contributed to an increase in the number of studies on attitudes toward new curricula. Certain personal characteristics were found to be linked with a tendency to accept and implement the new curricula. Open-mindedness (Strawitz, 1977; Symington & Fensham, 1976), a preference for indirect and inductive teaching (James, 1971), and independent thought and action were linked to positive attitudes toward nontraditional curricula (Blankenship, 1965; Hoy & Blankenship, 1972). Less rigid control was aligned with practices advocated by Biological Sciences Curriculum Study (Jones & Blankenship, 1970). Conflicting research findings were reported on the effect of using the new curriculum on teaching practices. Hall (1970) reported that using a nontraditional curriculum did not affect teaching behaviors, whereas Orgren (1974) found that teachers changed their teaching behaviors as a result of using a new curriculum.

The second body of attitude research focused on identifying variables such as self-concept, coursework, age, cooperating teachers' attitudes, and knowledge related to teacher attitudes about teaching science. Self-concept was found to be directly related to teacher attitudes (Campbell & Martinez-Perez, 1977). Butts and Raun (1969a, 1969b) reported that the number of science courses taken was linked to attitudes toward teaching inquiry science with fewer courses linked to more positive attitudes, whereas Douglass (1979) found that more courses were linked to more positive attitudes. Other studies examined the correlation of age with attitudes. Schwirian (1969) reported that younger teachers were more positive, whereas Shrigley and Johnson (1974) found no relationship. Cooperating teacher attitudes were not found to influence student teachers' attitudes (James, 1971). Low correlation between teacher attitudes and knowledge was reported (Shrigley, 1974).

The third body of attitude research examined the effectiveness of interventions in affecting attitudes toward a number of variables. Role playing was used to improve attitudes toward teaching science (Hughes, 1971); essay writing generated positive attitudes toward using Bloom's taxonomy (Kauchak, 1977). Teaching process skills improved teachers' attitudes toward using a process approach (Butts & Raun, 1969a), as well as toward teaching science (Kennedy, 1973). Recognition of the importance of process skills led elementary teachers to change their teaching practices (Bradley, Earp, & Sullivan, 1966), and modeling recommended practices produced positive attitudes toward the practices modeled (Bratt, 1977). Researchers found that preservice teacher preparation programs could affect preservice teachers' attitudes toward teaching science (Gabel & Rubba, 1977), toward student-centered classrooms (Downs & DeLuca, 1979), and toward inquiry (Barufaldi, Huntsberger, & Lazarowitz, 1976). Using inquiry-based curricula was also found to improve attitudes toward inquiry (Lazarowitz, 1976). Researchers reported that early field experiences did not affect preservice teachers' attitudes (Weaver, Hounshell, & Coble, 1979). Inservice workshops improved attitudes toward teaching science (Moore, 1975), toward teaching environmental education (Jaus, 1978), and toward a new curriculum (Ost, 1971) and could affect teaching practices (Mayer, Disinger, & White, 1975; Welch & Walberg, 1967). Jaus (1977) reported that microteaching was

found to improve inservice teachers' attitudes about teaching science, but Bergel (1977) found that microteaching had no effect on the attitudes of preservice teachers. In general, most of the studies indicated that planned interventions positively affected teacher attitudes, at least in the short term.

## ASSESSING ATTITUDES AND BELIEFS

### Quantitative Assessments

Traditional measurements of attitudes in the early research literature relied almost exclusively on quantitative methods. The most popular method of quantitatively measuring attitude was survey instruments with Likert scales where subjects ranked their level of agreement to statements with the use of a five-point scale (Behnke, 1961; Bratt, 1977; Golman, 1975; Sutman, 1969). Semantic differentials were also used to measure intensity of feeling about a statement (Butts & Raun, 1969a; Sunal, 1980). These scales were constructed by generating a series of adjective antonym pairs and placing each pair on opposite sides of a marked continuum. Respondents indicated relative attitude about a construct by placing a mark on each continuum closer to the adjective that described their feelings about the construct. Common examples of adjective antonyms used were *happy-sad*, *interesting-dull*, and *harmful-helpful*. Sentence completion and word associations were also used to assess teacher attitudes (Hovey, 1975; Lowery, 1966; Moyer, 1977). A few examples of qualitative methodologies for assessing attitudes, such as interviewing, were found in the literature but were used in conjunction with quantitative methodologies (Soy, 1967; Thomson & Thompson, 1975). See Pearl (1974) for a comprehensive review and critique of early attitude measurement techniques.

### Qualitative Assessments

About the time research on teachers' attitudes declined in favor of examining teachers' beliefs, qualitative methodologies gained acceptance. This shift in research methodology reflected a movement away from a behaviorist view of the teaching-learning process and toward a more individualized and context-based approach. These qualitative assessments of attitudes and beliefs sought to *understand* the complex relationships among beliefs, experiences, and practices, with less emphasis on predicting and controlling teachers. Even with the growing use of qualitative methods, quantitative methodologies such as semantic differentials (DeSouza & Czerniak, 2003) were occasionally used, and Likert scale instruments (Aikenhead & Otsuji, 2000; Brown, 2000; Pedersen & McCurdy, 1992) remained a popular way for measuring attitudes and beliefs. [For examples of Likert scale instruments used to measure science teachers' attitudes and beliefs see the following: Science Teaching Efficacy Beliefs Instrument for preservice science teachers (Enochs & Riggs, 1990), Science Attitude Scale (Thompson & Shrigley, 1986), Science Support Scale (Schwirian, 1968), Test of Science-Related Attitudes (Fraser, 1981), and Context Beliefs about Teaching Science (Lumpe, Haney, & Czerniak, 2000)].

Whereas attitude researchers have generally favored quantitative techniques, belief research methodologies have tended to be primarily qualitative. There has also been an increase in the number of research studies applying multiple data col-

lection methods (Simmons et al., 1999; Yerrick & Hoving, 1999), though qualitative traditions have dictated selection of methodologies. Interviews have become one of the most popular ways to examine individuals' beliefs and attitudes (Appleton & Kindt, 1999; Duffee & Aikenhead, 1992; Skamp, 2001; Tsai, 2002). Teacher biographies and journaling (Stuart & Thurlow, 2000), open-ended questions (Plucker, 1996; Windschitl, 2000), and case studies (Abell & Roth, 1992; Briscoe, 1991; Zahur, Barton, & Upadhyay, 2002) are also widely used as methods to assess attitudes and beliefs. These latter research tools have enabled researchers to go beyond simply identifying attitudes and beliefs to documenting the complex system of beliefs while shedding light on the development of belief systems within individuals. For a thorough review of the history of research on teachers' beliefs and attitudes, see Richardson's chapter in the 1996 *Handbook on Research in Teacher Education*.

## THEORETICAL MODELS

### Predicting Behavior

Initial interest in teacher attitudes was based on a fairly simple linear model that predicted that positive attitudes toward a behavior were sufficient for implementation of that behavior. Over time, increasingly complex models have been developed to account for the multiple variables affecting decisions to engage in certain behaviors. A behaviorist frame for early attitude/belief research provided a linear model with a stimulus eliciting an attitude that in turn produced an observable response. However, research employing this model indicated a weak to modest correlation of attitudes with behavior; models grew in complexity to encompass other variables. One widely used model, the Theory of Reasoned Action (Ajzen & Fishbein, 1980; Fishbein & Ajzen, 1975), suggests that behavior can be predicted from an examination of an individual's intent to perform the behavior. Intent is dependent on personal attitude toward the behavior and social influences (subjective norm) in favor of or against performing the behavior.

Another widely used model is the Theory of Planned Behavior. Whereas the Theory of Reasoned Action is limited to behaviors over which the individual has volitional control, the Theory of Planned Behavior takes into account the degree to which an individual perceives control (Ajzen, 1985, 1988; Zint, 2002). This model includes perceived behavioral control as a predictor. This variable represents the perception that an individual holds about the opportunities and resources available to perform the behavior. For example, applying this theory to environmental risk education suggests that teachers would teach environmental risk education when they have a favorable disposition toward the instruction, when they perceive social pressure to teach environmental risk education, and when they are confident that they can successfully accomplish the instruction (Zint, 2002).

## SOCIOCULTURAL MODEL OF EMBEDDED BELIEF SYSTEMS

Figure 35-1 illustrates a blended theoretical framework developed by reviewing science teacher attitude and belief literature and by borrowing heavily from theoretical models of social psychology (Jaccard, Litardo, & Wan, 1999). We will use this

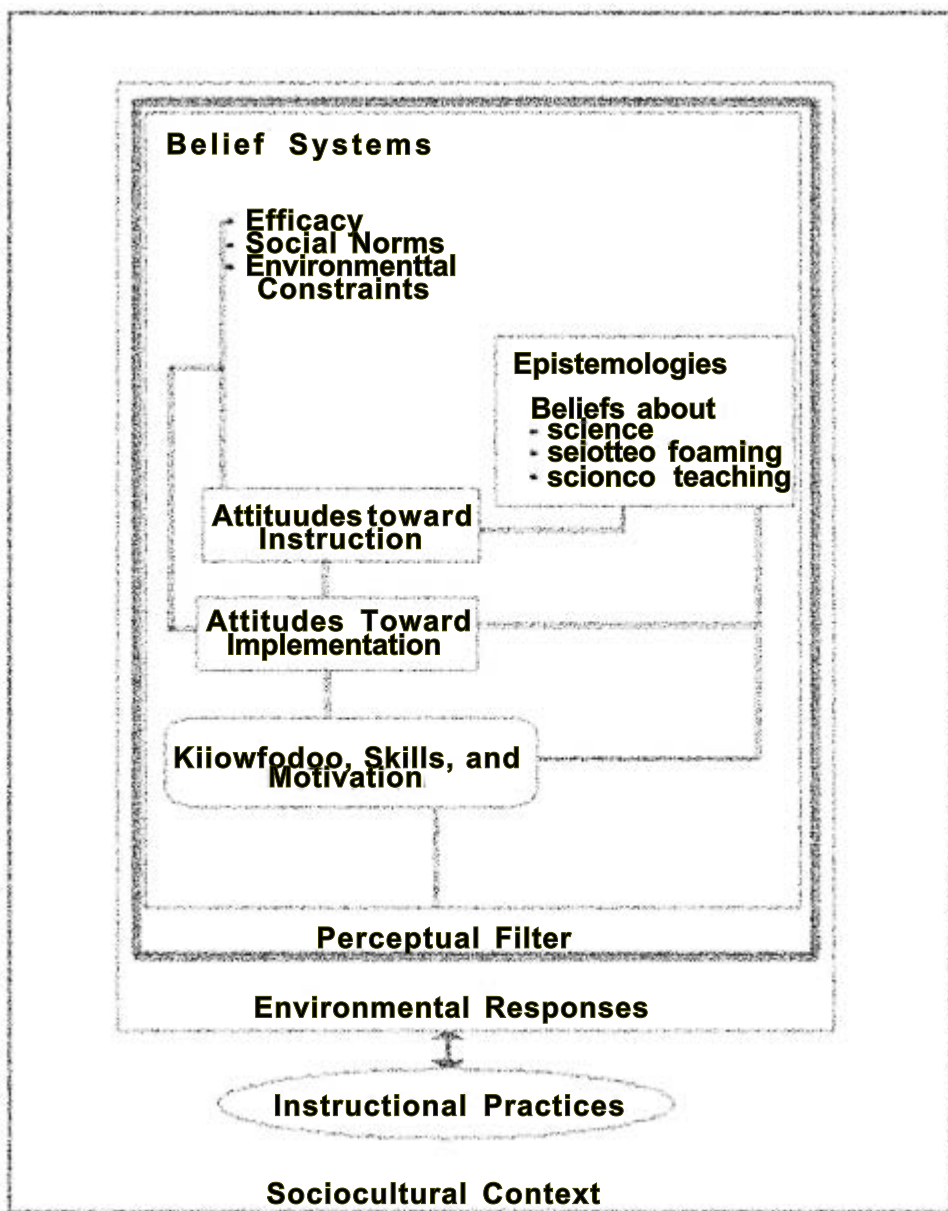

FIGURE 35-1. Sociocultural model of embedded belief systems.

model, the *Sociocultural Model of Embedded Belief Systems*, as a basis for framing recent research on science teacher attitudes and beliefs and as a tool for understanding the construction and development of beliefs and attitudes.

Although the two-dimensional restrictions on illustrating the model may imply linearity of the components, this is not the intention; we acknowledge multiple reciprocal interactions. It is important to note that this model is bound by the socio-

cultural context of the teacher (peers, students, culture, etc.). The cyclical nature of the model denies a point of origin, but we will begin the explanation with motivation, knowledge, and skills. Here it is illustrated that knowledge and skills, as well as motivation, are prerequisites for engaging in a particular instructional practice. Although facilitating construction of knowledge and skills is complex, changing existing belief and attitude structures that underpin the motivation to engage in a set of behaviors is a daunting task.

In this model, motivation is affected by two sets of attitudes, one related to the attitudes about the instructional practice, the other related to attitudes toward implementing the practice. Each attitude set incorporates related belief systems; the relative strengths of the systems determine the strength and direction (positive or negative) of the resultant attitude. The direction and relative strength of each attitude set, defined as a disposition to act, will contribute to the strength of the motivation toward the instructional practice.

As shown in the model, science teachers' attitudes are strongly influenced by epistemological beliefs. From an epistemological viewpoint, knowledge is socially constructed, but beliefs are individually constructed. Thus, a personal epistemology is made up of belief systems that form the perspectives with which one views a particular behavior. Science teachers' epistemologies—which include beliefs about science, beliefs about teaching science, and beliefs about learning science—affect the type of instructional behaviors that occur in science classrooms (van Driel, Verloop, & de Vos, 1998). That is, science teachers' epistemologies frame their teaching paradigms. Preservice teachers enter professional development programs with these core beliefs firmly in place (Cobern & Loving, 2002). Therefore, regardless of a teacher's place along the professional continuum, an instructional strategy perceived as incongruent with that teacher's teaching paradigm will generate a negative attitude response toward that strategy.

The level of motivation is influenced by attitudes toward instructional practices. Attitudes *toward* performing particular instructional practices may have a direction and a strength that are different from attitudes *about* these practices. For example, a study comparing the attitudes of elementary teachers in self-contained classrooms and attitudes of elementary science resource teachers revealed that although resource teachers had a more favorable attitude toward teaching science, there was no difference between the two groups in attitudes about science (Earl & Winkeljohn, 1977). Although having a positive attitude about a behavior and a negative attitude toward implementing a behavior may be interpreted as resulting from conflicts within belief systems, this model emphasizes the highly contextualized nature of instructional practices. Here the relative weights of the beliefs are highly dependent on interactions of a number of factors (Lederman, 1992; Ritchie, 1999; Strage & Bol, 1996), factors that may be overlooked in the research literature (McGuinness & Simmons, 1999). Although we acknowledge that this model of belief systems has multiple components, we have included only those variables that have been repeatedly substantiated in the research literature, including self-efficacy, perceived social norms, and context.

Self-efficacy, or beliefs about one's ability to successfully implement an instructional strategy, has been identified in several studies as a major component in the instructional decision-making process (discussed later in this chapter). Lumpe et al. (2000) outlined the multiple contributions that emerge from the possible inter-

actions of content and efficacy beliefs and showed that decisions about practice are influenced by the relative weights of the components of the belief system.

Perceived social norms, that is, what a teacher believes is expected by others in terms of the teaching and learning process, also influence attitudes about implementing an instructional practice. Perceived environmental constraints, or physical factors that can impede success, such as lack of resources or lack of time, have been identified as underpinning this belief. Strong belief systems that lead to strong teacher identities have been shown to lessen the influence of environmental constraints (Hawkey, 1996).

The relative strengths of all these components at any given time, in any given context, can shift, producing a negative or positive attitude toward implementing the instructional practice. That is, the sociocultural environment as perceived by the teacher ultimately determines whether the instructional practice is enacted, by affecting the relative weights of the major determinants.

Once instructional behaviors are enacted, responses to teachers' actions affect their beliefs, just as beliefs affect actions (Haney, Lumpe, Czerniak, & Egan, 2002). For example, students' epistemologies can affect how they respond to a teacher's instruction (Laplante, 1997). If students have a traditional view of what it means to learn science, they may respond negatively to a teacher's attempt to implement a nontraditional strategy. In turn this response is filtered back through the teacher's perceptions. Whether or not the response will have an impact on a teacher's decision to continue to implement the strategy will depend on the strength of the students' responses as well as the strength of the teacher's beliefs about the practice.

If both attitude sets are negative, then there is no motivation to implement the instructional practice, whether or not the knowledge and skills to do so are present. If one attitude is positive and the other is negative, the relative strengths of attitudes will determine whether there is motivation to undertake the task. Perceived environmental constraints, weak content background, and weak instructional skills all eliminate the possibility of alignment of practice with beliefs (King, Shumow, & Lietz, 2001). If motivation is present but knowledge and skills are not, the instructional practice will either not be enacted or will not be realized in the way it was intended (Sequeira, Leite, & Duarte, 1993).

## **Recent Attitude and Belief Research**

The following sections describe the attitude/belief research from the 1980s to the present day. Although we made no attempt to review every research article on science teacher attitudes and beliefs over the last two decades, a cross section of studies representing research on the major mediators of teaching behavior is included. The research methodologies of the last two decades are distinctly different from earlier research. The knowledge claim shift in attitude/belief research from post-positivist to social constructivist required a shift to qualitative methodologies more suited to examining the complexity and individuality of teaching (Creswell, 2003). Data collection methods in the last two decades have centered on observations and interviews, which are most appropriate for revealing the nature of teachers' thinking and worldviews (Richardson, 1996). Although the evaluative nature of attitudes is still acknowledged, the dynamic nature of the system in context has moved to the forefront.

The *Sociocultural Model of Embedded Belief Systems* frames the sections that follow. The first sections review literature on teachers' epistemologies, sets of beliefs that contribute to the decisions teachers make about their practice. These sections are followed by sections reviewing literature on the personal and environmental constraints perceived by teachers as affecting their instructional decisions.

## SCIENCE TEACHERS' EPISTEMOLOGICAL BELIEFS

Epistemologies are sets of beliefs about knowing and learning that play a mediating role in the processing of new information. Teachers' personal epistemologies emerge from formal and informal learning experiences and serve as mental exemplars for constructing and evaluating their own teaching practices. The research reviewed includes studies examining the origins of beliefs, the influence of belief systems on practice, epistemological shifts, and factors that contribute to belief and practice inconsistencies.

### ORIGINS OF EPISTEMOLOGIES

Prospective teachers enter teacher education programs with images and models of teaching that they experienced as students (Eick & Reed, 2002; Laplante, 1997; Lortie, 1975; Southerland & Gess-Newsome, 1999). As they move through their teacher education programs, these beliefs serve as filters for new ideas (Meyer, Tabachnick, Hewson, Lemberger, & Park, 1999). That is, prospective teachers make sense of practices promoted by the preservice education curriculum in terms of their personal epistemologies. If students' personal epistemologies are not aligned with those of the program, the outcome of instruction may be different from what had been promoted and anticipated (Bird, Anderson, Sullivan, & Swidler, 1993).

Adams and Krockover (1997) investigated the origin of the teaching and learning beliefs of four beginning science teachers. They found that one student adopted a model of teaching based on his own high school experiences. Another student's foundational experience was teaching horseback riding. The other two borrowed primarily from their experiences as teaching assistants, and all borrowed quite heavily from experiences in science content courses.

Smith (2003) examined the prior experiences of two elementary teachers who had similar backgrounds, teaching experience, and time spent teaching science and found that teachers' experiences of learning directly affected their beliefs and practices as science teachers. For example, one of the teachers, Vicki, was not allowed to work on the farm where she grew up or spend much time out of doors. Vicki preferred learning through expository teaching and listening to information transmitted by a teacher. She learned science through courses where teachers taught with lecture and discussion and became successful at memorizing science content. The other teacher, Hannah, used constructivist practices and described her interest in science as beginning with participation in science fairs. Hannah and her family spent time together reading science tradebooks, learning to use microscopes and telescopes, and exploring the geology along a river. Hannah described her best science experiences in learning science in school as those that involved "real life"

(p. 29) applications and deepened her understanding of science. Smith argued that early experiences outside of formal education may have a greater impact on teachers' beliefs about teaching and learning science than their formal education.

This significant link between prior experiences and beliefs about teaching practices has been shown in other studies. Stuart and Thurlow (2000) examined preservice teachers' beliefs during a science and mathematics methods course and found that preservice teachers filtered their developing beliefs about teaching through their prior experiences. "I arrived at these beliefs of how students learn because . . . I've witnessed it in my classroom, and more importantly I've experienced it myself as a student" (p. 118). This relationship was also documented by Skamp (2001) in a study of Canadian preservice teachers who reported that their prior experiences as learners in university undergraduate science classes as well as science methods classes formed their images of good science teaching. However, Skamp observed that this changed once they began to teach in the schools. At this point, teacher education field experiences were most influential in shaping beliefs about good teaching as they saw what worked with their students.

## **EPISTEMOLOGIES AND SCIENCE INSTRUCTIONAL PRACTICES**

Despite the latest reform efforts, most science teachers in the United States tend to hold epistemological beliefs aligned with a behaviorist tradition. Although professional development workshops have successfully encouraged the adoption of some constructivist strategies, the adoption of these practices does not necessarily affect the teachers' epistemologies. For example, in 1996 a survey of K-12 teachers ( $N = 148$ ) indicated that although many had adopted instructional practices aligned with constructivism, the majority did not believe that students learned by constructing their own understanding (Czerniak & Lumpe, 1996).

Taiwanese teachers have also been found to hold a traditional or transmission view of the nature of science, learning science, and teaching science. Tsai (2002) interviewed physical science teachers and found that more than half of the teachers believed that learning science is acquiring knowledge, that science provides correct answers (nature of science), and science is taught best by transferring knowledge from the teacher to the students. Less than 15 percent of the Taiwanese teachers in the study held constructivist views of learning science, teaching science, or the nature of science.

Several research studies have clearly indicated the influence of epistemologies on practice. Hashweh (1985) examined the relationship between being a constructivist teacher and the types of teaching strategies used. He found that teachers who held constructivist beliefs had a larger repertoire of teaching strategies and used strategies that would promote conceptual change.

Benson (1989) reported that epistemological beliefs at odds with a constructivist curriculum inhibited the implementation of a constructivist curriculum. A case study of two middle-grades teachers implementing a curriculum on wildlife species revealed that beliefs about learning science as a body of facts inhibited the implementation of the discovery-oriented curriculum (Cronin-Jones, 1991).

Brickhouse (1990) found that teachers' views about how scientists construct knowledge were consistent with how they believed students should learn science.

For example, one of the teachers in the study believed that scientists use scientific theories to make sense of observations and therefore believed that students should use theories to explain their observations within the science classroom. Furthermore, teachers' beliefs about science influenced explicit lessons about the nature of science as well as the implicit curriculum about the nature of scientific knowledge. Gallagher (1991) reported that science teachers who hold positivist views of science tended to emphasize the scientific method and the objective nature of science.

Hashweh (1996) studied 35 Palestinian science teachers who described themselves as either constructivist or empiricist (as defined by a questionnaire). He found that the constructivist teachers were more likely to recognize students' alternative conceptions and to indicate they would use a variety of teaching strategies than did empiricist teachers. Hashweh argued that constructivist teachers view the development of knowledge as residing at the student level and as a result view science as a process of conceptual change. Thus, the teachers in this study selected instructional strategies that were congruent with their beliefs about science and science learning.

A case study by Richmond and Anderson (2003) of three secondary science teacher candidates clearly revealed the influence of their epistemologies on practice. One teacher's beliefs about science as a body of facts shaped his planning and teaching. Furthermore, his focus on science as facts led him to assess low-level understanding rather than conceptual development. Another teacher viewed her primary role as a science teacher as helping students appreciate science. As a result, she spent her planning time creating an engaging instructional setting and much less time on determining if students had developed the targeted scientific understandings.

Zipf and Harrison (2003) conducted a qualitative study of two Australian elementary science teachers and examined the relationship between these teachers' beliefs and their teaching practices. Patty, a more traditional teacher, tended to use worksheets and emphasize content in her teaching. She used the textbook in her planning to map out the content and stated, "I'm happy for the text to choose what we teach . . . the textbook has to be not only a student reference but the main resource for the lesson" (p. 7). Furthermore, Patty believed the textbook was the tool that allowed her to meet the wide variation in her students' abilities: "[We need a textbook] that's got a bit of everything in it for all learners, low, middle, high ability" (p. 7). In contrast, Tina wanted to use a textbook that would support her belief in teaching relationally and would allow her "students to experience and actively participate in science" (p. 9). The differences in these two teachers' beliefs about teaching and learning were further translated into their assessment practices. Tina used open-ended formative assessments in her instructional unit to provide her with continuous feedback on student learning, whereas Patty "favored end-on marks-based assessment techniques focusing on science content and felt that she 'must have marks'" (p. 6).

## EPISTEMOLOGICAL BELIEF SYSTEMS AND CHANGE

Teachers' epistemological beliefs tend to be relatively stable and resistant to change (Pajares, 1992). This is particularly true of experienced teachers. Luft (2001) found that an inservice program designed to promote inquiry teaching changed the be-

liefs of induction teachers, but changed only the practices of experienced teachers. BouJaoude (2000) used metaphors to assess preservice science teachers' beliefs as they progressed through their teacher education program and found that the program was successful in affecting beliefs. The types of metaphors the prospective teachers used showed that 75 percent of the preservice teachers held a transmission view of teaching at the beginning of the year; this number dropped to 34 percent by the end of the year. The number of teachers who held constructivist-based views grew from 1 percent at the beginning of the year to 50 percent at the end of the year. BouJaoude also found that biology teachers were more likely to hold a transfer model of teaching than chemistry or physics teachers throughout the course of the study. Teachers' metaphors have been used in many studies to elicit teachers' epistemological views, because metaphors can reveal the subtle assumptions and frames that teachers apply to their practices.

Although preservice and induction teachers' beliefs tend to be more malleable (Salish I Research Project, 1997), research has indicated that the belief systems of these groups may remain virtually unchanged, despite the constructivist traditions of their teacher education programs. Cronin-Jones and Shaw (1992) reported that preservice teachers' beliefs remained relatively unchanged by participation in a science education program. These researchers found that their elementary and secondary preservice teachers had similar clusters of beliefs about teaching and learning both before and after their participation in a methods class.

Even if a teacher education program is successful in moving students toward a constructivist epistemology, the stability of this change is dependent on the socio-cultural context. Stofflett (1994) reported that a preservice teacher education program had successfully moved preservice science teachers from a traditional epistemology to a constructivist epistemology. However, Stofflett found that classroom practice during student teaching was not likely to be constructivist unless the cooperating teacher supported the classroom practice. In another example of sociocultural influences on instruction, Haney and McArthur (2002) conducted a case study with four preservice science teachers, examining their beliefs about constructivist practices and how consistent these beliefs were with classroom practices. They identified central or core beliefs (those that are both stated and enacted) and peripheral beliefs (those that are stated but not enacted). During student teaching, the preservice teachers whose beliefs were a mismatch with those held by their cooperating teachers had the most difficulty incorporating new beliefs into changes in teaching practices. At times, peripheral beliefs moved into core beliefs when preservice teachers felt supported by the cooperating teacher. When peripheral beliefs were not supported, they did not move from stated beliefs to implemented beliefs.

In a large-scale research project on beginning teachers' beliefs and practices, Simmons et al. (1999) indicated that although beginning teachers espoused a student-centered approach, perhaps as a result of their undergraduate programs, their practices were not aligned with their beliefs. They found that beginning teachers held many beliefs about science teaching and learning, and that these beliefs were not always aligned with any one belief system. The study also revealed the vacillation between beliefs that many teachers articulated in the early years, as well as the articulation of beliefs that contradicted their practices. However, by the third year, many teachers espoused the teacher-centered beliefs that aligned with their teacher-centered practices.

A survey of nine teacher education programs found that the characteristics of the program determined whether graduates of the program adopted the advocated philosophy (Tatto, 1998). The more successful programs in achieving this alignment had the following characteristics: a consistent philosophy promoted throughout the program, faculty who maintained and espoused a consistent vision, context-relevant experiences, learning cohorts, and personalized programs.

Moss and Kaufman (2003) surveyed preservice science teachers' beliefs about classroom organization, management, and rules and found that teachers hold complex views about class management that were not supported by their philosophical and theoretical stances. Although preservice teachers may have held progressive ideas about teaching, they felt unable to implement these views in their teaching and instead focused on control and maintaining order.

Yerrick and Hoving (2003) examined preservice teachers' beliefs about teaching and learning that the teachers held while enrolled in a field-based course that focused on culturally diverse students. Prospective teachers who made changes in their instruction were reflective and engaged in the production of new knowledge of teaching. Other teachers, who were unable to make changes, tended to filter their perspectives through their own prior educational experiences. This latter group of teachers Yerrick and Hoving called "reproducers" (p. 404) because they sought to reenact their own recollected science experiences with new groups of students. These reproducers rarely mentioned student learning in their reflections and tended to focus on management of student behavior as a measurement of their success in teaching. Other prospective teachers, designated as "producers," saw themselves as learners and recognized the need to change. These producers altered their beliefs and changed their instruction to more effective strategies.

Yerrick, Parke, and Nugent (1997) found that inservice teachers participating in a professional development workshop held traditional views on entering the workshop and left the workshop with many of these views intact. The researchers observed that teachers changed the way they talked about teaching and did indeed incorporate some of the ideas from the workshop into practice. However, the researchers noted that the participants had "rooted out" strategies that conflicted less with existing belief systems and had incorporated those ideas into their existing belief structures.

## Summary

Recent attitude/belief research has revealed how individuals' epistemological systems are constructed through their formal and informal experiences as students. These systems are extremely stable because new information is filtered through these systems and because the enactment of this system has been modeled for a number of years.

Preservice teachers' systems seem less resistant to change, although lack of content and pedagogical knowledge may inhibit change. Inservice programs have been successful in getting teachers to assimilate new practices, but without a corresponding change in beliefs. Preservice and inservice programs should be cognizant of existing belief systems, should assist teachers with recognizing their beliefs, and should provide long-term support to newly born epistemological practices. Researchers have argued that significant changes in teachers' instructional practices

come only after there are fundamental changes in teachers' belief systems and that these changes are not necessarily linear. Therefore, there may be a lag time between changes in beliefs and changes in practices that may not be captured by the research project. What is clear from some research is that the process of making epistemological and personal beliefs explicit is critical for professional development. Teachers may not recognize the contradiction between their beliefs and practices (Tobin & LaMaster, 1995). According to Kagan (1992), "If a program is to promote growth among novices, it must require them to make their preexisting personal beliefs explicit; it must challenge the adequacy of those beliefs; and it must give novices extended opportunities to examine, elaborate, and integrate new information into their existing belief systems" (p. 77).

### **BELIEF AND PRACTICE MISMATCH: CONSTRAINTS TO PRACTICE**

In the previous section on epistemological change, belief-practice mismatch seemed to be a result of either the stability of the initial epistemological system or lack of support for the enacted constructivist epistemology. Many studies have substantiated belief-practice inconsistencies in other contexts, and other factors that may contribute to this mismatch have emerged.

Justi and Gilbert (2002) investigated teachers' beliefs about the use of models and modeling for teaching science phenomena. The researchers argued that to learn science, students need to know major scientific models; to learn about science, students should understand the nature of scientific models and role of models in scientific inquiry; and to understand how to do science, students must be able to create and test their own models. Through the use of a semistructured interview with 39 Brazilian teachers (four different grade levels from primary to university), Justi and Gilbert explored teachers' beliefs about the status and value of models in science as well as how these beliefs were translated into instructional practices. Teachers in the study noted that they believed that models could (a) make science more interesting; (b) provide a framework for explanations of phenomena; (c) make abstract concepts more understandable; (d) promote conceptual change; and (d) promote learning about the nature of science. Although the teachers in the study valued using models to help students learn science, they did not widely report using models in practice.

Part of the developmental process of moving from student to teacher involves a shift in focus from self to one's students (Jones & Vesilind, 1995). Regardless of belief systems, there is evidence that novice teachers make instructional decisions for their students based on their own needs and not their students' needs. Peacock and Gates (2000) examined newly qualified United Kingdom teachers' perceptions of textbook selection and use. They found that these teachers did not base their decisions about textbook use on their students' needs but instead made decisions based on their beliefs about the demands that would be placed on them as teachers.

In a study of preservice teachers' beliefs, Lotter (2003) examined teachers enrolled in a secondary science methods course and found that preservice teachers expressed the most concern about issues related to themselves rather than their students. These same teachers expressed positive attitudes about the value of inquiry

teaching as a way to increase students' critical thinking, motivation, ownership of science, and comprehension.

### SOCIAL NORMS

Teacher beliefs are situated in the contexts of the existing social norms of the school community. Social norms influence how teachers believe their enacted practices will be perceived. For science teachers, this tension between beliefs and practices may arise when they are teaching about controversial issues such as evolution.

Elementary and secondary teachers' beliefs about teaching science-technology-society (STS) as part of the science curriculum were investigated by Lumpe, Haney, and Czerniak (1998). Through the use of both open and closed questionnaires, teachers' beliefs about STS were assessed within Ajzen and Madden's (1986) Theory of Planned Behavior. The questionnaires were designed to elicit teachers' beliefs about the advantages and disadvantages of implementing STS, beliefs about who might approve or disapprove of their implementation of STS in their classroom, and factors that might encourage or discourage them from STS implementation. Teachers indicated that they believed STS would help students learn science and would assist students in applying science to their everyday lives. However, teachers were concerned about the time it takes to implement STS as part of the science curriculum. Other concerns about STS centered on teaching controversial issues as well as concerns about religious groups' reactions to STS instruction.

### ENVIRONMENTAL CONSTRAINTS

Teachers may state that they hold one set of beliefs about teaching and learning while revealing their perceptions of constraints to enacting their beliefs. Collison (1993) found, as have many researchers, that teachers who reported that they did not use hands-on science indicated they could not because they lacked the materials and supplies needed.

In many cases, the contradictions between beliefs and practices arise from the perceived sociocultural context. An in-depth look at the beliefs and actions of an experienced high school science teacher revealed beliefs about teaching science that were at odds with beliefs about how students learn. Although this dichotomy in thinking was revealed to the science teacher, the teacher felt that his beliefs were aligned with practice. He explained that he was acting out his belief systems as well as he could in the *context* in which he was teaching (Lyons, Freitag, & Hewson, 1997). In contrast, a case study of a novice middle-grades science teacher indicated that he was aware that his beliefs about science were not aligned with his beliefs about learning science, but he felt that institutional constraints left him little time to reflect on this misalignment (Brickhouse & Bodner, 1992).

A study of Chinese teachers' and teacher educators' epistemological beliefs about inquiry-based learning showed that although Chinese teachers believed that inquiry-based teaching was a good way to teach science, these teachers believed there were significant barriers to implementing inquiry teaching (Zhang et al., 2003). In this study, 220 teachers and teacher educators completed a questionnaire about their constructivist and traditional views of science and science education, and 12 in-

dividual interviews were conducted to obtain more in-depth data. The Chinese science educators indicated that barriers to implementing inquiry-based teaching included the need to prepare students for the college entrance examination, which did not assess inquiry, the need for different curricular frameworks and materials for inquiry, large class size (including issues with class management), and concerns about a lack of teacher preparation to teach with inquiry.

DeSouza and Czerniak (2003) explored teachers' intent to collaborate with other teachers to address their students' needs and found that their perceived behavioral control was more significant than their attitudes toward the behavior. The teachers believed that collaboration to provide instruction for students from diverse backgrounds would not occur unless there was more time to collaborate, good facilities and technology, and support from colleagues.

## Summary

Research has shown that teachers can believe that an instructional practice is important but, for any number of reasons, resist engaging in the practice. This contradiction may emerge as a result of lack of knowledge or because other instructional issues, such as discipline, take precedence. Also, teachers may feel that some practices are controversial and the risk of engaging in a particular instructional strategy outweighs the perceived benefits. In addition, science teachers consistently note that there are insufficient time and materials to support new practices. However, the contradictory nature of a belief/practice system may not be totally negative. Constraints, which may have appeared insurmountable, may be viewed differently if belief systems are changed (Tobin, Briscoe, & Holman, 1990). This conflict between belief and practice may produce the disequilibrium needed for change to occur.

## EFFICACY, EPISTEMOLOGIES, AND TEACHING PRACTICES

Research indicates that teaching efficacy is a complex construct influenced by a number of variables. Desouza, Boone, and Yilmaz (2003) assessed 300 teachers from India, with the use of the Science Teaching Efficacy Belief Instrument (STEBI-A) developed by Riggs and Enochs (1990). They found higher teaching efficacy for teachers who held a science degree and who spent more time teaching science each week. Interestingly, teachers with more experience were less confident of their students' achievement (outcome expectancy) than those teachers with less experience.

There is research evidence that teachers who lack confidence about teaching a subject will give it minimal emphasis within the curriculum. This pattern is painfully evident in elementary science instruction. Jones and Levin (1994) examined elementary teachers' attitudes toward science and science teaching and found that preservice teachers had significantly more confidence about science teaching than inservice teachers, and males had more confidence than females. The researchers also found that there was a positive relationship between the number of science courses teachers had completed and their attitudes about teaching science. Teachers who had completed three or more science courses ranked science as a higher instructional priority than teachers with fewer science courses.

Woolfolk and Hoy (1990) suggested that teaching efficacy (in a general sense) is related to teachers' experiences managing and motivating students. Furthermore, beginning teachers' success or failure in acting on their beliefs about student management may influence the development of a sense of efficacy. The researchers assessed 182 preservice teachers' teaching efficacy, personal teaching efficacy, pupil control ideology, and motivational orientation (controlling or autonomous). They found that preservice teachers possessed teaching efficacy independently of personal efficacy. Personal efficacy included beliefs about responsibility for positive student outcomes and beliefs about responsibility for negative student outcomes. Woolfolk and Hoy reported that prospective teachers who had high teaching efficacy were more humanistic in relation to pupil control than those prospective teachers who were low in teaching efficacy. However, the authors noted that this was true only for prospective teachers who also had high personal efficacy and believed that they could make a difference in student achievement.

Cakiroglu and Boone (2000) explored the relationships between elementary preservice teachers' self-efficacy and their conceptions of photosynthesis and inheritance. Teachers who had relatively high personal science teaching efficacy held fewer alternative conceptions related to photosynthesis. Surprisingly, the study failed to find any relationship between the number of high school and college courses completed and the number of alternative conceptions held by the prospective teachers.

### **Affecting Self-Efficacy**

Students' responses to instructional practices can alter teachers' beliefs about teaching and learning science. A recent study (Sweeney, Bula, & Cornett, 2001) elucidated the change in the personal practice theories of a first-year chemistry teacher from a goal of preparing future scientists to a belief that this job meant preparing scientifically literate citizens.

For teachers to believe that changes in instruction will make a difference, Bandura (1986) suggested that teachers need to have feedback, experience success, observe models of success that are credible, and be persuaded that the concerns can be overcome with positive benefits. Bandura also suggested that affective feelings that arise from success will affect the teacher's self-efficacy. Evidence for the relationship between attitudes, beliefs, and affect was found in a set of case studies of prospective elementary teachers conducted by Palmer (2002). He reported that elementary teacher candidates' attitudes changed when they had external validation for their work, experienced success teaching children, and had a confident and supportive teacher who modeled teaching behaviors and used simple, understandable language. These factors increased the preservice teachers' positive interest and self-efficacy.

As beginning teachers experience success, the type of support they receive may affect their self-efficacy. Luft, Roehrig, and Patterson (2003) studied three types of induction programs (general support, science-focused support, and no support) and found that teachers who participated in a science-focused induction program were more likely to implement student-centered inquiry lessons, believe in student-centered practices, and feel fewer constraints within their teaching than teachers who participated in either the general support group or did not participate in an induction group. In addition, the science-focused support group participants were

more likely to use laboratories and to implement standards-based lessons than teachers in the other groups. Teachers in the no induction group held significantly more didactic beliefs about teaching than teachers in the science-focused support group. This study provided evidence that beliefs can be shaped and scaffolded by appropriate support during the early stages of learning to teach.

## Knowledge and Skills

One obvious reason for the conflict between beliefs and practices as indicated in the *Sociocultural Model of Embedded Belief Systems* (Fig. 35-1) is a lack of knowledge and skills needed to implement the preferred practice. Not knowing how to implement a specific teaching behavior is an insurmountable roadblock to engaging in the strategy, regardless of strength of beliefs about its effectiveness. Atwater, Gardner, & Kight (1991) studied primary (K-3) urban teachers' attitudes toward physical science and found that early-grade teachers believe that using hands-on approaches is the best way to teach physical science (100 percent), that they feel insecure about attempting to teach physical science (60 percent), and that it makes them nervous to even think about having to do a physical science experiment (84 percent). Tosun (2000) assessed prospective elementary teachers' prior science coursework, achievement in science courses, and science teaching self-efficacy and found that prospective elementary teachers had overwhelmingly negative attitudes toward science, using terms such as "boring," "meaningless," "scared," and "impossible" (p. 376) to describe their previous science coursework.

According to Tobin et al. (1990), teachers may have a misalignment of beliefs and practice without knowing how to address the mismatch. One teacher was dissatisfied with her practice and believed that science teaching should be other than what she was doing, but had no vision of practice. Through intervention she was gradually able to align her belief and practices.

In a case study of a preservice elementary teacher, Bryan and Abell (1999) observed that inconsistencies between teacher practice and vision emerged during the student teaching experience. The resulting tension between the beliefs and practice led to professional growth. The authors stated that professional knowledge emerges as a result of experience, not before experience.

## Environmental Response

The link between professional growth and the belief-practice mismatch was also examined by Guskey (1986). He proposed that changes in teachers' beliefs come only after teachers have changed their teaching practices, which results in changes in their students' learning (the environmental response seen in the *Sociocultural Model of Embedded Belief Systems*, Fig. 35-1). Guskey suggested that staff development leads to changes in teachers' classroom practices, which change students' learning outcomes. Changes in teachers' beliefs and attitudes follow changes in behavior. Guskey stated, "Evidence of improvement (positive change) in the learning outcomes of students generally precedes and may be a prerequisite to significant change in the beliefs and attitudes of most teachers" (p. 7). The model is based on observations that teachers believe a strategy can be successful only after they have seen it successfully work in their own classroom.

## Summary

Research suggests that teachers with more science content knowledge spend more time teaching science; teachers who lack confidence tend to teach content less. In addition, teachers with greater teaching efficacy tend to be more humanistic in relation to pupil control, and teachers with high science teaching efficacy may hold fewer alternative conceptions than teachers with less science self-efficacy. A teacher's self-efficacy is influenced by responses of others to her teaching practices. Therefore, the sociocultural context may inhibit change as cooperating teachers, colleagues, administrators, parents, and students challenge practices that do not align with their vision of teaching and learning.

## Teachers' Beliefs and Educational Reform

*A systems view of beliefs.* As the *Sociocultural Model of Embedded Belief Systems* (Fig. 35-1) shows, instructional practices are influenced by a complex set of belief systems, prior knowledge, epistemologies, attitudes, knowledge, and skills. Many efforts to reform science education have come and gone with minimal impact because they failed to conceptualize reform as situated within this complex system. The emerging research on attitudes and beliefs sheds light on why reform movements have failed to have a lasting impact.

In a survey of 1000 elementary teachers (Bayer Corporation, 1995), a majority of the teachers reported that they were not knowledgeable about recommendations for the reform of science education. Only 56 percent of the respondents indicated that they were well qualified to teach science. Only a third of the teachers reported that they were scientifically literate enough to understand stories about science on TV, in newspapers, or in magazines. A majority of the teachers believed the emphasis on science education should increase and that teachers should use more hands-on science instruction and experimentation. When teachers were asked about their perceptions about obstacles to teaching hands-on science, 73 percent indicated lack of time, 70 percent indicated a lack of equipment, 51 percent felt they lacked an understanding of science, 30 percent believed their administrators did not place a priority on teaching science, and 38 percent noted they lacked interest in teaching more hands-on science.

*Intent to reform: The theory of planned behavior.* Feldman (2002) found that the degree to which reform curricula in physics were implemented varied greatly from teacher to teacher. To investigate this phenomenon, he compared two physics teachers with similar teaching situations and backgrounds, but with different degrees of experience in implementing the new curriculum. Both teachers indicated that they had concerns about how much time was needed to implement the new curriculum to allow for student investigation, and both indicated that they saw the potential of the new curriculum to intellectually engage and develop students' understandings. Despite these similarities, one teacher enthusiastically embraced the new curriculum, and the other did not. Feldman concluded that many factors trigger teachers' acceptance of a new curriculum, including epistemological stances, situational contexts, and knowledge of the epistemological basis of the curriculum.

## Concerns about Reform

Haney, Czerniak, and Lumpe (1996) examined teachers' beliefs about the state of Ohio's competency-based science model and their intent to implement the reform strands (scientific inquiry, scientific knowledge, conditions for learning science, and applications for science learning) by applying Ajzen's (1985) Theory of Planned Behavior. This theory suggests that attitude toward the behavior, the subjective norm, and the perceived behavioral control (primarily variables), accompanied by salient beliefs can predict whether a person will behave in a particular way. Salient beliefs, according to the Theory of Planned Behavior, include the extent to which an individual believes the behavior will lead to a favorable outcome, the belief that other people think the behavior should be performed, and the beliefs about the extent to which internal (ability, skill, and knowledge) and external (opportunity, cooperation, and resources) factors exist. This theory has been applied to students' learning in science (Allen & Crawley, 1993; Crawley & Black, 1992; Crawley & Koballa, 1992) and to teachers' intentions to engage in reflective teaching (Desouza, 1994). Haney et al. (1996) surveyed 400 teachers and found that teachers' attitudes about implementing the reform model significantly influenced their intent to implement the model into their classroom practices. Furthermore, they found that the resources teachers believed were available (obstacles and enablers) were less important to them than their beliefs about whether the reform would have positive or negative outcomes. The teachers surveyed did not believe that significant people in their teaching environment would support their efforts to implement the Ohio reform effort, or that the available support was valuable. Female teachers in the study indicated they were more likely to implement the reform model than male teachers, and elementary teachers were more likely than middle or high school teachers.

Beck, Czerniak, and Lumpe (2000) examined Ohio elementary, middle, and high school teachers' beliefs about implementing components of constructivism (personal relevance, crucial voice, shared control, scientific uncertainty, and student negotiation) within the Theory of Planned Behavior. Teachers who held bachelor's and master's degrees had more positive attitudes toward teaching for personal relevance than teachers who had doctoral degrees. Not surprisingly, attitude toward teaching for critical voice was a significant predictor in the study of teachers' intent to implement critical voice in their classroom. Teachers expressed concern about the amount of time it takes to prepare and teach for personally relevant instruction as well as concerns about having to cover less content in order to teach for personal relevance. Although teachers believed that teaching for shared control can "help students take a vested interest in and ownership of their learning" (p. 336), they were concerned about students' immaturity and inexperience in the use of shared control in learning contexts. Across grade levels, teachers were concerned about classroom management but held positive attitudes about teaching for student negotiation. Teachers believed that a lack of planning and class time was a barrier to implementing constructivist practices. Some felt that planning for constructivist teaching took too long and that it took too long for students to develop understandings of concepts.

Haney et al. (2002) selected six teachers from a National Science Foundation systemic change project in Ohio and analyzed their teaching practices in terms of self-efficacy. With the exception of one subject, teachers with higher self-efficacy

tended to engage more frequently in constructivist teaching practices such as inquiry, collaborative projects, and preassessments.

Perceptions of constraints are often contextualized and situation specific, as shown in a study by Yerrick and Hoving (1999) that examined teachers' perceptions of obstacles to their implementation of new technology. In particular, the researchers focused on teachers' perceived behavioral control and social support. Teachers in the study received the same resources, including financial and curricular support, but differed in their implementation of the project based on their specific context. For example, one group of teachers used the new technology for real-time data collection and inquiry, whereas another group of teachers used the technology to complete traditional tasks such as looking up information or preparing presentations. Differences in implementation were accompanied by differences in perceived control and support. For example, the teachers who used technology with inquiry viewed obstacles as problems to be solved and believed their school culture supported their efforts to meaningfully implement new instructional technology. The more traditional teachers perceived obstacles as reinforcement for their beliefs that change within the school context was impossible; as a result they were unable to successfully overcome barriers for the implementation of the new technology.

## Summary

Teachers have distinct beliefs about efforts to reform science education, and these beliefs shape the subsequent implementation of new innovations and reform efforts. Studies have shown that elementary teachers believe they lack time, equipment, administrative support, interest in science, as well as knowledge of science. Efforts to introduce an innovation are filtered through teachers' beliefs about the goals and purposes of the innovation as well as the amount of time teachers perceive an innovation will require. Other studies have shown that there are differences in the implementation of reform by gender and the amount of professional preparation that a teacher has completed. Concerns about specific classroom contexts as well as beliefs about class management influence how reform is perceived by teachers. Finally, the degree to which teachers believe the school culture supports their efforts to be innovative can affect the success of reform implementation.

## BELIEFS ABOUT SCIENCE EDUCATION AS A ROAD TO EMPOWERMENT AND SOCIAL JUSTICE

During the 1980s, an interest in teaching for social justice emerged from constructivist research (Creswell, 2003). Social justice researchers proposed that the primary goal of research should be the development of action agendas to address the lives of marginalized groups. The sections that follow describe the influence of teacher beliefs on teaching practices from a social/political point of view.

## Controversial Issues

Teachers' beliefs about the role of science and science instruction in the future of their students' lives affect the topics they teach and how topics are framed within

the curriculum. The teaching of controversial issues is one way that teachers promote democratic participation and social justice. An international study of teachers' beliefs about the role of controversial issues in the teaching of science found that all of the teachers reported teaching about controversial topics in science, such as nuclear energy or global warming. Furthermore, teachers indicated that they believed this was an important part of their job, "as responsible citizens—we teachers are charged with the education of the future citizens and leaders of this country—we have an obligation, so we have to (teach) . . . issues such as global warming, deforestation, and rain forest" (Cross & Price, 1996, pp. 323–324). The teachers surveyed indicated that they recognized the political and economic aspects of science related to social justice, and some of the teachers felt the need to provide their students with information so they could participate democratically in the debate over controversial issues. Teachers varied in their beliefs about whether or not teachers should express their own positions in discussions of controversial issues.

Environmental education used with preservice elementary teachers has been shown to improve prospective teachers' attitudes about science. Brown (2000) measured preservice teachers' attitudes before and after an environmental science course and found that the course had a positive impact on preservice teachers' attitudes about the social benefits of science and the problems that accompany scientific progress.

### **Empowerment through the History of Science**

One way that science educators have promoted social justice and empowerment is through the inclusion of the history of science in science instruction. This position is based on beliefs that for students to become scientifically literate and capable of participating in democratic decision-making, they need to be able to understand the past complexities of science and society (Conant, 1951) as well as the conceptual, procedural, and contextual aspects of science (Klopfer, 1969). Wang and Marsh (2002) surveyed and interviewed elementary and secondary teachers to determine their beliefs about the value of the history of science and their practice in using it in their science teaching. Teachers at both elementary and secondary levels indicated that they did not believe the history of science was appropriate for elementary science instruction. The teachers who included the history of science in their teaching believed that teaching the history of science is a way to show that science is a human endeavor and helps students understand how social factors or political power are tied to science. Furthermore, some teachers used the history of science as a way to show the contributions of different cultures and to teach students about cultural heritage and diverse role models. Teachers indicated that the curriculum was overcrowded and as a consequence only incorporated history of science topics when they could be blended into the existing curriculum.

In another study, Wang and Cox-Peterson (2002) reported that elementary teachers, more than high school teachers, placed emphasis within the history of science on helping students understand the role of science in society, developing positive attitudes toward the study of science, and as a way to bring role models or diversity to students' conceptions of science. High school teachers tended to use the history of science as a way to help students understand science content, the nature of science, and science process skills. In addition, Wang and Cox-Peterson found that although elementary, middle, and high school teachers expressed beliefs about the importance of teaching the history of science, this belief was not congruent with

their instructional practices. An earlier study by King (1991) examined preservice teachers' beliefs about teaching and learning the history and philosophy of science. She found that the majority of preservice teachers thought that history and philosophy of science are important, but they "did not have a clue how to teach this way, or even enough knowledge to (in one student's words) 'ask the right questions'" (p. 238).

### **Social and Community Change**

Other teachers go beyond teaching a few topics to promote social change to framing their overall teaching role within the larger goal of promoting student empowerment and social change within the community. A case study of one science educator in Pakistan found that this teacher believed that science education "ought to be about empowering students to make physical and political changes in the community" (Zahur et al., 2002, p. 899). The case study showed that this Pakistani teacher believed that students' low levels of achievement were tied to poor children's families' lack of power and influence over the processes of schooling, and that one way to address social inequities is to provide students with knowledge of health and environmental issues. The purpose of science education for this teacher was to bring students and families together to make changes for the improvement of the society (including addressing garbage, sewage, clean water, and pollution control).

### **Summary**

There is increasing research that explores how teachers use science teaching as a mechanism for social justice and empowerment. Teachers who view their profession as a way to make the lives of the students better use their teaching to evoke change. Studies have shown that teachers report that they believe teaching the history of science can teach students about science as a human endeavor, the social and political factors related to science, and the impact culture can have on science investigations. Other studies have shown that some teachers believe they can promote social change within the community by teaching students to address social inequities related to health and the environment.

## **CULTURE/CONTEXT**

Some of the most insightful studies in the area of beliefs and attitudes conducted in the last decade have examined how belief systems differ across contexts and cultures. Within the *Sociocultural Model of Embedded Belief Systems* that we have presented (Fig. 35-1), the sociocultural context undergirds belief systems and is tied to attitudes, motivation, knowledge, and skills. By examining commonalities and differences for teachers in different instructional settings, we can better understand the situated nature of belief systems.

### **The High School/College Divide**

Razali and Yager (1994) examined how perceptions of the importance of knowledge and skills needed by students when they enter college chemistry differed for high school and college chemistry teachers. College teachers identified students' per-

sonal attributes as significantly more important than specific knowledge and skills. High school teachers indicated that knowledge and skills were more important for college preparation than personal attributes. Razali and Yager speculated that high school teachers have traditionally viewed the goal of secondary science as preparing students to take examinations over a prescribed syllabus, whereas the college professors seek independent learners who have attributes such as study skills, imagination, interest, creativity, and inquisitiveness.

### **Sociocultural Factors and Attitudes**

Context emerged as the critical factor in a study of teachers' attitudes toward the philosophy of science (Gwimbi & Monk, 2003). Teachers' responses to a questionnaire designed to measure teachers' views of the philosophy of science were analyzed by school affluence. The attitudes of teachers from poorer schools were significantly different from those of teachers from wealthier schools. Teachers from richer schools had more relativist and deductionist attitudes, whereas teachers from poorer schools were more positivist and inductivist. Gwimbi and Monk noted that, although the richer schools were able to hire better qualified teachers, the school context reinforced the differential distribution of attitudes. The researchers maintained that teachers teach the way they do not because of how they think, but instead because of where they work.

### **Cross-Country Contexts**

Studies of teachers from different countries have shown that the impact of teacher education is influenced by the beliefs and values of the larger culture. Through the use of questionnaires and interviews, Thompson and Orion (1999) compared pre-service teachers' attitudes and perceptions from Israel and England/Wales during and at the end of the teacher education programs. Teachers from both regions initially had similar reasons for wanting to teach, and both groups changed their views about science education after the program. The British teachers held a more pupil-oriented approach to teaching science and management than the Israeli teachers. However, the Israeli teachers held a more progressive view of the socializing aspects of education than the British teachers. Both groups were overconfident and underestimated the complexity of skills needed to be a successful teacher. Thompson and Orion noted that teaching is held in higher status in England and Wales than in Israel. In addition, approximately 75 percent of Israeli teachers were female, whereas only 40 percent of English teachers were female. Salaries were also lower in Israel, where teaching is sometimes viewed as a secondary wage for women whose spouses provide the primary support for the family.

Egyptian, Korean, and United Kingdom teachers' attitudes about the aims of practical work in science education were studied by Swain, Monk, and Johnson (1999). When UK teachers were compared with Korean teachers, the Korean teachers valued practical work for finding facts and arriving at new principles, as a creative activity, to verify facts, to elucidate theoretical work, and to help remember facts and principles more than UK teachers. The UK teachers rated practical work as more important for seeing problems and seeking new ways to solve them, pro-

moting a logical reasoning method of thought, developing an ability to cooperate, and developing a critical attitude. The Korean teachers viewed the practical as content-focused and fact-oriented. The UK teachers viewed science as more focused on investigating problems and manufacturing new knowledge. Egyptian teachers, when compared with UK teachers, tended to view practical work as important as a creative activity focused on developing self-reliance and giving students experience with standard techniques. Overall, Korean teachers tended to have a positivistic approach to science. The researchers linked the teachers' attitudes to their work conditions and suggested that the Egyptian teachers' large classes, limited equipment, and restrictive curriculum affected their views of practical experiences. For the Korean teachers, the researchers suggested that the habit of competition and emphasis on factual knowledge dominated their perspectives on practical work. According to the researchers, the UK teachers' perspectives were shaped by their concerns about doing investigations. For these teachers from three different countries, their attitudes appeared to be shaped by their cultural context and conditions of work.

Aikenhead and Otsuji (2000) examined Canadian and Japanese teachers' perceptions of science, science and culture, everyday knowledge, and teaching and learning science. Using a Likert scale assessment instrument, the researchers found that Canadian teachers held a more reductionist view of science than their Japanese counterparts, who viewed science and nature as one entity, including themselves as part of nature. Furthermore, more Japanese teachers than Canadian teachers believed school science was reflected in the local culture. Aikenhead and Otsuji found that neither set of teachers seemed aware of the cultural clashes that students experience in the typical science classroom. Similarly, Plucker (1996) found that although teachers were concerned about gender inequity for their students, they were generally not familiar with the range of possible causes (including their own behavior).

### **Religion, Beliefs, and Instructional Practices**

A teacher's religious beliefs as well as the cultural beliefs of the society affect how instruction is framed and interpreted. Haidar (1999) examined United Arab Emirates preservice and inservice teachers' beliefs about the nature of science through the use of a questionnaire in which participants responded to items on a continuum from traditional to constructivist views. Traditional views were held by teachers for the role of a scientist, constructivist views were held for scientific knowledge, and mixed perspectives were held about scientific theories, scientific method, and scientific laws. Haidar speculated that the mixed views emerge from the teachers' Islamic beliefs: "The purpose of science is to discover God's wisdom in the universe; knowledge can be acquired by the scientific method as well as by other means . . . truth is not absolute, we see only what God permits us to see; and the only absolute truth is what God knows" (Haidar, 1999, p. 808).

The teachers' Islamic beliefs were also influenced by historical perspectives from the 1960s and 1970s, when government officials viewed science as a way to fight ignorance, imperialism, and underdevelopment and officials encouraged citizens to adopt science as a way to promote development. According to Haidar, teachers' constructivist views were congruent with Islamic views, suggesting that the scientific method is not the only way to gain knowledge and knowledge is "only humanity's best effort to understand the world" (p. 818).

## Summary

The growing research that examines belief systems across cultures and contexts has highlighted the power of contextual influences on teachers' beliefs. Contexts, such as level of schooling (high school versus higher education) or wealth of the school community, have been associated with differences in teachers' attitudes and beliefs. Other studies compared beliefs of teachers from different countries and have shown that culture plays a powerful role in shaping beliefs about teaching strategies and approaches. Finally, a teacher's religious beliefs may frame a teacher's views of the goals and nature of science. These cultural and contextual studies have begun to provide a richer view of teachers' attitudes and beliefs while highlighting differences across teachers in different contexts.

## CONCLUSIONS

There has been consistent acknowledgment of the importance of science teachers' attitudes and beliefs over the decades. However, the initial model for examining attitudes was a simplistic cause-and-effect model. Situated in a behaviorist framework, this research noted relationships between variables without gaining insight into the development of attitudes across time and without understanding how the larger cultural context influenced the development of attitudes. Over the years, the model has become more complex as research findings have elucidated the myriad of variables likely to affect a teacher's instructional practices.

The vast majority of research has focused only on one particular aspect of the decision-making process, making it difficult to construct a cohesive picture of the research. Significant to understanding teachers' instructional practices is the socio-cultural context, the importance of which has recently been recognized. The research to date provides evidence of the complexity of the decision-making process in instructional settings and the critical role of teacher beliefs in reforming science education.

Much of the current research about beliefs has focused on individual teachers or small groups of teachers in case-study or ethnographic formats. Although these have been valuable in informing the science education community about the complexity of belief systems, future research is needed that can include larger samples, such as the study by Simmons et al. (1999). There is emerging evidence that patterns in belief systems can be identified across cultures and contexts. Further research is needed that examines beliefs across subcultures, as well as developmental trends as teachers move along the novice-to-expert continuum. Studies that can cross the boundaries of different countries to explore commonalities across teachers have the potential to inform us about the underlying structures of teacher belief systems as well as strategies that can be effective in promoting teacher development across subpopulations. This new generation of research on teacher belief studies is crucial to promoting growth and sustaining reform within science education.

Research highlighted in this chapter has shown that teachers' belief systems influence their attitudes. Studies have shown that teachers' content knowledge, confidence, self-efficacy, experience, and social context are linked to belief systems and practices. Teachers' epistemological beliefs about the nature of science, science learning, and science teaching further affect these belief systems, attitudes, and practices.

Furthermore, research has shown that these complex belief systems influence how teachers interact with students, the strategies they use for instruction, their classroom management systems, their selection of topics and subtopics, and their assessment practices. As teachers try new instructional methods, the responses of those in the educational environment further influence their perceptions and their belief systems. It is becoming increasingly clear that teachers' belief systems are embedded in the larger sociocultural environment, which includes students, peer teachers, parents, administrators, families, communities, and political/government environments.

## FUTURE RESEARCH

The study of teachers' beliefs is in its infancy, and there are numerous areas yet to be researched. It is not clear how epistemological assumptions and patterns of reasoning may differ for individuals across content domains, and whether there is a developmental relationship between epistemologies and beliefs within a domain (Hofer & Pintrich, 1997).

The differences in elementary and secondary teachers' views about science and science teaching persist across programs and contexts. What experiences contribute to these differences across teachers? What factors influence an individual to enter elementary education versus secondary education? Are there dispositions or abilities that encourage a teacher to select one area over another? How do attitudes and belief systems influence dispositions or abilities (or vice versa) if they do exist? Are there differences in biology and chemistry teachers' attitudes, as BouJaoude (2000) has suggested? If content differences exist, what contributes to the development of these differences?

The growing diversity of student populations necessitates an understanding of how teachers' beliefs about culturally diverse students affect their interactions and instruction (Bryan & Atwater, 2002). How can we make teachers' beliefs about culturally diverse students explicit to become a tool for professional and personal growth?

There is only limited research that explores whether teachers' and students' attitudes and beliefs differ. If teachers hold beliefs and attitudes that are different from those of their students, does this difference affect student learning? In one of the few studies in this area, Cary and Smith (1993) explored the challenges of teachers' use of a constructivist approach to science that were at odds with students' objectivist views of science. If teachers' and students' views of science differ year after year, how does this affect students' development?

Pajares (1992) and DeSouza and Czerniak (2003) have suggested that confidence involves both personal and social components—including classrooms, teacher teams, schools, and school districts—and that together these contribute to a sense of collective efficacy. We know that attitudes and beliefs are influenced by significant other people in our environments. How systems of beliefs situated within individuals and the greater sociocultural context contribute to teachers' attitudes about teaching and learning can inform the teacher development process has yet to be researched.

Although most researchers accept that there is a strong link between teachers' beliefs and teaching practices, research that documents how changes in beliefs subsequently affect teaching behaviors is limited (Hashweh, 1996). Where in the complex model of beliefs do changes make the most impact in instructional practice? Ediger (2002) argued for measuring preservice teachers' attitudes toward science as

a way to ensure that teachers have the qualifications to be good science teachers. What would these types of assessments look like? Can we really measure attitudes and beliefs in a valid way? What are the ethical implications of making decisions about teacher education candidates based on their beliefs?

For decades, despite reform efforts, traditional teaching has maintained a strong foothold in our science classrooms. The literature suggests that some teachers believe that traditional methods are most effective for teaching science. However, a great number of teachers hold a vision of science teaching that is aligned with national standards, but do not enact this vision in the classroom. Some lack content knowledge and so avoid teaching science. Some lack pedagogical skills, such as maintaining classroom discipline, which limits their ability to effectively teach science. Others lack pedagogical content knowledge and are unsure about how to implement an inquiry lesson or how to lead a class discussion to make sense of data. The task of addressing these issues seems easier than addressing the attitudes and beliefs which inhibit student-centered practices. The most significant contribution of attitude/belief research would lead to developmentally sequenced preservice, induction, and professional development programs, so that knowledge and skills are given sufficient time and support to develop. Additionally, these programs would be structured to acknowledge and address environmental constraints. And most importantly, these programs would make salient for teachers their own attitude beliefs systems as well as the complex factors that contribute to the development of these systems.

Our definitions of ourselves as science teachers (and learners) is bound to our belief systems, epistemologies, prior experiences, motivation, knowledge, and skills. These factors are all linked to each other with reciprocal influence and are embedded in the larger sociocultural environment. Only through further research that can take a systems view of attitudes and beliefs can we truly understand how attitudes and beliefs shape instructional practice and use this knowledge to achieve reform.

# CHAPTER 36

---

## Research on Science Teacher Knowledge

**Sandra K. Abell**

*University of Missouri, Columbia*

It is commonly held that the teacher is the most important factor in student learning (Committee on Science and Mathematics Teacher Preparation, 2001). We who educate future and practicing teachers assume the veracity of this statement. However, what characteristics of teachers are crucial to student learning? Do teachers who know more science make better science teachers? If this were true, surely the best science teaching would take place at the university level by individuals who possess a Ph.D. in their science field. Yet we know that this is not necessarily so; university science students cite poor teaching as one of the main reasons for dropping out of science majors (National Science Foundation, 1996). What should science teachers know in addition to subject matter knowledge? What do future and practicing science teachers know and how do they come to know it? How does their knowledge interact with beliefs, goals, and values? How does their knowledge affect their practice and their students' learning? Such questions have generated a plethora of research in science education.

Although science education researchers have been studying science teacher knowledge since the 1960s, the theoretical foundations and methodological strategies have changed greatly over the years. This chapter begins with a historical overview of teacher knowledge research, including the variety of terms and approaches that have been applied. I then describe the model of teacher knowledge that frames the review. This theoretical foundation leads into a review of the research literature on science teacher knowledge. The chapter ends with implications for science teacher education and recommendations for future research.

### FOUNDATIONS OF THIS REVIEW

#### Historical Views of Teacher Knowledge

*Teacher knowledge* has assumed a number of meanings in educational research over the past 50 years. Fenstermacher (1994) examined the epistemological aspects of

various research programs about teacher knowledge and developed a classification scheme. In his scheme, he distinguished knowledge about teaching (TK/F or formal knowledge) from knowledge derived from teachers participating in teaching (TK/P or practical knowledge). Research in the 1960s and 1970s, for the most part, did not make explicit mention of teacher knowledge. These process-product studies aimed to define effective teaching based on studying the relationships among particular variables and treatments. In the science education literature, teacher knowledge was defined as a static component (a qualification or competency) of the broader category of teacher characteristics that was then compared with teacher practice (Bruce, 1971; Smith & Cooper, 1967) or student outcomes (Northfield & Fraser, 1977; Rothman, Welch, & Walberg, 1969). In such studies, teachers were the objects of research, what Fenstermacher called the “known,” and the emphasis was on producing a “knowledge base” (Reynolds, 1989) to summarize the TK/F that was needed for teaching.

In the 1980s, a new set of research programs arose that changed the face of teacher knowledge research. In these programs, teachers were seen as the “knowers,” and the focus shifted to examining their practical knowledge (TK/P). Fenstermacher (1994) outlined four such research programs: Clandinin and Connelly’s work on personal practical knowledge through teacher narrative (e.g., Clandinin & Connelly, 1996); Schön’s notions of reflective practice for professional development (Schön, 1983, 1987); Cochran-Smith and Lytle’s leadership in the teacher researcher movement (Cochran-Smith & Lytle, 1993, 1999); and Shulman’s research program on teacher knowledge types (e.g., Shulman, 1986). These research programs shifted the perspective from knowledge about teaching produced by others to teacher knowledge residing within teachers, from teachers as objects of research to teachers as co-researchers.

Although differing in epistemological details (see Fenstermacher, 1994), the first three research programs were similar in their focus on teachers producing and possessing their own knowledge. The Shulman program was substantially different. Shulman and his colleagues attempted to answer the question “What knowledge is essential for teaching?” by studying teachers from different subject areas (e.g., English, science, social studies). This work differed from earlier attempts to develop a knowledge base for teaching in that it derived from studies of what teachers know about their subject and about teaching, assuming teacher as “knower,” not from studies of effective teaching where the teacher was the “known.” In the United States, Shulman’s model served as the foundation for the development of teaching standards for beginning teachers (e.g., *Standards for Science Teacher Preparation*, National Science Teachers Association, 1998). The model has also catalyzed scores of studies concerning teacher knowledge. This review uses Shulman’s theoretical model, explained in more detail in the next section, as its organizational base.

## **Shulman’s Model of Teacher Knowledge**

In 1986, Shulman proposed a model for understanding the specialized knowledge for teaching that distinguishes teachers from subject matter specialists. Shulman and his colleagues (Hashweh, 1985; Grossman, 1990; Shulman, 1986, 1987; Wilson, Shulman, & Richert, 1987) defined pedagogical content knowledge (PCK) as the knowl-

edge that is developed by teachers to help others learn. Teachers build PCK as they teach specific topics in their subject area. PCK is influenced by the transformation of three other knowledge bases: subject matter knowledge (SMK), pedagogical knowledge (PK), and knowledge of context (KofC) (Grossman) (see Fig. 36–1).

Shulman’s view of SMK was derived from the work of Schwab (1964), who defined two types of subject matter knowledge: substantive and syntactic. The substantive structure of a discipline is the organization of concepts, facts, principles, and theories, whereas syntactic structures are the rules of evidence and proof used to generate and justify knowledge claims in the discipline. Shulman and colleagues added two other categories of subject matter knowledge: knowledge of content (facts,

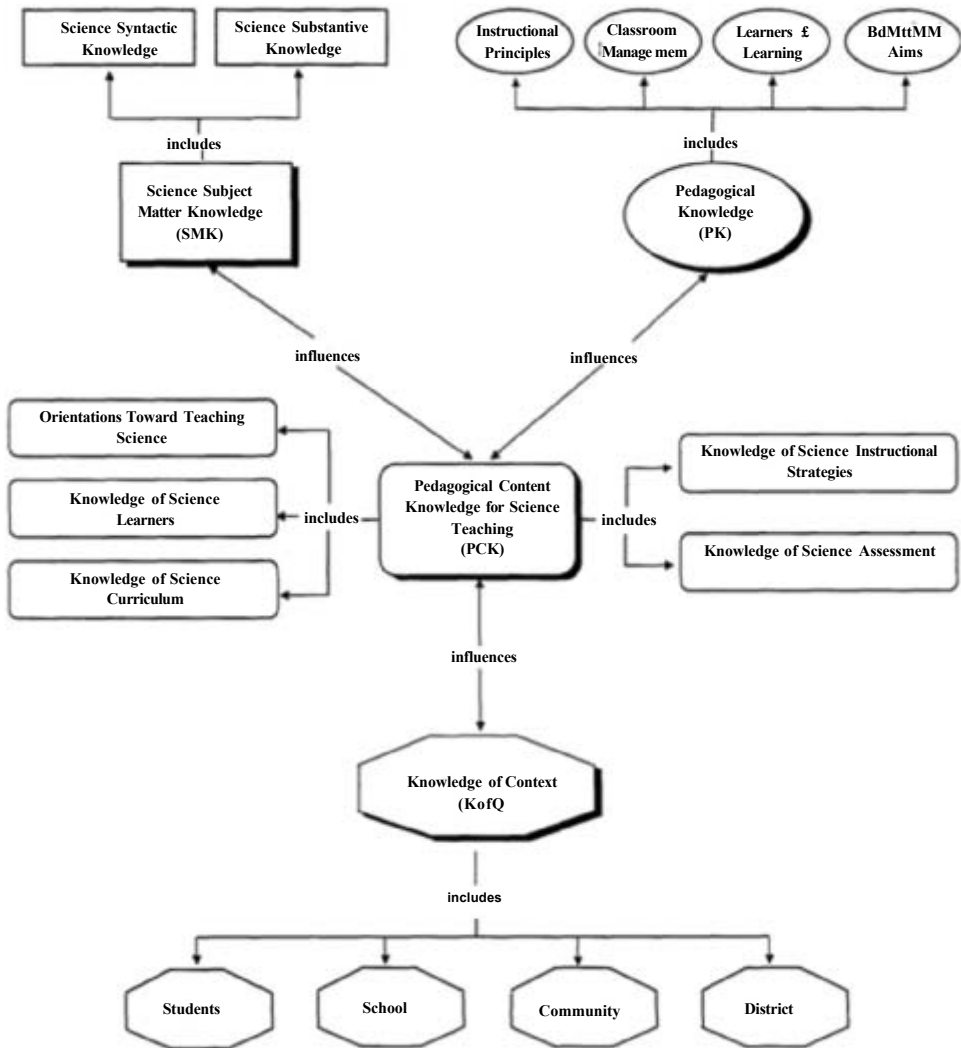

FIGURE 36–1. A model of science teacher knowledge (modified from Grossman, 1990 and Magnusson, Krajcik, & Borko, 1999).

concepts, and procedures) and beliefs about the discipline (Grossman, Wilson, & Shulman, 1989). Carlsen (1991c) criticized this scheme, claiming that in science it is difficult to determine whether knowing a particular concept or principle is an example of substantive knowledge or content knowledge. For the purpose of this review, I examine studies of science SMK that could be considered either substantive knowledge in Schwab's terms or knowledge of content in Grossman's. For the most part, I leave a discussion of research on teacher knowledge of the syntactic structure of science and beliefs about the discipline to Lederman's chapter in this volume.

Pedagogical knowledge (PK) includes the general, not subject-specific, aspects of teacher knowledge about teaching, such as learning theory, instructional principles, and classroom discipline. Knowledge of context (KofC) was formalized by Grossman (1990) to account for the knowledge of communities, schools, and student backgrounds that teachers use in their teaching. For the most part, this review does not concentrate on these types of knowledge, since they are not specific to science teachers. Together SMK, PK, and KofC influence and are translated by a teacher's PCK into instruction.

Magnusson, Krajcik, and Borko (1999) defined PCK as consisting of five components: (a) orientations toward science teaching, which include a teacher's knowledge of goals for and general approaches to science teaching; (b) knowledge of science curriculum, including national, state, and district standards and specific science curricula; (c) knowledge of assessment for science, including what to assess and how to assess students; (d) knowledge of science instructional strategies, including representations, activities, and methods; and (e) knowledge of student science understanding, which includes common conceptions and areas of difficulty (see Fig. 36-1). These components represent a broader view of PCK than the original conceptualization, which focused on topic-specific case knowledge, or what Hashweh (1985) called subject-matter pedagogical knowledge. Since its introduction, Shulman's model has been translated, explicated, revised, and extended by numerous science educators (Appleton, 2002; Barnett & Hodson, 2001; Carlsen, 1991c; Gess-Newsome & Lederman, 1999; Magnusson et al., 1999; Tamir, 1988; Veal, 1997), and the model has formed the theoretical framework for much research on science teacher knowledge. However, a full discussion of the different views of PCK is beyond the scope of this chapter. Admitting the problematic nature of the Magnusson et al. model, I maintain it is a useful heuristic for organizing the research on science teacher knowledge.

## Situating This Review

The research on teacher knowledge has been reviewed a number of times in the past 15 years (Ball & McDiarmid, 1996; Borko & Putnam, 1996; Calderhead, 1996; Carter, 1990; Grimmer & MacKinnon, 1992; Munby, Russell, & Martin, 2001). These reviews are immensely informative accounts of the theoretical and empirical bases of teacher knowledge in general. However, because they are not science education specific, they are of limited use to science education researchers.

Previous reviews of science teacher knowledge research exist, but cannot claim the comprehensive nature of the present project. The Anderson and Mitchener chapter in the Gabel handbook (1994) focused on preservice and inservice science teacher

education with only passing attention to research on science teacher thinking; the authors reported nothing related to teacher knowledge. The chapter on alternative conceptions by Wandersee, Mintzes, and Novak in the same volume devoted a one-page section to teachers' alternative conceptions in science. The Fraser and Tobin handbook (1998) acknowledged the topic of science teacher knowledge in two chapters. The de Jong, Korthagen, and Wubbels chapter reviewed only the European research on teacher knowledge about teaching. The Cochran and Jones chapter on SMK reported only on research with preservice science teachers, and a chapter by de Jong, Veal, and van Driel (2002) reviewed teacher SMK about chemistry. In the volume on PCK edited by Gess-Newsome and Lederman (1999), the Gess-Newsome (1999) review of SMK encompassed research on mathematics, social studies, and English teacher knowledge in addition to science.

The current chapter provides an integrative review of the research on *science* teacher knowledge, including SMK, PK, and PCK. The review includes studies of both preservice and practicing teachers at all levels of instruction. I systematically reviewed the science education research since 1960 reported in dissertations and published internationally in journals and book chapters. For these reasons, this chapter is a comprehensive review of science teacher knowledge research.

Selecting research to review for this chapter was problematic. First of all, teacher knowledge goes by a variety of designations, partly as an artifact of the theoretical orientation of the time. For example, teacher knowledge has been reported as *craft knowledge*, *personal practical knowledge*, *wisdom of practice*, *practitioner knowledge*, *knowledge in action*, and *event-structured knowledge* (see Carter, 1990). Are these categories mutually exclusive renderings of teacher knowledge, outside of Shulman's model? I also debated how to review research on teachers' beliefs, conceptions, perspectives, ideologies, and theories. When do such studies belong here versus in a chapter on teacher attitudes and beliefs (see Chapter 35, this volume)? The distinction between knowledge and beliefs is not always clear in the research or agreed upon by the researchers (see Fenstermacher, 1994). Numerous studies concern teacher thinking (e.g., planning, decision making, reflecting, reasoning). Should such studies be included in a chapter on teacher knowledge? Shulman (1999) made his point of view clear, that teacher cognition is not the same as teacher knowledge. However, I was not ready to dismiss science-specific studies in this realm.

With these issues in mind, I selected studies that were about science teacher subject matter, pedagogical, or pedagogical content knowledge. In some cases, studies that referred to "beliefs" were also included, when I could interpret them as referring to part of a comprehensive "knowledge and beliefs" system (see Magnusson et al., 1999) rather than to the domain of "attitudes and beliefs." I reported studies of teacher thinking and studies that used different terms for teacher knowledge within the category of PCK when they were specifically about knowledge and reasoning in science classrooms, but omitted studies of teacher attitudes (Chapter 35, this volume), teacher knowledge of the nature of science (Chapter 28), and teacher views of learners from various backgrounds or with special needs/talents (see Section 2). I also avoided studies where teacher knowledge development was reported as a teacher learning outcome influenced by teacher preparation (Chapter 37), professional development (Chapter 38), or teacher research (Chapter 39), when the teacher education "treatment" appeared the more salient subject of study. In addition to ERIC searches using teacher knowledge key words, the contents of 22 science edu-

cation and educational research journals were scanned by hand for relevant articles. I also mined the bibliographies of existing reviews and relevant studies for additional research reports.<sup>1</sup> Although I am sure that my decisions about what to include and exclude from this chapter were far from perfect, and some studies that could arguably be included do not appear, I believe that what follows is a comprehensive review of science teacher knowledge research.

## RESEARCH ON SCIENCE TEACHER SUBJECT MATTER KNOWLEDGE

Most early studies in science education equated the number of science courses taken, and in a few case grade point average in those courses, to teacher SMK. A few researchers administered tests of science knowledge, usually in true/false or multiple-choice formats. An interesting exception was a study by Jena (1964) in which the researcher inferred SMK through observations of the teaching errors made by secondary student teachers while teaching. Later, Kennedy (1998) clarified the character of SMK needed by teachers as going beyond the “recitational” to include understanding of central ideas, relationships, elaborated knowledge, and reasoning ability. As the characterization of teacher knowledge shifted from a “quantity” view to a conceptual understanding view, methods for assessing teacher knowledge also changed. Written tests included open-ended items and requested explanations in addition to answers (e.g., Ginns & Watters, 1995). Concept mapping emerged as a useful tool for examining the subject matter structures held by teachers (Ferry, 1996; Jones, Rua, & Carter, 1998; Willson & Williams, 1996). Researchers also administered individual interviews, where they asked participants to explain phenomena, sort concept cards, and respond to hypothetical teaching situations (e.g., Hashweh, 1985). A few studies examined SMK *in situ*, while teachers worked to solve a science task (Moscovici, 2001) or taught science lessons to students (Veiga, Costa Pereira, & Maskill, 1989). Do varying epistemological and methodological assumptions guiding studies of SMK lead to different conclusions? The following sections review studies of science teacher SMK in part to answer this question.

### General Science Subject Matter Knowledge

Early science education research defined teacher knowledge from a “quantity” perspective, claiming that prospective and practicing science teachers did not have enough (Mallinson & Sturm, 1955; Raina, 1967; Swann, 1969; Uselton, Bledsoe, & Koelsche, 1963). Often SMK was defined by the number of science courses taken. The study of teachers’ SMK via understanding their conceptions in science became a popular field in the 1980s, on the heels of the work with student science ideas.

---

1. I would like to acknowledge the contributions of Abdulkadir Demir in performing library searches, requesting and copying books and articles, and constructing the final bibliography for this chapter. His work was invaluable to me.

However, understanding teachers' misconceptions<sup>2</sup> in science can be traced back much earlier (Blanchett, 1952; Ralya & Ralya, 1938). Using a true/false written test, researchers found that prospective elementary<sup>3</sup> teachers (Ralya & Ralya) and practicing teachers (Blanchett) held a large number of misconceptions about science and science-related issues. The Ralya and Ralya study is interesting in that misconceptions they identified for a significant number of teachers became key targets for research on both student and teacher science conceptions 50 years later (e.g., causes of the seasons, force and motion, heat and temperature).

In their 1994 review of research on alternative conceptions, Wandersee et al. claimed that the research in the 1980s on teachers' science conceptions demonstrated that "teachers often subscribe to the same alternative conceptions as their students" (p. 189), a claim that they described as not "particularly surprising." The examination of teacher SMK continues to the present and includes studies of a mixture of life and physics science concepts as well as discipline-specific studies of conceptions in biology, chemistry, earth and space science, or physics. By far the most studied group has been preservice elementary teachers, although preservice secondary teachers and practicing teachers at all levels have been subjects of study.

Several studies in the 1980s expanded the work of the New Zealand Learning in Science Project by examining teachers' science concept understanding. Among New Zealand elementary student teachers, Hope and Townsend (1983) found that biology concepts (plant, animal, living) were relatively well understood, whereas performance on physics concepts (force, friction, gravity) was similar to that of fourth-form students. Ameh and Gunstone (1985, 1986) examined preservice secondary teachers in Australia and Nigeria with the Learning in Science survey. Contrary to the observations of Hope and Townsend, they found evidence of misconceptions in both life and physical science: only 26 percent of their teachers held the scientific view of animal, 71 percent of living, 30 percent of force, 66 percent of gravity, and 40 percent of current. Furthermore, they found no evidence of cultural influences in the responses. Other researchers developed written instruments for collecting data on a variety of science concepts. Working with science teachers in the United Kingdom (Carré, 1993; Lloyd et al., 1998; Smith, 1997), Singapore (Lloyd et al.), Estonia (Kikas, 2004), and the United States (Schoon & Boone, 1998; Wenner, 1993), researchers consistently found that misconceptions or alternative conceptions that had been reported for children persisted into adulthood.

Going beyond the limitations of survey data that were focused on defining correct/incorrect conceptions, Harlen (1997; Harlen & Holroyd, 1997) designed a two-phase study of SMK among practicing primary teachers in the United Kingdom. In the first phase, the researchers sent written surveys to 514 teachers to evaluate their knowledge and confidence on a variety of concepts. In the second phase, they interviewed a smaller sample of 57 teachers, from which they defined three groups of concepts: (a) concepts already understood by most teachers (e.g., water exists in different states, bones move at joints because of muscles); (b) concepts in which understanding developed during the interview itself (e.g., water from air condenses on

---

2. Although I recognize the problematic nature of the term, and am aware of possible alternatives, I use *misconceptions* when the authors of these studies do.

3. For convenience and clarity, I use the American *elementary* throughout to refer to this grade range.

cool surfaces; muscles pull, not push); and (c) concepts less commonly understood and resistant to change (e.g., reflection of light; energy flow in circuits). They also determined sources of teachers' inaccuracies (e.g., inappropriate analogy, everyday language; mechanisms without evidence). This approach provided a value added to studies that merely catalogued misconceptions, including clear implications for science teacher education—designating concepts to which to devote time and describing how to help teachers overcome various inappropriate ways of reasoning.

Few studies have examined the development of science teacher SMK over time. Arzi and White (2004) investigated SMK in a 17-year longitudinal study of secondary science teachers. They found that the school science curriculum was "the most powerful determinant of teachers' knowledge, serving as both knowledge organizer and knowledge source" (p. 2). This study is significant both for the rarity of its longitudinal methods as well as the resulting phase model of teacher SMK development that could be a useful tool in science teacher education.

Several studies examined teacher syntactic SMK in science, such as teachers' ability to control variables (Aiello-Nicosia, Sperandeo-Mineo, & Valenza, 1984), understanding of assumptions (Yip, 2001), hypothesizing skills (Baird & Koballa, 1988), knowledge of modeling (Justi & Gilbert, 2002b, 2003; van Driel & Verloop, 1999), conceptions of scientific evidence (Taylor & Dana, 2003), and use of data representation (Roth, McGinn, & Bowen, 1998). Lawson (2002) studied preservice biology teachers' arguments in response to a set of hypotheses. He found that the future teachers were more successful when the hypothesized causal agent was observable and made many errors when the hypothesis involved nonobservable entities. (Other studies of teacher syntactic SMK as related to the nature of science are reported in Chapter 28.)

In another group of studies, researchers sought to correlate general science substantive SMK with other teacher characteristics—confidence, attitude, and self-efficacy. In the United Kingdom, several research programs were interested in future elementary teachers' subject matter confidence and competence as related to the National Curriculum (Carter, Carré, & Bennett, 1993; Harlen, 1997; Russell et al., 1992; Shallcross, Spink, Stephenson, & Warwick, 2002; Sorsby & Watson, 1993). Harlen found that, in general, science background and confidence to teach are related. Studies from other parts of the world have been less definitive. Appleton (1992, 1995) claimed that factors other than increased science study affected confidence to teach science but admitted that teachers who experienced success in learning science content did become more confident. Appleton also warned science educators not to confuse confidence with competence. Waldrip, Knight, and Webb (2002) reported a significant correlation between preservice elementary teachers' perceived ability to explain scientific language and their perceived competence to teach science concepts, but no correlation between their actual explanations and perceived competence to teach. Shrigley (1974) noted low positive correlation between SMK and attitude on the part of preservice teachers. Studies attempting to correlate SMK with measures of teacher self-efficacy have been inconclusive (Schoon & Boone, 1998; Stevens & Wenner, 1996; Wenner, 1993, 1995). The question of the relation of general science SMK to various teacher characteristics remains open for study.

The studies reviewed so far investigated teachers' SMK within a number of different concept areas across two or more science disciplines. The remaining review of SMK is organized within the major science disciplines in which the research was conducted. Furthermore, a number of studies have attempted to understand the re-

relationship between SMK and teaching practice. I consider these studies at the end of this section.

### Teachers' SMK in Chemistry

Teacher SMK in chemistry<sup>4</sup> has been a subject of study since 1987, when Gabel, Samuel, and Hunn examined preservice elementary teachers' ideas about the particulate nature of matter. Using the Nature of Matter Inventory, they asked teachers to draw pictures of atomic/molecular arrangements, given certain scenarios. Teachers ignored conservation and orderliness of particles in over 50 percent of the answers. Furthermore, only 4 percent of the variance in performance was accounted for by the number of chemistry courses taken. In a cross-cultural study of preservice elementary teachers in Spain and the United Kingdom, Ryan, Sanchez Jimenez, and Onorbe de Torre (1989) examined understanding of conservation of mass via a two-part questionnaire that included a definition and a task to solve. More Spanish teachers could give an acceptable definition of mass and conservation of mass, but all teachers had trouble solving the problems, regardless of nationality. The researchers hypothesized that the more term-focused Spanish curriculum led to better performance on the definition question but did not improve understanding. Contrary to Gabel et al.'s findings, the more science-experienced teachers in both groups performed better. Roth (1992) conducted an experimental study of preservice elementary teachers' ideas about the particulate nature of matter in which participants explained changes in water and ice when heated. Prior to the treatment, involving the use of concrete models to explain activity results, all 17 teachers explained phase change at a phenomenological level. Two weeks later, the treatment group used the particle model to explain melting and evaporation, but not to discuss volume changes. Similarly, Kruger and Summers (1989) and Kruger, Palacio, and Summers (1992) found that practicing elementary teachers did not refer to molecules or energy to explain changes in materials. Martin del Pozo (2001) asked prospective elementary teachers to evaluate the concept map of a hypothetical 13-year-old about the composition of matter. Teachers confused the relationship among topics such as substance/element, mixture/compound, element/atom, and compound/molecule. Birnie (1989) compared the conceptions about particle theory in gases held by elementary students, teachers, and parents. He found that elementary teachers and parents performed at the same level as ninth-grade students, whereas intermediate and secondary teachers performed better. These findings and others (e.g., Ginns & Watters, 1995) concerning preservice and practicing elementary teachers' SMK in chemistry are, in the words of Wandersee et al. (1994), not particularly surprising.

However, college students other than preservice elementary teachers also demonstrate poor understanding in chemistry. Kokkotas, Vlachos, and Koulaidis (1998) asked prospective secondary teachers in Greece to evaluate children's answers to items involving understanding of the particulate nature of matter. They found that preservice teachers lacked the SMK necessary to accurately score the answers. In a study of college student understanding of the greenhouse effect (Groves & Pugh,

---

4. Some topics could be reasonably classified as either physics or chemistry. I chose to include studies of SMK of the particulate nature of matter and conservation of mass under chemistry, while placing studies of SMK of thermal properties of materials under physics.

1999), students across disciplines, including preservice teachers, gave incorrect answers about the causes and consequences associated with this phenomenon. Indeed, problems in understanding college chemistry are not limited to prospective elementary teachers.

Another group of studies examined chemistry SMK among practicing high school chemistry teachers around the world. The results of these studies are perhaps more troubling than the studies with future elementary teachers, given the discrepancy in formal subject matter preparation. Widespread misconceptions have been found among chemistry teachers in the United Arab Emirates about the concepts of atomic mass, mole, conservation of atoms, and conservation of mass (Haidar, 1997); in Singapore about chemical reactions (Lee, 1999); in India about chemical equilibrium, Le Chatelier's principle, rate and equilibrium, and acid-based and ionic solutions (Banerjee, 1991); in Spain about Le Chatelier's principle (Quílez-Pardo & Solaz-Portolés, 1995); and in Sweden about the mole (Strömdahl, Tulberg, & Lybeck, 1994). Some studies compared practicing chemistry teachers' SMK with student knowledge. Teachers had a better understanding of the mole concept than their students, but some ambiguities in their thinking were still apparent (Gorin, 1994; Tulberg, Strömdahl, & Lybeck, 1994). Teachers and students held similar alternative conceptions about gases and displayed similar misuses of the gas laws (Lin, Cheng, & Lawrenz, 2000). A review of the research on teacher SMK about chemistry (de Jong et al., 2002) corroborates the observation that even teachers who have strong preparation in chemistry lack understanding of concepts fundamental to their field.

## Teachers' SMK in Earth and Space Science

The examination of teachers' views of earth and space science concepts has occurred more recently in the history of SMK research. These studies have been conducted largely with elementary teachers (preservice and practicing) about concepts that have also been studied with students: day/night (Atwood & Atwood, 1995; Mant & Summers, 1993; Parker & Heywood, 1998), seasons (Atwood & Atwood, 1996; Kikas, 2004; Mant & Summers; Parker & Heywood; Schoon, 1995), moon phases (Mant & Summers; Parker & Heywood; Schoon; Suzuki, 2003; Trundle, Atwood, & Christopher, 2002), geological time (Trend, 2000; 2001), the solar system (Mant & Summers), and atmospheric phenomena (Aron, Francek, Nelson, & Bisard, 1994). These studies documented that preservice teachers lack scientific views in earth and space science, but more so in astronomy topics than in geology (Schoon, 1995). The Aron et al. study compared preservice earth/physical science teachers with students and prospective elementary teachers and found that, although the future secondary teachers performed better than the elementary teachers and students, they still held many misconceptions. Preservice teachers in this study performed better on a question about the seasons than in other studies involving this topic, which is most likely a function of method: the researchers used a multiple-choice survey as opposed to the other studies that assessed SMK with a combination of open-ended questionnaires and interviews requiring teachers to generate causal explanations. For example, in the Mant and Summers (1993) study, interviewees demonstrated 13 distinguishable models of astronomical phenomena, with only 4 of the 20 participants holding the scientific model.

Two other studies of SMK in earth and space science (Barba & Rubba, 1992; 1993) were substantially different in that they adopted an expert/novice theoretical framework to study inservice/preservice and novice/veteran teachers' declarative and procedural knowledge about a variety of earth and space science topics. Aligned with their theoretical frame, they found that expert teachers had better content knowledge structures, gave more accurate answers, used information chunks in solving problems, solved problems in fewer steps, and generated more solutions. Novice teachers moved between declarative and procedural knowledge more often and were less fluent in solving earth/space science tasks overall.

### Teachers' SMK in Biology

Unlike the majority of studies of SMK in other disciplines, the research in biology education includes both studies of substantive and syntactic knowledge, or what the researchers have called "subject matter structures." Only a few researchers in biology education have been interested in finding out teachers' conceptions of specific concepts. For example, Sanders (1993) studied South African teachers' conceptions about respiration, Gayford (1998) examined British teachers' understanding of the concept of sustainability, and Greene (1990) researched U.S. preservice elementary teachers' understanding of natural selection. Jungwirth (1975) and Barass (1984) pointed out the misconceptions perpetrated by biology textbooks and the teachers who used them about cells, respiration, gas exchange, and homeostasis. More researchers have been concerned with uncovering the teachers' understanding of relations among biological concepts. For example, Douvdevany, Dreyfus, and Jungwirth (1997) studied Israeli junior high biology teachers' conceptions of living cell by asking them to link topics via two activities—a card sort and a lotto game. Hoz, Tomer, and Tamir (1990) used concept mapping to determine biology (and geography) teachers' knowledge structures. Tamir (1992) asked preservice and practicing teachers to organize biology topics and comment on their perception of their own knowledge and topic importance. In most areas, perceived knowledge lagged behind perceived importance.

The study of biology teachers' subject matter structures (SMSs) was marked in the 1990s by two research groups. In her dissertation, Hauslein (Hauslein, 1989; Hauslein, Good, & Cummins, 1992) studied five groups: biology majors, preservice teachers, novice teachers, experienced teachers, and scientists, using a card-sort task of 37 terms. Finding that veteran teachers and scientists had a deep-versus-surface understanding of subject matter structure, the researchers claimed that teachers restructure their thinking about biology as they gain more teaching experience. In the second research program, Lederman and his students (Gess-Newsome & Lederman, 1993; 1995; Lederman, Gess-Newsome, & Latz, 1994; Lederman & Latz, 1995) examined the subject matter structures of preservice and practicing secondary teachers, primarily in biology. For example, Gess-Newsome and Lederman studied 10 preservice biology teachers. Rather than provide the terms used in the card sort, the researchers asked teachers to first generate their own terms and then diagram the relationships. Data collection occurred at several times throughout the preservice program and during student teaching, culminating with a final interview. Teachers typically chose topics derived directly from their college biology course titles. Their

subject matter structures changed over time with the addition of more terms and greater integration of topics. The researchers concluded, "It does not appear that preservice biology teachers are cognizant of their SMSs or that these SMSs are stable" (p. 42). Both of these research programs lend support to the commonly held notion that teachers improve their SMK through teaching.

Other research concerning biology teachers' SMK has been concerned with the relationship between SMK and teaching practice (e.g., Carlsen, 1991a, 1991b, 1993; Gess-Newsome & Lederman, 1995; Hashweh, 1987). I review these studies in a later section.

## Teachers' SMK in Physics

By far the most research on teachers' SMK in science has taken place in the domain of physics. These studies have examined both preservice and practicing teachers, elementary through secondary, around the globe (including Australia, Canada, Estonia, Hong Kong, India, Israel, Italy, Nigeria, Pakistan, Portugal, South Africa, the United Kingdom, and the United States). Topics that have been studied with children have also received attention in studies of teachers. This line of research commenced in the 1980s with the Lawrenz (1986) study of inservice elementary teachers. Using a multiple-choice test, she found that teachers understood some concepts (over 50 percent of teachers gave correct answers for items about atomic structure, off-center balancing, density, and stars) and did not understand others (less than 50 percent gave correct answers for electric current, mixture of gases, temperature, motion, and light). About the same time in the United Kingdom, a research program devoted to understanding elementary teachers' SMK in physics was under way. In response to the British National Curriculum and the increased role for science content in primary schools, Kruger and colleagues (e.g., Kruger, 1990; Kruger, Palacio, & Summers, 1992; Kruger & Summers, 1988; Summers & Kruger, 1994) undertook the Primary School Teachers and Science Project. They studied teachers' ideas about energy, forces, gravity, and materials, first through interviews and later via large-scale surveys. Finally they developed teacher education materials based on their findings (Summers, 1992). Golby, Martin, and Porter (1995) criticized this research program, questioning the "orthodoxy of the deficiency model" (p. 298) that they claimed supported a transmission view of teaching and learning, a claim debunked by Summers and Mant (1995) in response.

From the 1980s until the present, a host of studies have examined teacher SMK for the following concepts:

1. Light and shadows (Bendall, Goldberg, & Galili, 1993; Feher & Rice, 1987; Jones, Carter, & Rua, 1999; Smith, 1987; Smith & Neale, 1989);
2. Electricity (Daehler & Shinohara, 2001; Heller, 1987; Heywood & Parker, 1997; Jones et al., 1999; Pardhan & Bano, 2001; Stocklmayer & Treagust, 1996; Webb, 1992; Yip, Chung, & Mak, 1998);
3. Sound (Jones et al., 1999; Linder & Erickson, 1989);
4. Force and motion (Ginns & Watters, 1995; Kikas, 2004; Kruger, Palacio et al., 1992; Kruger, Summers, & Palacio, 1990b; Mohaptra & Bhattacharyya, 1989; Preece,

- 1997; Summers & Kruger, 1994; Trumper; 1999; Trumper & Gorsky, 1997; Yip et al., 1998);
5. Energy (Kruger, 1990; Kruger et al., 1992; Nottis & McFarland, 2001; Summers & Kruger, 1992; Trumper, 1997; Yip et al., 1998);
  6. Heat and temperature (Frederik, Valk, Leite, & Thorén, 1999; Jasien & Oberem, 2002; Veiga et al., 1989);
  7. Thermal properties of materials (Sciarretta, Stilli, & Vicente Missoni, 1990);
  8. Sinking/floating (Ginns & Watters, 1995; Parker & Heywood, 2000; Stepans, Dyche, & Beiswenger, 1988);
  9. Air pressure (Ginns & Watters, 1995; Rollnick & Rutherford, 1990);
  10. Gravity (Ameh, 1987; Kruger et al., 1990a; Smith & Peacock, 1992).

The overall finding from these studies of teacher SMK in physics is that teachers' misunderstandings mirror what we know about students. This finding holds regardless of the method used to assess teacher knowledge: true/false (Yip et al., 1998), multiple choice (e.g., Lawrenz, 1986), open-ended surveys (Mohaptra & Bhat-tacharyya, 1989), interviews (Linder & Erickson, 1989; Smith, 1987), and observation techniques (Daehler & Shinohara, 2001; Pardhan & Bano, 2001). Several studies also included strategies and materials for science teacher educators to improve teacher SMK (Bendall et al., 1993; Heywood & Parker, 1997; Jones et al., 1999; Summers, 1992). Unlike studies in chemistry SMK, researchers have not examined the relation of number of courses taken to physics SMK, most likely because the amount of formal coursework in physics typically taken in high school or university is lower than the amount of coursework completed for other science subjects. Unlike the biology SMK studies, most researchers of physics have been more interested in teacher understanding of specific concepts rather than their subject matter structures (see Abd-El-Khalick & BouJaoude, 1997, for one exception). Understanding how physics teachers understand the structure of the discipline and the relation among concepts remains a largely unmapped field of study.

## Relation of SMK to Teaching

The studies reviewed up to this point have focused on describing, and in some cases treating, science teacher SMK. Another body of literature has attempted to uncover the relationships between SMK and science teaching. In general, these researchers wanted to know if teachers with better SMK were also better science teachers. The connection between SMK and teaching has been of interest among science educators for many years. Early attempts often correlated a teacher's science background (usually in the form of the number of science courses taken) with some measure of teaching effectiveness. According to Dobey (1980), studies conducted before the post-Sputnik wave of science curriculum reform supported a "positive correlation between the amount of science background and various teaching competencies" (p. 13). In a meta-analysis of 28 studies conducted between 1957 and 1977 of science teacher characteristics by teaching behavior, Druva and Anderson (1983) found a small but significant positive relation between "science training" and "teaching effectiveness."

However, a closer examination of selected studies relating science background to teaching proves less conclusive. Some researchers found no or a negative relationship between science background and teaching. Bruce (1971), in a study of elementary teachers using *Science Curriculum Improvement Study* materials, found no relationship between a teacher's formal science background and the use of higher level questioning. Butts and Raun (1969) found no evidence of a relationship between course hours in science and classroom practices among elementary teachers using *Science—A Process Approach*. Perkes (1975) found that, among prospective elementary teachers, the number of college science courses was negatively related to both preference for and sense of adequacy to teach science. In Stalheim's (1986) study of secondary biology teachers, the number of science courses was not a predictor of the use of classroom inquiry, but the year of the most recent course was. Because these researchers operationalized effective teaching differently in these studies, their findings are difficult to compare.

Other researchers who correlated formal science background with teaching found a positive relationship. For example, Wish (in Dobey, 1980) tried to explain the teaching behaviors of elementary science student teachers in terms of the number of college courses taken and found that formal science background was significantly and positively correlated with teaching science processes. Smith and Cooper (1967) surveyed 1,504 elementary teachers about their use of eight teaching techniques and correlated these with a set of teacher characteristics, including formal study in science. They found a positive relationship between science background and use of demonstration, pupil-conducted experiments, pupil recording and reporting, and individual and group projects. Furthermore, the use of textbooks "decreased steadily with increased amounts of formal study in science" (p. 562). In an observational study of elementary science teachers, Anderson (1979) provided convincing evidence that, "Lack of science content . . . made it virtually impossible for them to structure the information in lessons in ways preferred by science educators" (p. 226); the teachers avoided spontaneous questions from students, emphasized minor details in discussion, and failed to develop important concepts.

In the 1980s, researchers began to define SMK in new ways. Dobey, in his dissertation (Dobey, 1980; Dobey & Schafer, 1984), studied 22 preservice elementary teachers' SMK and level of inquiry teaching via their planning and teaching of a pendulum unit to fifth graders. The researchers measured SMK, not by the number of college science courses taken, but by performance and training on topic-specific tasks. The findings were mixed. Teachers in the "no knowledge" group were more teacher-directed than those with "intermediate knowledge," but not more so than the "knowledge" group teachers. The "no knowledge" teachers did not pursue new avenues of investigation during the lesson and allowed the least number of student ideas. The "no knowledge" group did not give out pendulum information in the lesson, and one-half of the "knowledge" group lectured at some point. This study demonstrates the complexities of correlating SMK with teaching.

It was followed by others that measured SMK with methods other than counting the number of science courses and assessed teaching effectiveness in a variety of ways. One of the most heavily cited studies in the area is Hashweh's dissertation (1985, 1987). He studied three biology and three physics teachers' SMK on a physics topic (simple machines) and a biology topic (photosynthesis) with the use of free

recall, concept map line labeling, and sorting tasks. He also assessed their "preactive" and "simulated interactive" teaching of each topic. The teachers had a strong SMK base in their field of expertise, which affected their simulated teaching behaviors. "When activities were provided by the textbook, unknowledgeable teachers followed them closely. Knowledgeable teachers made many modifications. . . . When no activities were provided, only knowledgeable teachers could generate activities on their own" (Hashweh, 1985, p. 247). Furthermore, knowledgeable teachers asked higher level questions on tests and were more able to detect student misconceptions. Hashweh demonstrated that SMK was related to another kind of knowledge for science teaching.

In a series of articles derived from his dissertation, Carlsen (1988, 1991a, 1991b, 1993) examined the SMK and teaching behavior of four novice biology teachers. He measured SMK via a card sort task of 15 topics, interviews about sources of knowledge, and analysis of the teachers' undergraduate science course records. Identifying high-knowledge and low-knowledge topics for each of the teachers, he analyzed lesson plans and observed actual lessons taught by the teachers for both kinds of topics. The results are complex and not easily summarized. Teachers used lectures, quizzes, and tests more with high-knowledge topics and group work more with low-knowledge topics. Three of the four teachers asked more questions on low-knowledge topics; all teachers asked higher level questions with high-knowledge topics. Teachers talked more in laboratories when they were knowledgeable, but labs on high-knowledge topics were less "cookbooky," and teacher talk in these labs was more responsive than initiative. Carlsen concluded that teacher SMK influenced their instructional decisions, but failed to recognize other types of teacher knowledge that might have been involved.

A host of other studies have examined connections between SMK and actual classroom practice. In a conceptually rich study, Sanders, Borko, and Lockard (1993) observed three experienced secondary science teachers as they taught disciplines for which they were certified and noncertified. Although the teachers acted similarly in terms of general pedagogical knowledge, they differed in their planning, interactive teaching, and reflection based on SMK; within their certification area, teachers talked less, chose more "conversationally risky" activities, and involved students more. In her dissertation study of five experienced biology teachers, Gess-Newsome (Gess-Newsome & Lederman, 1995) compared the teachers' subject matter structures with their classroom practice, concluding that the "level of content knowledge had a significant impact on how content was taught" (p. 317). Newton and Newton (2001) found that elementary teachers with less SMK (based on formal science background) interacted less, asked fewer causal questions, and spent more time lecturing. According to Smith (1987), elementary teachers' difficulties with the physics of light affected their ability to focus on the conceptual understanding of light in science activities and limited their use of examples and metaphors. Abell and Roth (1992) found that when Roth, an elementary student teacher, taught a low-knowledge topic, she started lessons late and ended early, used fewer hands-on activities, and relied more on text-based lessons. Lee (1995) found similar results in a case study of a middle-level science teacher whose limited SMK was associated with heavy reliance on the textbook and seatwork and avoidance of whole class discussion.

Researchers have also correlated SMK to teaching behaviors of preservice teachers with the use of simulated teaching activities. Smith (1997), in attempting to relate preservice teachers' success on class assignments such as lesson planning with their SMK, claimed that "knowledge of science does enhance teaching, but not in a straightforward manner" (p. 151). Lloyd et al. (1998) tested preservice elementary teachers on their SMK and pedagogical content knowledge, and although teachers held misconceptions in both areas, the researchers did not find a direct relationship between SMK and PCK. Symington (1980) found that preservice elementary teachers who were given a scientific explanation of a phenomenon did not generate more teaching options in response to written cases, but did demonstrate reduced teacher directiveness. Examining preservice elementary teachers as they planned a science lesson, Symington and Hayes (1989) demonstrated that inadequate SMK led to limitations in planning, and that future teachers had few strategies for coping with their lack of science understanding. However, in another study, Symington (1982) found no direct relationship of SMK to a preservice teacher's ability to plan appropriate materials for student investigation. According to Symington, there must be other kinds of knowledge and abilities that "compensate for a lack of scientific knowledge" (p. 70). In an interesting twist on studying the relation between SMK and teaching, Shugart and Hounshell (1995) examined the relation between SMK (as measured on standardized tests) and teacher retention among 83 secondary science teachers; they found that the higher the science test scores, the more likely teachers were to leave teaching by the 9th or 10th year.

The studies of the relationship between SMK and science teaching represent a variety of participants (preservice and practicing teachers at the elementary, middle, and high school levels) and a variety of methods for assessing SMK (courses taken, surveys, interviews) and teaching behaviors (indirect methods such as responses to hypothetical teaching situations and direct observations of teaching). Despite this mixture of settings and methods, the evidence does support a positive relationship between SMK and teaching. Although Lederman and Gess-Newsome (1992) were less enthusiastic about this claim, their evidence included studies of teachers' views of the nature of science, studies that are not considered here. Could it be, as Lederman and Gess-Newsome suggested, that some minimal SMK is necessary, but that studies at different grades, or with preservice versus practicing teachers, cannot be compared fairly? Or could it be that SMK does have an effect on science teaching, but that this effect is mediated by other types of teacher knowledge? This was implied in many of the studies reported. Perhaps SMK is necessary, but not sufficient, for effective teaching. A review of studies of PK and PCK could be instructive.

## SCIENCE TEACHER PEDAGOGICAL KNOWLEDGE

Grossman's (1990) formalization of Shulman's model of teacher knowledge included a component of pedagogical knowledge separate from PCK that she labeled general pedagogical knowledge (PK). PK includes knowledge of instructional principles, classroom management, learners and learning, and educational aims that are not subject-matter-specific. Theoretically, these types of knowledge interact with PCK

for teaching of a particular topic in a discipline (see Fig. 36–1). In the science education literature, most of the research on teacher pedagogical knowledge logically falls into the category of PCK, pedagogical knowledge for teaching science topics (see next section). Some studies that claimed to be about PK actually cited science-specific teacher knowledge (see Gustafson, Guilbert, & MacDonald, 2002) and are better placed in the PCK category. However, the few studies that examined the PK of science teachers in particular are reviewed here.

Science teachers' generic meaning of learning (Aguirre & Haggerty, 1995) and their metacognitive knowledge of higher order thinking (Zohar, 1999) have been investigated. Another group of studies focused on science teachers' knowledge of classroom management. Three studies examined "pupil control ideologies" with a written instrument developed for the purpose (Harty, Andersen, & Enochs, 1984; Jones & Blankenship, 1970; Jones & Harty, 1981). As is all too familiar in the science education literature, researchers coined a new term for a hypothetical construct, developed a measurement tool, and used the tool in a few studies. Then the construct and the tool disappeared from the literature. In another study of classroom management, Latz (1992) used an open-ended questionnaire to learn about pre-service teachers' knowledge of management and discipline. He suggested a link between instructional approaches and teachers' "preventative" view of classroom management.

One interesting outcome of several case studies of science teachers has been that a majority of assertions have concerned PK rather than PCK (Gallagher, 1989; Mills, 1997; Treagust, 1991). For the most part, the findings of such studies could relate to teachers of any discipline; what makes these studies significant to the science education community? Could it be that the influence of PK on PCK needs to be better articulated? I believe that more attention must be paid to the interaction of PK with PCK—for example, the role of caring, classroom management, or general learning views—in how teachers teach science.

## SCIENCE TEACHER PEDAGOGICAL CONTENT KNOWLEDGE

### Frameworks and Methods of Representation

Pedagogical content knowledge (PCK) has been defined as "the transformation of subject-matter knowledge into forms accessible to the students being taught" (Geddis, 1993, p. 675). Grossman (1990) and later Magnusson et al. (1999) defined separate components of PCK, including orientations, knowledge of learners, curriculum, instructional strategies, and assessment. Yet, the PCK literature in science education is not nearly as tidy as the SMK literature. Some researchers directly studied PCK, but only a small portion explicitly discussed a particular kind of PCK. Most use PCK as a generic term across several of the subsections. Others did not mention PCK at all, either because they preceded Shulman's work in the mid-1980s, or used frameworks other than Shulman's to interpret the findings. Still other researchers who used the PCK framework introduced new constructs into the literature, including "activities that work" (Appleton, 2002), "pedagogical content concerns" (de Jong,

2000; de Jong & van Driel, 2001), and “pedagogical context knowledge” (Barnett & Hodson, 2001). Moreover, the words researchers used for “knowledge” have been conflated within and across studies, and included terms such as *conceptions*, *perceptions*, *theories*, *concerns*, and *beliefs*, in addition to *knowledge*. For example, Porlán and Martín del Pozo (2004) studied teachers’ “*conceptions* about science teaching and learning” (p. 43) by using the Inventory of Science Pedagogical *Beliefs*.

For these reasons, the science education PCK literature lacks coherence (for example, there are few common citations) and is difficult to categorize. However, I felt compelled to impose some order on this large literature. I tried to fit studies, without forcing, into the five PCK categories (see Fig. 36–1), whether the researchers were explicit about such a categorization or not. Other studies that did not fit neatly into one type of PCK are discussed in this introductory section. Here I also discuss some of the common methods for representing teacher PCK that have been used.

Several lines of research used frameworks other than Shulman’s to understand science teacher knowledge. For example, science education researchers have used Schön’s theory of reflective practice to understand the development of “professional knowledge” (Abell, Bryan, & Anderson, 1998; Anderson, Smith, & Peasley, 2000; Munby, Cunningham, & Lock, 2000; Munby & Russell, 1992; Russell & Munby, 1991). These studies demonstrated how teacher knowledge develops over time with respect to various inputs and perturbations, but did not classify teacher knowledge as Shulman did.

Another line of science teacher research concerned itself with teacher planning. Although this research typically did not mention Shulman or PCK, being more often framed by a teacher cognition perspective, notions of teacher knowledge were often implicit. The planning literature in teacher education is rich (see Clark & Peterson, 1986; So, 1997), but science education is not well represented. Science education studies on teacher planning have examined both preservice (Davies & Rogers, 2000; Morine-Dershimer, 1989; Roberts & Chastko, 1990) and practicing (Aikenhead, 1984; Sanchez & Valcárcel, 1999; So, 1997) science teachers in an attempt to understand how teachers plan and what knowledge and beliefs influence their planning. Peterson and Treagust (1995) used Shulman’s model of pedagogical reasoning to study the stages of science teacher reasoning while planning. While planning, preservice teachers relied on SMK and curricular knowledge, but during instruction, their reasoning “considered the teaching sequence, the science content and curriculum knowledge, the prior knowledge of the learner, and the explanations they would use for the activities to be discussed” (p. 300). The “Lesson Preparation Method” (Valk & Broekman, 1999) was introduced as a strategy to uncover science teacher PCK, and lesson planning has been used in other studies of science teacher knowledge (de Jong, 2000; de Jong, Ahtee, Goodwin, Hatzinikita, & Koulaidis, 1999). However, the findings of Peterson and Treagust lend some degree of skepticism to the method of representing PCK solely by planning activities and suggest that studies of PCK during teaching need to simultaneously occur.

Another method of representing teacher PCK has been via metaphors (Bradford & Dana, 1996; Briscoe, 1991; Hand & Treagust, 1997; Munby 1986; Tobin & LaMaster, 1995). Munby claimed that “metaphorical figures can be studied with a view to comprehending a teacher’s construction of professional reality” (p. 206). Although none of these studies used Shulman’s views of teacher knowledge as their theoret-

ical framework, their findings do help in understanding the knowledge/orientations of science teachers.

Loughran and colleagues (Loughran, Gunstone, Berry, Milroy, & Mulhall, 2000; Loughran, Mulhall, & Berry, 2004; Loughran, Milroy, Berry, Gunstone, & Mulhall, 2001) developed a system for representing science teacher PCK. Their work began by writing cases of PCK, a process they called “classroom window” methodology. Finding deficits in this method of representation, they next developed PaP-eRs, Pedagogical and Professional-experience Repertoires. The PaP-eR characterizes teacher knowledge around a specific science topic and is an amalgam of types of PCK. The researchers called this mode of representation a breakthrough in capturing a teacher’s PCK. At this writing, it is too soon to tell if the PaP-eR will find a more widespread use among researchers and science teacher educators.

A host of other methods, including expert/novice studies (MacDonald, 1992; Pinnegar, 1989), interviews (Fernández-Balboa & Stiehl, 1995; Koballa, Gräber, Coleman, & Kemp, 1999), classroom observations (van Driel, Verloop, & de Vos, 1998), and analysis of teacher study group discussions (Daehler & Shinohara, 2001; Geddis, 1993) have been employed to understand science teacher PCK. Given the complexity of representing PCK, studies that use multiple methods over time to understand teacher knowledge seem to be the richest. For example, Bellamy (1990) observed and interviewed high school biology teachers teaching genetics. The teachers demonstrated similarities in their PCK for genetics teaching through the use of common teaching sequences and activities. Sanders, Borko, et al. (1993) observed and interviewed three secondary science teachers as they planned, taught, and reflected on their science teaching both within and outside of their certification area. Their study generated a rich data set from which they made numerous claims concerning SMK, PK, and PCK. van Driel, de Jong, and Verloop (2002) studied pre-service chemistry teachers’ PCK via questionnaires, interviews, and workshop session conversations over one semester and were able to describe teachers’ PCK and its development.

Research on science teacher PCK resides in a formative phase, where researchers continue to define the terms and methods that guide their work. The research has raised several questions. For example, Peterson and Treagust (1995) suggested that the knowledge a teacher uses for teaching may not be the same as that represented in written surveys or instruments. What forms of represented PCK are most trustworthy? What research designs are most viable? Appleton (2002) reported that elementary teachers of science consider “activities that work” the basis of their science instruction, and he claimed that this notion is the centerpiece of elementary teachers’ science PCK. Should PCK be defined differently for teachers at different grade levels? Other researchers cause us to question Shulman’s model itself—do we need to add new terms such as *pedagogical context knowledge* and *pedagogical content concerns* to our research lexicon? Science educators have embraced Schulman’s work as a useful theoretical framework. The PCK framework has been used to understand science teacher knowledge across grade levels and career spans. It has also been suggested as a viable model for thinking about the knowledge that science teacher educators hold, or should develop, to be effective (Abell, Smith, Schmidt, & Magnusson, 1996; Smith, 2000). However, we must continue to ask if the theoretical construct of PCK is supported, disconfirmed, or in need of expansion, using evidence

derived through empirical research. The following sections examine empirical research within the five components of PCK shown in Fig. 36–1.

## **Orientations toward Science Teaching**

Anderson and Smith (1987) introduced the term “orientation” as a way to categorize disparate approaches to science teaching (activity-driven, didactic, discovery, and conceptual-change). Grossman’s (1990) model of PCK included the category “conceptions of purposes for teaching subject matter” (p. 5), for which Magnusson et al. (1999) substituted the label “orientation.” They used the label to represent teacher knowledge of the purposes and goals for teaching science at a particular grade level, after Grossman, but also called an orientation a “general way of viewing or conceptualizing science teaching” (p. 97). They expanded Anderson and Smith’s list of four orientations to nine. The inclusion of “orientations” in the PCK model is problematic. First of all, an orientation is theorized as a generalized view of science teaching, not topic-specific knowledge. Second, these general views of science teaching and learning are often studied as an interaction among knowledge, beliefs, and values, not strictly as knowledge structures. Furthermore, these general views have been called by a number of different names in the literature. Although some will undoubtedly question the inclusion of some of the studies in this section, I believe their presence in the literature must be acknowledged, so that we can understand the field and develop a more cohesive research agenda.

Very few studies set out to explicitly understand teachers’ orientations to teaching science. Studies by Greenwood (2003) and Friedrichsen (2002; Friedrichsen & Dana, 2003, 2005) are notable exceptions. Friedrichsen called orientations “a messy concept” (p. 11) because either researchers provided no clear definition, or they introduced new terms into the mix. For example, researchers have used labels such as “conceptions of science teaching” (Hewson & Hewson, 1987; Porlán & Martín del Pozo, 2004), “functional paradigms” (Lantz & Kass, 1987), “world images” (Wubbels, 1992), “preconceptions of teaching” (Weinstein, 1980), and “approaches to teaching” (Trigwell, Prosser, & Taylor, 1994) to study what appears to be teaching orientations. For this section, I selected studies that examined teacher knowledge of guiding purposes and frameworks for science teaching and left studies of teacher views of curricular goals and instructional models to later sections.

One line of research on orientations followed the work of Anderson and Smith (1987). Roth (1987) studied 13 experienced junior high life science teachers and found three groups of teaching orientations: fact acquisition, conceptual development, and content understanding. Smith and Neale (1989, 1991) imposed four orientations on their data: discovery, processes, didactic/content mastery, and conceptual change. Hollon, Roth, and Anderson (1991) examined the cases of two middle-level science teachers and claimed that teacher practice was governed not only by SMK, but also by “deeply held patterns of thought and action that have developed over many years” (p. 176). Anderson et al. (2000), using interviews as primary data sources, described the development of five preservice teachers’ “conceptions” across one year of teacher education. The authors claimed that the students entered the teacher education program along a particular trajectory and focused their learning on aspects of teaching congruent with these conceptions. However, one student, Mindy, expe-

rienced a more dramatic change: from a teacher-centered conception of science teaching to a view where students took center stage. Bryan and Abell (1999), although not studying orientations directly, found a similar progression in one student teacher's thinking. Barbara began student teaching with a teacher-centered view that blamed students for their inability to learn and progressed to a deeper understanding of the requirements for learning. This line of research changed over time from a concern with labeling specific teaching orientations to understanding how these orientations develop.

Another line of research on orientations introduced the term "conceptions of teaching" as "the set of ideas, understandings, and interpretations of experience" concerning teaching, learning, and the nature of science that teachers use to make decisions (Hewson & Hewson, 1989, p. 194). Hewson and Hewson (1987) defended the construct and then designed an interview task (1989) for identifying teacher conceptions of teaching science. In subsequent studies, they refined the protocol and used it to study the conceptions of teaching held by both preservice and practicing science teachers (Hewson, Kerby, & Cook, 1995; Lemberger, Hewson, & Park, 1999; Lyons, Freitag, & Hewson, 1997; Meyer, Tabachnick, Hewson, Lemberger, & Park, 1999). In particular, they were interested in how teachers built their understanding of conceptual change science teaching.

Other than these two lines of research, studies of teacher orientations have not formed a coherent line of thought, often because researchers introduced their own terms rather than building on the existing literature. Several studies categorized teaching orientations. Lantz and Kass (1987) studied how three chemistry teachers translated curriculum materials into practice. They interpreted teacher comments to represent three views of teaching: pedagogical efficiency, academic rigor, and motivating students. They used the term "functional paradigm" to describe the teachers' views of chemistry, teaching, students, and the school setting and claimed that a teacher's functional paradigm (or what Shulman might call PK or Magnusson et al. (1999) would call orientation) influenced how curriculum materials were interpreted and implemented. Freire and Sanches (1992) used both "orientations" and "conceptions of teaching" to describe Portuguese physics teachers' views. They derived five conceptions of teaching physics—traditional, experimentalist, constructivist, pragmatist, and social—but did not find them demonstrated in practice. Huibregtse, Korthagen, and Wubbels (1994) identified goals and approaches to teaching held by Dutch physics teachers. They found that the teachers favored approaches to teaching that fit their own learning preference, but had limited conceptions of teaching overall. In one of the few studies on college science teacher PCK, Trigwell et al. (1994) found 24 chemistry and physics professors to hold one of five "approaches to teaching": (a) teacher-centered to transmit information (13 instructors); (b) teacher-centered so students acquire concepts (6 instructors); (c) teacher-student interaction so that students acquire concepts (3 instructors); (d) student-centered so students develop conceptions (1 instructor); and (e) student-centered aimed at students changing their conceptions (1 instructor). Huston (1975) measured the "values orientations" of chemistry teachers and students in Canada and found that students were more highly oriented to the humanistic and technological aspects of chemistry, whereas teachers were oriented to the more abstract and theoretical. Cheung and Ng (2000) defined five curriculum orientations: academic, cognitive processes, society-centered, humanistic, and technological, and asked secondary science teachers

in Hong Kong which orientations they most valued. They found that teachers were most enthusiastic about the cognitive processes orientation but valued all of the orientations. These findings resonate with Friedrichsen's (2002) study of secondary biology teachers. Orientations shifted based on which course the teacher was teaching and the "perceived needs of a particular group of students" (p. 143). Thus a teacher's orientation is not a single static entity with neat boundaries, but a fluid set of components influenced by a host of issues.

Attempting to categorize and understand orientations by the use of common terms from the literature is not the only approach that has been used to study this component of PCK. Some studies used open-ended questionnaires to ask teachers about their conceptions of science teaching and learning (Aguirre, Haggerty, & Linder, 1990; Gurney, 1995; Parsons, 1991) or a survey to find out their "conceptions of purposes" for science teaching (Zeitler, 1984). Another strategy for studying teaching orientations has been to examine teacher views of good science teaching (Brickhouse, 1993; Guillaume, 1995; Skamp, 1995; Skamp & Mueller, 2001; Stofflett & Stefanon, 1996). Other researchers adopted a case-study methodology as a way to understand science teachers' frameworks (Adams & Krockover, 1997; Cornett, Yeotis, & Terwilliger, 1990; Feldman, 2002; Geddis & Roberts, 1998; Johnston, 1991; Maor & Taylor, 1995; Ritchie, 1999; Sweeney, Bula, & Cornett, 2001). Mellado (1998) constructed cases of four Spanish student teachers—elementary and secondary—and their conceptions of teaching and learning science. All four teachers demonstrated an "apparent constructivist orientation" (p. 204) toward learning, but they assigned different values to student ideas. Furthermore, their classroom practices were closer to traditional models of teaching than to the orientation they espoused.

Orientation is indeed a messy construct. Some researchers adopt PCK as their theoretical perspective, some use theories other than Shulman's to guide their work, and others appear to be atheoretical in their approach. Researchers need to come to a clear consensus about what they are studying in this realm. Rather than introduce new terms, it would benefit the field to more deeply understand the existing constructs. Nevertheless, a few conclusions seem reasonable based on the literature: (a) orientations influence teacher learning and practice, although that influence is not direct (Anderson et al., 2000; Lantz & Kass, 1987; Lemberger et al., 1999); (b) orientations (or whatever they are termed) are much less coherently held and much more context-specific than the theoretical literature led us to believe (Cheung & Ng, 2000; Friedrichsen, 2002; Friedrichsen & Dana, 2005); (c) teachers often do not possess a tacit knowledge of their conceptual framework (Gallagher, 1989); (d) although teachers possess or value a range of orientations that guide practice, their set of teaching strategies is much more narrow (Freire & Sanches, 1992; Gallagher, 1989; Huibregtse et al., 1994; Mellado, 1998); and (e) orientations can change over time (Anderson et al., 2000; Bryan & Abell, 1999; Feldman, 2002; Sweeney et al., 2001). However, much more work is needed to understand the frameworks that guide science teachers in their planning and enactment of instruction.

## **Knowledge of Science Learners**

This category of PCK pertains to knowledge teachers have about student science learning: requirements for learning certain concepts, areas that students find diffi-

cult, approaches to learning science, and common alternative conceptions (Magnuson et al., 1999). The research in this area has concentrated on teacher knowledge of alternative conceptions, teacher images of the ideal science student, and more general views of science learning.

A logical extension of the research on children's and teachers' science conceptions was to examine teacher knowledge of student science ideas. As early as 1981, Nussbaum asked biology and chemistry student teachers to respond to hypothetical students' science explanations about the structure of matter that contained three major misconceptions. Although 45 percent of the teachers detected one misconception, only 7 percent found all three and 22 percent found none. The chemistry student teachers performed no better than the biology student teachers. In a similar study, Kokkotas et al. (1998) found that preservice secondary teachers could not identify student problems in thinking about the particulate nature of matter. Deficiencies in teacher knowledge of student ideas about heat and temperature (Fredrik et al., 1999) and electricity (Stocklmayer & Treagust, 1996) have also been found.

Survey methods were used in some studies to determine teacher knowledge about student science ideas. Pine, Messer, and St. John (2001) surveyed 122 elementary science teachers in the United Kingdom. When asked to give examples of common ideas held by students, 90 of the teachers produced 130 responses, in all areas of the science curriculum. The researchers concluded that teachers had a strong awareness of student alternative ideas. This finding stands in stark contrast to the results of other studies. For example, McNay (1991) asked a small group of Canadian elementary teachers to read several research articles about students' science ideas. Some teachers did not believe what they read until they interviewed their own students and heard the ideas firsthand. In a study of secondary physical science teachers in Portugal (Sequeira, Leite, & Duarte, 1993), only 45 percent stated they had heard about alternative conceptions, even though 80 percent of university instructors claimed it was part of the preservice program. Of the teachers who had heard of alternative conceptions, most recognized them from a list and stated that such ideas can be hard to change. In Malaysia, Halim and Meerah (2002) asked 12 prospective physics teachers how they thought students would respond to a set of questions. The researchers found that many teachers were unaware of students' likely misconceptions and had inadequate SMK. In an interview setting, Berg and Brouwer (1991) asked 20 high school physics teachers to predict student responses to questions about force and gravity. In addition to demonstrating several alternative conceptions themselves, the teachers underestimated the number of students who would hold various conceptions and overestimated the number of students who would respond with the correct answer.

Several studies examined teacher knowledge of student conceptions within the context of teaching. de Jong and van Driel (2001) asked prospective chemistry teachers to discuss their concerns before teaching a lesson in grade 9 and then to discuss the difficulties they had after teaching. Prior to the lesson, only 3 of the 8 students mentioned any concerns about student learning. After the lesson, a few more discussed student learning difficulties in their reflection. Jones et al. (1999) engaged elementary and middle-level teachers in interviewing students and teaching lessons and assessed their pre/post SMK and knowledge of teaching. They found that teachers were "shocked" by the science concepts revealed by students and that student concepts served as catalysts for the teachers to reevaluate both their SMK and

their pedagogical practices. Geddis, Onslow, Beynon, and Oesch (1993) found that two chemistry student teachers, in the context of teaching about isotopes, did not realize the difficulties students would encounter in learning weighted averages, given their familiarity with simple averages. The veteran teacher, in contrast, was able to predict and plan around these difficulties. Likewise, Akerson, Flick, and Lederman (2000) found a big difference between how two veteran elementary teachers and a student teacher dealt with student ideas. The veterans viewed children's ideas as perceptually dominated, structured, coherent, experience-based, and resistant to change and repeatedly tried to elicit student ideas. The student teacher, on the other hand, discouraged student expression of their science ideas, and focused on eliminating student ideas so she could proceed with her instruction. Morrison and Lederman (2003) found that the four secondary science teachers in their study valued diagnosis of student preconceptions, but had varying degrees of understanding of possible preconceptions.

A host of other studies have attempted to understand teacher knowledge of students with the use of various frameworks. For example, Pinnegar (1989) used an expert/novice frame and a repeated interview technique to study high school science teachers' knowledge of students. She found that teachers' knowledge of students came mostly from classroom observations and interactions, and that their knowledge increased over time. Experienced teachers were able to provide evidence to support their interpretations of students. Two studies examined teacher views of excellent science students (Bailey, Boylan, Francis, & Hill, 1986; Raina, 1970). Teachers often mentioned traits of good students (e.g., obedience, good listener, completing tasks), as well as personality traits (organized, neat), as opposed to traits associated with scientific or creative thinking.

As views of science learning broadened, so did attempts to understand teacher knowledge of science learning. In a study of exemplary secondary science teachers in Australia (Gallagher, 1989), teachers characterized learning as driven by motivation. Several studies of preservice teachers (Geddis & Roberts, 1998; Gustafson & Rowell, 1995; Lemberger et al., 1999; Zembal-Saul, Blumenfeld, & Krajcik, 2000) described teacher views of science learning as part of an overall orientation to science teaching. Others related teachers' views of learning to their views of the nature of science (Abell & Smith, 1994; Flores, Lopez, Gallegos, & Barojas, 2000; Hashweh, 1996a, 1996b). These researchers claimed a connection between a positivist epistemology and a behaviorist or discovery-oriented view of science learning. Hashweh demonstrated that teachers holding what he called "empirical" beliefs of knowledge and learning were more apt to judge student alternative conceptions as acceptable than were teachers holding "constructivist" views. The research on teacher knowledge of science learning has employed a broad range of methods and lacks cohesion in terms of the research questions addressed. Overall it appears that teachers lack knowledge of student science conceptions, but that this knowledge improves with teaching experience.

## **Knowledge of Science Curriculum**

Magnusson et al. (1999) defined two types of science curriculum knowledge: (a) knowledge of mandated goals and objectives (e.g., state and national standards)

and (b) knowledge of specific curriculum programs and materials. Few studies attempted to directly study teacher knowledge of science curriculum, or cited Shulman's model as a theoretical foundation for the research. One notable exception is Peterson and Treagust (1995), who found that knowledge of curriculum was an essential component of preservice teacher pedagogical reasoning around lesson planning and instruction.

Science teacher knowledge of curricular goals has been researched, but studies typically asked teachers to rank the relative importance of the goals, rather than examine teacher knowledge directly. Tamir and Jungwirth (1972) asked Israeli biology teachers familiar with the BSCS biology curriculum to rank 18 teaching objectives. A majority ranked "developing critical thinking" as most important, and 54 percent assigned bottom rank to "accumulation of biological knowledge." However, there was not agreement about objectives such as "understanding the role of science in everyday life" or "understanding the nature and aims of science." In 1982, Finley, Stewart, and Yarroch surveyed 400 U.S. science teachers in four science disciplines about their perceptions of the difficulty and importance of 50 topics in their discipline. Teachers rated a number of topics important, but not difficult, for students to learn (e.g., cell theory, periodic table, energy and energy conservation, Earth/Moon system). Finley and colleagues made no attempt to link teacher perceptions with local or state curricular goals. Science teachers' goals have been studied around the world, with the use of terms such as "goal conceptions," "goal orientations," and "views of goals," in Australia (Schibeci, 1981), Finland (Hirvonen & Viiri, 2002), France (Boyer & Tiberghien, 1989), Israel (Hofstein, Mandler, Ben-Zvi, & Samuel, 1980), Spain (Furió, Vilches, Guisasola, & Romo, 2002), the United Kingdom (Carrick, 1983), and the United States (McIntosh & Zeidler, 1988). Although science teachers recognize a variety of goals for science teaching, they tend to emphasize content goals over attitudinal or process goals.

In a study of teaching goals in action, Geddis et al. (1993) examined the curricular knowledge that comes into play in the teaching of a particular topic. The researchers introduced the term "curricular saliency," to explain how veteran teachers cope with a curriculum full of concepts and decide what is important to teach. Teacher rankings of goals is only a small part of the knowledge that comes into play when curricular decisions are made.

In the wake of the standards-based science education reforms of the 1990s, it is surprising that so little attention has been paid to understanding teacher knowledge of science standards. A few studies have addressed this (Fischer-Mueller & Zeidler, 2002; Furió et al., 2002; Lynch, 1997), but more are needed. Although educators often bemoan the lack of reform-minded science teaching, researchers have not contributed an understanding of the curriculum knowledge that is necessary for the reforms to be effective.

Science teacher knowledge of curriculum programs and materials (the second type of knowledge of science curriculum defined by Magnusson and her colleagues (1999)) likewise suffers from a dearth of research attention. One of the earliest studies of this type of knowledge looked at teacher awareness and use of population education materials (O'Brien, Huether, & Philliber, 1978) and found that 60–70 percent of U.S. population education teachers were not familiar with a range of curriculum materials. Schriver and Czerniak (1999) compared U.S. middle school science teachers to those in junior high settings on a number of variables, including self-efficacy

and knowledge of developmentally appropriate curriculum. Knowledge of developmentally appropriate curriculum was higher for the middle school teachers, positively correlated with level of outcome expectancy, but unrelated to self-efficacy. Peacock and Gates (2000) examined the perceptions of 23 newly qualified elementary teachers in the United Kingdom regarding the role of the textbook in science learning. Teachers thought of the text as peripheral to science activities and as needing to be adapted before use. Textbook selection was based on surface features and was not related to a teacher's SMK. Although several tools have been generated in the United States for teacher use in curriculum analysis (Kesidou & Roseman, 2002; National Research Council, 1999), we know little about the knowledge teachers bring to bear on the analysis, selection, or design of science curriculum materials. One recent study (Lynch, Pyke, & Jansen, 2003) offers insight into this process.

### **Knowledge of Science Instructional Strategies**

This type of teacher knowledge includes subject-specific strategies (e.g., learning cycle, use of analogies or demos or labs) and topic-specific teaching methods and strategies, including representations (examples, models, metaphors), demonstrations, and activities (labs, problems, cases) (Magnusson et al., 1999). The research has examined both categories of teacher knowledge but is lacking in studies of teacher representations of science content.

A small group of researchers has studied teacher understanding of science teaching approaches (Jones, Thompson, & Miller, 1980), including the learning cycle (Marek, Eubanks, & Gallagher; 1990; Marek, Laubach, & Pedersen, 2003; Odom & Settlage, 1996; Settlage, 2000), the Generative Learning Model (GLM) (Flick, 1996), and STS instruction (Tsai, 2001). Flick found that U.S. elementary teachers could not completely distinguish between the GLM and direct instruction teaching models. Olson (1990) found a similar confusion among UK teachers: "They tended to think of discovery teaching approaches as if they were variants of more familiar teacher directed forms" (p. 210). Settlage and colleagues reported a lack of understanding of the learning cycle among preservice elementary teachers after instruction but found no relation between this knowledge and anxiety about teaching science. Marek and colleagues found that both elementary and secondary science teachers who demonstrated a sound understanding of a Piagetian view of learning also had a deeper understanding of the learning cycle. Hashweh (1996a) related teachers' epistemological views to their knowledge of conceptual change teaching strategies and found that teachers holding constructivist views possessed richer repertoires of such strategies.

Although we emphasize inquiry-based teaching and instructional models such as the learning cycle in science teacher education programs, we have little empirical knowledge of what teachers learn. According to Keys and Bryan (2001), research on teacher knowledge of inquiry-based instructional strategies has not been sufficiently developed. More science education research should be devoted to examining what teachers understand about classroom inquiry strategies and science teaching models, and how they translate their knowledge into instruction.

Other studies have looked at PCK related to strategies for teaching specific topics within chemistry (de Jong, Acampo, & Verdonk, 1995; de Jong & van Driel, 2001; Geddis et al., 1993; Tulberg et al., 1994; van Driel et al., 1998, 2002; see also de Jong

et al., 2002, for a review), biology (Mastrilli, 1997; Treagust, 1991), and physics (Halim & Meerah, 2002). Geddis and colleagues compared the teaching of isotopes between two novices and a veteran teacher. Both of the novices taught procedural knowledge—calculating average atomic masses—with the use of accurate examples. The veteran, however, was more concerned with conceptual understanding and used inaccurate examples to scaffold student learning. The researchers claimed that this is a clear instance of a teacher transforming SMK by using instructional strategies that take student learning into account. In contrast, de Jong, Acampo, and Verdonk observed the teaching of redox reactions by two experienced chemistry teachers and found that the teachers had many difficulties developing viable instructional strategies.

Researchers have also studied teacher knowledge and use of general science instructional strategies. Enochs, Oliver, and Wright (1990) found that one-third or more of Kansas science teachers never used teaching strategies such as demonstrations, cooperative learning, or laboratories. Others examined the use of strategies such as analogies (Mastrilli, 1997; Nottis & McFarland, 2001), models (Justi & Gilbert, 2002a, 2002b; van Driel & Verloop, 2002), and demonstrations (Clermont, Borko, & Krajcik, 1994; Clermont, Krajcik, & Borko, 1993). Clermont and his colleagues found differences in the PCK for chemical demonstrations between experienced and novice demonstrators. The experienced teachers discussed more alternative chemical demonstrations for each topic and provided more detail about their alternatives than the novices. They also generated more variations on the demonstration presented. Novices occasionally discussed inappropriate content or pedagogically unsound demonstrations. These studies demonstrate that knowledge of instructional strategies is linked to SMK and knowledge of learners, but also demands understanding of the subtleties of the strategy in use.

A conceptually rich study of the content representations of two elementary student teachers as they engaged in two cycles of planning, teaching, and reflecting (Zemal-Saul et al., 2000) provides a window into the development of teacher knowledge of instructional strategies. In an initial teaching cycle, these preservice teachers were able to plan many scientifically accurate content representations but included too many topics that were not sequenced well. Furthermore, during teaching, they had difficulty in helping students make connections among the topics. In a second cycle, the teachers again planned multiple and accurate representations of the content, but were more selective and better able to connect activities and representations during class discussions. Following these teachers into student teaching, the researchers found that although one of the teachers was able to maintain and enhance content representations in science, the second teacher was not (Zemal-Saul, Krajcik, & Blumenfeld, 2002). These studies demonstrate the complexity of science teaching in terms of the interplay of SMK and PCK. They also illustrate how future teachers can learn from the authority of experience (Munby & Russell, 1994) and how context affects a student teacher's content representations.

## Knowledge of Science Assessment

According to Magnusson et al. (1999), this type of teacher knowledge includes knowledge of what to assess in science as well as methods for assessing. A few studies have attempted to directly study teacher assessment knowledge by a variety of

methods. Pine, Messer, and St. John (2001) described the methods UK elementary teachers used to find out what students know, which included discussion, brainstorming, past records, questioning, testing, and predicting. Duffee and Aikenhead (1992) interviewed six 10th-grade urban science teachers regarding student evaluation decisions within an STS curriculum. Although teachers used a variety of techniques, tests and lab assignments were weighted most heavily to determine final grades. How and what the teachers chose to assess were mediated by their beliefs and values. For example, the four teachers who integrated STS and the nature of science into their teaching assessed students' abilities to solve problems and reason, and the two teachers who thought of science as factual relied more on objectively scored items with one right answer.

However, knowing what assessment methods teachers use does not provide insight into how assessment is enacted. In attempting to understand science teacher assessment knowledge in action, Sanders (1993) asked 136 South African biology teachers to mark student answers about respiration. The teachers used different criteria to mark the answers, resulting in a wide distribution of final scores. Many teachers looked for correct statements only, ignored wrong answers, and failed to provide feedback to students. The majority of positive feedback referred to the logical structure of the essay (34 percent) or neatness (22 percent), and 11 percent gave general positive comments even when student ideas were wrong. Kokkotas et al. (1998) attributed Greek preservice secondary teachers' inability to identify problems in student answers about the particulate nature of matter to their lack of SMK. In addition, teachers scored answers too strictly or leniently based on factors other than student responses, including their perceptions of the difficulty of the topic and their attitude toward the need to encourage students. Morrison and Lederman (2003) found that the science teachers in their study did not use any assessment tools to diagnose student preconceptions, even though they recognized the importance of student prior knowledge. Bol and Strage (1996) found a similar contradiction between biology teacher goals and assessment practices.

Two case studies of science teachers emphasized assessment knowledge and practices. Kamen (1996) found that a third-grade teacher was able to shift her assessment practices when her image of science instruction changed from hands-on to minds-on, supported by learning new assessment methods. Briscoe (1993) claimed that Brad, a veteran high school chemistry teacher, viewed assessment as rewards and punishments and equated assessment to testing, thus was resistant to change. According to Briscoe, a teacher's ability to change his/her assessment practices is "influenced by what the teacher already knows or understands about teaching, learning, and the nature of schooling" (p. 983). These studies of teacher knowledge of assessment in science provide rich research models that demonstrate a link between PCK for assessment and science teaching orientation. More studies are needed to better understand what teachers know about assessment, and how they design, enact, and score assessments in their science classes.

## DISCUSSION

The science education research on teacher knowledge rests on firm theoretical and empirical foundations, yet continues to develop both conceptually and methodolog-

ically. The research on SMK is cohesive, partly because definitions of SMK are commonly shared even when research methods differ. In contrast, the research on PCK is less cohesive. Researchers do not agree about what constitutes PCK, or do not evenly apply their meanings to their research. In addition, frames other than PCK have been used to ground research on teacher pedagogical knowledge. Nevertheless, I believe we can use this review of this literature to derive implications both for science teacher education and for further research.

## Implications for Science Teacher Education

Science educators have recognized the value of Shulman's model of teacher knowledge as an organizer for science teacher education. Cochran, DeRuiter, and King (1993) proposed a revision to Shulman's model that combined SMK and PCK, claiming that all teacher knowledge is pedagogical. They also posited that, because knowledge is not a static state but an active process, PCK should be changed to PCKg, pedagogical content knowing, and that such a model could inform teacher education programs. However, this idea has not been pursued in the literature.

Several science educators have used the PCK framework to design teacher preparation programs for elementary (Mellado, Blanco, & Ruiz, 1998) and middle-level (Doster, Jackson, and Smith, 1997) science teacher education. Zembal-Saul, Haefner, Avraamidou, Severs, & Dana (2002) demonstrated how to employ the PCK framework not only to structure learning goals and teaching methods, but also to design performance-based tools for evaluating teacher learning. Although Shulman's model is useful for practice in science teacher education, the teacher knowledge framework is necessary, but not sufficient. Windschitl (2002) reminds us that, although teacher knowledge is essential in what he calls constructivist instruction, considerations of cultural and political dilemmas are also necessary if a teacher is to be successful. Science teacher education must honor not only formal teacher knowledge, but also the local and practical knowledge of teachers in the field and the sociocultural contexts that frame their work.

Understanding the development and interaction of science teacher SMK and PCK is critical for our success in science teacher education. It also has implications for teacher education policy. Teacher certification in many countries is governed by accrediting agencies that define necessary SMK and PCK in terms of university coursework and/or teaching standards. Policy makers decide how much SMK, PCK, and other kinds of knowledge are needed for beginning teachers. Current U.S. federal policy implies that only SMK is needed to produce highly qualified teachers (U.S. Department of Education, 2002). This review provides evidence to the contrary.

## Recommendations for Future Research

Science education researchers are often queried by our scientist colleagues about the value of educational research. Within our own research community, we wonder if progress has been made. Have we built on the work of earlier research to generate a viable knowledge base about science teacher knowledge?

In the area of science teacher SMK, much "normal science" (Kuhn, 1996) has occurred. Landmark studies are commonly cited, research methods are fairly con-

sistent, and findings confirm theory, perhaps because science conceptual understanding for all learners has an agreed-upon meaning. Although researchers are unlikely to turn up anything revolutionary here, they fit a few more pieces into the puzzle with each study. The area in which the SMK literature is less clear is the relation of SMK to other forms of teacher knowledge, to teacher beliefs and values, and to classroom practice. We need more studies that take place within the teaching context to examine how SMK develops, how it plays out in teaching, and how it is related to other kinds of teacher knowledge (see Ball & McDiarmid, 1996).

The research on science teacher PCK is markedly different from the SMK literature. It is more like what Kuhn (1996) would call pre-science. Researchers do not yet agree about terminology or methodology. The research as a whole is less coherent; and researchers do not build on previous studies or reference a common body of literature. As researchers continue to sort out the viability of Shulman's framework and introduce new variations into it, we must ask ourselves if these new terms are conceptually necessary to understand science teacher knowledge. It would benefit the research if conceptual frameworks were made explicit. Furthermore, it would behoove researchers in this area to become more familiar with the literature and attempt to build a coherent conceptualization of PCK. More studies need to focus on the essence of PCK—how teachers transform SMK of specific science topics into viable instruction (see van Driel et al., 1998).

The research in both SMK and PCK has predominantly been at the level of description. In the current area of standards-based education and accountability for student learning, science education researchers should make more efforts to connect what we know about teacher knowledge to student learning. Although we have a good understanding of the kinds of knowledge that teachers bring to bear on science teaching, we know little about how teacher knowledge affects students. Answering this question will require more work in classroom settings of all kinds (see Fernández-Balboa & Stiehl, 1995; Keys & Bryan, 2001) and more complex research designs. The ultimate goal for science teacher knowledge research must be not only to understand teacher knowledge, but also to improve practice, thereby improving student learning.

## ACKNOWLEDGMENTS

# CHAPTER 37

---

## Learning to Teach Science

**Tom Russell**

**Andrea K. Martin**

*Queen's University, Canada*

We write as teacher educators who are passionate about improving teacher education. As teaching becomes increasingly complex, those learning to teach science deserve all the help we can provide. We argue here that such help involves much more than the transfer of insights derived from research on science teaching and science teacher education. Teacher education is also becoming more complex, and therein lies part of our challenge. In this chapter we draw on our experiences as teacher educators to inform our accounts and interpretations of research related to learning to teach science.

One of the most striking observations we can offer concerns the extent to which science education research appears *not* to be extended and extrapolated to programs of science teacher education. Research appears to confirm what our own experiences as teacher educators tell us: *A fundamental challenge resides in the prior teaching and learning beliefs and experiences of those learning to teach*, just as a fundamental challenge of teaching science resides in students' prior beliefs about phenomena. The research associated with constructivism and conceptual change reminds us that beliefs and experiences are deeply intertwined. Just as children in elementary, middle, and secondary schools tend to be unaware of their initial beliefs about phenomena and unaware of how personal experiences shape and constrain those beliefs, so those who are learning to teach science tend to be unaware of their initial beliefs about what and how they will learn in a program of science teacher education. In our experience, many prospective teachers assume that they know very little about teaching, that they will learn teaching ideas in university classes, and that they will apply what they learn in classes during their school practicum experiences. Is this really very different from children's assumptions in a science class? Do they not assume that they know little about science, that they will be taught science concepts, and that they will apply what they learn when given opportunities by their teachers? *"Science separates knowledge from experience"* (Franklin, 1994). Similarly, school and university alike often treat students in ways that imply that experience has little to do with knowledge. Those learning to teach tend to be unaware that they may have

learned more about *how* to teach science than about science and scientific concepts while they were studying science in school and university classes.

Northfield (1998) tackles this theme in a discussion of how science teacher education is *practiced*. He begins by quoting an unnamed individual's provocative comment about teacher education: "Teacher preparation is necessary and worthwhile, but it is generally conducted in the wrong place, at the wrong time, for too little time" (p. 695). Northfield's concern is one that we share: *How does school experience influence an individual's learning to teach?* And he immediately offers a challenging answer: "If experience is seen as a place to *apply* the ideas and theories of the course, then the campus program could be seen to be out of step with the demands and concerns of the new teacher (the wrong time, the wrong place and too little time)" (p. 696).

Northfield makes the following assertions that help us frame our task in this chapter:

As a starting point, consider the proposition that teacher educators could overestimate what they can teach new teachers, while also underestimating their ability to provide appropriate conditions for them to learn about teaching. Such a proposition serves to shift the teacher education task (at both preservice and inservice levels) from one of delivering what has to be known by teachers to one of providing better conditions for learning about teaching. (p. 698)

Whether in the science classroom or in the science teacher education program, how individuals learn from experience remains a poorly understood phenomenon.

Chapters in research handbooks often attempt to provide comprehensive surveys of published research. While we are attentive to such research, our major goal in this chapter is to stimulate new perspectives for thinking about the values and actions that occur in preservice programs for those who are learning to teach science. We summarize our overall argument in the following points:

1. Calls for change to how science is taught in schools and universities can be traced to the 1960s and even earlier in the twentieth century. Dewey's (1938) contrast between traditional and progressive education shows just how little the fundamentals of school culture have changed (Sarason, 1996).
2. Teaching for conceptual development and change has been a dominant theme in the science education research literature for several decades, and only a small fraction of that research considers how individuals learn to teach science in preservice programs.
3. Teaching practices are far more stable (Sarason, 1996) than those who call for change (see Handelsman et al., 2004) seem to realize. Logic alone cannot change teaching practices that were initially learned indirectly and unintentionally from one's own teachers.
4. Conceptual change research indicates that achieving more complete conceptual understanding (and the significant epistemological change that must accompany that understanding; see Elby, 2001) requires dramatic changes in how we teach (Knight, 2004, pp. 42–45).
5. Learning from experience is an undervalued and neglected aspect of science teaching and learning that is similarly undervalued in programs where individuals learn to teach science. This undervaluation is rooted in the value that the university associates with rigorous argument and positivist epistemology.

While learning from experience is being recognized as an element of teachers' professional development (Russell & Bullock, 1999) as attention is given to teacher research and action research, these tend to be undervalued as inferior forms of research.

6. Learning to teach science must *model* conceptual change approaches both for teaching fundamental concepts of science and for teaching fundamental concepts of teaching and learning.

One of this chapter's major contributions involves highlighting the need for explicit attention to epistemological issues associated with teaching science and learning to teach science. As long as the university's dominant epistemology is fundamentally positivist, we conclude that breakthroughs in how science is taught and learned are unlikely to be achieved.

To acknowledge, at least modestly, the need for attention to narrative as well as propositional knowledge, we include a number of "narrative boxes" that document some of Tom Russell's personal learning from experience over a quarter-century of teaching individuals how to teach science. Each narrative box ends with an italicized question related to learning from one's own teaching and learning experiences.

### THE COMPLEX CHALLENGE OF CONCEPTUAL CHANGE

Venturing into the literature of conceptual change is daunting but absolutely essential to learning to teach science. Pfundt and Duit (1994) refer to approximately 3500 studies related to students' alternative conceptions in science. Research on this topic has moved from simply identifying conceptual changes and bringing students' beliefs more in line with scientists' to mapping how conceptions are developed (White, 2001). The nomenclature itself is varied, and the labels used include *misconceptions*, *alternative conceptions*, *preconceptions*, *naïve conceptions*, *intuitive science*, or *alternative frameworks* (Guzzetti, Snyder, Glass, & Gamas, 1993). Whatever the label, conceptual change is central to learning and teaching science (see Chapter 2, this volume) and to learning to teach science.

#### Narrative Box 37-1

#### Is Experience Important for Learning?

I began teaching as a Peace Corps Volunteer in northern Nigeria. For two years, with my students' help and patience, I taught myself to teach—learning from experience as best I could. During a master's program in which I gained certification as a physics teacher, I noticed that I had many more questions than most people in my classes. Experience generates questions, both for teachers and for students.

*Were your own science classes rich in hands-on experiences that stimulated your personal interest in understanding science concepts? How important is experience for motivating you to understand a topic more fully and completely?*

As Duschl and Hamilton (1998) point out, conceptual change involves the restructuring of both declarative and procedural knowledge. Prospective science teachers need to reframe their own understanding of science learning to recognize the inherent challenges associated with subjecting prevailing concepts to scrutiny and validation. Unless new teachers understand why conceptual change is so complex, they are unlikely to be able to effect changes in patterns of classroom interaction.

## Teaching Conceptual Change

The extensive work of Novak (1987, 1989, 1993) provides a framework both for understanding why conceptual change is so critical if students are to *learn how to learn* in science and for understanding why instruction often fails. Novak builds on Ausubel's (1968) hypothesis that the single most important factor influencing learning is prior knowledge and Kelly's (1955) personal construct theory that emphasizes the view that knowledge is constructed and is highly personal, idiosyncratic, and socially negotiated. Novak and Gowin (1984) advance a set of three knowledge claims about the preconceptions that students carry into their science classes, with subsequent effects on their learning (Wandersee, Mintzes, & Novak, 1994).

1. Learners are not "empty vessels" but bring with them a finite but diverse set of ideas about natural objects and events, which are often inconsistent with scientific explanations.
2. Students' alternative conceptions are tenacious and resistant to extinction by conventional teaching strategies. Wandersee (1986) suggests that the similarities between students' ideas and ideas that science has discarded can provide a worthwhile heuristic opportunity as students struggle with their own conceptual shortcomings.
3. Alternative conceptions are the product of a diverse set of personal experiences that include direct observation of natural objects and events, peer culture, everyday language, the mass media, as well as teachers' explanations and instructional materials.

Novak and his group also advance three claims regarding successful science learners: (a) the process of constructing meanings relies on the development of elaborate, strongly hierarchical, well-differentiated, and highly integrated frameworks of related concepts; (b) conceptual change requires knowledge to be restructured by making and breaking interconnections between concepts and replacing or substituting one concept with another; and (c) successful science learners regularly use strategies that enable them to be metacognitive and to plan, monitor, control, and regulate their own learning (Mintzes, Wandersee, & Novak, 1997).

Posner, Strike, Hewson, and Gertzog's (1982) theory of conceptual change makes a valuable contribution to understanding its complexity and the conditions necessary for change to occur. Duit and Treagust (1998) describe it as the most influential theory on conceptual change in science education, with wide-ranging applications in other fields as well. Posner et al. propose that conceptual change will not occur unless learners experience some level of dissatisfaction with their current beliefs or understandings. For a new idea to be accepted, it must meet three conditions: *intelligibility* (understandable), *plausibility* (reasonable), and *fruitfulness* (useful). Learners

need to understand what an idea means, what its potential or actual utility is, and why scientists are concerned with coherence and internal consistency. If an idea is plausible, then learners need to be able to reconcile the idea with their own beliefs and to be able to make sense of it. Hodson (1998) points out that “making sense” in scientific terms may be very different from a commonsense point of view. If an idea is fruitful, then learners will gain something of value as a result.

Dissatisfaction with current beliefs or understandings is built on *cognitive conflict* where students’ conceptions and scientific conceptions are at odds. Central in the Posner et al. (1982) framework are the issues of status and conceptual ecology. Status is determined by the conditions of intelligibility, plausibility, and fruitfulness, and “the *status* that an idea has for the person holding it is an indication of the degree to which he or she knows and accepts it” (Hewson, Beeth, & Thorley, 1998, pp. 199–200). Yet ideas cannot be considered in isolation, for each learner has a *conceptual ecology* that deals with all the knowledge that a person holds, recognizes that it consists of different kinds, focuses attention on the interactions within this knowledge base, and identifies the role that these interactions play in defining niches that support some ideas (raise their status) and discourage others (reduce their status). Learning something, then, means that the learner has raised its status within the context of his or her conceptual ecology (Hewson et al., p. 200).

Thus teachers need to incorporate multiple opportunities for classroom discourse that explores students’ conceptual ecologies explicitly. Kagan (1992) summarizes the recommendations of Posner et al. for how teachers can promote students’ conceptual change. Teachers must (a) help students make their implicit beliefs explicit, (b) confront students with the inadequacies of their beliefs, and (c) provide extended opportunities for integrating and differentiating old and new knowledge, eliminating brittle preconceptions that impede learning and elaborating anchors that facilitate learning. By extension, similar efforts are required of teacher educators working in science teacher education programs.

Any discussion of conceptual change must include Piagetian ideas, specifically *assimilation*, *accommodation*, *disequilibrium*, and *equilibration* (Duit & Treagust, 1998). Clearly, Piagetian notions have been incorporated into the conceptual change literature and into constructivist approaches to learning and teaching. Cognitive conflict, built on disequilibrium and equilibration, plays a predominant role in the work of Posner et al. (1982), and the themes of active learning and constructivism feature prominently in the work of Novak and colleagues, as already discussed.

Central to Vygotskyian theory is the influence of sociocultural factors on cognitive development. Duschl and Hamilton (1998) credit Vygotsky’s work with stimulating research that addresses the social context of cognition and learning. This includes work in the areas of reciprocal teaching, collaborative learning, guided participation, and authentic approaches to teaching, learning, and assessment. Constructs such as situated cognition, apprenticeships, cognitive apprenticeships, and the social construction of meaning can be linked to Vygotskyian theory. Each of these involves the contextual nature of learning and the interrelation of individual, interpersonal, and cultural-historical factors in development (Tudge & Scrimsher, 2003). Putnam and Borko (2000) have summarized the major arguments and implications of situated cognition for teacher learning. Science teacher educators will do well to consider carefully the themes associated with the situative perspective: “that cognition is (a) situated in particular physical and social contexts; (b) social in

nature; and (c) distributed across the individual, other persons, and tools" (Putnam & Borko, p. 4).

## Teaching for Conceptual Change

Misconceptions are persistent and highly resistant to change (Duit & Treagust, 1998; Guzzetti et al., 1993; Mintzes et al., 1997). During the 1970s and 1980s, the predominant assumption was that students' misconceptions had to be extinguished before they could be replaced by the correct scientific view; however, there appears to be no study that confirms that a particular student's conception could be totally extinguished and then replaced (Duit & Treagust). Most studies reveal that the preexisting idea stays "alive" in particular contexts (Duit & Treagust), a phenomenon that diSessa (1993) describes as refinement, rather than replacement, of concepts.

The essence of teaching *for* conceptual change is restructuring of knowledge (Mintzes et al., 1997). This is far easier said than done, given the range and variability of students' responses to cognitive restructuring. Hodson (1998) provides a helpful overview of students' resistant responses. Some students may look for evidence to confirm rather than disconfirm their existing ideas. Often, their original notion prevails. Hodson points to variations in personality traits that may make some students more receptive to new ideas, whereas others may be reluctant to pursue alternatives because what they know (or think they know) is consistent with their own cognitive schema. If they hold on to what they know, they avoid the anxiety of the unknown or uncertain.

The work of the Children's Learning in Science (CLIS) group at the University of Leeds (e.g., Driver, 1989; Scott, Asoko, & Driver, 1992; Scott & Driver, 1998) is seminal in the area of constructivist approaches to conceptual change. CLIS suggests that certain commonalities extend across scientific disciplines and support reconceptualizations. These can be characterized as instructional activities that involve a teaching approach designed to address a particular learning demand (Scott et al.; Scott & Driver). These are sequenced as follows: (a) orientation or "messing about," which uses students' prior knowledge and existing conceptions as a starting point; (b) an elicitation phase where conceptions that are global and ill-defined are differentiated (e.g., heat and temperature, weight and mass); (c) restructuring, where experiential bridges are built to a new conception; and (d) constructing new conceptions through practice or application. If students' preconceptions are incommensurate with scientific conceptions, then Scott and Driver recommend that the teacher acknowledge and discuss students' ideas, indicate that scientists hold an alternative view, and present that model. They caution that the sequence should not be construed as a recipe, given that teaching for conceptual change requires learning activities in a variety of forms (e.g., reading, discussion, practical activity, teacher presentation). In contrast to the typical question-and-answer interchanges focused on "right" answers, discussion needs to be based on supporting and evaluating differing views in the light of evidence. Small-group discussions, poster presentations, and student learning diaries can provide students with valuable opportunities for sharing their understandings.

There is a growing body of work on strategies to support students' learning of science in ways that challenge their conceptual frameworks. Novak and Gowin's

(1984) work on concept mapping is helpful in assessing students' conceptual problems in science learning and in promoting metacognition. Originally developed as a science education research tool, concept maps are now widely used as a learning tool, as well as for curriculum design and instructional planning, implementation, and evaluation. As an example, Mason's (1992) two-year study looked at the operationalization of concept maps in preservice science teacher education. She concluded that the science majors in her study had acquired verbal information (declarative knowledge) in their undergraduate science courses but lacked a conceptual understanding of science. "These students did not exhibit an inability to enter the phase of learning required for understanding and application, but simply had been programmed to memorize terms and learn algorithms" (Mason, pp. 59–60).

[Without fostering conceptual restructuring that would sensitize the prospective teachers to] their lack of comprehension of the body of scientific knowledge and its origin, they would present a misinterpretation of the nature of science and perpetuate, in their own students, the inability to transfer conceptual understanding to novel situations. As a result, these teachers would tend to continue the cycle of science classroom environments which develop negative student attitudes toward science. (p. 60)

Mason found that her participants were able to develop maps that were less linear and term-oriented. They learned to produce maps that demonstrated the interrelatedness of scientific concepts and, in so doing, restructured information that had been presented to them discretely in previous undergraduate courses. One of the students wrote that concept mapping "gave the knowledge a fluid character, not simply a number of facts to outline and remember" (p. 57).

In addition to concept mapping, strategies such as concept webs, concept circle diagrams, Vee diagrams, and semantic networks can serve as conceptual tools that "fill different niches in meta-cognition" (Mintzes et al., 1997, p. 436). Because of their graphic organization and representation of concepts, there is an opportunity for students to "see" science, to better understand the interconnections between and among concepts, and to more actively engage in the construction and reconstruction of knowledge. Other approaches use student drawings and diagrams as a springboard to encourage and support the development of scientific discourse within the classroom community (e.g., Driver, 1989; Hayes, Symington, & Martin, 1994; Nussbaum & Novick, 1982). Tobin (1997) describes this as re-presentations, where students can use their visual representation as a basis for framing questions for their peers and their teacher. By incorporating a public accounting where students explain the science behind their drawings (Nussbaum & Novick), they can be initiated into the process of learning how to set forth a knowledge claim, justify it, and respond to challenges.

Creating conditions for cognitive conflict where teachers challenge students to look for limitations in their views or deliberately provide examples of discrepant or surprising events, often through hands-on demonstrations or activities, can spur reconceptualization (Hodson, 1998). However, we question the extent to which preservice teacher education anchors science courses within a conceptual change framework, explores conceptual change theory, probes the concepts that teacher candidates hold about science and learning science, provokes cognitive conflict, and exposes candidates to instructional approaches and strategies to support conceptual change. Unless prospective teachers are *directly* challenged to confront their own alternative

conceptions and work through the process of conceptual change, it is highly unlikely that they will be able to support their own students in doing so.

### **Teaching for Conceptual Change in Preservice Science Teacher Education**

Elby (2001) signals the potential significance of epistemological issues when teaching for conceptual change in physics, and we would extend Elby's insights to the significance of epistemological issues associated with concepts of teaching and learning. The following excerpt from Elby's report signals that attention to epistemological development must be explicit: "Many of the best research-based reformed physics curricula, ones that help students obtain a measurably deeper conceptual understanding, generally fail to spur significant epistemological development. Apparently, students can participate in activities that help them learn more effectively *without* reflecting upon and changing their beliefs about how to learn effectively" (p. S54). Elby concludes that "even the best reform curricula, however, have not been very successful at helping students develop more sophisticated epistemological beliefs" (p. S64).

We immediately extend Elby's conclusion to the context of learning to teach science by declaring that significant attention must be given to the epistemological beliefs of prospective science teachers, both in terms of the science concepts they will teach and in terms of the educational concepts they bring to a preservice program. Here we draw on an argument by McGoey and Ross (1999), both secondary science teachers, in which they provide a vivid account of student resistance to conceptual change and the complex teaching skills needed to negotiate it:

We suspect that almost every teacher who has used a CC [conceptual change] model in the classroom has borne the brunt of student anger, frustration, and criticism. Students do not like having their ideas elicited in a nonjudgmental manner, only to have those ideas revealed as inadequate (whether it be mere seconds or days later). Some students eventually just stop giving their ideas. . . . Dealing with this without disaffecting students emotionally and intellectually requires delicate, precise, and theoretically sound skills of the teacher. (p. 118)

The challenges continue when students respond in ways that confirm that they do hold significant epistemological beliefs:

The really messy stuff appears when the teacher gets a range of different (though adequate) models from the students. Now the fat is really in the fire. If the teacher refuses to give a single answer, positivist-minded students demand the right answer. Give a single answer and you may promote positivism. Give them a few rules (beware logical empiricism!) and the students interpret it as *carte blanche* for relativism or conventionalism. Another response of students is to challenge the teacher's practice outright. These attacks assert that since everybody knows that science is simply a universal body of facts and methods, just give us the recipe and tell us the answer so we can study for the test. (pp. 118–119)

These two teachers then extend their discussion to teacher education and to the stress that candidates experience when they sense cognitive conflict associated with

relying extensively on content knowledge. Again, we see that epistemological assumptions about teaching and learning are implicit:

Teacher interns are often deeply troubled to have their content knowledge questioned. They are already nervous enough about whether they can get in front of 30 adolescents for 80 minutes. . . . Content knowledge is often their major life-saving device. When student teachers engage in action research activities that undermine overreliance upon content knowledge, they experience considerable distress. The experience is extremely unsettling. (p. 119)

In this extended discussion of conceptual change in the context of learning to teach science, we have provided an overview of major arguments with respect to conceptual change in science teaching as a prelude to extending the topic of conceptual change to learning to teach science. In both contexts we believe that Elby's (2001) attention to epistemological beliefs is essential for making productive changes to how science is taught. We turn next to another issue with significant epistemological overtones: learning from experience and the associated authority of experience.

## **LEARNING FROM EXPERIENCE AND THE AUTHORITY OF EXPERIENCE**

### **The Authority of Experience**

In our culture, we speak easily of "learning from experience" in everyday life, and yet we also hear many stories in which people seem not to have learned from experience. Just as propositional knowledge claims are easily forgotten and links are not always made from one context to another, so it is with learning from experience, which seems to be a marginal feature of many classrooms in the formal learning contexts of schools and universities. Science teachers are often credited with an advantage of being able to use everyday materials, yet laboratory experiences are rarely described by students as major contributing activities in their learning of concepts. Because learning from experience is not a significant feature of many classrooms, when those learning to teach science begin a professional preparation program, the role of learning from experience may never have been considered. Quite universally, student teachers report that the practicum is the most significant element of their preparation for teaching, yet this does not mean that new science teachers understand how they learn from experience or that they are proficient in learning from experience. Munby and Russell (1994) addressed this issue when they introduced the phrase "the authority of experience":

Listening to one's own experience is not the same as listening to the experience of others, and the [physics method] students seem to indicate that they still place much more authority with those who have experience and with those who speak with confidence about how teaching should be done. They seem reluctant to listen to or to trust their own experiences as an authoritative source of knowledge about teaching. We wonder how and to what extent they will begin to hear the voice of their own experiences as they begin their teaching careers.

The basic tension in teacher education derives for us from preservice students wanting to move from being under authority to being in authority, without appreciating the

potential that the authority of experience can give to their learning to teach. The challenge for teacher education is to help new teachers recognize and identify the place and function of the authority of experience. (pp. 93–94)

## Action Research and a New Scholarship

In recent years there has been a small but significant shift in teachers' continuing professional development toward learning from experience. After 1990, we began to read much more about "teacher research" and "action research," two closely related fields in which individual teachers attempt to learn from their firsthand classroom experiences (see Chapter 39, this volume). Often such inquiry begins with questions such as: How can I help my students improve the quality of their learning? Research by teachers in their own classrooms represents a major shift from the cultural norms of our schools and universities, and it is in the university that such research would most readily be challenged for being subjective, for not being generalizable, and for lacking in rigor. Schön (1995) saw this problem in the context of a "new scholarship" and framed the challenge in terms of introducing an alternative to the university's standard epistemology:

The problem of changing the universities so as to incorporate the new scholarship must include, then, how to introduce action research as a legitimate and appropriately rigorous way of knowing and generating knowledge. . . . If we are prepared to take [this task] on, then we have to deal with what it means to introduce an epistemology of reflective practice into institutions of higher education dominated by technical rationality. (pp. 31–32)

Within the very large community of teacher educators, there is a subset of individuals who have addressed this epistemological issue by focusing on the study of their own teaching practices within preservice teacher education programs. By working collectively in conferences, books, and journal articles, the self-study of teacher education practices has achieved significant levels of recognition for an "epistemology of reflective practice." A two-volume international handbook (Loughran, Hamilton, LaBoskey, & Russell, 2004) illustrates in many ways their individual and collective efforts to learn from experience.

The issue of experience in relation to education was explored extensively by Dewey (1938), and Schön's (1995) work emerged directly from that of Dewey. One of Dewey's many points is that familiar educational patterns persist as tradition, not on their rationale. Bringing the authority of experience into programs for learning to teach science will involve all the familiar challenges of learning from experience: "There is no discipline in the world so severe as the discipline of experience subjected to the tests of intelligent development and direction. . . . The road of the new education is not an easier one to follow than the old road but a more strenuous and difficult one. . . . The greatest danger that attends its future is, I believe, the idea that it is an easy way to follow" (Dewey, p. 90).

We find it interesting that the issue of learning from experience and the associated epistemological issues tend not to be raised in the conceptual change literature, and here we call attention to the issue of learning from experience because it represents an important, perhaps essential, perspective for helping individuals learn to teach science.

A strong case for recognizing the authority of experience in the science classroom appears in the findings and recommendations reported in a book intended for those who teach first-year undergraduate courses in physics. Knight (2004) summarizes 25 years of physics education research on students' concepts and problem-solving strategies with three conclusions that have direct implications not only for teaching science *but also for learning to teach science*:

1. Students enter our classroom not as 'blank slates,' *tabula rasa*, but filled with many prior concepts.
2. Students' prior concepts are remarkably resistant to change.
3. Students' knowledge is not organized in any coherent framework. (p. 25)

These statements remind us that, in contrast to what is learned from textbooks, that which is learned from experience can be powerful without being coherently organized. Knight closes his analysis with five "lessons" for teachers:

1. "Keep students actively engaged and provide rapid feedback" (p. 42).
2. "Focus on phenomena rather than abstractions" (p. 42).
3. "Deal explicitly with students' alternative conceptions" (p. 43).
4. "Teach and use explicit problem-solving skills and strategies" (p. 44).
5. "Write homework and exam problems that go beyond symbol manipulation to engage students in the qualitative and conceptual analysis of physical phenomena" (p. 44).

The first four lessons can be translated directly from teaching science to learning to teach science. The fifth lesson could easily be reshaped to "engage students in the qualitative and conceptual analysis of educational phenomena." In "traditional" preservice teacher education programs, one might view these as research findings to include in the "knowledge base" to be transmitted to preservice science teachers. Our analysis of the research literature confirms that it is *entirely counter-productive* to simply transmit such lessons to teachers as content. Rather, preservice science teacher education programs *must* explore the implications of these lessons through all the learning experiences created in teacher education classrooms (see Segall, 2002).

## Reflection by a Teacher Educator

To illustrate learning from experience in the context of preservice science teacher education, we recount briefly Russell's personal learning from experience as a teacher educator trying to understand how experience helps those learning to teach. In both 1991 and 1992, he arranged to teach one class of physics in a local high school; in return the school's regular physics teacher helped teach the physics method course at Queen's. Building on the 1991 experience, he arranged for one of his physics method classes in 1992 to be held each week in the room where he taught physics, with an invitation to preservice teachers to observe his class if they wished. Despite

being in the physics classroom himself and holding some of his classes in the school rather than at the university, the impact on the preservice teachers seemed minimal. A series of interviews with some of the preservice teachers led Russell to develop a list of potential barriers to learning from experience that the preservice teachers seemed to bring to their efforts to learn to teach. Just as Knight (2004) reports, the future physics teachers did not arrive as blank slates; they had strong views that did not change easily. Five years later, when the preservice program at Queen's changed dramatically to begin with 14 weeks of teaching experience, the barriers implicit in the 1993 candidates were replaced by more constructive "frames" generated by their learning from experience (see Table 37.1).

### Reflection by those Learning to Teach

Two recent papers report on significant efforts to understand and improve learning to teach science at the elementary level, with special reference to learning from teaching experience. These papers emphasize the importance of reflection in relation to learning from experience, and we value their attention to structuring and supporting reflection by those learning to teach. Early in Bryan and Abell's (1999) case study of a student teacher named "Barbara," the authors declare their perspective on the role of experience in learning to teach: "The heart of knowing how to teach cannot be learned from coursework alone. The construction of professional knowledge requires experience. . . . Experience influences the frames that teachers employ in identifying problems of practice, in approaching those problems and implementing solutions, and in making sense of the outcomes of their actions" (pp. 121–122).

The case of Barbara begins with an account of what Barbara believed about science teaching and learning and moves on to describe her vision for teaching elementary science as well as the tensions within her thinking about her professional responsibilities. Of particular interest is Barbara's initial premise that a teacher should

**TABLE 37.1**  
**Barriers to Learning to Teach and Frames for Learning to Teach**

Barriers to learning to teach: Prior views of preservice science teachers who gained teaching experience gradually during an eight-month program.	Frames for learning to teach: Views of preservice science teachers who began a nine-month program with 14 weeks of teaching experience.
Teaching can be told.	Teaching cannot be told.
Learning to teach is passive.	Learning to teach is active.
Discussion and opinion are irrelevant.	Discussion, opinion and sharing of experiences are crucial.
Personal reactions to teaching are irrelevant.	Personal reactions to teaching are the starting point.
Goals for future students do not apply personally.	Goals for future students definitely must apply personally.
Theory is largely irrelevant.	Theory is relevant.
Experience cannot be analyzed or understood.	Experience can be analyzed and understood.

*Note:* From Russell (2000, pp. 231–232, 238–239).

continue to teach a scientific concept until all children show that they understand it. Once the process of reflection became apparent, “Barbara began to shift her perspective and reframe the tension between her vision and practice. Her professional experience provided feedback that forced her to confront the idea that in teaching science, teachers need to consider more than students getting it” (Bryan & Abell, p. 131). This case study could help new science teachers anticipate the challenges and prospects of student teaching, although the real help would probably be realized *during* rather than *before* the student teacher assignment. The implications for further study of learning from experience are clear:

Barbara’s case implicitly underscores the fallacy of certain assumptions underlying traditional teacher education programs: (a) that propositional knowledge from course readings and lectures can be translated directly into practice, and (b) that prospective teachers develop professional knowledge before experience rather than in conjunction with experience. . . . Teacher educators are challenged to coach prospective teachers to purposefully and systematically inquire into their own practices, encouraging them to make such inquiry a habit. (Bryan & Abell, p. 136)

Just as a conceptual change approach to teaching science begins with students’ experiences, so Bryan and Abell conclude that “the genesis of the process of developing

Narrative Box 37–2  
Narrowing the Gap between Practice  
and Theory, Actions and Values

In 1983, in my sixth year of teaching a preservice science course and visiting candidates in their practicum classrooms, I was feeling acutely aware of the gaps between educational theory and practice. Many of the strategies I promoted in my classes could not be observed in my students’ classes in the practicum setting. A colleague loaned me a copy of Schön’s (1983) *The reflective practitioner: How professionals think in action*. My first sabbatical leave later that year provided an opportunity to study this book and prepare a research proposal that would let me explore this new perspective in the context of preservice teacher education. Years of work with the ideas have led me to conclude that Schön’s terminology is more readily adopted than it is understood. I see Schön arguing two main points:

1. Learning from teaching experience involves finding new frames or perspectives (perhaps from the research literature) to better understand surprising and puzzling events of practice.
2. Improving as a teacher involves deliberately narrowing the inevitable gaps between our values as teachers and the effects of our teaching actions on those we teach.

*How do you react when asked to “reflect”? Do you have enough experiences to reflect about? Would it help if someone undertook to teach you how to reflect?*

professional knowledge should be seen as inherent in experience" (p. 136). "A pre-eminent goal of science teacher education should be to help prospective teachers challenge and refine their ideas about teaching and learning science and learn how to learn from experience" (Bryan & Abell, p. 137).

The paper by Zembal-Saul, Krajcik, and Blumenfeld (2002) focuses on representation of science content to children during teaching experiences. Three case studies describe the context in which individuals taught, their representations of science content, and the support provided for learners. The authors build on the earlier conclusion of Bryan and Abell (1999) that "experience plays a significant role in developing professional knowledge" (p. 121). To this they add their own conclusion that "what we do know . . . is that experience alone is not enough. It needs to be coupled with thoughtful reflection on action" (Zembal-Saul et al., p. 460). Their overall conclusions make important points that remind science teacher educators yet again of the importance of the cooperating teacher in supporting (implicitly, if not explicitly) the student teacher's professional learning: "There is evidence that cooperating teachers who facilitate students' meaningful learning in general and support student teachers in their efforts to continue to emphasize science content representation can positively influence the territory student teachers attempt to master" (p. 460). Reminding us that our collective understanding of how experience contributes to learning to teach still requires attention and development, the authors conclude: "There is an urgent need to understand better the role of experience in learning to teach, in particular the aspects of teaching experiences that support or hinder new teachers' continuing development in the often fragile domain of science content knowledge and its representations" (p. 461).

This material on learning from experience and on reflection, both in science classrooms and in science teacher education settings, completes our introduction of perspectives on conceptual change and the authority of experience. We turn next to an earlier review of research on learning to teach science.

## **DOMINANT THEMES IN EARLIER RESEARCH ON LEARNING TO TEACH SCIENCE**

Anderson and Mitchener's (1996) extensive review of research on science teacher education provides a strong foundation for the issues of learning to teach science that are explored and developed in this chapter. They describe a "traditional model" of preservice science teacher education that seems very much with us a decade after their review. The model has three familiar elements—educational foundations, methods courses, and field experiences and student teaching. Anderson and Mitchener conclude their review with statements that bear repeating:

Looking back, this three-pronged traditional model of preservice teacher education has survived relatively intact since its birth in the normal school. . . . The challenge facing science teacher educators today is this: how will you address in a coherent, comprehensive manner such emerging issues as new views of content knowledge, constructivist approaches to teaching and learning, and a reflective disposition to educating teachers. In addition, thoughtful science teacher educators need to attend to the theoretical orientation of their programs and how important professional issues are addressed within these orientations. (p. 19)

Narrative Box 37-3  
Can Reflection Be Taught?

In 2001, one of my classes included an individual who knew that he would never be a teacher. He had to wait 18 months to begin a training program, and his future employers were willing to support his time in a preservice education program. As a result, he had more time than most to critique the various elements of the program. At the end of the year, we revisited a series of weekly practicum reports that he had volunteered to send me (and to which I replied quickly). He suggested that our corresponding about his practicum experiences had done more than any other program element to teach him how to reflect. He offered advice to my colleagues and me: "Don't tell people to reflect. Instead, teach them how to reflect and then show them that that is what you have done." Subsequent attempts to follow this advice have paid positive dividends.

*What specific meanings do you associate with the words "reflect" and "reflection"? Do you see reflection as something that can be taught? Is it possible to reflect during teaching as well as after?*

These reviewers went on to identify six dominant themes in research on the preservice curriculum in the twentieth century: an "established preservice model," "inadequate subject matter preparation," "haphazard education preparation," the "importance of inquiry," "reliance on the laboratory," and "valued educational technologies" (Anderson & Mitchener, pp. 21-22). We find little to indicate that these dominant themes have changed. Anderson and Mitchener describe criticisms directed at the traditional model and then offer important conclusions:

Considering the longevity and volume of such efforts, one would expect a review of preservice science teacher education programs to portray a rich landscape, complete with diverse views, cohesive images, and defined detail. Research on these programs, however, is neither accessible nor diverse.

Indeed, there is a dearth of literature describing preservice science teacher education programs. . . . Actual portrayals of comprehensive programs—including conceptual and structural components—are rare. . . .

Differences that do exist among programs are most often found at the course level. Innovative efforts in reforming science teacher preparation usually are directed at changing one or two isolated components within a program, as opposed to the program as a whole. (p. 23)

Our review of literature on the development of teachers' knowledge (Munby, Russell, & Martin, 2001) and our examination of research available since Anderson and Mitchener's review lead us to the conclusion that the six dominant themes they identified continue to appear in research related to learning to teach science, despite repeated calls for change and reform in science education and in preservice teacher education.

## SCIENCE TEACHER EDUCATION PROGRAMS THAT WORK TO MAKE A DIFFERENCE

We have already noted Anderson and Mitchener's (1996) observation that detailed accounts of preservice teacher education programs are uncommon. Here we consider two such accounts, one from Monash University in Australia and one from the University of Wisconsin–Madison in the United States. Each is an account of efforts to achieve coherence around a focused set of understandings related to how and why students learn science.

### Monash University

In theory, coherence and a set of guiding principles within a preservice science teacher education program should be valuable and productive. Gunstone, Slattery, Baird, and Northfield (1993) present seven propositions underlying the program at Monash University in Australia that we summarize as follows: A program must consider the needs of teacher candidates and recognize that needs change as development occurs. Collaboration with other candidates is essential, and candidates construct new views based on previous experiences and perceptions. Teacher educators need to model the principles they are teaching as they strive to enact a program seen as worthwhile yet inevitably and necessarily incomplete because it precedes full teaching responsibilities. Finally, teacher educators need to demonstrate to candidates the reflective practice that they expect of those learning to teach.

The authors speak bluntly about the challenges of creating and enacting an effective program of preservice science teacher education:

After at least 16 years' experience as learners, students come to programs with well-developed but often simplistic views of teaching and learning. . . . These views are very persistent and often at odds with the views we hope to cultivate. Failure to respond to this issue can result in student teachers either reconstructing what they encounter in the program so as to leave their initial views unchanged, or simply rejecting what does not fit the initial views. . . . Hence the views need to be identified, discussed, and evaluated by student teachers by means of carefully managed teaching/learning experiences. (pp. 51–52)

Gunstone et al. see two types of managed experiences for student teachers: "revealing and challenging perceptions of one's own learning" and exploring "perceptions of teaching and pupil learning" (p. 52). They are quick to emphasize the complex nature of these activities: "Most graduates in teacher education programs require considerable assistance and support to even begin to take control of their own learning in this constructivist way. . . . The assistance and support must be in the context of what is seen to be learning of value by the learner; that is, it must be woven through the usual course as an ongoing influence on the pedagogy adopted by those teaching the course" (p. 52).

The authors go on to discuss the issue of preservice science teachers' understanding of their science subjects, reminding us that teachers trained in one science may benefit from opportunities to study topics in other sciences. Attention also turns to the complex issue of how well study of a science subject prepares one for the demands of teaching that subject to others.

It is relatively common for [student teachers] to hold naïve, alternative and erroneous conceptions in areas they have studied intensively. . . . This issue must be handled with considerable sensitivity, as much of the self-esteem which student teachers possess on commencing teacher preparation is derived from their successful academic study. The identification of alternative conceptions should occur in the context of personal experience of constructivist views of learning and teaching. (p. 53)

In the second half of their paper, Gunstone and his colleagues consider the propositions they have set forth in light of the experiences of one seminar group in the 1987 academic year. This study is essential reading for any group of teacher educators intending to study the impact of their own program on prospective teachers. The study also provides valuable insights into what is possible in a coherent program that seeks to foster a conceptual change approach to the teaching of science.

The authors acknowledge and illustrate the importance of views brought by prospective teachers, just as science teachers committed to conceptual change must work with the views their students bring to their classrooms. Finally, keeping the familiar parallels between conceptual change and reflective practice, the Monash group stresses the importance of modeling the principles they teach and of ensuring that new teachers are aware of the principles and limitations of their program.

## University of Wisconsin–Madison

A set of papers from University of Wisconsin–Madison (UW-Madison) (*Science Education*, 83(3), 1999) contrasts with the paper from Monash University in interesting ways. The UW-Madison researchers worked with elementary or secondary science methods courses and an action research seminar, whereas the Monash researchers were able to work with the entire preservice program. Significantly, teacher educators subjecting their own practices to scrutiny is far more apparent in the Monash study than in the UW-Madison study, even though the UW-Madison researchers allude to the importance of such scrutiny. The UW-Madison experience also merits close examination for its rich array of hypotheses.

The researchers offer an excellent summary of the task facing all science teacher educators who would challenge their students to move beyond the truism that “we teach as we were taught”:

These prospective teachers’ understanding of the nature of knowledge was a critical factor in their teaching. . . . There were almost no indications that, upon graduation from the program, these prospective teachers thought it was necessary to give class time for their students to consider the relative status of alternative conceptions. We suggest that this is not surprising from a positivist perspective in which the truth of scientific information is not at issue. (Hewson, Tabachnick, Zeichner, & Lemberger, 1999, p. 378)

The array of evidence gathered in the UW-Madison study points to a fundamental problem that lies outside the domain of teacher education: the way that science is taught and assessed in universities:

It appears that prospective teachers were inadequately prepared by their content courses to do anything more than the mostly transmissionist teaching we observed. . . . We suggest that this is the result of the teaching and assessment strategies of college science

courses that do little to emphasize the integration of course content. Lectures seldom encourage students to think about and relate concepts to each other, and multiple choice testing procedures ask for information in a piecemeal fashion. (Hewson et al., pp. 379–380)

This paper set concludes with a range of valuable but familiar comments about the need for school placements that support student teachers working for conceptual change as well as the need for communication and collaboration between university and school personnel.

As Anderson and Mitchener (1996) observed, the science education and teacher education communities devote far more time and effort to studies in science classrooms than to studies in science teacher education classrooms (where all who are learning to teach science must spend time before moving into their own classrooms). As the reports of the Monash and Wisconsin programs indicate, theoretical and empirical insights about learning science in classrooms can be extended to learning to teach science in teacher education classrooms. Important progress in programs where individuals learn to teach science seems unlikely to occur until coherent frameworks are extended to programs as a whole rather than to individual program elements (Russell, McPherson, & Martin, 2001), with sound research studies that make conceptual and structural gains available to those learning to teach and to those who teach them.

### **The Project for Enhancing Effective Learning**

The Project for Enhancing Effective Learning (PEEL) (see <http://peelweb.org>) is a unique example of a teacher-directed, teacher-sustained collaborative action research. PEEL is a comprehensive school-based program for improving the quality of teaching in schools. With supportive links to nearby universities, PEEL began in 1985 in one school in the western suburbs of Melbourne, Australia. The key issues were deceptively simple:

The major aim of PEEL is to improve the quality of school learning and teaching. Training for this improvement is centered on having students become more willing and able to accept responsibility and control for their own learning. Training has three aspects: increasing students' knowledge of what learning is and how it works; enhancing students' awareness of learning progress and outcome; improving students' control of learning through more purposeful decision making. (Baird & Mitchell, 1986, p. iii)

Thus PEEL is a comprehensive program of inservice professional development for teachers as well as a project for enhancing effective student learning.

A central element of PEEL involves *reframing* the activities of teachers *and* the activities of students within the classroom context. The power of PEEL resides in its extensive array of specific, practical procedures for the various steps that are inevitably involved in helping students develop a metacognitive stance toward their own learning. To present specific PEEL approaches to a beginning teacher with no teaching experience is to accomplish nothing at all. To use PEEL approaches to help beginning teachers interpret early teaching experiences in relation to their own goals and beliefs is to facilitate conceptual change. To practice PEEL approaches in teacher

## Narrative Box 37–4

## Do Students Notice Your Major Goals For Teaching?

When I began teaching preservice candidates in 1977, my three years of work with experienced teachers had a major impact. I had just finished working with a group of history teachers in a program that taught them how to analyze their own teaching. As a group, their overall reactions to their analysis can be summarized in two conclusions: (1) “We talk far more than we realized we did,” and (2) “It is extremely difficult to change how much talking we do.” Imagine how confused my first teacher education classes were when I tried to teach by talking less than most of my colleagues, a strategy that I attempted because I wanted to try for myself the challenge that the history teachers had identified. One early issue became “How do I model doing LESS of something?”

*What major values do you hold for your teaching that will require you, as a teacher, to act in ways that differ from the norms of teacher behavior?*

education classrooms as well as in school classrooms is to begin to realize the need for epistemological reframing in both contexts.

To extend our earlier references to the importance of epistemological considerations both in teaching science and in learning to teach science, we turn now to perspectives on knowledge acquisition and on knowledge construction in learning to teach.

## ACQUIRING AND CONSTRUCTING KNOWLEDGE

We find it helpful to link the work of the PEEL project to Chinn and Brewer’s (1998) framework for “understanding and evaluating theories of knowledge acquisition” (p. 97). There is a strong parallel between this framework and the practical knowledge developed within PEEL: each account is driven by constructive logical analysis of the domain of interest. Of eight questions posed by Chinn and Brewer, we here focus particularly on question 5: “What is the fate of the old knowledge and the new information after knowledge change occurs?” (p. 97). Chinn and Brewer make it clear that conceptual change can be of at least five types:

1. B replaces A, with A being forgotten or ignored.
2. A is reinterpreted within the framework of B.
3. B is reinterpreted within the framework of A.
4. A is incorporated into B.
5. A and B are compartmentalized. (p. 106)

Teaching may be conducted most easily by assuming that the first fate—simple replacement—will occur, but if it did, we would hardly need research on conceptual change. Compartmentalization is something most teachers wish to avoid, for it seems counterproductive to restrict the application of more complex and complete

explanations for phenomena. The territory suggested by the other three “fates” indicates the breadth and complexity of the work of teachers and reminds us of the challenges of planning for teaching. The procedures constructed and organized by PEEL over nearly two decades of teacher collaboration provide potential support for teachers concerned about what happens to “old knowledge.” Making this process explicit is a powerful initial step in the reframing that we argue is critical to conceptual change. As a venture in collaborative action research, PEEL is specifically committed to fostering students’ change from nonawareness to awareness and then using that awareness to support conceptual change itself.

## Knowledge Construction in Learning to Teach

Oosterheert and Vermunt (2003) present an intriguing addition to the literature of reflection in learning to teach. Schön (1983) gave considerable impetus to the “teacher as reflective practitioner” movement with his distinction between problem-solving and problem-setting. Reframing problems to develop and enact new approaches became an attractive image for teachers thinking professionally about their work. The argument has intrinsic appeal in the context of teacher education and learning to teach, and it readily extends to the conceptual change approaches so often advocated in the science education community.

Oosterheert and Vermunt (2003) distinguish between “external” and “internal” sources of regulation in constructing knowledge. External sources (which would include experience with phenomena of science and practicum teaching experiences) provide information from outside the learner (whether child or adult). Internal sources of regulation refer to the capacities of the brain “to process information and to reconstruct existing knowledge” (Oosterheert & Vermunt, p. 159). To the familiar idea of “active” internal sources of regulation, the authors add the category of “dynamic” internal sources of regulation and argue that these are essential in learning to teach. In doing so, they build on Iran-Nejad’s (1990) challenge of the assumption that learning involves incremental internalization in response to external sources. Whereas active processing is “slow,” “deliberate,” and “sequential,” dynamic processing is “rapid,” “non-deliberate,” and “simultaneous” (Oosterheert & Vermunt, p. 160).

Teacher educators who have employed reflective practice perspectives may quickly recognize these contrasts as similar to Schön’s (1983) contrast between *solving* problems and *reframing* problems. We are particularly interested in the implications of seeing internal sources of regulation as both “active” and “dynamic.” Whereas “active” self-regulation appears to capture the familiar tasks of *schooling*, including note-taking, homework, reviewing, quizzes, and tests, “dynamic” self-regulation appears to lead to the conceptual changes that science teachers often take as goals and genuine indicators of their success in teaching. Similarly, whereas “active” self-regulation appears to capture the familiar tasks of *learning to teach*, including class participation, preparing and presenting practicum lessons, and completing assigned work, “dynamic” self-regulation appears to lead to the shifts of understanding and perspective that teacher educators often take as genuine indicators of their success in helping individuals learn to teach. Oosterheert and Vermunt (2003) suggest that “dynamic self-regulation is a prerequisite in constructive learning. Active self-regulation may be helpful, but is never sufficient nor always necessary” (pp. 160–161).

This complex paper draws to a close with an important conclusion: “Active self-regulation can be very helpful, but never sufficient in conceptual change. In learning to teach as well as in academic learning, dynamic sources should be more involved” (Oosterheert & Vermunt, 2003, p. 167). Oosterheert and Vermunt’s overall contribution involves recognizing that learning involves more than activities in which students proceed “deliberately and intentionally” (p. 170). In their view, learning also involves “non-deliberate processing strategies” (p. 170), which we take to be essential to conceptual change. These ideas merit consideration in the teacher education classroom as well as in the science classroom.

One of the key features of “dynamic” self-regulation, as introduced by Oosterheert and Vermunt (2003), is that it is characterized by “rapid, spontaneous, non-deliberate, simultaneous” processing of “sensorial” information leading with “ease” to “reconceptualization” and “understanding” (p. 160). These are not qualities that we typically associate with learning. At first we found it puzzling that the authors speak of student teachers relying on dynamic sources when teaching, when “most of their decisions and actions require no deliberate thought” (Oosterheert & Vermunt, p. 165). Later they use a term that we have also found very helpful with respect to learning to teach. They suggest that student teachers may rely on a “default teaching repertoire” that they associate with dynamic regulation. We take this to refer to the “default” (do-it-without-thinking) style that every individual is capable of after more than 15 years of schooling, a style learned spontaneously, nondeliberately,

Narrative Box 37-5  
Identifying One’s Default Teaching Style

In 1997–1998, the preservice program at Queen’s University changed dramatically. After registration and brief introductions to professors and fellow students, candidates began their practicum experiences on the first day of school. Only during a two-week return to the university after eight weeks of teaching did individuals begin to get to know each other. The intensity of discussions was unlike anything I had ever experienced. I was challenged to assist people who would be returning to the same classes in the same schools and who sought answers and insights appropriate to very pressing questions of engagement, motivation, planning and discipline. For the first time I began speaking of “default” teaching styles—the teaching moves we make based on reflex, not on thought, the teaching moves we make that are comfortable and familiar because our own teachers used them when teaching us. This prompted the conclusion that each new teacher needs to identify and understand her or his own default teaching style before being able to modify that style to include deliberately chosen teaching behaviors.

*Do you find it helpful to think of your own teaching behaviors in terms of default styles and deliberate efforts to modify them to enact teaching moves that will enhance the quality of student learning?*

simultaneously, sensorially, and unintentionally by observation of one's own teachers, typically without understanding. Here again, the parallel to learning science is strong, for children acquire "default" understandings of the phenomena of science from their everyday experiences, and these can readily accumulate without deliberate processing.

This concludes our account of important arguments about acquiring and constructing knowledge in the context of learning to teach. Programs for learning to teach continue to operate on patterns guided more by tradition than by arguments such as these. Thus we turn next to the issue of whether teacher education programs can move beyond the rhetoric of reform.

## MOVING BEYOND THE RHETORIC OF REFORM

White (2001) contends that the last two decades have produced a revolution in research on science teaching. "The change in the amount of research is sufficient alone to warrant the term *revolution*, but even more significant is its nature" (White, p. 457). Against a background of revolution, the foreground offers clarion calls for reform and the improvement of science education (e.g., American Association for the Advancement of Science, 1989, 1993, 2001; Council of Ministers of Education, Canada, 1997; Curriculum Corporation, 1994a, 1994b; National Research Council, 1996). Prominent among the recommendations are changes in science classrooms whereby instruction is situated in a context that supports students' explorations of questions that develop deeper understandings of science content and processes and encourages learners to share developing ideas and information (Crawford, Krajcik, & Marx, 1999).

More broadly, reform efforts urge closer attention to students' conceptions of the nature of science and scientific inquiry (see Chapter 29, this volume). Lederman (1998) makes the case that, unless teachers have a functional understanding of these concepts, there is little hope of achieving the vision of science teaching and learning that is detailed in the reform literature. It is but a small step to argue that these understandings must be embedded appropriately in teacher education programs if prospective teachers are to move beyond the rhetoric of reform, become scientifically and pedagogically capable themselves, and then enable their students to do likewise.

### Learning What Science Is: Beyond Facts to Concepts and Discipline

Duit and Treagust (1998) relate learning science to the conceptions held by students and teachers of science content, conceptions of the nature of science, the aims of science instruction, the purpose of teaching events, and the nature of the learning process. The complexity of the construct "learning science," with its multiple components, points to many of the issues that confound science teacher education. These include the tenacity of students' conceptions about science and scientific inquiry as well as the tenacity of their experiences learning science—the procedural aspects in addition to the propositional, the pedagogy they were exposed to in their science classes, and the (subconscious) interpretation they attached to it.

## Challenges to Science Teachers and Science Teacher Educators

The complexity of learning to teach science for comprehension and understanding is obvious, and the agenda for successful science teachers is full: teaching about the nature and limitations of scientific knowledge, helping students to understand and apply scientific laws and theories, and enabling them to participate in scientific discourse and inquiry processes. For teacher educators, the agenda is doubly full because, in addition to the above, teacher education also requires a better understanding of the demands placed on teachers as they introduce their students to the nature of science, as they engage them in classroom discourse, and as they enable them to pursue scientific inquiry (Anderson, 2000). *How we teach* must be a major focal point for all who are concerned with teaching and learning science and with how individuals learn to teach science.

### The Significance of Discourse

Often teacher candidates entering classrooms are ill-prepared for the fallout from students' years of exposure to an alienating discourse: "We hardly do anything except copy notes that the teacher has written (not our own words) and do experiments that the teacher does for us. All we do is sit there and watch demonstrations and listen to the teacher talk. Everyone just sits there and looks like they're listening. I hate science" (Baird, Gunstone, Penna, Fensham, & White, 1990, p. xx).

How, if at all, do teacher educators address the discourse of science and its myriad representations and effects? How do they ready prospective teachers for less than enthusiastic responses from students, and how do they deconstruct those responses? When science is presented as a series of knowledge claims verified by others, it becomes no more than a compendium of facts to be warehoused, and

#### Narrative Box 37-6

##### The Importance of Coherence in Teaching

As we were completing this chapter, I was teaching two online courses for physics teachers. The courses had just been rewritten to focus on recent research findings (Knight, 2004), the significance of students' prior views, teaching strategies for fostering metacognition and the role of choice and motivation. The highly positive responses demonstrated the power of a coherent set of perspectives on learning to teach science. Where teaching to "cover the curriculum" typically involves teachers looking only for right answers, teaching to foster understanding necessarily involves looking for conceptual change. Exposing students' prior views of phenomena is crucial.

*How coherent are the many messages conveyed by teacher educators to those learning to teach science?*

learning entails stockpiling “prefabricated knowledge that then is stored in memory” (Duit & Treagust, 1998, p. 6).

Baird and Mitchell (1986) link the familiar transmission model of learning to students’ conceptions of what, for them, counts as schoolwork and what does not. Essentially, whatever is not presented in this mode is not considered real work, and discussions where alternative perspectives are advanced or meanings negotiated are perceived as time wasting and counterproductive. This perspective is not exclusive to students and may (unwittingly) be shared by teachers and teacher educators. Thus the discourse of the classroom, be it elementary, secondary, or post-secondary, reveals much about *how* students learn science and *what* their conceptions of scientific knowledge and inquiry are. Discourse is pivotal to understanding the resistance teacher educators encounter when alternative frameworks and conceptualizations are introduced. Thus we see changes in classroom discourse at all levels as central to moving beyond the rhetoric of reform.

## CONCLUSION

Our examination of literature about learning to teach science suggests that, in general, science teacher educators continue to be reluctant to practice in their own teaching what their research suggests that new and experienced teachers should do. Just as teachers are learning that action research is a way to explore in practice the challenges of teaching for conceptual change, so teacher educators must explore those challenges as they work with those learning to teach science. It continues to be easy to pin the hopes for improved teaching of science on those who are just entering the teaching profession; this approach seems fundamentally flawed. Experienced teachers and teacher educators who ask of new teachers what they have not attempted themselves are ignoring the reality that we learn to teach more by what is modeled than by what is told.

Anderson’s (2000) introduction to a series of papers on the challenges facing science teacher education identified a central issue for the development of the profession: “We need to develop teacher education programs that promote the qualities of practice that we value” (p. 294). The Narrative Boxes included in this chapter posed questions about the practice of science teacher education. Here we revisit those boxes to suggest a course for future research on learning to teach science.

1. Experience is important for learning science and for learning to teach science. How can science education researchers help teachers and teacher educators understand the many challenges involved in giving credence to students’ first-hand experiences within classroom learning activities?
2. The gap between practices and values in education goes back much further than Dewey and Schön, who were major twentieth-century figures calling attention to this gap. How can science education researchers help teachers and teacher educators navigate the tensions between theory and practice, finding the courage to think in new ways about learning and then weave the resulting insights into practice?
3. The call for more and more critical reflection by those learning to teach has been evident for more than 20 years, since Schön (1983) stressed the role of

reflection-in-action in professional learning. There is little public evidence that reflection is actually being taught, and there is little public evidence that teacher educators are themselves engaging in reflection-in-action. Can researchers find ways to address this lack of evidence and expose the complexities of making reflection-in-action a meaningful element of professional development?

4. Can researchers help teachers find productive ways to rethink the familiar background of teaching in our schools and universities? We hope that those learning to teach science will go on to improve how science is taught, yet how science is taught does not seem to change. Can researchers help teacher educators prepare new teachers who realize the profound challenges that accompany efforts to improve the practices of science teaching?
5. Science teacher education naturally seeks to inspire new teachers to develop best practices supported by research evidence. Yet research evidence also shows the importance of addressing explicitly students' prior views. Can science education researchers move beyond the studies of conceptual change in science classrooms to document the parallel complexity of conceptual change in prior views of teaching and learning that are evident in new teachers' earliest teaching moves, or default styles?
6. Schools and universities are often expected to be "all things to all learners," and this generates a significant risk that the result will be many fragmented pieces rather than a clear and interconnected picture. Can researchers help us develop coherent perspectives in our teaching and document the effects of messages that interact and support each other?

Methodologically, research on learning to teach science that explores the issues we have raised in this chapter will use predominantly qualitative methods. After all, we are concerned here about the *quality* of the learning experiences of those learning to teach. Action research and self-study are two prominent methodologies that are well illustrated in the research literature (Loughran et al., 2004). The field of science teacher education research has much to learn from the methods that have moved teacher research forward since 1990.

Many people are not optimistic about the prospect of actually moving beyond the rhetoric of reform. In this chapter we have endeavored to show that moving forward requires an epistemological revolution, a reframing of not just how we think about teaching science, but also how we think about learning to teach science. Progress demands that perspectives that move us forward in teaching science be extended to the context of learning to teach science. Science education research has produced compelling insights that must be developed coherently as those learning to teach science move through their initial teaching experiences.

We concur with Schön's (1995) call for a new epistemology that must be developed both in universities and in schools. Thus we must consider conceptual change not just as change in how students—and prospective teachers—think about phenomena but also as change in how students—and prospective teachers—think about education. Conceptual changes happen not just to students but also to prospective teachers, experienced teachers, and teacher educators—to teachers in schools and in universities. The entire argument always needs to complete the circle of reasoning about theory and practice. In the process, we must find ways to recognize and develop the authority of experience within our teaching and learning practices.

# CHAPTER 38

---

## Teacher Professional Development in Science

**Peter W. Hewson**

*University of Wisconsin-Madison*

Professional development for science teachers is of considerable current importance. This is an era in which, around the world, a new vision of learner-centered instruction is being developed. This grows out of a major, extended research enterprise over the past quarter-century. The focus of attention on what learners know and can do when they enter classrooms, and how this influences the instruction that they receive, has led to significant advances in our understanding of student learning and the implications this has for teaching. In parallel with these reforms, there has been a major push to develop new curricula and to identify explicit standards that together represent significant changes in what it is that students are expected to learn and do. A third circumstance of considerable importance is the increasing recognition of the systemic nature of the educational enterprise, arising in part from the difficulties experienced by reformers who sought to introduce new curricula and new teaching approaches. Aligning different components of educational systems is not a straightforward matter and has led to the investment of large amounts of resources for systemic reform. A notable example in the United States is the large number of Systemic Initiatives funded by the National Science Foundation (NSF) throughout the last decade of the twentieth century (see Chapter 30, this volume): a considerable portion of their budgets funded teacher professional development activities. Another circumstance that has considerable implications for teacher professional development is the growth of more extensive testing of students at all levels. Most, if not all, states in the United States have instituted their own proficiency tests and use these to judge the quality of schools and teachers. Furthermore, the No Child Left Behind legislation in the United States extended these testing requirements throughout the country. In part, these initiatives have been driven by international studies, such as the Third International Mathematics and Science Study and the Programme for International Student Assessment, that have raised issues of national performance. In a number of countries, the perception of inadequate performance has been a driving force for reform.

There are several arguments to be made to support the idea that responses to these national and international circumstances should necessarily, if not exclusively, focus on practicing teachers and their professional development. The first argument addresses the question, why focus on teachers? There is currently a broad consensus that teachers play a central, key role in any model of educational improvement. We are long past the era of so-called teacher-proof curricula. We have also tried, and found wanting, the assumption that teachers could be replaced by computers. Much of this recognition has come from recent research into the nature of a teacher's practice and expertise. What teachers do is not a formulaic following of rules, but nuanced, professional practice in which teachers constantly make important decisions and judgments in how they interact with their students to facilitate their learning. What this means is that if teachers are not involved, educational reform will not happen.

A second argument addresses the question, why not put our efforts into initial teacher education? If the teaching profession as a whole has to change its practices, this cannot happen solely through the introduction of new teachers into the profession. There are several reasons for this. If a teacher's effective teaching life is 25 to 30 years, the proportion of new teachers entering the profession each year is a small subset of the total teaching force. In other words, it will take a long time to change the teaching force if this is the sole means by which it is done. It is also the case that new teachers enter the profession without much power. Their veteran colleagues have experience and expertise that they do not have, and the likelihood that new teachers will be able to teach in different ways and perhaps influence their colleagues is small.

A related argument is that it is an optimistic assumption that all teacher preparation institutions will certify teachers who are fully capable of teaching in ways that are consistent with current reforms. Another argument is that internationally there are many countries where the current teaching force is poorly qualified. This may be due to a lack of resources for teacher education, or the country may have only recently moved to expand its education to all children, thereby creating the need to produce many teachers very rapidly. Under the circumstances, it is clear that the quality of new teachers will be severely compromised.

A final argument addresses the question, why focus on teacher professional development for practicing teachers? This is necessary because in the current climate of reform, teachers' practices, even when they were highly effective at an earlier stage, may be in need of reconsideration and updating. In other words, as the educational context changes, teachers' existing practices and beliefs may not be well matched with the revised demands of new reform efforts.

The focus, then, of this chapter is teacher professional development in science. First, I identify the meaning of teacher professional development in science as used in this chapter, followed by several comments on the specific boundaries of the term as it is adopted in this chapter. Then, I consider some general comments on the difficulty of doing research in this area. Next, I outline three different perspectives on teacher professional development in science; these focus respectively, though not exclusively, on the various aspects of teachers' personal, social, and professional development; what it is that teacher professional developers attend to and do; and the enactment of teachers' professional development in their classrooms. Then, I review specific studies that connect professional development activities on the one

hand with the teacher participants in these activities, and on the other hand with learning outcomes of students in the classrooms of teacher participants. The chapter concludes with a discussion of issues raised by the review.

## **DIMENSIONS OF TEACHER PROFESSIONAL DEVELOPMENT IN SCIENCE**

What is teacher professional development in science? First, it is about teachers and their teaching activities involving curriculum, instruction, and assessment; about their students and their learning; and about the educational system in which they practice. Second, it is about teachers being professionals who have an extensive knowledge base of conceptions, beliefs, and practices that they bring to bear on the unique complexities of their daily work lives, a knowledge base that is shared within a professional community. Third, it is about teachers as adult learners who have an interest in and control over the continuing development of their professional practice throughout their working lives, a process that is greatly facilitated by working in community with their peers. Finally, it is about science and the epistemologies, methodologies, and bodies of knowledge about the natural world that give scientific disciplines their distinctive character.

What are the boundaries of teacher professional development in science as used in this chapter? Focusing first on professional development, an obvious answer would be to include only professional development activities themselves and the teachers who participate in them. An alternative viewpoint is to recognize that the ultimate purpose in providing professional development is the improvement of student learning. This, then, leads to the conclusion that the connection between professional development activities themselves and student learning should also be included. The problem with such a perspective is that this connection is lengthy and complicated; it is also difficult to separate it out from many other issues. Increasingly, however, professional developers are being called upon to evaluate their programs in terms of student learning. For these reasons it is necessary to expand the domain of professional development from a tidy, focused, coherent perspective on professional development activities and participants to include the complex, intertwined connection to student learning.

I have included only those research studies that focus on practicing teachers, as distinct from those involved in initial teacher education. Studies of prospective teachers involved in initial teacher education are examined elsewhere in this volume (see Chapter 37). Although this is a convenient division that reflects the reality that initial teacher education and inservice teacher professional development are most commonly different enterprises, it cuts through the important principle that teacher learning should be a continuum, something that happens across the whole professional life of a teacher (Feiman-Nemser, 2001). Although the emphasis and intensity of teacher learning change as teachers move from initial certification to their first teaching positions, there are important common features across these two phases that need to be preserved.

Next, I included only those studies that explicitly described a professional development program. This means that I excluded studies that only consider teacher learning and, possibly, its outcomes in teaching and student learning, or that consider

teachers who are their own professional developers. In identifying this limitation it is necessary to recognize, but reject, a possible implication of the distinction this makes between programs and teachers, that is, that programs and the professional developers who run them are active providers, and the teachers who are participants in these programs are passive recipients. On the contrary, it is of the utmost importance to recognize that the focus of any professional development program is the teacher, and that it is teachers themselves who are responsible for their own professional development (Kennedy, 1999; Shapiro & Last, 2002; Wilson & Berne, 1999). Any activity should have the purpose of supporting teachers in taking responsibility for their own learning, in making the topics of teacher professional development their own, and in being active learners.

Finally, included studies needed to have an explicit focus on teachers of science. This requirement arises from the nature of this volume. It also has the practical effect of limiting the number of studies to be reviewed. It goes without saying that the specific character of science is an essential ingredient of student learning, of teacher practice, of teachers' professional development, and thus of programs designed to facilitate these outcomes. That being said, it is also the case that there are many aspects of professional development that are shared across disciplinary contexts, and thus there is much to be learned from literature that makes no reference to the subject matter of science. While not explicitly addressing this literature might be regarded as a significant limitation of this chapter, its influence is apparent, however, in many of the studies included.

## **Research on Teacher Professional Development in Science**

What can be said about the nature of research on teacher professional development in science? The short answer is that it is complicated and difficult, because the object of study—teacher professional development in science—is itself inherently complex, consisting as it does of a number of interrelated components. Therefore it is necessary for research to focus on the nature of relationships between these components, while it concurrently explores each of these components in its own right.

Conceptually, research in this area is very difficult. Although the immediate focus is on the professional development activity itself and the teachers who participate in it, the ultimate purpose of professional development is the improvement of student learning. The pathways of influence of professional development from the original activity to student learning proceed through the intervening variables of teacher learning and classroom enactment. These pathways are complicated, not only by the time it takes for teachers to clarify their learning from professional development activities and translate this into effective curriculum and instruction, but also by everything else that is happening concurrently in the lives of students, teachers, schools, and the community; teacher learning in professional development activities, teachers teaching in classrooms, and student learning are not isolated from the educational and social environments of schools and communities.

There are also practical difficulties in conducting research in this area. Because of the number of components involved, the length of time it takes for teaching practice to mature, and the amount of detail and intensive research techniques required

to provide understanding of what is happening at each stage of the process, the cost of effective research on and evaluation of teacher professional development can be substantial. Inevitably there is a trade-off between the costs of the evaluation and the value of the information that is obtained. A valuable approach adopted by the NSF in the United States has been to contract with one organization, Horizon Research, Inc., to develop a set of evaluation instruments that can be used across many projects that NSF has funded to reform the teaching of mathematics and science (Weiss, 1999).

A final comment is that, as always, there is a close relationship between research into a topic and evaluation of that topic, even though they are inherently different activities. This is particularly so because of the complexity of teacher professional development. Thus, in this chapter clear distinctions are not made between research and evaluation, and in some cases these terms will be used interchangeably.

## **Perspectives on Teacher Professional Development in Science**

It is necessary to recognize two essential focal points when considering teacher professional development in science. One essential focus is on the *people* who are experiencing professional development—teachers of science—and the processes through which they are going. This is encapsulated in the language that teachers use—they talk about developing professionally. The question that arises from this focal point is: How do teachers develop professionally? The second essential focus is on the *programs* that have an explicit purpose of providing professional development to teachers. In most cases this means that one or more persons can be identified as professional developers whose purpose is to plan and implement activities for science teachers that are designed to further their professional development. Professional developers, likewise, use characteristic language: they talk about the professional development they are providing. The question that arises from this second focal point is: What is it that good professional developers do? As previously argued, however, it is necessary to follow the influence of programs into teachers' classrooms. Thus a third question to consider is: What is the relationship between teachers and professional development programs? These questions were addressed respectively in three studies that specifically considered the teaching of science, all of which produced theoretical frameworks that conceptualize these essential focal points.

### **How Do Teachers Develop Professionally?**

This question was addressed in a three-year research project, the Learning in Science Project (Teacher Development), in New Zealand (Bell & Gilbert, 1996). In the project, teachers of science learned about and implemented teaching approaches designed with students' thinking and ideas in mind. During this time they experienced development of different kinds that were interwoven with each other. Bell and Gilbert modeled this in terms of personal, professional, and social development, and argued that, if development is to happen, teacher development programs must address all three of these components. In the project, a total of 48 teachers of science, both elementary and secondary, participated in four teacher development programs. Each

program consisted of two-hour weekly after-school meetings over one or two school terms. In the meetings teachers shared their experiences of implementing new teaching activities that explicitly took account of students' thinking. The researchers collected multiple forms of data. In addition to that obtained in program meetings, the data included interviews, surveys, and classroom observations. Bell and Gilbert's model of teacher development is detailed in the following paragraphs.

In the initial phase, *Personal Development* involves teachers coming to realize that some *aspects of their practice are problematic*. This could be a slow process, starting with an inarticulate awareness that requires time to take shape. It could also be sparked by a specific event that crystallizes dissatisfaction. This realization then becomes the spur for teachers to seek ways to address the problem. There are, of course, many cases in which teachers get involved with programs even though they do not see their practice as problematic (e.g., a department chair has recommended attendance). Bell and Gilbert (1996) suggested that no progress happens without this phase of personal development. However, they pointed out that this is more likely to happen if teachers feel that overall their teaching is competent, with only a limited aspect being problematic. Related to this is *Social Development*, in which teachers become *aware of their professional isolation* from their peers and recognize that this, too, is problematic. This, then, helps to create a willingness to find ways of discussing their practice with others. A key element of this is the need to be able to trust that their peers will be supportive colleagues who offer critique in a nonjudgmental fashion. These developments support the initial phase of their *Professional Development* in which teachers are *prepared to try out new activities* in their classrooms. In doing so, they take on the role of teacher-as-learner, in which they become aware of the process of change and development; this is seen as a positive progression, the anticipated outcomes of which are better student learning and feeling better about themselves as teachers.

In the next phase, *Personal Development* involves *coping with the restraints inherent in teaching*. When new teaching activities and approaches are introduced, particularly if these give students more opportunities for input, the personal concerns include fear of losing control and not knowing when and how to intervene, uncertainty of the demands on their knowledge of the subject, worries about covering the curriculum and meeting assessment requirements, and concerns about dealing with students, parents, and others who may object to these changes. In this phase, *Social Development* involves teachers coming to *see the value of collaborating with their colleagues*. As trust in each other grows, teachers become more ready to share their experiences with each other, listen openly to their colleagues' suggestions and critiques, and offer their own ideas about ways to address questions, problems, and concerns. In the process, their own self-confidence and ability to reflect critically on their own practice grows. In effect, their collaboration involves their "renegotiating and reconstructing their shared knowledge about *what it means to be a teacher of science*" (Bell & Gilbert, 1996, p. 26, emphasis added). Their *Professional Development* in this phase manifests itself in *developing a more coherent practice*. Their conceptions of teaching science become more articulated, more nuanced, and more reflective. Their classroom practice becomes more flexible, more responsive, and more able to accommodate changes in appropriate ways. More importantly, they see the need to integrate their conceptions with their practice and thus to reconstruct what it means to be a teacher of science.

In the final phase in Bell and Gilbert's (1996) model of teacher development, *Personal Development* entails teachers *feeling more empowered* with respect to their own development. They come to trust that what they are doing will produce the outcomes they hope for, and that students will not let them down when they hand over control. Feelings of empowerment also extend to interactions with their colleagues: teachers feel good about contributing ideas and volunteering their time and energy. In this phase, *Social Development* takes place as teachers begin to initiate activities and relationships with their colleagues, thereby *fostering collaborative ways of working*. Closely related is the *Professional Development* they experience by seeking out or *initiating different development opportunities* beyond the programs in which they are involved.

The scenario outlined in the previous paragraphs is a plausible narrative of how the various phases of the three forms of development might be interwoven with each other. There is a progression through these phases as teachers initially see themselves as competent professionals who nevertheless have room for growth in some aspects of their practice. Next, as they learn new ideas, approaches, and activities, and become more self-aware, they reconstruct aspects of the practice, and they develop a new sense of being a teacher of science within their collegial group. A natural outcome of this development is that they feel empowered to take the initiative with respect to all three types of development. Bell and Gilbert (1996), however, emphasized that their model of teacher development is not a stage model. In other words, there are no requirements that teachers complete one phase before proceeding to the next, or that they have to go through each phase in their developmental journey.

## What Is It That Good Professional Developers Do?

This question was addressed by the professional development team of the National Institute for Science Education in the United States. The team explored the nature of professional development practice through a process of collaborative reflection over the period of a year with five accomplished professional developers in science and mathematics (Loucks-Horsley, Hewson, Love, & Stiles, 1998). Rather than thinking of their practice as the refinement and use of models of professional development that others could easily adopt, these professional developers felt that their practice was more complex. Instead, it combined components of different models in programs that were changing over time and tailored to the particular circumstances in which they were working. In other words, they agreed that the practice of professional development is a process of design. On the one hand, professional developers have a set of purposes that they want to achieve. On the other hand, they are working in a particular context, with a particular group of teachers, in a set of circumstances that are unique to this particular project. The process of design requires that purposes be matched with context. Although this inevitably will require compromises, the intent is that these decisions will be made in order to maximize desirable outcomes. These reflections were summarized, albeit greatly simplified, in the form of a framework for the design of teacher professional development in science and mathematics. The specific components of the most recent version of the design framework for professional development in science and mathematics (Loucks-Horsley, Love, Stiles, Mundry, & Hewson, 2003) are elaborated in the following paragraphs.

The design framework has several major elements. First, there is a generic *planning process*, the steps of which are likely to be familiar to readers. These steps start with a commitment to a vision and a set of standards, and an analysis of student learning data; move on to the setting of goals, the planning and doing, or implementing, of professional development; and conclude with evaluation. Second, there are a series of *inputs* into the steps of the planning process. These inputs represent the knowledge and expertise about professional development that developers bring to the process of designing programs. They include *knowledge and beliefs* about all aspects of the process and participants of professional development, knowledge of the specific *context* in which the specific project will be implemented, knowledge and awareness of the range of *critical issues* that any professional development project needs to address, and a knowledge of the range of possible *strategies* that can be used within a professional development project to achieve its particular purposes. Third, these inputs are most salient for different steps of the planning process. For example, knowledge and beliefs will strongly influence the step at which professional developers commit to a vision of professional development, whereas it is only at the planning step that professional developers will be making decisions about which strategies to use. This is not to say, of course, that these inputs will be exclusively considered at these different steps. Rather, once inputs have entered the planning process, they will be considered in subsequent steps. Finally, there is feedback from the reflective evaluation of the project not only to the process of the project, thereby leading to improvements in the design itself, but also to the various inputs into the process that are as a result extended, deepened, and enriched. In other words, this is a dynamic framework.

The first of the four inputs into the professional development design process are the *knowledge and beliefs* that professional developers hold. There are five major knowledge bases that all professional developers are likely to consider when they are designing any professional development project. Of course, it is not the case that this will lead to identical designs. On the contrary, the outcome of the design will be strongly influenced by the specific content of these knowledge bases, and this will change as different theoretical orientations are adopted and further research with respect to each is carried out. The first two concern the principal players at the heart of an educational system and the activities that they are involved in. Thus, professional developers use knowledge of *learners and learning* on the one hand, and *teachers and teaching* on the other, in the design process. The third knowledge base concerns the substance, the content of what is being taught; in this handbook the focus is on the *nature of science*. The final two knowledge bases are directly related to the process of professional development itself: the *nature of professional development* and the *change process*. Current thinking in the field with respect to these five knowledge bases is considered in detail in Loucks-Horsley et al. (2003, Chapter 2).

The second of the four inputs into the professional development design process is the set of *context* factors influencing professional development. If design is the process of marrying theory with reality, and the knowledge and beliefs that professional developers bring with them are theory, then the reality of the particular project to be designed is rooted in the local context. Thus professional developers need to know the teachers that they will be working with and their learning needs, and these teachers' students, the standards they are expected to achieve, and what they currently know. They also need to know what the local curriculum is, the forms of

instruction that teachers use, their assessment practices, and the learning environment in their classrooms. Professional developers will also need to know about the larger context in which these teachers' classrooms are situated. What is the organizational structure and culture in the school? Who are the leaders and what support do they give to education reform? What are the local, state, and national policies that influence education in the school? What resources are available to schools and teachers? What history of professional development is there in the school, district, or state? Who are the parents of the students in the school, and what is the nature of the community and its commitment to education? A detailed consideration of these context factors is contained in Loucks-Horsley et al. (2003, Chapter 3).

A third major input into the process of designing professional development is that of the *critical issues* that any professional development project will face. Although these may not be front and center for all projects, professional developers ignore them at their peril. First, there is the need to find *time* for professional development, either within the existing structures, or by influencing policies and practices to create more time. Next is the question of ensuring *equity*. In societies that are increasingly diverse, and needing a greater array of scientific expertise, specific attention needs to be given to ensuring access for all to science education. Another critical issue is the building of a *professional culture* for teachers that recognizes that teachers should be lifelong learners. Closely related to this is the issue of developing *leadership*, particularly with respect to ensuring an environment that facilitates teachers' transforming professional development experiences into classroom practice. A related critical issue is the need to build capacity for *sustainability*. A major failing of much professional development is the lack of sustainability: when a project ends, teachers and schools return to the status quo. Even if a project is successful in sustaining itself, however, another critical issue is *scaling up*. Will the new professional practice only be maintained or will it grow? A final critical issue is that of garnering *public support*. Professional developers need not only to build awareness of science initiatives in schools, but also to engage the public in supporting these initiatives. These critical issues are discussed in depth in Loucks-Horsley et al. (2003, Chapter 4).

The final major input into professional development design is that of *strategies* for professional learning. Even though Loucks-Horsley et al. (2003) documented a large number of potential strategies, they pointed out that strategies are the means of achieving ends that should already have been specified, rather than ends in themselves. It is for this reason that the design process should be quite advanced before suitable strategies are chosen. Any one project is likely to employ a number of different strategies to achieve its various purposes. One set of strategies focuses on the processes of *aligning and implementing curriculum*. When new curriculum materials are available, this is an obvious choice. Another set of strategies looks at a different part of classroom experience by *examining teaching and learning*. Teachers might focus on their own practice through action research, or on their students' thinking and work. A third set of strategies focuses on ways of teachers' *immersion* in the science content that they teach, either through inquiry and problem-solving in science, or by spending time in the world of scientists. A fourth set of strategies focuses on *teaching* itself through strategies such as coaching, mentoring, and demonstration lessons. Another set of strategies focuses more on the ways in which teachers *collaborate* with one another than on the content of their collaborations. Examples of these are

partnerships with scientists, professional networks, and study groups. A final set of strategies includes the *vehicles and mechanisms* that professional developers use in their projects: developing professional developers, technologies for professional development, and various structures such as workshops, institutes, courses, and seminars. Strategies for professional learning are considered in detail in Loucks-Horsley et al. (2003, Chapter 5).

### **What Is the Relationship Between Teachers and Professional Development Programs?**

Fishman, Marx, Best, and Tal (2003) explored the relationship between professional development programs and science teachers' practice and developed a model of teacher learning from professional development. In common with Loucks-Horsley et al. (2003), they viewed professional development as a process of design, in which professional developers consider a broad array of issues in order to design all the activities that constitute an effective professional development program. In considering professional development practice, they specifically focused on the issues that professional developers have control over, or "*design elements*," and categorize these in four ways that have much in common with the design framework proposed by Loucks-Horsley et al. (2003). Content is the first design element; this refers to the learning outcomes for teachers who participate in professional development. This might be pedagogical knowledge (e.g., assessment knowledge) or subject matter knowledge. The second design element is strategy, used much as Loucks-Horsley et al. (2003) did. The third design element is sites: these are the settings in which teacher learning happens. This element pays attention to aspects of context, format, and place. Media are the final design element. This pays attention to the means through which professional development might be carried out (e.g., video, computers, face-to-face interactions).

Fishman et al. (2003) focused explicitly on teacher practice as an outcome of professional development programs, going beyond Loucks-Horsley et al. (2003) in the process. For them, the primary criterion for deciding program effectiveness was teacher learning: the *knowledge, beliefs, and attitudes* that teachers acquire as a result of participating in *professional development activities*. However, they did not stop with teacher learning. Rather, they adopted from Richardson (1996) the viewpoint that one has to consider teachers' knowledge, beliefs, and attitudes as an interactive entity with their classroom *enactment* in which each influences the other. Thus, they saw a need to consider how teachers' knowledge, beliefs, and attitudes are enacted in classroom settings, and how enactment influences student learning, as evidenced in *student performance*. They also recognized a reciprocal, interactive relation in which student learning influences teacher learning, mediated through enactment. A final node in the framework is *curriculum*, about which they made two arguments. On the one hand, they saw curriculum influencing, and being involved in, professional development activities. On the other hand they argued that curriculum materials themselves may be educative.

This framework is valuable in the emphasis that it gives to tracking the influence of teacher learning, through its enactment in the classroom, and on to student learning. This emphasis gives explicit attention to various aspects that need to be

considered in evaluating teacher professional development. Their illustration of this point in terms of a project that they evaluate is considered elsewhere in this review.

## Summary

The three frameworks provide perspectives on teacher professional development in science that are complementary of each other. Together, they illuminate the many different components of the complex enterprise of professional development. Professional development programs have the goal of facilitating changes toward more effective teacher practices that ultimately are intended to improve students' science learning. Bell and Gilbert's (1996) model of teacher development focused on the teacher participants in professional programs and the interrelated strands of their personal, social, and professional development. Loucks-Horsley et al. (2003) highlighted the need for professional developers to pay explicit attention to a range of knowledge bases, to the wide variety of strategies for professional development, to the context of their particular programs, and to critical issues that arise for any program as they design their programs. Finally, Fishman et al. (2003) stressed the importance of being explicit about the connections between program, teacher practice, and student learning.

## RESEARCH STUDIES

While there are considerable numbers of research studies that focus on individual components of these frameworks of programs, teachers and their practice, and students, and many that consider the relationship between classroom practice and student performance, the number of studies that consider the effect of programs on other components of these frameworks, with specific reference to science, was considerably smaller. The only previous review of professional development that explicitly considered professional development in science (and mathematics) was that conducted by Kennedy (1999). She included studies if they considered benefits to students. Four of the 10 studies included in Kennedy's review focused on science.

One other review, by Wilson and Berne (1999), discussed a small number of professional development projects. Their criteria for inclusion required that projects also conducted research, thought about both the content and process of professional development, and conceptualized professional teaching knowledge in terms of knowledge of subject matter, of individual students, of cultural differences across groups, of learning, and of pedagogy. Only one of these studied the teaching of science.

One reason why there are so few studies of professional development in science is likely to be the complexity of what is being studied. Consider the question of how student learning is related to professional development activity. The first link is between the professional development activities, for which some relevant variables are their nature, content, and extent, and the teachers who participate in them. Next, the outcomes from teachers' engagement in these activities will be mediated by their knowledge, beliefs, attitudes, and skills, as well as by the contexts in which they work. These outcomes could include learning further knowledge and skills, and developing different beliefs and attitudes; they could lead to the planning and implementation of revised curriculum and instruction that through reflection become more

coherent. The next link, then, is between teachers, their professional practice, and their students' participation in classroom activities. Finally, as with teachers, students' learning outcomes are mediated by their knowledge, beliefs, attitudes, and skills, as well as by the contexts of school, home, and community. In other words, the connection is complex and involved. This conclusion is supported by Guskey's (2000) identification of five levels of professional development evaluation: participants' reaction, participants' learning, organizational support and change, participants' use of new knowledge and skills, and student learning outcomes.

Before considering studies in some detail, it is useful to address who should be considered as professional developers. Professional developers are people who are likely to play different but complementary roles, depending on their primary places of employment. Boyd, Banilower, Pasley, and Weiss (2003) identified a broad array of people who served as professional development providers for U.S. Local Systemic Change projects funded by the NSF. Their data demonstrated that teachers can be professional developers, as can their colleagues, heads of departments in schools, curriculum specialists in the school or in the district, staff development personnel in the district, personnel drawn from independent educational organizations, and/or people employed at tertiary-level institutions such as colleges or universities. Within this range, teachers released full-time from their teaching assignments constituted the largest group. Although teachers can be, and often are, their own personal professional developers, articles that focus on teachers' own self-study and development are not considered in this chapter, since this important group of studies is considered elsewhere in this volume (see Chapter 34). For the purposes of this chapter, a professional developer will be regarded as someone who is concerned with the professional development of others.

All of the research studies reviewed include descriptions of professional development programs with teachers of science. These studies are grouped in two ways. First, there are those that only consider the influence of these programs on the teachers who were participants in them. Second, there are those that include student outcomes from classes taught by teachers who participated in professional development programs. Within each group, studies are ordered, depending on the size of the study in terms of teacher participants: case studies of one or two teachers, studies of coherent groups of teachers, and large-scale samples of teachers.

## **Professional Development and Teachers of Science**

The first three studies reviewed are case studies of one or two teachers. This allowed the researchers to spend extended periods of time with each teacher and thus to consider in some depth a variety of aspects of the teachers themselves, the professional development activities they were engaged in, and their enactment of ideas and approaches considered in these activities. Because of the concentrated nature of the research, the data-gathering methods produced loosely structured, thick descriptions, and these were analyzed with qualitative techniques.

Appleton and Asoko (1996) presented a case study of an elementary teacher in the United Kingdom who taught a science unit in which he sought to implement his understanding of a constructivist view of learning. The teacher, Robert, taught the unit for nearly a year (10 months) after attending an inservice program whose primary focus was a constructivist view of learning and its implications for instruction.

The program consisted of four blocks of five days each over a period of 10 weeks. Teachers in the program learned key principles of learning and were given examples of teaching approaches derived from these principles. They also had opportunities within the program to plan lessons using these approaches and were encouraged to try them out in their classrooms between the blocks. Robert had been enthusiastic about the ideas in the program and had reported success in using them in his classroom. In the period between the end of the program and the case study, Robert had had no formal support in putting these ideas into practice. The case study itself took place over a three-week period, during which Robert implemented a science topic he had planned on his own in a class of 10-year-olds. While he maintained overall control of the unit, one researcher was a participant observer in the classroom and provided some support for the teacher, both in helping out in small groups and making suggestions about the teaching of the unit. Data sources included observational field notes, audiotapes of teacher talk and pupil discussion, interviews with Robert, and samples of pupils' work. Analysis showed that Robert implemented some of the principles of constructivist learning more effectively than others. Although he provided an encouraging classroom atmosphere that facilitated his being able to elicit pupils' prior knowledge, he was not able to articulate clearly defined conceptual goals for the unit (focusing more on classroom process than content), he did not consistently use teaching strategies that challenged pupils to develop new ideas, and he provided no opportunities for pupils to use new ideas in different contexts. The researchers noted that Robert held prior beliefs about teaching and learning that facilitated his assimilation of some of the principles, while hampering the assimilation of other principles. They concluded that Robert would have benefited from inservice programs that modeled the principles they are teaching more effectively and that provided regular ongoing support, since teacher change is difficult and incremental, particularly if it involves a teacher's core beliefs about teaching and learning.

Rosebery and Puttick (1998) presented a case study of a single science teacher in the United States involved in an intensive professional development project that extended for nearly two years. The project advocated a view that both learning science and practicing science teaching are socially and historically constituted sense-making practices. Consistent with this viewpoint was a perspective that, even for the most experienced teachers, their daily teaching would always involve challenges, dilemmas, and uncertainties. The teacher, Liz, was videotaped while she learned science in workshops and taught science in her sixth-grade classroom, and was interviewed about both her learning and her teaching. During the project, data were gathered as Liz taught the same unit twice and planned the way she would teach it a third time. The extensive, detailed data gathering demonstrated a strong connection between key aspects of her science learning and her classroom practice. Specifically, Liz valued the opportunities she had to explore her ideas in an environment that supported her struggle to learn, while challenging her thinking, and sought to construct her elementary science practice along similar lines. Critical colleagues and a set of resources (e.g., videotape) to facilitate reflection on both her science learning and her teaching of science were essential features in her journey toward teaching in ways that she had experienced as a science learner.

Hand and Prain (2002) detailed an extended case study of two science teachers' participation in an ongoing inservice program in Australia to develop pedagogical practices to support writing-to-learn strategies. The inservice program was set up

in response to the concerns of "a group of science teachers about the role of language in science . . . to generate strategies to diversify the types of writing used for learning science in each class" (p. 745). Eight junior secondary science teachers participated in the program. The article reported on two of these teachers, Alan and Chris, who were most open to innovation. The program's goal was to facilitate reflection on teachers' changing concerns arising from ongoing classroom practice, through an equal partnership between researchers and teachers. Although teacher ownership of the program remained high throughout the four-year time frame of the study, at times teachers assumed a cognitive apprenticeship role when researchers introduced and modeled different approaches in regular inservice sessions. Data sources included audiotapes of these inservice sessions, field notes of classroom observations, and interviews with teachers. Analysis of the data identified three issues that were central to the two teachers' concerns. The first issue was assessment, with teachers primarily seeing writing in science as an excellent assessment technique. Initially, they saw it as summative, but in time realized its many formative uses. The second issue was planning and setup of writing tasks in order to incorporate them into normal classroom practice. More specifically, they needed to develop strategies that supported students completing and, in time, planning writing tasks. The final issue concerned their changing roles as classroom teachers. They came to see that they needed to move from being a "wisdom-giver" (Hand & Prain, p. 750) to being a facilitator if students were to maximize the benefits they gained from writing-to-learn tasks. Critical features of this professional development experience were its long-term support for the teachers and the balance between the teachers' ownership and apprenticeship roles.

These studies understandably have strong similarities in their data-gathering and data-analysis techniques. They are, however, quite different from one another in the design of the professional development programs; there were differences with respect to the explicit content focus of the programs, the strategies that were used (examining teaching and learning, and immersion in inquiry), the extent to which teachers had input into the programs, and whether programmatic professional development overlapped with teacher enactment. The specifics of each program understandably carried through quite directly into the teachers' classrooms. Of particular interest is the considerable difference between the first study, where Robert's teaching was observed nearly a year after formal professional development activity concluded, and the latter two, in which teachers' implementation of different teaching approaches was interspersed with continuing interactions with professional developers and peers. On the one hand, Robert only adopted aspects that he could assimilate to his core beliefs about teaching (which he did not examine). On the other hand, there is evidence that the teachers in the other two studies became more aware of, and in some cases reconsidered, their core beliefs about teaching, as enacted in their classrooms.

The next two studies focus on larger groups of teachers who participated in a single professional development program. Briscoe and Peters (1997) in the United States explored how collaboration among elementary teachers from several schools, and with university researchers, supported them as they attempted change in their practices. Twenty-four teachers (mostly volunteers, with some specifically recruited) participated in a three-week summer workshop (four hours a day, four days a week) on problem-centered learning in science. The agenda implemented in the workshop

was negotiated between teachers and researchers. During the following semester, a researcher visited each teacher twice a month to observe him or her teaching science, and once a month all teachers and researchers held a day-long meeting. Data sources included initial structured interviews with teachers, field notes of classroom observations, transcripts of discussions, and collections of artifacts created by each teacher, representing respectively the implementation of problem-centered activities and the nature of teaching and learning. Analysis of the data showed that, as a result of the professional development, many teachers were thinking about changing their practices. Doing so was, however, difficult. Case studies of six teachers showed that having someone with whom to brainstorm ideas and discuss successes and failures was key to their learning both content and pedagogical knowledge, and sustaining their commitment to and enthusiasm for problem-centered learning.

Luft and Pizzini (1998) reported on a program designed to teach a structured model of problem solving in science (the Search-Solve-Create-Share (SSCS) model). Thirteen elementary teachers in the United States, all volunteers, attended a four-day workshop on the model, including information on the model, being a student in a model cycle, and planning implementation. During the following school year, they were encouraged to implement the model in their classrooms, to observe an experienced teacher demonstrating the model (up to four times), and to repeat the implementation. Seven of the teachers completed all of these phases and were the focus of the study. All implementations were observed by a researcher, and the teachers' use of the problem-solving model was assessed with a specially designed instrument, the SSCS Implementation Assessment Instrument, which focused on key categories of the problem-solving model, such as learning group performance, student participation, and the teacher's role in supporting a student-centered classroom. The level of SSCS implementation on each category before and after observing demonstration lessons was compared. Of eight categories, there were significant increases in three (time in groups, group cohesiveness, and active participation) at the 0.05 level, and two (teacher role and students generating problems and action plans) at the 0.10 level.

These two studies have strong similarities with the first group of studies with respect to similar, intensive data-gathering procedures and the differences in program structures and strategies. In both studies, program support structures and classroom implementation overlapped to provide the opportunity for the reflective cycles that are an essential part of effective teacher enactment (Fishman et al., 2003). Although to varying degrees, both studies stressed the value of collegial interaction in supporting this process. Finally, in both studies there was evidence that there were changes in teachers' classroom practices toward those advocated in the programs, though not as extensively as the professional developers had hoped for. A reasonable conclusion is that it is still an open question whether these changes will be embedded in teachers' continuing practice.

The final group of studies connecting professional development programs and teachers involved large numbers of teachers who participated in a broad range of different programs. Supovitz and Turner (2000) examined the relationship between professional development and teaching practice and classroom culture. The data were gathered, by means of a survey, from teachers in the United States involved with the Local Systemic Change initiative of the NSF. The survey was completed by nearly 3500 K-8 teachers in 24 diverse localities around the country, who had

received varying amounts of professional development, ranging from none to more than 160 hours. The professional development was assumed to be of high quality, with characteristics such as immersion in inquiry, intensive and sustained, embedded in classroom realities, focused on teachers' subject matter knowledge, consistent with standards for professional development, and connected to other aspects of school reform. These teachers reported on the extent and nature of the professional development they received, their teaching practices in science classrooms, and their classroom and school culture. Analysis showed that there was a strong relationship between the extent of teachers' professional development on the one hand, and their self-reported adoption of reform-oriented teaching practices (e.g., "design or implement their own investigation") and classroom culture of investigation (e.g., "encourage students to explain concepts to one another") on the other hand. The level of teachers' content preparation was also a strong influence on their teaching practice and classroom culture.

Garet, Porter, Desimone, Birman, and Yoon (2001) researched the effects of different characteristics of professional development on teacher outcomes in the United States. These characteristics, or structural features, included form of activity, duration (contact hours), and degree of collective participation, these being identified as elements of "best practice" in the professional development literature. Teacher outcomes focused on teacher knowledge and skills, and change in classroom teaching practice. These outcomes were determined by a survey of a national probability sample of teachers of science and mathematics who were involved in professional development provided through state and local institutions using national Eisenhower funding. The study showed that there were significant positive effects on teachers' self-reported increases in knowledge and skills and changes in classroom practices by core features from professional development activities. Mediating between structural features of professional development and teacher outcomes were content knowledge, active learning (observing and being observed; planning for classroom implementation; reviewing student work; and presenting, leading, and writing), and coherence of the professional development programs (being integrated into the daily life of the school).

Because of the large numbers of teachers involved, these studies differ from those previously discussed in this section in several ways. The sampling techniques together with the large numbers sampled provide assurances that the samples studied are representative of the whole population and the results can thus be generalized. The necessary use of surveys to gather information from teachers means, however, that the data gathered about classroom enactment, in particular, are qualitatively quite different. Data on teaching practices come from teacher self-reports in terms of categories provided by the researchers rather than from classroom observations.

### **Professional Development, Teaching, and Students' Science Learning**

The first four studies reviewed below focus on relatively small, coherent groups of teachers and their students. The groups, all with fewer than 20 teachers, were coherent because within each group teachers participated in the same professional development program, and, in the first two of these studies, the teachers taught in the same school.

Parke and Coble (1997) conducted a study in the United States that connected professional development, teachers' instruction, and student achievement. Professional development sessions for middle school science teachers were built around a strategy of curriculum development. Prior to focusing on curriculum, however, teachers were introduced to research on teaching and learning, as well as reform goals and standards, and, through dialogue, articulated their personal beliefs about teaching, learning, and assessment. They also worked to align their curriculum with the demands and constraints of their school and community environments through conversations with peers, administrators, and parents, and explored the implications of their revised curricula for assessment. Data were gathered in the same school from 19 teachers who participated in the project, and 11 control teachers who did not, and from 205 project students and 120 control students. Teachers were individually interviewed about their teaching practices and their perceptions of student attitudes toward learning science, and students were surveyed about their teachers' teaching practices and their attitudes toward science. Analysis of these data indicated statistically significant differences with respect to the frequency of in-class experiments and student collaboration (both higher for project teachers), and students' attitudes toward science class (more positive in project classrooms). There were, however, no significant differences between project and control classroom students on a state-mandated science test that emphasized factual information recall. The test was developed in 1960 and thus predated current reform efforts.

Barak and Pearlman-Avni (1999) reported on a two-year case study of a junior high school in Israel aiming to integrate the teaching of science and technology. The primary mechanism for achieving this was intensive and extended professional development for the school's eight science teachers and three technology teachers. Information on implementation of an integrated unit was gained from interviews with professional development providers, administrators, and teachers; from school visits; and from an achievement test and an attitude questionnaire (specifically designed for the study) at the end of the first year to assess pupil performance on a science-technology project. Geared to the quite different backgrounds of science teachers and technology teachers, the professional development opportunities were intensive in nature and extended over time. First, teachers were released for half a day each week throughout the school year to attend inservice courses offered by higher education institutions to improve relevant content knowledge of science for technology teachers, and vice versa, based on instructional materials specially prepared for integrating science and technology. Second, teachers attended individual, nonevaluative tutoring sessions about once every two weeks that focused on class activities, pupil achievement, and relationships with administrators and different subject area teachers. A key factor in the first-year implementation was the reluctance and, in one or two cases, the refusal of science teachers to teach the technical aspects of science-technology projects (e.g., combining the physics of sound with designing and constructing an audio amplifier). It should be noted that pupil achievement scores were noticeably higher on technology items. The authors concluded that a more realistic professional development goal was to develop awareness of the different field of study rather than expect teachers to teach both science and technology.

Fishman et al. (2003) illustrated their approach to linking teacher and student learning with professional development previously discussed in this chapter, in their report on a study with eight middle school science teachers in a large urban school district in the United States. The study was guided by their iterative model for eval-

uation of professional development that specifies that the design of professional development should be based on evidence of students' performance with respect to particular content standards. The implementation of the professional development should be evaluated by teachers who, in turn, enact ideas explored in the professional development. This enactment should be observed and student performance evaluated. This should then lead to redesign of the professional development, leading to a reiteration of the same cycle. In the study, the professional development was redesigned after an initial lack of student success on map reading and watershed concepts. Conducted in four Saturday workshops of six hours' duration held once a month, the professional development activities used strategies of curriculum review, peer information exchanges, and the examination of student work and consisted of an overview of the unit, modeling of a particular activity from the unit, and practice with a software tool used for building student understanding of watersheds. Teachers reported that their confidence in being able to support student learning had increased as a result of these workshops. Observations of their teaching showed that they used several strategies developed in the workshop. An evaluation of student learning, in this case with 755 students, showed that there was a statistically significant improvement in responses to water quality test items from the previous year.

A statewide NSF-funded systemic initiative (SSI) in the United States was the context for a study connecting professional development and student learning (Kahle, Meece, & Scantlebury, 2000). Ohio's SSI focused on middle school science and mathematics in urban districts through intensive teacher professional development activities. Teachers attended six-week summer institutes with six follow-up seminars throughout the course of the subsequent year. The institutes addressed teachers' lack of content knowledge and modeled inquiry teaching in science and mathematics, with a particular emphasis on standards-based teaching practices such as cooperative groups, open-ended questioning, extended inquiry, and problem-solving. Kahle et al.'s (2000) study was based on a subset of the data gathered in this project.<sup>1</sup> These data, gathered in two ways from students, included student achievement tests, prepared by the SSI from National Assessment of Educational Progress public-release items, and student questionnaires. The latter had subscales on student attitudes, standards-based teaching strategies used by their teachers, parents' involvement in science homework, and peers' participation in science activities. The data reported were gathered in eight middle schools, in each of which teachers who had participated in the SSI's professional development program were matched with one or more teachers teaching similar classes who had not. The data reported in this study were gathered in the science classrooms of eight SSI teachers and 10 non-SSI teachers. Analysis showed that there was a positive relationship between the SSI's standards-based professional development and students' science achievement and attitudes, especially for boys. This relationship was mediated by the reported use of standards-based teaching practices that were positively related with teachers' participation in the SSI's professional development.

---

1. At least 30 percent of the students in all schools in this study were minorities. The data reported were for African American students. Although this was a significant aspect of the published study, the ethnicity of students is not considered further in this chapter.

It is instructive to compare how the three components—professional development, teaching practice, and student outcomes—played out across these studies. First, the professional development provided to teachers in each of these studies had several commendable characteristics. In each case, professional development included intensive sessions where teachers had opportunities to build knowledge of new approaches and explore implications for teaching, followed by opportunities to teach using these approaches that were interspersed with follow-up—reflective sessions to talk through aspects of their implementation in the specific circumstances of their classrooms. Different professional development strategies were used, some in combination with each other; these included aligning and implementing curriculum, immersion experiences, and examining teaching and learning (Loucks-Horsley et al., 2003). Data on classroom teaching strategies were gathered in different ways, including classroom observations, interviews with teachers about their teaching, and student surveys of teaching strategies. The inclusion of students in these studies provided a further opportunity to gather data about teaching that was not provided by the teacher. Next, these studies reported different ways of gathering student achievement data, varying from the proximal to the distal. In two studies, tests were prepared by the researchers themselves, in one study tests specifically targeted to the purposes of the study were constructed from available national test banks (Kahle et al., 2000), and in another study (Parke & Coble, 1997), an independent, statewide assessment test was used. Finally, there were variations in how closely the relationships among these three components were followed, flowing in part from the data-gathering methods employed. The study by Fishman et al. (2003) is noteworthy in this respect. Guided by an iterative model for the evaluation of professional development, the authors were able to track the influence of professional development explicitly and directly through teachers' enactment to student performance on tests specifically designed for the study.

One large-scale study reported connections among types of professional development, classroom activities, and student achievement. Huffman, Thomas, and Lawrenz (2003) conducted an external evaluation of a large-scale, statewide professional development project in science and mathematics in the southern United States.<sup>2</sup> The professional development provided by the state was extensive and diverse, consisting of coordinated workshops in the summer, with extended follow-up through the school year. It utilized all five general categories of professional development strategies proposed by Loucks-Horsley et al. (1998). Across all of the sites at which the project was implemented, there were many opportunities for teachers to engage in long-term, intensive professional development. Because the teachers were free to decide in which opportunities they would engage, there were variations in the type and duration of professional development. The authors surveyed 94 eighth-grade science teachers about, first, the type and duration of professional development they had experienced, and, second, the type and frequency of use of standards-based instructional methods they used. Student achievement was measured with the existing state achievement test, "part of a criterion-referenced state assessment system designed to measure student achievement of the state standards" (Huffman et al., p. 381). The test included multiple-choice and short-answer

---

2. Only the science results are reported in this chapter.

questions and a comprehensive scientific inquiry task. Regression analyses were conducted with the independent variable being the type and duration of professional development. The dependent variables used were, first, the reported frequency of use of standards-based instructional methods, and, second, class mean scores on the state achievement test. The professional development strategies of curriculum development and examining practice were the only ones predictive of the use of standards-based instructional methods. Finally, there were no significant statistical relationships between any of the professional development strategies and students' achievement scores.

## DISCUSSION

The frameworks for considering teacher professional development in science adopted in this chapter include programs that provide professional development to teachers of science, the people—teachers—who participate in these programs, the classroom practices that emanate from this participation, and the people—students—who are the participants in these practices. Research studies reviewed in this chapter explicitly addressed professional development programs for teachers of science. Some were primarily concerned with the effect of these programs on teacher practice, and others sought to connect student performance to programs through classroom practice.

How has research been conducted on programs, teachers, classroom practice, and students in the studies reviewed in this chapter? First, the research on programs is largely descriptive. In most studies these descriptions focus on project design, including its purpose, the pattern and duration of professional development activities, the professional development strategies used in these activities, the focus of these activities (science content, teaching strategies, etc.), and the teachers who participate in these activities. In only a few cases were data gathered during program activities and from participants, and in only one case was the research focused on program activities themselves (Fishman et al., 2003). The intent, for the most part, was to treat the programs as contextual constraints on the professional development of the teachers. Second, the research on teachers is both descriptive and evaluative, rooted, as it is, in a large, growing body of literature on teachers of science and other disciplines that detail what teachers know and believe, how they teach, and how they learn to teach. Thus it uses the same variety of data-gathering procedures used in the larger literature, including surveys, interviews, and observations of teaching and, in a few studies, participation in program sessions. It is no surprise, therefore, that these studies provide a much clearer picture of the teachers and their teaching, than they do of their learning as a result of their participation in professional development programs. A few studies, such as that of Rosebery and Puttick (1998), paid close attention to teacher learning within professional development programs. Others, such as Parke and Coble (1997) and the large-scale studies, relied on implicit assumptions about how and what teachers learned as a result of the programs in which they participated. Finally, the research on students largely focused on student outcomes, as measured by scores on achievement tests. The tests used in these studies varied with respect to their proximity to program, from those

specifically designed within the context of the study, such as Barak and Pearlman-Avni (1999), to those that used existing, distal measures such as state tests, such as Huffman et al. (2003).

How have the ideas in the theoretical frameworks considered in this chapter been addressed in the studies that have been reviewed? First, consider the model of teacher development outlined in terms of three different components—personal, social, and professional—by Bell and Gilbert (1996). Although none of the studies reviewed used this framework, the case studies that gathered detailed data from teachers provided an opportunity to consider teacher development in these terms. For the most part, these teachers engaged in the first two phases of personal development: they implicitly accepted aspects of their teaching as problematic as they were dealing with aspects of the restraints of their classrooms and schools, with some rethinking their core beliefs about teaching. Barak and Pearlman-Avni (1999) provided a counterexample that strengthens the importance of personal development: some science teachers saw no need for the professional development program provided (to integrate science and technology) and refused to change their practice. In terms of professional development, most teachers in these studies tried out new activities and were engaged in developing their classroom practice. There was also social development through their expressions of seeing the value of collaborative ways of working. Of interest, however, is that there was little evidence presented to decide whether any of these teachers moved into the third phases of development: feeling personally empowered and initiating other activities and collaborative ways of working.

Second, consider the professional development design framework outlined by Loucks-Horsley et al. (2003). Derived from a consideration of the practice of professional developers, the framework considers the process of design as being informed by knowledge and beliefs about various aspects of professional development, the context in which professional development occurs, various critical issues that all professional developers need to consider, and a catalog of professional development strategies. Only one study (Huffman et al., 2003) explicitly used any components of this framework, categorizing strategies of professional development across a broad array of professional development programs. Few studies explicitly considered the knowledge and beliefs underlying professional development. Other studies, to varying degrees, considered some aspects of the framework—case studies generally included context and some discussion of critical issues, and most studies gave some indication of the professional development strategies used, such as Luft's and Pizzini's (1998) consideration of demonstration classrooms. No studies, however, used the framework in a systematic fashion in planning, or in formative or summative assessments of professional development programs.

Finally, consider the emphasis on enactment as an interactive entity involving teachers, their classroom practice, and student performance provided by Fishman et al. (2003). Only a few studies considered these interactions in the larger context of professional development programs. One obvious reason is the difficulty of keeping a detailed focus on the different components of enactment as an interactive entity; across the studies that attempted to do so, classroom practice and student assessment were components that were addressed in a distant or indirect fashion. Another reason is that, although there are persistent calls to assess the effectiveness

of professional development programs in terms of student achievement, there are other more proximal goals that professional developers might like to achieve, such as finding ways to reduce the out-of-class workload of teachers.

Kennedy's (1999) review of professional development in science and mathematics concluded that, based on evidence of benefits to students, the content of professional development (what to teach and how students learn it) is more important than its form and structure (its duration, whether it is interspersed with teaching, whether it advocates prescriptive or discretionary approaches). Kennedy also concluded that it was important to treat teachers as professionals. The studies reviewed in this chapter do not support Kennedy's conclusion that the content of professional development is more important than form and structure. On the contrary, the various case studies demonstrate that without continuing support during the critical phases of planning, implementing, and reflecting on instruction, teachers are unlikely to make major changes in their teaching, particularly if these changes require reconsideration of their core beliefs about science, teaching, learning, instruction, and/or assessment. Content is still important: the studies reviewed here largely included it in ways similar to the most effective studies in Kennedy's review. The conclusion about the importance of treating teachers as professionals is also relevant; it is a reminder that the role of program structure is facilitative and not causative. Teachers themselves are responsible for changing their practice and, in the process, empowering themselves. In this regard, the questions that Bobrowsky, Marx, and Fishman (2001) posed about whether participants in professional development programs are volunteers or not, and how to design effective professional development for non-volunteers who may need it most are clearly relevant.

Because of the complexity of professional development programs and their effects on teachers and students, it is not surprising that the variations across the studies reviewed in this chapter are extensive; with a finite amount of resources to devote to studies of these issues, trade-offs are necessary. Consider the number of participants in a study. By limiting the study to one or a few teachers, it is possible to focus in depth on a broad array of factors that influence a teacher's learning, practice, and influence on students. Although this leads to a rich, nuanced description of a teacher and a deep understanding of the complexities of his or her world, it does not provide pictures of the breadth, extent, and variation of teachers' professional development experiences across schools, districts, regions, or nations. In studies with large numbers of teachers, choices need to be made to limit the number of issues to focus on, and to choose efficient methods of data-gathering. For example, in order to reach over 3,500 teachers, Supovitz and Turner (2000) used teacher self-reports for information about their professional development experiences and their teaching practices, rather than data gathered by independent observers. Trade-offs also need to be made with respect to the components that are studied. Deciding to include programs, teachers and their practices, and student outcomes in a single study requires other limitations. For example, Parke and Coble (1997) relied on a state-mandated science test, developed some 30 years prior to their study, for information on student achievement. In contrast, Fishman et al. (2003) designed the achievement tests used in their study, but limited the study to a tightly constrained content area and a few teachers. In other words, in studying teacher professional development in science, trade-offs are inevitable. This means that it is essential that

there be a broad array of different methods and data that complement one another in providing an overall picture of the field. While the studies reviewed in this chapter illustrate the diversity of possible approaches, they also illustrate that many more studies are needed to paint a coherent picture of the field.

## CONCLUDING REMARKS

The complexity of teacher professional development in science points to its systemic nature and suggests that research consider not only the people involved in professional development, but also the systems in which these programs are embedded. A metaphor that provides some insight into this issue is that of pathways. In considering professional development programs, it is necessary to consider not only the outcomes that the programs seek to achieve but also the means, the processes, the pathways by which those outcomes will be achieved. It is seldom that outcomes are ignored; much more frequently, however, it is only when desired outcomes are not achieved that the pathways by which they might be achieved are considered. However, the likelihood of programs being successful is greatly enhanced if the pathways are explicitly included in the program design. The pathway metaphor itself is valuable because it suggests several important issues. First, it draws attention to the starting point, the endpoint, and the various ways by which they might be connected. Without knowing where one starts from, and identifying reasonable connections between various points along the way, the possibility exists of finding oneself on the wrong side of a chasm to be bridged that requires more resources than are available. Next, the pathway metaphor suggests the need to pay careful attention to the journey and the resources that are likely to be available along the way. In other ways it is necessary to understand the system components that facilitate progress along the pathway. Finally, the idea of a pathway draws attention to the time that will be needed to complete the journey. It does not happen instantaneously; specifying milestones along the way reminds us that this is the case.

Thinking systemically also highlights a particular aspect of the relationship between people and systems. Frequently, what makes sense to individual participants is at odds with what makes sense at the organizational level. If a system and the people who work within it are to work effectively, there are different conditions that need to be met. On the one hand, at an individual level, each person needs to believe that she or he is an important part of the enterprise, that his or her contributions are valued and respected, and that she or he has a measure of autonomy in carrying out his or her responsibilities. This means that each person needs to develop an understanding of the many facets of his or her job and become committed to the belief that it is fair, equitable, and worthwhile. The organization needs to be responsive to the needs and ideas of its members, and to be trusting of their abilities. In other words, each person needs to be able to take ownership of the position to which she or he is appointed, and the work that this entails. On the other hand, at an organizational level, if the system itself is to operate effectively, there needs to be coherency in its vision, a concerted working together to achieve common goals, and a lack of different groups working at cross purposes to one another. This requires leadership to create a vision, set goals to be achieved, and developing strategies for reaching those

goals. One of the key strategies needs to be the effective communication of the vision to all participants in the system. Individuals, then, can come to see that their efforts are responsive to, contributing to, and fitting in with an overall vision.

Bringing a system together such that what makes sense for the participants is coherent with what makes sense for the system does not happen of its own accord. There need to be strategies in place that allow reconciliation of these different perspectives to occur as a normal part of the functioning of the system, whether it be a classroom, a school district, or teacher professional development.

# CHAPTER 39

---

## Science Teachers as Researchers

**Kathleen J. Roth**

*LessonLab Research Institute*

It is a statement about the growing interest in teacher research that this volume includes a separate chapter addressing science teacher research. The 1994 *Handbook of Research on Science Teaching and Learning* did not review different research approaches (Gabel, 1994). And although the 1998 *International Handbook for Science Education* did address these topics, teacher research or teacher action research was mentioned only briefly in chapters about qualitative research, science teacher education, and grass-roots equity initiatives (Fraser & Tobin, 1998).

This lack of attention to science teacher research might reflect the relatively late entry of science teachers into the teacher researcher movement. Teacher research, which dates back to the late nineteenth and early twentieth centuries, initially investigated teaching and schooling in ways that cut across disciplinary boundaries, rather than with specific subject matter lenses. The re-emergence of the teacher research movement in the 1980s, however, was spearheaded by teacher inquiry groups focused on the literacy curriculum, especially in the area of writing (Atwell, 1987; Bissex & Bullock, 1987; Mohr, 1987; Myers, 1985; Wells, 1994). Investigations around issues of social justice and social change also played a prominent role (Beyer, 1988; Carr & Kemmis, 1986; Kemmis & McTaggart, 1988; Stenhouse, 1983). More recently the teacher researcher movement has gained momentum in other subject matter areas, including science.

In this chapter I describe the status of teacher research in science education, examine the advantages and pitfalls of science teacher research, and consider possibilities for the role of science teacher research in the future. In particular, how might science teacher research contribute to the professional development of teachers and the development of a knowledge base for science teaching and learning?

In the U.S. context, this is a particularly interesting moment in time to examine the contributions and potentials of science teacher research. On the one hand, the science education community, as well as the education community more broadly, is driven by content standards (American Association for the Advancement of Science [AAAS], 1993; National Research Council [NRC], 1996) and standardized tests.

Federal funding through the No Child Left Behind Act of 2001 (NCLB) is dependent on evidence from standardized tests that students are meeting high content standards and requires that federal grantees use their funds on “evidence-based” teaching strategies. NCLB guidelines define large-scale, randomized controlled trials as the kind of educational research that provides such rigorous evidence (U.S. Department of Education, Institute of Education Sciences, 2003). Thus, like the students, the field of educational research is challenged to reach new standards. By definition, teacher research, where teachers examine issues in their own classrooms, does not meet the standard of large-scale randomized trials. What is the role for teacher research in this climate?

Although the standards and testing movement as well as the debate about what counts as evidence in educational research (Burkhardt & Schoenfeld, 2003; Feuer, Towne, & Shavelson, 2002) seem to minimize or ignore the importance of the teacher research movement, there are at least two bodies of current educational research that suggest an important role for science teacher research. Research about teacher learning and research about the relationship between research and practice both point to the importance of teacher-conducted studies, especially studies of teaching about particular subject matter (e.g., science) content.

First, the research on teacher learning suggests that teacher research is likely an effective professional development activity for teachers. There is an increased recognition of the importance of teacher learning across a career span as well as a growing consensus about the kinds of professional development activities that best support such teacher learning. Although more studies examining the impact of professional development programs on teachers’ science teaching practice and on their students’ learning are needed (Kennedy, 1998), there is evidence that effective professional development activities (a) engage teachers actively in collaborative, long-term problem-based inquiries, (b) treat content as central and intertwined with pedagogical issues, (c) enable teachers to see these issues as embedded in real classroom contexts, and (d) focus on the content and curriculum teachers will be teaching (Ball & Cohen, 1999; Carpenter, Fennema, Peterson, Chiang, & Loef, 1989; Cobb et al., 1991; Cohen & Barnes, 1993; Cohen & Hill, 1998; Darling-Hammond & Sykes, 1999; Elmore, 2002; Garet, Porter, Desimone, Birman, & Yoon, 2001; Kennedy, 1998; Lewis & Tsuchida, 1997, 1998; Loucks-Horsley, Love, Stiles, Mundry, & Hewson, 2003; National Staff Development Council, 2001; Shimahara, 1998; Steiner, 1999; Stigler & Hiebert, 1999; Takemura & Shimizu, 1993; Whitehurst, 2002; Yoshida, 1999; Zeichner, Klehr, & Caro-Bruce, 2000). These features of effective professional development (see also Chapter 38, this volume) point to the need for ongoing, collaborative, and content-specific inquiry into practice. Most of the science teacher research studies reviewed in this chapter involved teachers who were engaged in these types of activities—analyzing their practice in terms of specific content learning goals and in collaboration with other teacher researchers.

Second, there continues to be a gap between research knowledge and science teaching practice. Science teacher research might help close this gap. Advocates of action research “claim that action research can lead to praxis, a position in which theory and practice are dialectically related” (Goodnough, 2003, p. 60) and that through action research the theory-practice gap can be bridged (Carr & Kemmis,

1986; Grundy, 1987). For example, although the traditional university-based research community has built a large body of knowledge about students' ways of thinking about specific science topics and phenomena, there is still much to be learned about how to best utilize that knowledge in teaching (Berry & Milroy, 2002; K. J. Roth, 2002). This is one example of a type of research that teachers are uniquely situated to explore. In order to understand what is possible in terms of student learning, the science education community can benefit from teachers' investigations into their attempts to give students' ideas a prominent role in teaching about specific content ideas and phenomena. In this way, teacher research can play an important role in contributing to the knowledge base in science education and in making links between the worlds of practice and research.

These two bodies of research suggest two important but different roles for science teacher research: to support teacher learning and professional growth, and to contribute to the research knowledge base about science teaching and learning. Much of the early work in action research or teacher research focused on its value as a strategy for teacher professional development. However, at least as early as Dewey, there was also the idea that teacher research could provide more than an avenue of professional development for the teacher involved in the research. In addition, it could contribute knowledge to the education community. To what extent has science teacher research played these two different roles?

I have organized this review into the following sections:

1. Part One: Definitions and Historical Context
2. Part Two: Science Teacher Research Supports Teacher Learning
3. Part Three: Science Teacher Research Produces Knowledge
4. Part Four: Issues in Science Teacher Research

In Part One, I provide a background context including definitions and descriptions of different types of teacher research and highlights of the history of the science teacher research movement. In Part Two, I describe examples of science teacher research, starting with teacher research conducted as part of preservice and inservice teacher education or professional development programs, where the focus is on the role of teacher research in supporting science teacher learning and professional growth. I consider the impact of these programs on preservice and inservice teacher learning. In Part Three, I consider the contributions of science teacher research to the knowledge base for science teaching. Examples of published teacher research studies are described and categorized to characterize the kinds of issues science teachers are investigating, the kinds of methodologies they are using, and the kinds of knowledge they are generating. In what ways do these studies contribute knowledge of interest to the larger science education community? In Part Four, I turn my attention to three important issues in teacher research: the benefits and pitfalls of teacher research, the criteria for quality in teacher research, and new directions in science teacher research: What role will science teacher research play in a standards and high-stakes testing environment? What new directions look promising? How might teacher research be both better nurtured and better studied? How can teacher research become more integral in building knowledge for science teaching?

## PART ONE: DEFINITIONS AND HISTORICAL CONTEXT

### Definition of Teacher Research

Teacher research, in its many forms, shares with other forms of research a goal of understanding educational practice. However, teacher research is distinct from other forms of educational research in its emphasis on “changing practice as a result of study and changing practice to better understand it” (Zeichner & Noffke, 2001, p. 306). This emphasis on change and improvement of practice plays out in different ways in different forms of teacher research, with teachers entering into teacher research for a variety of purposes—to know more about how students learn, to understand a particular aspect of one’s teaching practice, to improve a particular aspect of one’s teaching, to try out a new teaching approach, to become a more reflective practitioner, to document successful teaching approaches, and so forth (Fischer, 1996; Zeichner, 1997).

Teacher research is defined in this chapter using the definition provided by Cochran-Smith and Lytle (1993, 1999) in their seminal works about the teacher research movement in North America in the last two decades. They defined teacher research in the broadest possible sense to encompass all forms of practitioner inquiry that involve “systematic, intentional inquiry by teachers about their own school and classroom work” (Cochran-Smith & Lytle, 1993, pp. 23–24). Included in this definition are inquiries that are referred to as action research, practitioner inquiry, teacher inquiry, first-person research, and so forth. It does not include reflection on one’s own educational practice or being thoughtful about one’s work unless that reflection is intentional and systematic.

The teacher research studies reviewed in this chapter share an additional feature: the teacher research was done with the intention of being shared in some way. The work was shared both locally with a group of collaborators in a teacher inquiry group or class, and more widely through presentations at professional conferences or teacher research festivals and through publication in a variety of professional formats. Thus, all of the studies reviewed in this chapter were made available for public scrutiny. This is consistent with Stenhouse’s (1975) definition of research as “systematic critical inquiry made public.”

Teacher research comes in many forms, but all forms focus on issues of teaching practice. Teacher research is distinguished from other forms of research in the deliberate fusing of the work of teaching and the work of inquiry (Ball, 2000): “What most clearly distinguishes first-person inquiry from other approaches to the study of teaching and learning is that it deliberately uses the position of the teacher to ground questions, structure analysis, and represent interpretation” (Ball, 2000, p. 365).

Shafer (2000) described three forms of teacher research placed on a continuum from reflective practice to action research to qualitative inquiry (teacher research). This continuum reflects the historical development of these forms of teacher research, with each successive form incorporating features of the previous one while adding new features.

*Reflective practice* is most closely tied to the ongoing work of teaching and does not require any special research plan or design. The goal is to heighten awareness

and deliberation about teaching (Abell & Bryan, 1997; G. Erickson & MacKinnon, 1991; Grimmett & Erickson, 1988; Schön, 1983, 1988). To be considered as teacher research by Cochran-Smith and Lytle's (1993) definition, reflective practice must have some intentional element. Teacher narratives written after a process of reflection on teaching represent teacher research where the intentional element arose after the teaching act.

*Action research* is more planned and, as its name suggests, has traditionally had a goal of improving practice (Carr & Kemmis, 1986; Loucks-Horsley et al., 2003; Reason, 2001). Teachers identify a problem of practice that they want to understand and address, develop a method to study the problem, collect data to inform the problem, and analyze the data to generate ideas for improving practice. The learning from the research is documented and shared. In some settings, action research is seen as a cycle, with results informing changes in practice and the generation of new questions to investigate (Corey, 1953; Loucks-Horsley et al.). However, in practice, action research studies are often carried out as stand-alone studies, using a more linear set of steps from question to results (Taba & Noel, 1957; Zeichner & Noffke, 2001). Most proponents of action research encourage a collaborative process in order to help individual practitioners develop inquiry and reflection skills (Miller, 1990; Reason & Bradbury, 2002).

Action research projects have been used as central activities within science professional development programs delivered by universities and other providers outside of school districts (*Colorado College Integrated Science Teacher Enhancement Project*, 2004; *Continuous Assessment in Science Project*, WestEd, 2005; *Project to Enhance Effective Learning*, Baird & Northfield, 1992; Baird & Mitchell, 1986; *Florida State University and Dade County Public Schools*, Sweeny & Tobin, 2000). However, action research projects are also initiated and supported by schools and school districts (Love, 2002; Zeichner et al., 2000).

Some action research takes on a critical, activist stance that has goals of bringing about a more just and humane society and understanding social forces so that practitioners can gain access to processes for change and overcome oppressive situations (Carr & Kemmis, 1986). *Participatory action research* is a variant of action research that is intended to reclaim the common person's knowledge and wisdom by involving them in the action research process (Kemmis & McTaggart, 2000). This form of research has occurred in developing countries as well as Europe, Australia, and North America (Fals-Borda 1997; Park, Brydon-Miller, Hall, & Jackson, 1993; Rosas, 1997). In science education, Barton's work as a science teacher and researcher collaborating with parents and community members in an after-school science program in a homeless shelter in New York City fits the description of participatory action research (Barton, 2003; Barton, Johnson, & the students in Ms. Johnson's Grade 8 science classes, 2002).

*Teacher research* emerged as distinct from action research in the 1980s, and, according to Zeichner and Noffke (2001), teacher research differs from action research in at least four ways. First, teacher research does not have the "action" emphasis of action research; understanding practice and documenting knowledge held by expert teachers are valid goals of teacher research that do not necessitate change in practice. Second, teacher research incorporates more qualitative methods than was typical of action research prior to the 1980s. Thus, teacher research includes case studies and conceptual research, such as the teacher essays by Karen Gallas (Cochran-

Smith & Lytle, 1993; Gallas, 1995, 1997). Third, and reflective of the qualitative research methodology, a teacher researcher's questions change and evolve during the inquiry process. Thus, the path from question to data to interpretations is not as linear and prescribed as in traditional action research projects. And finally, the teacher research movement included a new focus on the value of teacher-generated knowledge as having unique contributions to make to the field of educational research because of its insider status (C. W. Anderson, Butts, Lett, Mansdoerfer, & Raisch, 1995; G. Anderson, Herr, & Nihlen, 1994; Cochran-Smith & Lytle, 1993; Northfield, 1996). Thus, teacher research is as much about empowering teachers and making teacher voices a part of knowledge generation efforts as it is about teacher professional development and improving the practice of individual teacher researchers.

*Lesson study*, a process originating in Japan where teacher groups develop, teach, analyze, revise, and publish lesson plans, is a special type of teacher research focusing on collaborative analysis of practice (Fernandez & Yoshida, 2004; Lewis & Tsuchida 1997, 1998). In the United States, lesson study groups with a science teaching focus are a recent development (Hedman, 2003). For the purposes of this review, lesson study groups as well as study groups that meet to analyze artifacts of practice (student work, lesson videos) are considered as "first person" teacher research only if the teachers are intentionally studying their *own* lessons or artifacts of practice. This excludes teachers who participate in seminars or courses where they examine lessons and artifacts of practice from other teachers.

Teacher research takes place in the university setting as well as in P-12 schools. Two variants of teacher research carried out by university faculty have had a significant impact on the way educational research is defined in academia. The first is what Ball names "*researcher teacher*" (Ball, 2000). In this form of teacher research, university-based academics trained in research conduct research on their own teaching in P-12 school settings. The pioneering researcher-teacher work of Magdalene Lampert and Deborah Ball in elementary school mathematics classrooms stimulated a series of such studies in mathematics education (Chazen, 2000; Heaton, 2000; Lampert & Ball, 1998). In science education, university-based researchers such as Sandi Abell, Elaine Howes, Jim Minstrell, Jeff Northfield, Margery Osborne, Kathleen Roth, Wolf-Michael Roth, and David Wong have studied their own P-12 science teaching practice (Abell, 2000; Abell, Anderson, & Chezem, 2000; Howes, 2002; Loughran & Northfield, 1996; Osborne, 1993; Rosaen & Roth, 2001; K. J. Roth, 1993, 1994, 2000, 2002; W.-M. Roth & Boyd, 1999; W.-M. Roth & Tobin, 2004; Wong, 1995).

University professors also engage in research on their university-level teaching. Such *self-study research* has been growing in acceptance as a valid form of scholarship, especially among teacher educators, at colleges and universities. In the field of science education, Abell, Martini, and George (2001), Bianchini and Solomon (2003), Duckworth (1987), Feldman (1995), Loughran and Russell (1997), Munby (1996), Northfield (1998), Russell (1997), Smith (2001), and van Zee (1998a, 1998b, 2000) provide examples of such self-study research.

Whereas Cochran-Smith and Lytle (1990, 1993, 1999) considered teacher educators doing self-study on their own teaching as teacher researchers, I focus in this chapter on P-12 science teacher research in all of its various forms. (John Loughran discusses examples of university teachers' self-study in Chapter 34, this volume).

## Historical Context

Excellent reviews of the literature regarding the history of the action research and teacher research movements can be found in a chapter written by Mary Olson (1990) and in Zeichner and Noffke's (2001) chapter in the *Handbook of Research on Teaching*. Articles by Cochran-Smith and Lytle (1990, 1999), Hall, Campbell, and Miehch (1997), and Huberman (1996) also contribute to the story of the history of teacher research. In this section, I focus on the extension of teacher research from an early focus in the areas of literacy education and equity issues into the subject matter areas of mathematics and science.

Prior to the 1990s, teacher research in the United States focused mainly on the literacy and writing curricula or on issues of social justice in schooling. During the late 1980s and 1990s, teacher research began to move into other areas of educational interest. Of particular interest to science educators was the development of a movement toward subject matter investigations by teacher researchers. In the late 1980s Magdalene Lampert and Deborah Ball taught elementary school mathematics each day as part of their teaching load at Michigan State University. In the early 1990s, Lampert and Ball received funding to document their elementary school mathematics teaching over the course of a year. The products from this research played an important role in making concrete the potential contributions of subject-matter-focused teacher research. The products included descriptions of their analyses of mathematics teaching dilemmas (Ball, 1993; Lampert, 1990, 2001; Lampert & Ball, 1998), as well as videotapes of lessons and associated lesson artifacts (student work, teacher logs, etc.). These multimedia products captured the interest of researchers, teacher educators, teachers, as well as mathematicians and suggested the power of new technologies to enhance the impact and reach of teacher research studies. This work also inspired teacher research doctoral dissertations in mathematics (Heaton, 2000), writing (Lensmire, 1997), and science (Osborne, 1993).

The 1980s also marked some pioneering efforts in science teacher research. During the early part of the decade, Jim Minstrell, a high school physics teacher, initiated a productive line of research in his own classroom. Influenced by his mentor, Arnold Arons at the University of Washington, and by his participation in the development of the *Project Physics* curriculum and in the *Project for Assessing Conceptual Development*, Jim began to study his students' learning and his own teaching. Over the years, he was successful in getting research grant money to release himself from some of his teaching responsibilities to allow time for more in-depth research activities, using analysis of audio- and videotaped lessons and student interviews to uncover student misconceptions and develop methods for helping students develop conceptual understanding of physics concepts. The insights he gained about his students' thinking and learning, and the results of his efforts to design, implement, and study teaching strategies that would better help students develop deep understandings of science content, had a tremendous impact on the science education community. His teacher research work was well received both in the world of science teachers (Minstrell, 1982b, 1983) and in the world of academic research (Minstrell, 1984, 1989). In fact, although Minstrell retired from the classroom in 1993 (to focus full time on research and development projects), videotapes of his teaching still

provide useful sources of data that inform teaching practice and influence the policymaking world. For example, Schoenfeld's development of a "theory of teaching-in-context" was based, in part, on a close analysis of Minstrell's teaching practice (Schoenfeld, 1998). In addition, Minstrell's teacher researcher work was highlighted as an example of research on effective teaching in the widely cited National Research Council book, *How People Learn* (Bransford, Brown, & Cocking, 2000).

Influenced by the teacher research work of Jim Minstrell, Deborah Ball, and Magdalene Lampert, I began my own line of teacher research in the late 1980s. After finishing my doctorate in science education in 1985, I was eager to return to my classroom roots to find out what might be possible if I focused my teaching practice on students' thinking and learning. The knowledge I brought from my doctoral studies and my dissertation study convinced me that students had the potential to develop much deeper understandings of science than science teaching was typically tapping. During the 1988–1989 school year, I taught science and social studies to 29 fifth graders and traced their thinking and understanding of science content and the nature of science across the school year. The experience transformed my science teaching practice, my thinking about the teacher role, and my vision of research on science teaching and led to a line of teacher research in elementary school classrooms throughout the 1990s (Hazelwood & Roth, 1992; Rosaen & Roth, 1995; K. J. Roth, 1993, 1994, 1996, 2000, 2002; K. J. Roth et al., 1992). I was particularly interested in the usefulness of the videotapes that I had collected for research purposes, so I also explored the usefulness of creating video products from my work (K. J. Roth, 1998).

The teacher research and action research movements became more active and visible in the science education community during the 1990s when some teacher education, master's degree, and teacher professional development programs began to require teachers to conduct inquiries into their practice. Multiple events are likely to have contributed to this movement.

For example, such requirements came at a time when both research on science teaching and learning and the development of standards for science teaching at state and national levels had made clear the complexity of teaching science effectively (AAAS, 1993; Mintzes, Wandersee, & Novak, 1998; NRC, 1996; West & Pines, 1985). Research on students' personal experiences and ideas about specific phenomena and topics in the science curriculum suggested that teachers needed more than knowledge about the science content and generic science teaching strategies. In addition, they needed knowledge about students' ways of thinking about key ideas in the science curriculum and pedagogical strategies for addressing students' personal theories and supporting them in learning about specific science ideas (C. W. Anderson & Smith, 1987; Driver, 1989; Driver, Osoko, Leach, Mortimer, & Scott, 1994; Hewson, Beeth, & Thorley, 1998; Hewson & Hewson, 1984; Hollon, Anderson, & Roth, 1991; Posner, Strike, Hewson, & Gertzog, 1982). Shulman (1987) named this type of knowledge "pedagogical content knowledge"—knowledge of teaching strategies that are specific to key ideas within the curriculum rather than generic science teaching strategies. For example, a teacher needs to know specific strategies to support students in changing and deepening their personally constructed ideas about how light helps you see, why coats keep you warm, how plants get their food, and the source of water that appears on the outside of cold drink containers. According to

Loucks-Horsley et al. (2003), "To succeed in such a complex environment, teachers need opportunities to develop their pedagogical content knowledge through critical reflection on their own and others' classroom practice" (p. 41).

In addition, this was a period when research documented the limitations of pre-service science teacher education programs (Feiman-Nemser & Buchmann, 1985, 1989; Howey & Zimpher, 1989; Rosaen, Roth, & Lanier, 1988), science curriculum materials (C. W. Anderson & Smith, 1987; Eichinger & Roth, 1991; Kesidou & Roseman, 2002; K. J. Roth, Anderson, & Smith, 1987), and the traditional "one-shot" workshop approach to teacher professional development in preparing effective science teachers (Loucks-Horsley, 1996; Loucks-Horsley, Hewson, Love, & Stiles, 1998). At this time, many researchers were also convinced that research had some compelling ideas to inform science teaching but that, despite the apparent usefulness of the research, the research-to-practice gap was not narrowing (C. W. Anderson & Smith, 1987; Pekarek, Krockover, & Shepardson, 1996; Penick, 1986). In addition, studies of teaching practice revealed how little science teaching reflected the kinds of teaching recommended by research (K. J. Roth et al., 2005; SALISH I Project, 1997; Simmons et al., 1999; Weiss, Pasley, Smith, Banilower, & Heck, 2003).

The professional development school movement that started in the early 1990s also contributed to a view of teaching as inquiry by supporting collaborative inquiries among K-12 school-based teachers and university-based researchers and teacher educators (Holmes Group, 1990). As a result of these collaborations, more teachers in these sites (and the preservice teachers working with them) became involved in carrying out classroom research, making presentations at conferences, and participating in the publication process (K. J. Roth et al., 1992).

In response to one or more of these trends, as well as the growth of teacher research in other subject matter areas (especially literacy), preservice and inservice programs for teachers sought to develop reflective science teachers who could make research-based decisions to support their efforts to help students meet the new science standards developed at state and national levels. These program requirements acknowledged the complexity of teaching science for understanding for all students and the limits of existing teacher education programs, professional development programs, and curriculum materials in supporting such teaching.

Another event that stimulated interest in teacher inquiry was the release of the first *TIMSS Video Study* (Stigler & Hiebert, 1999), which brought attention to the unique Japanese lesson study approach to teacher professional development. In the United States, this led to a growing interest in using or adapting the Japanese lesson study model to support teacher inquiries into some of their practice (Fernandez, Chokshi, Cannon, & Yoshida, in press; Fernandez & Yoshida, 2004; Lewis, 2002; Lewis & Tsuchida, 1997, 1998). In the area of science, the statewide *California Science Project* incorporated lesson study activities into some of their professional development programs (see <http://csmmp.ucop.edu/csp/resources/lessonstudy.html>).

One of the results of these various science teacher research efforts was modest but increased attendance of K-12 practitioners at research conferences such as the National Association for Research in Science Teaching (NARST). This challenged the NARST research community and other organizations to acknowledge the lack of teacher voices in science education research. Although a teacher research special interest group had been established in the American Educational Research Associa-

tion in 1989, it was not until 2000 that a similar interest group was established at NARST. That same year, NARST began an annual practice of including a teacher researcher reception at the annual meeting.

Another indication of the increased interest in science teacher research was the December 2000 Conference on Teacher Research in Science and Mathematics, funded by the Spencer Foundation, the National Science Foundation, and the U.S. Department of Education Office of Educational Research and Improvement. Thirty-five teacher researchers, including newcomers as well as experienced teachers from established groups such as the Brookline Teacher Research Group, the ChecheKonnen Collaborative, the Fairfax County Teacher Researcher Group, the Philadelphia Teachers' Learning Cooperative, and the Prospect Archives and Center for Education and Research, joined five university-based researchers to explore children's classroom talk and work in science and mathematics (Ballenger & Rosebery, 2003). One reason given for the focus on science and mathematics was the growing number of teacher researchers expressing an interest in moving outside of the language and literacy area to examine science and mathematics learning issues.

## **PART TWO: SCIENCE TEACHER RESEARCH SUPPORTS TEACHER LEARNING**

After a brief review of different perspectives about the role of science teacher research in supporting teacher learning, I describe in this section examples of science teacher research efforts embedded in teacher education and teacher professional development programs. I focus first on science teacher research inquiries that occurred within preservice teacher education programs. I next consider programs for inservice teachers, starting with descriptions of science teacher research within degree-awarding programs and then turning to science teacher research within non-degree-awarding professional development programs.

### **Perspectives on Teacher Research and Teacher Learning**

In 1996, Pekarek et al. stated that the idea of teachers as researchers "ought to be incorporated in science teacher preparation and professional development programs" (p. 112). Others agree that teacher research can play an important role in enhancing science teacher learning, and a variety of rationales are used to support this view. Research on teacher reflection, for example, makes a strong case that reflection is a central and critical part of a professional educator's responsibility, requiring the teacher's consideration of many factors in deciding how to act in a particular situation (Abell & Bryan, 1997; Grimmer & Erickson, 1988; Schön, 1983). The importance of the role of reflection in teaching is underscored by the growing body of research knowledge about how difficult and complex it is to teach science (and other subject matters) so that all students, including those at risk for academic failure, develop meaningful understandings of central concepts and scientific ways of knowing (C. W. Anderson & Roth, 1989; Mintzes et al., 1998). There is wide agreement in the science education community that science teaching cannot be reduced to a set of techniques and knowledge that can be quickly given to teachers (NRC, 1996).

Thus the complexity of the teaching environment in the twenty-first century suggests that learning to teach science is a lifelong undertaking and that teachers need to learn how to learn from experience (Akerson & McDuffie, 2002; NRC). As Stenhouse suggested in 1975, and Duckworth elaborated in 1987, teaching should be viewed as a form of inquiry, experimentation, or research.

There are other arguments supporting the case for teacher research as a way to improve science teacher learning. For example, van Zee (1998a) suggested that teachers who are attempting to put new reform approaches to science teaching into their practice may receive better support from administrators, parents, and colleagues if they have clearly articulated and studied their intentions and practices. Others point to the motivational value of learning in the context of practice. By studying their own practice rather than simply reading research about other teachers' practices, teachers are more likely to be engaged in their learning and personal growth (Hewson, Tabachnick, Zeichner, Blomker, et al., 1999). Still others suggest that inquiry into practice provides an opportunity for teachers to experience the kinds of inquiry that characterize science itself (Akerson & McDuffie, 2002; McGoey & Ross, 1999). McGoey and Ross argued that, just as science is the construction of new knowledge representations and new understandings, so science teaching should involve construction of new knowledge about teaching science. "In order for science teachers to demonstrate authentic inquiry, we must be engaged in authentic research ourselves. Researching our practice is a natural fit" (McGoey & Ross, p. 118).

Because of the potential for teacher research to enhance teacher learning, various forms of teacher research have been incorporated into preservice and inservice science teacher education and professional development programs. Examples of these efforts and their findings are presented next, beginning with preservice teacher education efforts, and then we turn to inservice teacher professional development programs.

## Preservice Programs and Science Teacher Research

Both teachers and teacher educators suggest that preservice teacher education programs should include teacher research experiences. In an editorial in the *Journal of Research on Science Teaching*, McGoey and Ross (1999), two high school science teachers working with student teachers, argued that "the way to deal with the research-practice gap is to engage new teachers in action research from the very beginning of their own practice" (p. 118). Teacher educators Abell and Bryan (1997) concurred, challenging teacher educators to "coach prospective teachers to purposefully and systematically inquire into their own practice, encouraging them to make such inquiry a habit that will become increasingly valuable throughout their careers" (p. 136). Loughran (2002) noted that the possibilities for preservice teacher learning could be enhanced through effective reflective practice. Kyle, Linn, Bitner, Mitchner, and Perry (1991) went so far as to claim that "the process of recognizing the role of teachers-as-researchers should permeate every teacher education course" (p. 416).

Examples of efforts to carry out and study this view of preservice science teacher education are summarized in Table 39.1. The examples differ in their target preservice teacher population (elementary versus secondary, post-baccalaureate versus undergraduate) and in the length of the teacher research projects. In some programs

**TABLE 39.1**  
**Teacher as Researcher in Preservice Science Teacher Education Programs**

<i>Citations</i>	<i>Participants</i>	<i>Context</i>	<i>Length</i>	<i>Description of project</i>	<i>Results</i>
Featherstone, Munby, & Russell, 1997; Russell & Bullock, 1999	Preservice secondary science teachers	Bachelor's of Education; Queens University	One semester action research project in conjunction with teaching practicum and field-related course	Teacher educators sought to develop student teachers' "authority of experience" by engaging them in sustained analyses of their student teaching experiences. They supported two student teachers, Featherstone and Bullock, in publishing the story of their learning through inquiry into their own practice.	Preservice teacher Featherstone's ideas about science teaching and learning changed as a result of his efforts to listen to students and be responsive to students' ideas in his teaching. Preservice teacher Bullock identified a conflict between his vision of science teaching and his practice, studied these contradictions, and changed his teaching practice to allow student exploration with less teacher direction. Surveys showed high levels of satisfaction with the research-based rationale paper experience. Effectiveness of the action research might have been due to: 1) Students were required to revisit their research-based rationales,
Tillotson, Ochanji, & Diana, 2004	Preservice secondary science teachers	Syracuse University Science Teacher Education Program	2-year program with data collected during a 12-week student teaching experience	Prior to student teaching, students developed a research-based rationale paper describing how they will teach science. During a 12-week student teaching period, they examined one aspect of this rationale in an action research project carried out in collaboration with the host teacher.	

<p>The study and rationale were presented in a final portfolio session at the end of the program.</p>	<p>2) Studying teaching rationales in the context of teaching gave credibility to the research review process</p> <p>Additional benefit: Research collaboration with the host teacher allowed research results to reach the inservice teacher audience.</p>
<p>van Zee 1998b</p> <p>Preservice elementary teachers</p> <p>University of Maryland teacher education program</p> <p>1 semester course</p>	<p>In an elementary science methods course, van Zee engaged preservice elementary teachers in doing research while learning how to teach science. In addition to a science inquiry project (phases of the Moon), students conducted an inquiry into teaching practice. The teaching inquiries included interviewing students and adults about a science topic, engaging students in conversations about the topic, assessing student learning, writing reflections on students' learning and their own learning, and participating in a research festival with experienced teacher researchers.</p>

teacher research activities were embedded in single courses, while in others teacher research projects developed across both course and student teaching experiences. The programs also differed in the extent to which they studied their preservice teachers' learning from the experience. In many cases, such examinations of preservice teacher learning were limited to student self-report; in contrast, the study of teacher learning in the University of Wisconsin–Madison program was studied rigorously with the use of interviews and observations of preservice teachers. The results of these various efforts to integrate teacher research into preservice teacher education programs highlight the successes, challenges, and limitations of our knowledge about the relationship between teacher research and preservice teacher learning.

### **Impact on Preservice Teacher Learning**

All of the preservice programs described in Table 39.1 were studied by the faculty members who developed and taught them. Thus, all of these researchers were conducting self-study in one way or another. Both van Zee and Tabachnick and Zeichner made this self-study aspect of their work explicit in their writing. What do we learn from this set of self-studies in science teacher education? What evidence do they provide that teacher research can enhance preservice teacher learning about science teaching? Although these studies represent only a subset of similar studies, they provide important insights about what we know and do not know about teacher research and preservice teacher learning.

First of all, these studies provide evidence that teacher research conducted during a student teaching experience is possible and that preservice teachers can find it valuable. Many preservice teachers and teacher educators wonder whether a novice teacher can simultaneously learn how to teach and learn how to conduct research on teaching: It is not a trivial matter to be able to act in the classroom and to step outside of that action to observe and analyze. However, in these programs preservice teachers were able to do this at some level and to value the process.

Second, the studies showed some impact on preservice teachers' awareness, beliefs, and knowledge. Most commonly, preservice teachers became much more aware of and oriented to students' ideas and ways of thinking. In some cases, they became aware of conflicts between their beliefs and visions and their teaching practice.

Finally, although some preservice teachers reported changes in their teaching as a result of the action research (e.g., Featherstone, Munby, & Russell, 1997), there is little evidence that the teacher research components of these programs had much impact on the teaching practices of the preservice teachers. This is not surprising, given the short time frame of the programs (one course to two years) and the many demands placed on the preservice teachers, especially during their student teaching experiences, which typically lasted 8–12 weeks. It is not realistic to expect that preservice teachers' conceptions of science teaching will undergo significant change in such a short time period. In addition to developing a new concept of teaching, they are also challenged to translate that vision into action without many models of what the new practice might look like. However, this finding suggests possibilities for future exploration, including longer-term studies of preservice teachers and the development of more robust teacher research experiences within teacher education programs.

The reports of these programs also highlight the need to collect more in-depth data about the development of preservice teachers' knowledge about science teaching and the role that teacher research projects play in that learning process. Most of the studies reported here relied predominantly on end-of-program surveys filled out by the preservice teachers. To better understand the role of teacher research in the teacher learning process, we need studies that trace the unfolding impact of these activities on preservice teachers' thinking and actions. In addition, follow-up studies that examine these prospective teachers' views toward teacher research during their initial years of teaching would provide important data about impact.

## Inservice Programs and Science Teacher Research

*Degree-awarding inservice programs.* There are many degree-awarding programs for practicing teachers that now include teacher research or action research as a core component. Teacher research is built into these programs primarily because of its potential to support teacher learning that will lead to changes in teaching practice rather than contribute to the science education community's knowledge base. Many of these programs are not targeted only to science teachers, whereas others are designed specifically to support teacher research in science classrooms. Examples of three programs are summarized in Table 39.2.

*Non-degree-awarding inservice programs.* Teacher research is also a component of a variety of professional development activities that occur outside of degree-awarding programs. Some of these activities are local, state, or federally funded professional development programs (Hedman, 2003; Reardon & Saul, 1996; Saul, 1993, 2002), research collaborations initiated and supported by university faculty (Goodnough, 2001a, 2001b, 2001c; Lehrer & Schauble 2002), school district initiatives or school-university collaborations, university-sponsored programs, and more grassroots teacher research study groups. In some of these programs, teacher research is more than an opportunity to support teacher learning; it is also a vehicle for bringing teachers' voices into the larger science education research community. Thus, these programs and teacher groups vary in their relative emphasis on the goals of teacher professional development or the generation of knowledge for the wider science education community. Examples of these programs are described Table 39.3.

*Impact on inservice teacher learning.* As these examples suggest, science teachers are becoming involved in teacher research, and some in teacher research programs that have continued over time. These indicators and others, such as teachers' participation in conference presentations and publications of their work, suggest that teachers find value in teacher research. In fact, most of the programs presented in Table 39.3 claim positive outcomes of teacher research on inservice teacher learning. Most are careful, however, to limit the claims to changes in teacher beliefs, knowledge, and analytical abilities, rather than to changes in teachers' practice and their students' learning. Tabachnick and Zeichner (1999) referred to "a voluminous literature representing work in several countries (that) has consistently reported that teachers who engage in action research generally become more aware of their own practices, of the gaps between their beliefs and their practices, and of what their pupils are thinking, feeling, and learning" (p. 310).

**TABLE 39.2**  
**Teacher as Researcher in Inservice, Degree-awarding Programs**

<i>Program and Citations</i>	<i>Participants</i>	<i>Degree</i>	<i>Length</i>	<i>Description of Program</i>	<i>Results</i>
Science for Early Adolescence Teachers (FEAT), Florida State University; McDonald & Gilmer, 1997	65 Teachers, grades 5–9	Master's Degree	3 years	The program included three 5-week summer academic sessions and associated activities during the intervening academic years. An action research project during the second year was a core part of the program. Questions for inquiry grew out of analysis of videotapes of the teachers' own teaching during the first year. Results were presented in written form and at a research colloquium. In a synchronous, web-based program, inservice teachers were introduced to research from the outset of the program in a summer course on interpretive methodology. They became teacher researchers right away, undertaking inquiries into their own practice during both academic years of the program. The action research part of the program was further developed within each of the science education courses.	65 of 72 teachers who started the program completed it. Twelve teachers' action research reports were published (McDonald & Gilmer, 1997; Spiegel, Collins, & Lappert, 1995). For example: Graham, 1995; Ioanos, 1997; Thompson, 1995; Veldman, 1997.
Florida State University-Dade County Distance learning program in science education; Sweeney & Tobin, 2000	250 elementary and middle school science and mathematics teachers	Master's or specialist degree	3 years (3 summers and 2 academic years)		Twelve of these teacher inquiries were published in a monograph (Sweeney & Tobin, 2000). For example: Bagley, 2000; Britton, 2000; Fink, 2000; Ormes, 2000. Tobin emphasizes the benefit of the studies to the participating teachers and their students.
Nottingham Trent University, UK; Ovens, 2000	Primary teachers	Certificate in Science Teaching	2.5 terms	The year-long course engaged teachers in three core activities: (a) developing science knowledge and investigative ways of learning, (b) developing ideas about students' development of science knowledge and skills, and (c) investigating some aspect of one's science teaching. Teachers took the lead in identifying areas of inquiry.	Ovens wrote 6 case studies of the of the teacher researchers and their development in this program. Commonalities across the 6 included: 1. Increased science knowledge, 2. Increased confidence in teaching science and guiding their own development, 3. Increased understanding of students' science learning, and 4. Appreciation of and skill in carrying out action research.

Action Research Laboratory, Highland Park High School, Highland Park, Illinois; Senese, n.d.; Senese, Fagel, Gorleski, & Swanson, 1998.	High school teacher researchers	Ongoing since 1995	Constructivist approach to both student and teacher learning Interdisciplinary collaboration among teachers	Teachers work in cross-disciplinary teams of 3 to investigate ways to apply research to their practice. Each team picks a theme that will cut across disciplinary areas—such as assessment or gender equity. Results of the action research projects are shared in writing with building and district administrators, faculty, and the school board. Some are shared on local cable television, in local newspapers, and through professional publications.	The program documents both teacher growth and student achievement gains, using a variety of research strategies. Evidence of impact includes: 1. increased communication and collaboration among departments, 2. increased experimentation and risk-taking, and 3. more awareness of research about best teaching practices. 4. online publications (e.g., McDaniel Hill, 1996; Gapinski, Hill, & Solis, 2000). A focus on children's ideas and questions typically "leads both teacher and students deeper into the conceptual territory of the scientific phenomenon they are studying" (Ballenger & Rosebery, 2003, p. 297). The Center has published research reports about both teacher and student learning. The Center hosted two conferences for teacher researchers that centered on teaching cases in mathematics and science. Teacher researchers have published (e.g., DiSichino, 1998).
ChecheKonnen Center at TERC, Cambridge MA; Ballenger & Rosebery, 2003	Elementary and middle school teacher researchers	Ongoing since 1987	Urban science teaching Science learning for language minority students, issues of language and discourse	The Center conducts long-term, intensive partnerships with 13 public school districts to develop self-sustaining, inquiry-based programs of teacher professional development. The Center uses a professional development model of teaching as inquiry where teachers engage in science inquiries and in inquiries of their teaching practice. Teachers focus their analyses on what "puzzling children" in their classrooms say and do. They read relevant literatures and question their assumptions about children, science, language, culture, learning and teaching.

Classroom Action Research Madison Metropolitan School District, Madison, Wisconsin; Carow Bruce & Zeichner, 1998	K-12 teacher researchers	Ongoing since 1990	Supporting teachers of all subject areas in conducting action research as a district-wide professional development strategy	This school-district sponsored action research professional development program involves teachers, principals, and other staff. Teachers participate for a school year, with the option to continue a second year. Teachers meet once a month for a full or half day in small groups supported by two experienced action researchers. The group facilitators are supported in seminars held about every six weeks. Teacher researchers write reports of their work that are published and circulated within the school district.	Reports of teachers' inquiries are posted online and include 20 that focus on science teaching (e.g., Field, 2001; Schoenmann, 2003). Study of the program has identified critical features, common obstacles (most are related to time), how useful the research is to others in the district, and how the program influenced teachers' thinking about their practice.
CRESS Center Teacher Research Program, University of California, Davis; <a href="http://education.ucdavis.edu/cress/">http://education.ucdavis.edu/cress/</a>	K-12 teacher researchers	Ongoing since 1992	Supporting teachers of all subject areas in conducting systematic inquiries about how their students learn	A year-long set of seminars supports teacher researchers. At twice-monthly small-group meetings, teachers learn various approaches to classroom research, discuss logs of their classes with other teachers, and share research questions, plans, and data. Some groups are discipline-based; most are school-based. Teachers write a report of their research.	Teachers report an increased sense of control, increased professionalism, a stronger disposition to be analytical about their teaching decisions, and an increased focus on student thinking and learning. Some teacher research reports are published in <i>Windows on Our Classrooms</i> , a collection of 7 volumes produced by the CRESS Center (e.g., Carlton, 1996). An annual Spring conference, "Voices from the Classroom," brings teacher researchers together.
Elementary Science Integration Project; University of Maryland—Baltimore County; Saul, 2002, 1993; Reardon & Saul, 1996	Elementary teacher researchers		Applying whole-language approaches to the teaching of inquiry science	Teachers are supported in integrating literacy activities in their teaching of inquiry-based science. In parallel to this activity, they support each other in developing and carrying out inquiries about their efforts to change their science teaching practice.	Three edited volumes have been published by these teachers (e.g., Blackwood, 1993, 1999; Dieckman, 2002a, 2000b; Pearce, 1993; Reardon, 2002)

<p>Goodnough action research group; Goodnough, 2001a, 2001b, 2001c, 2003</p>	<p>Elementary, middle, and high school science teachers</p>	<p>1998–99</p>	<p>Use of multiple intelligence theory in the context of science teaching</p>	<p>Five teachers (2 elementary, 1 middle, and 1 high school) formed an action research group with Goodnough as facilitator. The teachers wanted to improve their own science teaching and were interested in ways in which multiple intelligence theory might help them. Goodnough was interested in developing more empirical data regarding the use of multiple intelligence theory in science teaching.</p>	<p>Teachers reported positive outcomes such as:</p> <ol style="list-style-type: none"> <li>1. becoming more reflective in planning,</li> <li>2. being more sensitive to the diverse learning needs of students,</li> <li>3. learning about multiple intelligences theory,</li> <li>4. gaining confidence in teaching science.</li> </ol> <p>Goodnough attributes these positive outcomes to the supportive learning community within the group.</p> <p>Generated preliminary empirical evidence regarding the challenges and benefits of using multiple intelligences theory in science teaching at different grade levels.</p> <p>The program has served 200 teachers. There are 149 papers published online; 11 of these studies focus on science teaching (e.g., Cucchiarelli, 2001; DeSouze-Wyatt, 2002; Dougherty, 2000; Gaither, 2000; Gonzalez, 1999; Hermann, 2002; Hicok, 2000; Jinks &amp; Stanton, 2002; Tracy, 2002; McGee, 2000).</p> <p>Program evaluation shows an impact on beginning teachers' development as reflective practitioners who focus on meeting students' needs. <i>Program and Citations</i>	<i>Participants</i>	<i>Longevity</i>	<i>Focus</i>	<i>Description of Program</i>	<i>Results</i>
Modeling in Mathematics and Science Program, University of Wisconsin and schools in Verona, WI (Lehrer & Schauble, 2002)	Elementary teacher researchers	Ongoing since 1998	Understanding students' thinking about important ideas in mathematics and science, such as data modeling.	Elementary teachers work in a cross-grade forum to improve and study student learning in mathematics and science. The work was initiated by a collaboration between teachers and researchers at the University of Wisconsin and has been subsequently sustained by teacher governance. The goal of the group is to improve teaching and learning by developing a public and sharable field of knowledge about the long-term development of student thinking in important ideas in mathematics and science, such as data modeling.	Teachers report that understanding student thinking supports teaching decisions in action. Teachers have published their findings as chapters in a book edited by Lehrer and Schauble, 2002 (e.g., Clement, 2002; Curtis, 2002; DiPerna, 2002; Gavin, 2002; Putz, 2002; Wainwright, 2002)
Physics Teachers Action Research Group (PTARG), San Francisco Bay Area, California; Feldman, 1994b, 1996	High school and community college physics teachers	Ongoing since 1990	Physics teaching	The group began as an occasional meeting of high school and community college physics teachers in the Bay area who gathered to discuss the teaching of physics and to hear presentations from physicists on current research. A new focus on collaborative, systematic inquiry into their teaching evolved.	Feldman analyzed the group's meetings and noted that knowledge about physics, teaching, learning, and pedagogical content knowledge was generated and shared by the group. In addition, teachers began to see themselves as researchers as well as teachers. They have made presentations at national conferences and published in <i>The Physics Teacher</i> . PEEL teachers contributed chapters to a book that was well received by teachers. The PEEL project and now includes groups in Canada, New Zealand, Sweden, and Denmark as well as Australia.
Project for Enhancing Effective Learning (PEEL), Melbourne, Australia; Baird & Mitchell, 1986	Grew from one small group of high school teacher researchers to many, multi-grade level groups	Ongoing since 1985	Promoting more metacognitive learning across the curriculum	This teacher-initiated program started at a high school in Melbourne, Australia where Mitchell was interested in using Baird's research about students' poor learning strategies to improve his science teaching. Teachers formed collaborative action research groups and received support and resources from university-based participants.	

<p>It remains an active community of action research teachers despite being unfunded and voluntary. Concurrent with geographic expansion, there was a drop in the percentage of teachers involved at the level of presenting findings to outside audiences.</p>				
<p>PAVOT teachers published a book that includes reports of 15 teacher research studies (Loughran, Mitchell, &amp; Mitchell, 2002), including one that is science focused (Berry &amp; Milroy, 2002).</p>				
	<p>This began initially as an unfunded offshoot of the PEEL project. The PAVOT teachers wanted to be more systematic about their research. Teachers received support in conducting research, writing for publication, and making public presentations of their research. Funding from two 3-year Australian Research Council grants provided teachers with short-term classroom release for writing and attending PAVOT meetings as well as funding to support presentations of their findings at educational conferences.</p>	<p>Closer collaboration with academic researchers to carry out more systematic research across the curriculum</p>	<p>Started in 1994</p>	<p>Primary and secondary teacher researchers</p>
	<p>Following a variant of the Japanese lesson study model, teachers meet in small groups to choose a student learning goal and deliberate together to develop, teach, analyze, and revise a lesson plan that addresses this learning goal. Video technology enhances deeper analysis of lessons than is possible with observations.</p>	<p>Lesson study approach in high school science teaching</p>	<p>Ongoing since 2001</p>	<p>High school science teacher researchers</p>
<p>The group has grown in size and is now interested in developing a model of effective science teaching to inform their planning. The group's writing about their lesson study inquiry is limited to progress reports that are not widely available.</p>

**TABLE 39.3**  
*(Continued)*

<i>Program and Citations</i>	<i>Participants</i>	<i>Longevity</i>	<i>Focus</i>	<i>Description of Program</i>	<i>Results</i>
Science Inquiry Group (SING), Maryland; D. Roberts, 2000; van Zee, 2000; van Zee, Iwaskyk, Kurose, Simpson, & Wild, 2001	Elementary teacher researchers	Ongoing since 1996	Documenting things that are working well in science teaching Collaborations between preservice and inservice teachers	This group focuses on collecting data to communicate to others what is working well rather than to guide actions for improving problematic situations. Experienced teachers meet in small groups in monthly after-school meetings. The group develops case studies which start with written abstracts presented at Research Festivals where experienced teachers discuss their ongoing research with preservice teachers. The Research Festivals serve as a basis for writing proposals for presentations at conferences as well as a place to rehearse conference presentations.	Teachers in this group have been active in making presentations at conferences, and some of the participating teachers have refined their conference papers into published pieces (e.g., Kwan, 2000; Lay, 2000; Nissley, 2000; D. Roberts, 1999, 2000). The teachers report favorably on their interactions with preservice teachers.

They also pointed to studies that show that action research sharpens teachers' reasoning capabilities and supports the development of the disposition to monitor one's own practice (Biott, 1983; Feldman 1994b, 1996; Noffke & Zeichner, 1987; Rud-dick 1985; Zeichner 1993).

Akerson and McDuffie (2002) found that several elementary teachers and teacher educators improved their science teaching with a reflective teacher approach (Aker-son, Abd-El-Khalick, & Lederman, 2000; Dickinson, Burns, Hagen, & Locker, 1997). Other researchers demonstrated the importance of action or teacher research in de-veloping teachers' abilities to reflect on and improve their own science teaching (Chandler, 1999; Fueyo & Neves, 1995; Scott 1994; Stanulis & Jeffers, 1995; van Zee, 1998a, 1998b; Winograd & Evans, 1995). In his work with physics teachers, Feldman (1996) found that action research played an important role in helping teachers iden-tify and reflect on their underlying assumptions about science and teaching, but that this growth in knowledge and understanding led to only modest changes in teaching practice, which he described as "enhanced normal practice" (Feldman & Minstrell, 2000).

Regarding teacher research as a mode of professional development, teacher re-searchers often testify to the power of the research process in changing their way of thinking about their teaching practice and their students' thinking and learning (Aladro & Suarez, 2000; Osler & Flack, 2002; Valverde, 2000). Despite the challenges, those who persist report positive learning outcomes: "As I reflect on my research, I see that I have learnt much more than I ever anticipated . . . There are many things that this first attempt at teacher research has taught me" (Boyle, 2002, p. 86).

Beyond teacher researchers' self-reports, however, there is limited evidence— from either teacher research or larger-scale studies of teacher researcher learning— about the impact of teacher research on changes in teaching practice that result in improved student learning outcomes. Do teacher researchers use research findings to change and improve their practice, or do their findings simply confirm their ex-pectations and justify their current practices? Does teacher research stimulate pro-fessional learning and growth and help teachers scrutinize their practice more rig-orously (Kennedy, 1996a)? Or does teacher research lead to stagnation and even self-delusion as the status of research is used to justify and maintain current teaching practices (Hodgkinson, 1957, as cited in Zeichner & Noffke, 2001; Huberman, 1996)?

One of the few attempts to make teacher researchers the subjects of a research study was conducted by Kennedy (1996a). This teacher researcher learning study examined 78 teachers involved in conducting research in their own classrooms. Kennedy found that these first-time teacher researchers, whose participation came as a result of either a master's program requirement or a district-sponsored action research program, clearly believed that what they learned through the research pro-cess was important. Most mentioned positive emotional or intellectual benefits, and many expressed interest in doing another research project. However, most of the teachers also reported that their study validated the teaching approach under study rather than challenging it ("I did interactive writing with my students, and this re-inforced to me that it needs to be part of the classroom curriculum" (p. 5)). Only a small fraction of the teachers reported that their research challenged them to revise their thinking about their teaching.

In another study, Kennedy (1998) examined professional development programs in science and mathematics that looked at program impact in terms of changes in

teaching practice and student learning outcomes. She identified only four such studies in science, and none of these programs was organized around teacher research. Clearly, more research is needed to assess the impact of teacher research on science teaching and on student learning.

### **PART THREE: SCIENCE TEACHER RESEARCH PRODUCES KNOWLEDGE**

What kind of knowledge is being produced by science teacher research? In what ways might this knowledge be of interest beyond the individual teacher researcher and her/his immediate collaborative group or school?

To address these questions, I reviewed 78 examples of science teacher research. In order to represent the broad range of teacher researchers, I included in this analysis all studies that I was able to access in print format, but limited my review to only one representative study from each teacher researcher. Many, but not all, of the selected studies were developed as part of programs summarized in Tables 39.1, 39.2, and 39.3, and are cited there. The studies were selected from a variety of sources, including research journals (*American Educator*, *Educational Action Research*, *Journal for Teacher Research*, *Journal of Curriculum Studies*, *Journal of Research in Science Education*, *Teachers College Record*, *Teaching and Change*), ERIC documents, books (Barton, 2003; Doris, 1991; Gallas, 1995; Howes, 2002; Loughran & Northfield, 1996), edited collections of teacher research (Atkinson & Fleer, 1995; Lehrer & Schauble, 2002; Loughran et al., 2002; McDonald & Gilmer, 1997; Minstrell & van Zee, 2000; Saul, 1993, 2002; Spiegel, Collins, & Lappert, 1995; Sweeney & Tobin, 2000), online publications (*Networks: An Online Journal for Teacher Research*), and teacher research web sites (e.g., Brookline Teacher Research Group, Cheche Konnen Center, CRESS Center at University of California–Davis, Fairfax County Public Schools, Highland Park High School, Language Minority Teacher Induction Program at George Mason University, Madison Metropolitan School District Classroom Action Research). Additional studies that I reviewed but did not list in Tables 39.1 through 39.3 include one of my own teacher research studies (K. J. Roth, 2002) and the following: Barnes, Hamilton, Hill, Sullivan, & Witcher (2003); Donoahue (2000); Elliot (1995); Genovese (2003); Hayton (1995); Irwin (1997); Jesson (1995); Joseph (2002); Lin (1998); McGlinchey (2002); Minstrell (1982a); Osborne (1997); Painter (1997); Pinkerton (1994); A. Roberts (1999); W.-M. Roth (2000); and Stahly, Krockover, and Shepardson (1999).

Of the 78 studies, 45 focused on elementary science teaching and 30 focused on secondary science teaching (13 at the middle school level and 17 at the high school level). The remaining three studies spanned multiple grade levels, including the college level.

#### **Issues Addressed in the Science Teacher Research Studies**

One way of describing the knowledge produced by these studies is to examine the issues addressed in the teacher inquiries. As shown in Table 39.4, 71 percent of the studies focused primarily on the use of particular science teaching strategies or approaches. These teacher researchers tried out teaching approaches recommended in

**TABLE 39.4**  
**Issues Addressed in 78 Science Teacher Research Studies**

<i>Issues Addressed</i>	<i>Percentage of Studies</i>
Use of particular teaching strategies	71
Use of science inquiry strategies	24
Use of language-related strategies (journal writing, strategies for English language learners, science talks, trade books, etc.)	29
Other (assessment strategies, group work, multiple intelligences strategies, technology, outdoor environment)	18
Teaching and learning of a particular science concept or topic (sound, light and shadows, the moon, electricity, force and motion, plants and photosynthesis, water cycle, nutrition, rocks, particulate nature of matter)	14
Equity issues in science teaching	5
Other (teacher researcher role, becoming a teacher researcher, dilemmas of science teaching, theoretical analyses)	10

the research literature or in national science education documents and considered their impact. For example, 24 percent of teachers explored their efforts to use inquiry approaches to science teaching or a “science workshop” approach where students are encouraged to ask questions and to act as scientists in investigating their questions. Twenty-nine percent of the studies explored language issues such as engaging students in science talks, using journal writing, and so forth. Within this group of studies, there was a particular interest in strategies to support English language learners.

Fourteen percent of the studies focused primarily on a particular topic or concept in the science curriculum with the goal of examining students’ activities and learning related to that topic. These studies described the teaching of a particular topic or idea and usually focused heavily on student thinking and learning: How were students making sense of this science content? These topic- or concept-focused studies used a variety of strategies to examine student thinking and learning, including student interviews and videotapes of focus students, but the majority of them examined students’ thinking and learning in the context of instruction, primarily through analysis of classroom talk and student work. Within this group, there was some (although limited) focus on analyzing what Ballenger and Rosebery (2003) refer to as “puzzling students.”

Only 5 percent of the reviewed studies looked directly at equity issues in science teaching. Ten percent of the studies were classified as “other.”

## Data Types

What kinds of data did the science teacher researchers in these studies use? Table 39.5 summarizes the commonly used sources of data.

A common feature of the studies was at least some attention to student learning, thinking, and actions. However, the types and quality of evidence used to support claims about student learning varied widely. Most of the studies presented

**TABLE 39.5**  
**Types of Data Used in 78 Science Teacher Research Studies**  
**to Provide Evidence of Student Learning**

<i>Types of Data</i>	<i>Percentage of Studies*</i>
Student work	56
Transcripts of classroom talk	28
Student interviews	25
Teacher journal/logs	25
Videotapes	12
Pre-post measures of student learning	12
Quantitative measures—elementary teachers	9
Quantitative measures—secondary teachers	32

*Note:* \*Percentages do not sum to 100 percent because studies used more than one data type.

examples of students' work to support evidence of student learning, but these examples were used in different ways, and some provided more insight into student thinking and learning than others. In many cases, the examples of student work were presented as exemplars, showing what is possible without addressing how other students or groups of students performed the same task. In a much smaller number of studies, teacher researchers presented student work illustrating "puzzling students"; these studies revealed students' alternative ways of thinking about the science content rather than those intended by the teacher. Still other teacher researchers attempted to show a range of student work. This was sometimes accomplished by describing a particular assessment task and then reporting students' scores on the task, usually reported as a percentage of correct answers rather than an analysis of the facets or features of students' understandings and misunderstandings. Rarely did the studies present a sequence of student work to illustrate changes in student thinking over time.

Other methods for providing evidence of student thinking and learning and the effectiveness of the teaching strategies were used less frequently. As with the use of student work, transcripts of classroom interactions were more often used to demonstrate exemplars of the quality of student thinking and questioning that is possible rather than to demonstrate student understanding of particular content, to explore student confusions and difficulties, or to raise dilemmas of teaching. Both student interviews and teacher journals/logs were used in 25 percent of the studies, but in many cases data from these sources were not presented in the published report.

Pre-post measures or other indicators of change in student thinking and learning over time were used in only 12 percent of the studies. These assessment strategies were usually given to all students in the class, rather than focusing on case studies of individual students (as might be expected, given teachers' responsibility for teaching all students). The type of pre-post measures varied and ranged from yes/no questions about students' attitudes toward particular topics or aspects of doing science to standardized multiple-choice test questions to teacher-designed questions designed to assess student understanding, such as concept mapping tasks or application questions. Pre-post measures were not always written tasks; for example, one teacher researcher compared students' discussion of the same question before

and after a unit of instruction. Other data sources that might provide evidence of change in student thinking over time, such as case studies of individual students or student interviews across time, were evident in only a few of these studies.

Secondary teacher researchers were more likely than elementary teacher researchers to use quantitative measures (32 percent of students in secondary versus 9 percent of elementary school studies), to conduct surveys of their students, and to set up experimental comparisons of different conditions. Secondary teachers' interaction with a larger number of students might explain their interest in more quantitative methods, and their work with multiple groups of students in a school day might create a more natural condition for comparing different teaching approaches.

Videotaping was used in only 12 percent of studies. This is a surprisingly low percentage, given the wide availability of this technology and its potential for enabling teachers to examine their own practice (Hiebert, Gallimore, & Stigler, 2002). This issue is revisited in the section on new directions for science teacher research.

## Knowledge Contribution

What contributions might this group of 78 teacher researcher studies make to the larger science education community? What contributions do they make to teachers, to the research community, and to the knowledge base for science teaching?

As a group, the studies do not provide sufficient evidence of impact on student thinking, learning, and actions to use them to make any recommendations about effective science teaching. Larger-scale studies and closer analyses of changes in student learning over time are needed to make such claims. However, the studies do provide valuable insights into how science education research and reform recommendations are being implemented in classrooms, what makes such implementation challenging within real classrooms, teachers' assessment of the value and usefulness of these recommendations, and what issues science teacher researchers are and are not studying.

For example, there are a considerable number of studies that examined teachers' efforts to teach science with an inquiry orientation (e.g., Doris, 1991; Hayton, 1995; Iwasyk, 2000; Kurose, 2000; Kwan, 2000; Lay, 2000; Nissley, 2000; Pearce, 1993, 1999; Reardon, 2002; D. Roberts, 2000). Each of these studies provides a portrait of how such inquiry teaching was interpreted and implemented in one classroom. Descriptions of these teaching efforts give other teachers concrete and varying images of what inquiry science teaching might look like and how students might respond. The studies are for the most part inspirational, presenting captivating images of students engaged in scientific inquiry. Such images are necessary to help teachers translate the rhetoric of reform into a reality in the classroom. In this sense, teacher researchers are the pioneers, the ones who are willing to not only try new approaches in their science teaching, but to also make that effort visible for others. These pioneering inquiries provide valuable images for other teachers and provide important knowledge to the larger research community.

The research community can examine these studies to ascertain which features of inquiry teaching are being implemented and which are not and use this knowledge to develop future research agendas. Keys and Bryan (2001) reviewed many of the same studies reviewed for this chapter and used them (along with other studies)

to develop a proposal for a science education research agenda that examines research on inquiry in diverse classrooms with a special focus on modes of inquiry-based instruction that are designed by teachers.

Another interesting finding from the review of these studies of science inquiry is the emphasis on addressing authentic student questions (studying a local oil spill, local traffic flow, family recycling bins, and so forth). In contrast, teacher researcher studies of inquiry science teaching less frequently looked at inquiry within the context of addressing the development of the canonical science knowledge that is the focus of many science standards, benchmarks, and state or local learning goals and objectives. Such an observation could be used to stimulate discussion and debate within the science education community about the possible need for more studies of inquiry teaching that include a focus on canonical knowledge development.

Science teacher researchers' emphasis on student inquiry and relative inattention to the large body of research about students' naive conceptions, alternative frameworks, or misconceptions also provides important knowledge for the science education research community. Is this an important gap to be addressed in future teacher research? Or is "conceptual change" science teaching, and the development of understandings of science canonical ideas viewed as incompatible with inquiry teaching? This is an important issue for the science education community that the teacher research studies place before us.

While teacher research does not lend itself to making quantitative claims and generalizations about student learning or about which strategy works better than another, teacher research does provide a rich context for exploring what's possible and what's difficult in teaching a given topic, concept, or inquiry skill. For example, a group of teachers in Wisconsin provided rich descriptions of their efforts to help first-through third-grade students learn how to organize and interpret data in various representations (Clement, 2002; Curtis, 2002; DiPerna, 2002; Gavin, 2002; Putz, 2002; Wainwright, 2002). These teachers were exploring new ground in terms of challenging young students to use rather sophisticated data organization and reasoning strategies. These teachers explored curricular territory that is usually reserved for much older students who are more able to think abstractly, and their efforts challenge our assumptions of what's possible for young students to understand.

Berry and Milroy's study (2002) of their efforts to use a conceptual change approach to the teaching of the particulate nature of matter to year 10 students in Australia provides important insights about "what's difficult" in implementing research-based, theoretical perspectives in the classroom. They successfully identified their students' thinking that matter is continuous rather than particulate, but then struggled to figure out how to help students understand the scientific view of matter as particulate. They drew from the research literature to help identify the students' conceptual difficulties, but found that the research literature was largely silent about how to help students reconcile their ideas with scientific concepts. As Berry wrote in her journal: "This is so frustrating! I can find probes of students' conceptions all over the place [in the research literature] but there's nothing really that says what to do next!! Bits and pieces, nothing more" (Berry & Milroy, 2002, p. 200). Their efforts to develop a curriculum to address students' naive ideas represent a first step in building the knowledge that they could not find. But their efforts also communicate the need to the larger research community that this kind of knowledge is needed by classroom teachers.

The results of this review of science teacher research in many ways parallel Dressman's (2000) review of 61 examples of classroom research published in *Language Arts*. He found that the most common teacher research genre was the "good practice narrative" in which teachers reported their largely successful efforts to instantiate theory into practice. The same can be said of the majority of the studies in this review. Science teacher researchers are creating interesting learning contexts where there is much to report about student thinking and learning that is exciting and holds promise for the future. But there is an underrepresentation of studies that examine problems, learning difficulties, and discontinuities between intended and actual learning outcomes.

Both Dressman (2000) and Ballenger and Rosebery (2003) challenged teacher researchers to reveal more of the factors that "give teaching and learning their texture, their contour, and all too often, their outcome" (Dressman, p. 57). Fecho and Allen (2003) agreed, suggesting that the teacher researcher should reveal, embrace, and interrogate dissonances within his or her practice. Ballenger and Rosebery emphasized the importance of scrutinizing moments of confusion and "puzzling students," viewing this activity as the core of their teacher research practice. The idea is to delve into something that is confusing, perhaps unsuccessful, and to try to understand it better. This approach is at the core of the Brookline Teacher Research Group and the Cheche Konnen Center. This approach is evident in some of the published science teacher research, but it is the exception rather than the rule. For example, Judy Wild (2000) described how much difficulty her fourth-grade students had in understanding the basic idea of a complete electric circuit. She examines the discontinuities between students' abilities to build circuits and their difficulties in predicting whether given circuits will allow a light bulb to light. Many teachers might assume that the successful building of a circuit represents evidence of understanding circuits, but Wild's examples challenge this assumption and encourage teachers to take a deeper look at student understanding. In another example, Margery Osborne (1997) considered the dilemmas she faced in addressing the needs of the group and the needs of the individual when using a constructivist approach in her first-grade science teaching.

## PART FOUR: ISSUES IN SCIENCE TEACHER RESEARCH

Part Four addresses the benefits and pitfalls of science teacher research and the debate about criteria for judging quality of teacher research, and considers new directions for the future.

### Benefits and Pitfalls of Science Teacher Research

Is teacher research an effective model for teacher learning and professional development? Can teacher research make valuable contributions to the knowledge base for science teaching? Clearly, more research is needed to understand the impact of teacher research on teacher learning, on teaching practice, and on knowledge development in the science education research community. Science teacher research is in its infancy, and there are many unanswered questions about its effectiveness in

supporting teacher professional development and in contributing to the knowledge base for science teaching. Given this context, there is debate about the effectiveness and usefulness of science teacher research. Both teacher researchers and academic researchers point to a number of potential benefits and pitfalls of teacher research. Many of the benefits and pitfalls relate to the standards of quality of teacher research, which are further discussed in the next section.

## **Teacher Is Both Teacher and Researcher**

Teacher research provides an insider view of teaching that is often invisible to outside observers (Ball, 2000; Cochran-Smith & Lytle, 1993; Zeichner & Noffke, 2001). Approaches to research that use the personal view of the teacher as a resource offer the possibility of new insights that an outsider could not see and might not think to ask about. Only the teacher, for example, knows what she was thinking when a class discussion veered off in an unanticipated direction (see Abell & Roth, 1995). Only the teacher knows the kinds of thinking that went on during the planning process. Although an outsider can try to tap into this knowledge through interviews and other research strategies, it is difficult for an outsider to ask the right question at the right moment and to build the level of trust needed for the teacher to reveal critical information. "Teachers offer special insights into the knowledge-production process that those studying someone else's teaching are unable to provide" (Zeichner & Noffke, 2001, p. 299).

But it is difficult—and essential—that teacher researchers step outside their own assumptions and preconceptions and maintain a healthy skepticism about their observations of themselves and their students (Ball, 2000). Huberman (1996) and Hodgkinson (1957) questioned the ability of teachers to bracket their preconceptions and to "avoid distortions and self-delusion" (as cited in Zeichner & Noffke, 2001, p. 299). "Understanding events when one is a participant in them is excruciatingly difficult if not impossible" (Cochran-Smith & Lytle, 1999, p. 20; Huberman). Ball was more optimistic, but highlighted the challenge of this role: teacher researchers must remain open and curious, defending against the natural urge to defend against questions raised by others without silencing the interior voice that provides the unique and critical insights. Unless the insider perspective can be balanced by this outsider perspective, there is the danger that the research will become too personal, resulting in products that are useless and sometimes even embarrassing (Behar, 1996).

## **Research Questions**

Teacher research can address questions that take advantage of the teacher's insider status and would be difficult for outsiders to pursue with as much insight (Ball, 2000). For example, the teacher researcher is uniquely positioned to examine her efforts to implement a new science teaching strategy. The teacher has unique access to knowledge about the full scope of the thinking and planning that took place before, during, and after her teaching and about how teaching with the new strategy was more or less difficult than strategies used in the past. In addition, the teacher has a special vantage point for understanding the variety of influences that contributed to her experience using the new teaching strategy: What role did curriculum mate-

rials play? Were interactions with colleagues important? What about professional development experiences? How did the students' reactions to the new instructional approach influence her decision-making?

Ball (2000) suggested that teacher research focus on such questions where a first-person account can contribute to making visible knowledge that is less likely to be accessed by outsiders, and she cautioned teacher researchers to avoid questions that are best examined by outsiders. For example, teacher researchers sometimes ask questions that are best explored through in-depth case studies of individual students in their classrooms: *How are mainstreamed special education students experiencing the inquiry science teaching in my classroom?* Such questions require special observations and interviews with individual students, whereas the teachers' responsibilities as teacher require her to attend to all students in the classroom. An outside observer would be better suited to carry out this kind of research. Similarly, teacher researchers sometimes develop questions designed to develop generalizations or comparisons that are difficult if not impossible to make within the classroom context, such as: *Do students develop better understandings of the nature of science in an inquiry-oriented science classroom or in a conceptual change science classroom?* While a middle school science teacher could set up such a comparison between two of his classes, it would be difficult for him to set up and maintain the two contrasting conditions, and the student learning results would not have the same weight as a larger-scale study. However, the teacher's knowledge about what it was like to implement the two different approaches would provide a valuable insider perspective that might not be revealed in a larger-scale study.

## Research Context

The science teacher researcher has daily access to a rich data set about students, teaching, teacher thinking and planning, and student learning that provides unique opportunities for research. Unlike teacher researchers, researchers who watch other teachers rarely have access to the daily unfolding of instruction, and they can tap into teacher thinking and planning only on an occasional basis. This rich context enables the teacher researcher to examine classroom events with much more knowledge relevant to the situation than can an outside researcher. Thus, teacher research provides the opportunity to explore the many particulars of teaching and their interactions (Akerson & McDuffie, 2002; Ball, 2000).

The rich context can also be problematic, however. The environment is so dense with information and events that it may be difficult for the teacher researcher to focus the area of inquiry (Baird & Northfield, 1992; Northfield, 1996). Knowing too much about the particulars can make it difficult to see patterns and to make any kind of claims that might be of interest to the consumers of the research (Ball, 2000).

## Collaboration

Those involved in teacher research commonly emphasize the importance and value of collaboration among teacher researchers, which challenges the prevailing norm of teaching as an isolated activity (Cochran-Smith & Lytle, 1990, 1999; Goodnough, 1991a; Northfield, 1996; Ovens, 2000; Zeichner & Noffke, 2001; Zeichner et al., 2000).

The opportunity to work with other teacher researchers plays a central role in helping teachers make sense of the particulars of their own classroom, it provides insights into other teachers' practices, and it can support teachers in learning to be more analytical about teaching by challenging their assumptions and preconceptions. Teacher researchers frequently comment on the valuable role collaboration played in their growth as a teacher and a teacher researcher (Berry & Milroy, 2002; Mohr et al., 2004).

Although collaboration certainly contributes to making teaching more visible, it is not always easy to establish norms of interaction that focus on analysis and criticism. Teachers have not been trained in research techniques, and they are not experienced in having evidence-based conversations about teaching. Scientific norms of skepticism, precision, and demands for evidence are not typically part of teachers' professional interactions. The science teacher researcher community needs to support the development of collaborative norms that challenge teacher researchers' analyses and lead to insights that will be more transformative for the teachers themselves and that will be of more interest to the larger science education community.

### **Teacher Voice, Professionalism, and Satisfaction**

Since the 1980s, increasing numbers of academic researchers have called for the valuing of teachers as producers of knowledge (Carr & Kemmis, 1986; Cochran-Smith & Lytle, 1993; F. Erickson, 1986; Richardson, 1994; Russell & Munby, 1994). They have argued that teachers' knowledge has too often been dismissed by the research community as anecdotal and that teacher voices should be more prominent in educational research. Teachers should gain more faith in their own experience and knowledge instead of relying primarily on outside authority. Self-reports from teacher researchers suggest that they do gain professional satisfaction and a new respect for their own knowledge and ability to learn and grow. But they also acknowledge the demands and frustrations of conducting research and teaching. Both teaching and research are time-consuming and intellectually challenging endeavors, and only a few teachers find the wherewithal to make both activities a part of their professional lives. Although some teacher researchers get financial support from grants or school districts to provide time to work on research-related activities (e.g., writing, attending conferences), most teacher researcher groups meet during after-school hours. They spend these hours learning to carry out research tasks that academic researchers acquired as part of doctoral studies. Is it realistic to expect that teachers can learn to do meaningful research within this structure, and is it fair to teachers to ask them to take on this new role without any accommodations to their regular teaching load?

### **Teacher Learning**

As noted earlier in this chapter, one of the major goals of teacher research is to stimulate and deepen teacher learning and to promote changes in teaching practice. However, there is also the danger that teacher research can be used to justify the status quo (Ball, 2000; Hodgkinson, 1957, as cited in Zeichner & Noffke, 2001; Kennedy, 1996a; Zeichner & Noffke, 2001). In fact, Kennedy's review of 78 teacher researcher

studies found that most of these teacher researchers found evidence to support their current practice; challenging current practice or raising problematic situations was an uncommon feature of these studies. Teacher researchers must be wary about their claims; the fact that something is stated from a first-person perspective and experience does not necessarily make it true (Ball, 2000).

## **Usefulness of Knowledge for Teachers**

As noted in the historical context section of Part One, there has been much concern over the years about the failure of educational research to affect teaching practice. Teacher research, with its focus on the particulars of teaching described in teachers' voices, offers the promise of providing research knowledge that will be useful to teachers. But are teachers any more likely to read each others' research than they are to read academic research? Is the research too specific to the situation to be of interest to other teachers? A study by Kennedy found that teachers did not always rate teacher research studies as more meaningful to them than more traditional academic research. They found that it was the persuasiveness and relevance of the research and whether or not it influenced their thinking that determined its value to them, rather than whether the source was an academic researcher or a teacher researcher (Kennedy, 1996b, 1997).

## **Quality of Knowledge Produced**

One of the biggest areas of debate concerning teacher research is the quality of the research knowledge that is produced. Some argue that teacher research is a new genre of research that will improve the knowledge base for science teaching by building on academic research and linking it more closely to practice. Teacher research builds the bridge linking academic research and practice. Teacher research, in this view, can extend academic research knowledge by exploring it in the context of real classrooms. For example, teacher researchers can examine specific teaching strategies that have been recommended based on preliminary research, studying questions such as: What is possible in terms of student learning when you use these strategies? What makes these teaching strategies/recommendations difficult to enact? What is it like for a teacher to try to change his teaching practice in these ways? What discrepancies emerge between what was intended and what occurs?

Skeptics question whether knowledge produced by teacher researchers meets the criteria of quality that will enable it to be integrated with academic research (Hodgkinson, 1957, as cited in Zeichner & Noffke, 2001; Huberman, 1996). In this sense, teacher research is also viewed as a new genre of research, but it is separate and not equal to traditional academic research because of limitations in its standards of validity, reliability, evidence, claims, and generalizability. These debates about quality are examined in the next section.

## **The Debate about Criteria for Quality**

The history of action research and teacher research includes much debate about the standards for quality of such research: Are there special criteria needed for judging

the quality of teacher research, or should the same standards used in academic research be used? And who should set the standards of quality for teacher research?

In its early days, educational action research in the U.S. context was judged by traditional, positivistic research standards, resulting in severe criticisms of the quality of the research. Hodgkinson (1957) described teacher research as “hobby games for little engineers” and asserted that “research is no place for an amateur” (as cited in Zeichner & Noffke, 2001, p. 299). Despite the efforts of Stephen Corey (1953) and others to defend action research as a legitimate form of inquiry, action research was ridiculed from the perspective of the conventional research standards of the day, and it largely disappeared from the U.S. literature until the late 1970s (Zeichner & Noffke, 2001).

The development of qualitative research standards in education, and the growing recognition of these standards as respectable and legitimate, contributed to the reemergence of the teacher research movement in the United States in the late 1970s and 1980s (Zeichner & Noffke, 2001). Since then, various researchers have attempted to define standards for quality in teacher research, drawing largely from standards developed for qualitative research. Although there is wide agreement that the qualitative standards are useful in teacher research, many researchers assert that traditional standards of reliability, validity, and generalizability are not appropriate for judging the quality of teacher research, especially given the wide variety of forms and purposes of teacher research (Altrichter, 1993; G. Anderson et al., 1994; Dadds, 1995; Feldman 1994a; Jacobson, 1998; Lomax, 1994; Munby, 1995; Stevenson, 1996; Zeichner & Noffke). Instead, they argue for new standards of quality that are designed specifically for teacher research. Others argue that teacher research should be held to the same standards as other types of research.

In the latter group, Huberman (1996) asserts that teacher researchers should be held to the same classic standards that are applied to all qualitative research, including “evidence, consistency, freedom from obvious bias and perceptions of the people involved” (p. 128) and minimally reliable methods to minimize “delusion and distortion” (p. 132). Eisenhart and Howe (1992) and Eisenhart and Borko (1993) propose a master set of criteria for all forms of classroom research, including both qualitative and quantitative teacher research.

Those who argue for special standards of quality for teacher research highlight issues unique to teacher research. After reviewing arguments made by a variety of researchers on this issue, I selected five proposed standards for teacher research that seem to me to address issues that are specific to teacher research: (a) insider-outsider stance, (b) trustworthiness, (c) collaboration and public dialogue, (d) complexity of context and triangulation, and (e) impact on teacher/student learning. I believe that careful attention to these criteria would improve the quality of the science teacher research reviewed in this chapter.

### **Insider-Outsider Stance**

This criterion is at the heart of teacher research and is the feature of teacher research that most sets it apart from other forms of research. It is also the most challenging criterion to practice effectively as a teacher researcher.

Because the teacher researcher role involves self-study, many emphasize standards of quality related to the teacher researcher’s stance toward his or her study.

Ball (2000) describes the need for teacher researchers to step back and view their own work as teachers as matters for scrutiny while also being caught up inside the day-to-day actions of teaching. They must assume a stance of inquiry and curiosity, instead of defending one's actions against questions that others might raise. The teacher researcher must value and listen to the insider voice while also adopting an outsider perspective: "This kind of research requires both an unusual concentration on, and use of, self, combined with an almost unnatural suspension of the personal" (Ball, pp. 392–393). Northfield (1996) described the need for the teacher researcher to reframe classroom situations, to suspend judgment rather than rely on preconceptions, and to regard their assumptions as problematic. O'Dea (1994) drew from the field of literary criticism to describe the need for teacher researchers to be authentic, true to themselves, and self-critical. Lather (1993), working from a feminist perspective, called for the disclosure and self-scrutiny of the teacher researcher's preconceptions and experiences.

I believe that the quality of science teacher research will improve as the teacher research community develops guidelines and other supports to help teachers adopt this challenging insider-outsider stance. Strategies, guiding questions, or routines can be developed to challenge and support teacher researchers as they try to be aware of both perspectives and to examine each from a critical stance.

### **Trustworthiness: Evidence-based Reasoning and Worthwhile Questions**

At the center of the debate about quality in teacher research are the issues of validity and generalizability. In defining standards in qualitative research more generally, Lincoln and Guba (1985) and F. Erickson (1986) asserted that conventional notions of validity and generalizability cannot be applied to research that does not fall within the positivist experimental design paradigm. Lincoln and Guba suggested abandonment of the idea of validity, to be replaced by a notion of trustworthiness. Zeichner and Noffke (2001) nominated the term *trustworthiness* as a replacement for *validity* in the context of teacher research. They argued that the term *trustworthiness* "better captures the need for practitioner research to justify its claims to know in terms of the relationships among knowers and knowledges" (pp. 314–315). A standard of trustworthiness challenges researchers to develop arguments that persuade the reader that their findings are worthy of attention.

I find the term *trustworthiness* interesting, because it captures both the importance of having "trustworthy" data and the importance of exploring questions that are "worthy" of investigation and of interest beyond the individual teacher researcher's classroom. In constructing a list of criteria to guide teacher researcher work, I would prefer to highlight these different meanings by creating two separate categories. The new categories might be named "evidence-based reasoning" and "worthwhile questions." The "evidence-based reasoning" criterion points to the need for justifying claims and developing arguments based on specific pieces of evidence that can come in a variety of forms. Under the category of "worthwhile questions," I would emphasize that in addition to being of interest to the teacher researcher, research questions in high-quality teacher research are also linked to the work of others and/or to theoretical perspectives. I believe that if teacher researchers learn about and connect with the work of others, the quality of their research will improve.

In addition, this process will help them in developing the outsider stance described in the previous criterion.

## **Collaboration and Public Dialogue**

Collaboration is important and critical to the success of many different kinds of research projects, and I would argue that it is an essential criterion of quality in teacher research. Partly because of the difficulties involved in analyzing a situation in which one is a participant and taking an outsider stance (Huberman 1996), collaboration is a crucial element in teacher research (G. Anderson et al., 1994; Northfield, 1996; Stevenson, 1996). It provides teacher researchers access to outside perspectives and knowledge and challenges their assumptions. Because teachers are typically isolated in their classrooms and are not trained in research, collaboration is necessary to gain research skills and to connect their personal research with others' situations and concerns. Anderson et al. defined a standard of dialogic validity that assesses the degree to which the research promotes reflective dialogue among the participants in the research. Related to this but coming from a feminist perspective, Lather (1993) and Dadds (1995) described the quality of relationships among the participants as a key criterion of quality research. Stevenson emphasized the importance of making results public and engaging in dialogue about them beyond the research group.

In my experiences with teacher research, I have observed that high-quality teacher researcher collaboration is difficult to achieve. And yet this difficulty is not made visible in most of the science teacher research accounts reviewed for this chapter. Collaboration that challenges teacher researchers to reveal their own practices and to consider outside perspectives is often uncomfortable in school cultures where teachers do not say things that might appear critical or "challenging" of someone else's practice. It is easier to collaborate in supportive ways than in challenging ways. And yet, I would argue that the quality and usefulness of science teacher research will not develop and flourish unless teacher research groups can develop strategies and norms for challenging as well as supporting each other.

Because so many of the studies reviewed in this chapter were made possible because of collaborations initiated by academic researchers, I am convinced that collaborations between teacher researchers and academic researchers provide one excellent avenue for developing norms of "challenging" collaboration. But this kind of collaboration can also be precarious. Academic researchers have the experience and expertise to bring the language of argumentation and "challenge" to the table, but they can easily do this in a way that is alienating to some teacher researchers. On the other hand, academic researchers can be so fearful of alienating teacher researchers that they refrain from bringing new norms of interaction to the group, and an important opportunity for growth within the group is lost. Discussing differences in norms openly and frequently in teacher researcher groups is necessary, and the development of materials, guidelines, and research stories that help teacher researchers and academic researchers learn how to communicate in both challenging and supportive ways will support progress in this arena.

## Complexity of Context and Triangulation

A key criterion of quality for teacher research is the examination of the complexity of the classroom context and the use of triangulation to make sense of this complexity (Feldman & Minstrell, 2000; Northfield, 1996; Stevenson, 1996). This criterion is important for at least two reasons. First, a unique strength of teacher research is the deep and broad insider knowledge held by the teacher researcher; good teacher research uses the richness of this knowledge to provide insights unavailable to an outside observer (Ball, 2000). Triangulation, which involves collecting data from several different views of the same situation, enables teacher researchers to mine the wealth of this complexity. Along with collaboration, such triangulation also supports the teacher researcher in looking at classroom events from multiple perspectives, not just the teacher perspective.

The complexity of context criterion is also important in addressing issues of external validity, providing readers with sufficient detail to understand similarities and differences with his or her own context. Teacher researchers need to provide enough detail to convince others that “what they have learned is true in the particular case of their teaching in their classrooms” (Feldman & Minstrell, 2000, p. 6).

Many of the science teacher research studies reviewed for this chapter did not reveal the complexities of the situation through such methods as proposing alternative explanations, considering various sources of data, or examining conflicting evidence. In part, this might be explained by the expectations of traditional educational research publications and expectations of readers/audiences who are looking for a nice, clean story told in a certain number of pages/minutes. In contrast, teacher researchers need to figure out how to tell a “messy” (complex) story in a certain number of pages/minutes and to have the story be compelling and meaningful to audiences. This is a challenge, but a worthwhile one to take on: How can a report of teacher research reveal the complexities and yet still reveal a clear story that is meaningful to the teacher and to others?

## Impact on Teacher/Student Learning

A criterion that is at the core of action research and of many other forms of teacher research is the degree to which the research has been transformative, leading to a change in the researcher’s understandings and/or practice (Stevenson, 1996). This was described by Lather (1991) and G. Anderson et al. (1994) as catalytic validity—to what extent does the research energize the teacher researcher to better understand and transform the teaching situation? Dadds (1995) identified improvements in teacher researchers’ practice and teacher researchers’ professional learning and growth as two different categories for judging the quality of teacher research.

Although some teacher researchers specifically focus on documenting and analyzing their practice rather than improving it, I would argue that high-quality inquiries and analyses should also prompt the teacher researcher to develop new understandings that have implications for his or her teaching. In addition, I propose that the best quality teacher research transforms teaching practice in ways that

improve student learning. This is a high bar to hold up for quality teacher research, but what is the value of teacher understanding and learning if it has no implications for student growth? Good teacher research, therefore, should ultimately transform the teacher researcher's knowledge and understanding, the teacher researcher's teaching practice, and his or her students' learning.

## **Who Decides?**

Many of those engaged in the debate about standards for quality in teacher research, including myself, are university-based academic researchers. Although teacher researchers themselves discuss and raise issues of quality (e.g., Threatt et al., 1994), publications in print about these issues are dominated by academic researcher voices. Zeichner and Noffke (2001) and Evans, Stubbs, Frechette, Neely, and Warner (1987) criticized this situation as a silencing of the voices of teachers: "P-12 educators need to assume a central role in formulating and applying standards for assessing the quality of their own work" (p. 322). The field would be well served by public discussion of these issues across teacher researcher groups.

## **New Directions for Science Teacher Research in an Era of Standards and High-Stakes Testing**

Cochran-Smith and Lytle (1999) described the future of teacher research in the standards movement era to be uncertain. They noted that pressures for accountability are likely to make research-based whole-school improvement models more widespread, with the voices of outside authoritative experts dominating over teachers' voices in educational research. Since Cochran-Smith and Lytle wrote of this concern in 1999, the high-stakes testing environment in the United States has only intensified with the federal No Child Left Behind legislation (NCLB, 2001). The NCLB legislation not only mandates extensive testing; it also explicitly states that teachers should implement teaching practices that are shown to be effective by high-quality research. The "gold standard" of high-quality research is defined as large-scale, randomized controlled trials.

Will the teacher researcher movement continue to grow and flourish in this environment? Teacher researchers will have to wrestle with both the accountability demands and the demands of teaching and research. Can they continue their inquiries and collaborations in ways that will be supported and valued in their schools? Can the changes they are making in their teaching as a result of their inquiries be linked to the kinds of improvement in their students' learning that will show up on high-stakes tests?

What Cochran-Smith and Lytle said in 1999 about the standards movement is even more valid with regard to the NCLB environment: "These and many other challenges undoubtedly will influence the direction, and perhaps the continued existence, of the teacher research movement in the years to come" (p. 22). They pointed to the history of teacher research as a compelling reason for optimism, noting how valuable teacher research is and has been to many teachers, teacher educators, and researchers.

However, science teacher research as a movement and a force in the research and policy communities is in its infancy. Cochran-Smith and Lytle's experiences with teacher research are in the literacy curriculum area, where there is a longer history of teacher research and a much larger body of published materials compared with science teacher research. Among science teacher researchers, there is less history and less momentum to sustain. Science teacher research is at a stage where it needs to be supported and nurtured in order to understand its potential contributions to teachers' professional growth and to the research knowledge base about science teaching and learning. What new directions might provide such support?

## Studies about Teacher Research

It may be that larger-scale studies conducted by academics about teacher research and its impact can contribute to the future flourishing of science teacher research. From the professional development perspective, for example, studies that examine the impact of teacher research on teacher learning and on teachers' practice could provide additional evidence to support the value of teacher research. Do teachers change their teaching practice as a result of their inquiries? Do these changes result in improvements in student learning? Two teacher researchers, McGoey and Ross (1999), pointed to a need for such formal studies in their guest editorial in the *Journal for Research in Science Teaching*: "We suspect that research-based initiatives in education reform will not thrive outside a community of professionals capable of sustaining an action research ethos, but we are unable to conduct formal studies. An answer to this question could significantly reduce wasted effort" (p. 119). They argued that such research knowledge would support the efforts of teacher researchers in communicating with their peers, school administrators, and parents.

## Teacher Research Syntheses

From the production of knowledge perspective, syntheses of science teacher research might make teachers' knowledge more accessible to other teacher researchers, to teachers who are not researchers, and to academic researchers. Research reviews or meta-analyses that synthesize science teacher research studies about particular aspects of science teaching might help make science teacher research more accessible as well as contribute to addressing the generalizability issue in teacher research. This might nurture the science teacher research movement by making more visible the value of the knowledge generated by teacher researchers.

## Searchable Online Libraries

The current body of science teacher research is not easy to access and search. Articles are published most frequently on web sites and in edited book volumes, which are usually organized as a collection of articles by teacher researchers within a given group rather than by topic, grade level, or issue. The production of an easily searchable, centralized teacher research online library that is organized not just by key words and authors, but also by grade level, curriculum materials, learning goals, and so forth, is another strategy that could make teacher research more accessible

and valuable to both teachers and researchers. For example, a teacher who is preparing to teach a unit or conduct an inquiry about electricity could access other teachers' studies that took place in the context of teaching this topic. Or a teacher who is struggling to implement language activities to support English-language learners could access research studies relevant to this issue. Research studies about patterns of use of such a library could assess the usefulness of the knowledge that is being generated by teacher researchers and contribute to establishing the value of teacher research.

### **A National/International Science Teacher Research Community**

But such tasks are not likely to be taken on by an individual teacher researcher or teacher research group. It is an effort that needs to be undertaken by organized professional communities or by collaborative teams of academic researchers and teacher researchers. The teacher research special-interest group at NARST might be a place to begin building such collaborations.

One debate within teacher researcher groups is the extent to which teacher researchers and more traditional academic researchers should partner. There is a fear among some teacher researchers that academic voices might drown out teacher voices and force teacher research to adopt the same norms and criteria of quality as academic research (Threatt et al., 1994). However, much of the science teacher research to date has been initiated through research grants or master's programs developed by academic researchers. Thus, there is active support for teacher research among academic researchers. This group of academic researchers can play an important role in the further development of science teacher research, and their opportunities to collaborate and meet with teacher researchers might help nurture the science teacher research movement.

### **Funding Opportunities**

Funding opportunities to support teacher research and to promote communications across science teacher research groups would also help nurture science teacher research. However, the teacher research movement faces a paradox in the funding situation. In order to make the case for the importance of teacher research, the teacher research community needs opportunities to grow and develop and especially to communicate across groups about standards for high quality in teacher research. Funding is needed to support such communication of science teacher research groups with each other and with teacher research groups with longer histories in other subject matter areas. But funding will be difficult to obtain until funding sources are convinced that science teacher research is likely to result in improved science teaching and learning.

### **New Modes of Representation of Teacher Research**

To date, science teacher research has been shared with the science education community through traditional publication and presentation routes, with a special emphasis on online publication. We do not yet know the extent to which such repre-

sentations of teacher research provide useful knowledge to other teachers and researchers. Dadds (1995) suggested that a larger variety of representations of teacher research might better reflect the needs and contexts of different teacher researchers. She argued for broadening what counts as legitimate forms of representing teacher research: "If we continue to limit our view of 'text' to the more conventional academic research genre . . . we may ignore the appropriateness of other forms of communication, written or spoken, that may have greater potential for shaping and communicating meaning, for putting the action in action research, for acting as catalysts for institutional action and change" (Dadds, 1995, p. 132).

Criteria for judging quality need to take into account the possibility of such alternative forms of representation, which might include educational actions, drama, photography, film, and poetry (Lomax & Parker, 1995; McNiff, Lomaz, & Whitehead, 1996).

There has been little experimentation with alternative modes of representation of teacher research, but one mode that seems particularly suited to communicating about teaching is video (Hiebert et al., 2002; Stigler, Gallimore, & Hiebert, 2000). Surprisingly, only 12 percent of the science teacher research studies reviewed for this chapter reported that they used video methodology in collecting data. One reason for its limited use might be the risks involved in making video images of teachers and students publicly available. In this digital age, this risk is even more important to address, and procedures and policies to minimize such risks to teachers and students need to be carefully developed and rigorously implemented.

Perhaps another reason for the limited use of video in these studies is a narrow vision of how such video might be used by teacher researchers. If video is considered only as a data collection strategy that must then be painstakingly analyzed, the use of video might seem too time consuming to be useful in the teacher research genre. But video could also be viewed as an alternative publication strategy that might better suit many teachers than writing research articles.

Videocases could be developed by teachers to be shared with other teachers, with preservice teachers, and with academic researchers. Videocases of teaching could be shared at any stage in the inquiry process, especially if they are presented in an online, digital format that allows for time-linked commentary by the teacher researcher. The teacher researcher could make the videocase available through an indexed and searchable online, digital video library. Other teachers, teacher researchers, and academic researchers could be invited to view the videocase and add their own comments, which could also be time-linked to specific places in the video. In this way, the "product" of a teacher's inquiry is actually still part of his or her inquiry process, providing outsider perspectives that can challenge and deepen the teacher researcher's study.

The video artifact from the inquiry process could also be useful as a teaching tool in preservice and inservice teacher education programs as well as a research data source for additional studies carried out by other investigators. For example, if the many studies about inquiry science teaching reviewed in this chapter had made teaching video available online, it would be feasible to build on the work of each individual teacher researcher by analyzing and comparing various instantiations of inquiry teaching.

The use of such video products over time could help the science education community develop a shared language for talking about science teaching that would be closely matched to visual images of what the ideas might look like in action in the

classroom. This would be a tremendous contribution of teacher research to the knowledge base for science teaching.

## CONCLUDING REMARKS

Science teacher research holds much promise for enhancing science teacher learning within preservice and inservice teacher education programs and teacher researcher inquiry groups. It has been used in a variety of teacher education and teacher professional development programs as a strategy for developing reflective, inquiring science teachers. Although there is evidence that science teacher research contributes to teachers' professional dispositions, learning, and growth, there is less evidence that it affects science teachers' practice in ways that result in improved student learning. Further research is needed to examine the impact of teacher research on science teachers' practice.

Science teacher research also holds promise for making important contributions to the knowledge base for science teaching. Although there are many pitfalls in science teacher research, it does offer a unique insider perspective that might help bridge the gap between traditional academic research and science teaching practice. But science teacher research is in its infancy as a movement within the science education research community. There are debates about the standards of quality for science teacher research, and it is unclear whether and how science teacher research will become widely accessible and usable within the science education community. Supports of various kinds, including funding and tools such as online, searchable text and video libraries, and collaborations between teacher researchers and academic researchers are needed to nurture the movement in order to explore its potential: "The partnership between researchers and practitioners is in its infancy. . . . We look forward to a day when collaboration between the academy and the classroom teacher is a commonplace of professional science teaching" (McGoey and Ross, 1999, p. 120).

Center for the Assessment and Evaluation of Student  
 Learning (CAESL), model, 1028–1031, 1029f  
*Changes in Attitudes about the Relevance of Science*  
 (CARS) questionnaire, 79–80  
 Chemical bonding, multiple meanings, 637–643  
 Chemical reactions  
 multiple meanings, 632–635  
 students' conceptual difficulties, 633–635  
 Chemistry, subject matter knowledge, 1113–1114  
 Chemistry curriculum, 631–652  
 course content structure, 636–637  
 courses developed from modern teaching and  
 learning perspectives, 635–637  
 looking forward, 648–649  
 multiple meanings through contexts, 643–644, 644f  
 multiple meanings through models, 645–647  
 multiple meanings through multimedia tools,  
 644–645  
 near-future reform, 643–648  
 potential perspectives, 632f  
 CHEM Study, 916, 918  
 Child rearing, in critical research, 22–23  
 Children's Learning in Science Project (CLISP),  
 Britain, 212  
 Civil Rights Restoration Act of 1987, 293  
 Classroom assessment of science learning, 965–1006  
 appropriateness, 992  
 authenticity, 993  
 coherent state systems, 1028–1034  
 consequences, 990  
 cultural validity, 991–992  
 equity and fairness, 991  
 fidelity and disclosure, 992–993  
 further research, 995  
 increasing the quality of, 988–990  
 manageability, 992  
 for multiple purposes, 967–971  
 political contexts, 966–967  
 theorizing assessment, 993–995  
 trustworthiness, 992  
 wider range of research on formats, 983–988  
 Classroom communities of inquirers, 406–407  
 Classroom environment  
 cross-national studies, 115–116  
 determinants of, 112–113  
 discourse in, 443–469  
 evaluation of educational innovations, 111–112  
 explanations, 376–377  
 future directions for indigenous students, 219–221  
 improving IK practice in, 212–213  
 learning problems worldwide, 249–250  
 questionnaires for assessment of, 105–109, 106f  
 research instruments, 109–116  
 school laboratory, practice and research, 419–426  
 sociocultural, 272–274  
 student and teacher perceptions, 112

- student outcomes and, 110–111  
 technology underutilization in, 472–473  
 use of qualitative research methods, 113–115  
 using cultural contexts in, 215–216
- Classroom Environment Scale (CES), 105
- Classroom learning, 103–124
- Cognitive Acceleration through Science Education* in Britain (Adey & Shayer), 33
- Cognitive conflict, in elementary science teaching, 511–512
- Cognitively based instruction, student diversity and, 178–179
- Cognitive tools  
 definition, 476–479, 477*f*  
*versus* digital resources, 471–491  
 gathering and analyzing data, 486–487  
 learning earth sciences, 661–678  
 transformation via, 479–482, 480*f*
- Cognitive Tools Framework, 479–487
- Collaboration, teachers of students with special needs, 294–295
- Committee of Ten, 785–786
- Commonplaces, in science learning, 6
- Community and government organizations, learning science from, 147–148
- Community-based programs, 147–148
- Competencies, in systemic reform, 925
- Composite culture, learning in urban settings, 332
- Computer-based assessment, 988
- Computers and the internet, science learning and, 150
- Computer software, demonstrations enhanced by, 375–376
- Computer Supported Intentional Learning Environment (CSILE), 484
- Computer-Supported Intentional Learning Environment (CSILE)*, 87
- Concept development  
 biology, 588–590  
 earth sciences, 661–662  
 laboratory activities, 420–421
- Conceptions of Scientific Theories Test (COST), 865
- Concept maps, 983–984
- Conceptual change  
 cold, 38  
 different meanings of, 36  
 in elementary science teaching, 511  
 knowledge, discourse and, 448–450  
 learning to teach science, 1153–1159  
 physics, 606–607, 606*f*  
 teaching for, 1156–1158  
 teaching of, 1154–1156  
 what changes during, 36–38
- Conceptual change theory (CCT), 4, 7–14, 59–60  
 characteristics of, 11–12  
 example, 7–8  
 junior high level atomic structure, 640  
 power and limitations, 12–14
- Conceptual conflict, 12
- Conceptual learning, 31–56  
 as acquisition, 35–39, 40–44  
 as addition/replacement, 42–43  
 in classroom settings, 48–50  
 cognitive approaches, 38–39  
 difficulties with atomic structure, 638–639  
 difficulties with chemical bonding, 640–642  
 difficulties with chemical reactions, 633–635  
 future research directions, 50–51  
 multimodal approach, 46–47  
 as participation, 45–48  
 starting points and trends, 32–34  
 structuring the review, 33–35  
 what changes, 36–38
- Conceptual profile, 43
- Conceptual tools, in science learning, 49
- Concrete models, 379
- Congruence, analysis of learning in urban settings, 331–333
- Congruent third space, 331
- Constructivism, 60  
 views of teaching and learning science, 232
- Constructivist Learning Environment Survey (CLES), 107–108, 111, 112, 114, 115
- Constructs, definition, 75
- Content knowledge structure (CKS)  
 biology inquiry-oriented curriculum, 568*f*, 569*f*  
 research in biology, 563–564
- Content-specific simulation programs, physics, 608
- Contextual Model of Learning, 129
- Continuous assessment, laboratory activity, 417
- Cooperative learning, 383–384
- Courses, in systemic reform, 923–924
- Critical consciousness, development of, in critical research, 24
- Critical discourse analysis, 446
- Critical incidents, 866–867
- Critical research tradition, 4, 20–25  
 characteristics, 23–25  
 culture of power, 21  
 discussion and implications, 23  
 example, 4, 20–2521  
 methods and interpretation, 22–23  
 power and limitations, 25
- Critical thinking, modeling, visualization, and simulation tools, 483–484
- Critiquing peer culture, in critical research, 22
- Cross-national studies  
 classroom environments, 115–116  
 findings, 236–243  
 student science learning, 232–233
- Cultural, understanding of NOS, 831
- Culturally congruent instruction, student diversity and, 178

# About the Authors

## **Sandra K. Abell**

Sandra K. Abell is professor of science education at the University of Missouri-Columbia, US, where she directs the university's Science Education Center. Her research interests focus on teacher learning throughout the career span and across the grade levels. She is a past President of the National Association for Research in Science Teaching (NARST).

## **Glen S. Aikenhead**

I have always embraced a humanistic perspective on science, as a research chemist in Canada and as a science teacher at international schools in Germany and Switzerland. This perspective was enhanced during my graduate studies at Harvard University in the late 1960s and has since then guided my research in science education at the University of Saskatchewan, Canada.

## **Charles W. Anderson**

Charles W. (Andy) Anderson has been a Peace Corps volunteer, middle school science teacher, and professor at Michigan State University, US, since 1979. Dr. Anderson's primary research interests are in using conceptual change and sociocultural research on student learning to improve classroom science teaching. He is a past President of NARST.

## **Ronald D. Anderson**

Ronald D. Anderson is professor of education at the University of Colorado at Boulder, US. The author of books and numerous research articles on science education reform, he is a past President of both NARST and the Association for the Education of Teachers in Science.

## **Ken Appleton**

After retiring recently, Ken Appleton was appointed an adjunct associate professor at Central Queensland University, Australia. He has published extensively in international journals in his areas of interest that include elementary science teaching and learning, constructivism, elementary science teacher knowledge, and science teacher professional development.

**Hilary Asoko**

Hilary Asoko is a senior lecturer at the University of Leeds, UK. She is particularly interested in the teaching and learning of science in primary schools and in science teacher education.

**J Myron (Mike) Atkin**

J Myron (Mike) Atkin, Professor of Education (Emeritus) at Stanford University, US, is a National Associate of the National Academy of Sciences, where he was a member of the National Committee on Science Education Standards and chair of the Committee on Science Education K-12. His current research and writing center on science education curriculum and assessment.

**Charles R. Ault, Jr.**

Charles Ault is professor of education at Lewis & Clark College, US, where he teaches science education courses in the Master of Arts in Teaching (M.A.T.) program for elementary and secondary teachers. His teaching emphasizes the interpretation of local landscapes and stems from his scholarly interests in learning earth science, with particular attention to children's conception of time and the nature of geological problem-solving.

**Dale Baker**

Dale Baker is a professor in the Division of Curriculum and Instruction in the College of Education at Arizona State University, US. She is a former editor of the *Journal of Research in Science Teaching*. Her research focuses on gender equity issues in the teaching and learning of science as well as in engineering education.

**Angela Calabrese Barton**

Angela Calabrese Barton's research focuses on the science practices of high poverty urban youth and on the role that community-based and case-based learning experiences can play in the development of science teachers' understandings of urban youth and their own science teaching. Her work has been published in numerous venues and her most recent book, *Teaching Science for Social Justice* (Teachers College Press), won the 2003 AESA Critics Choice Award. She is on the faculty of Michigan State University, US.

**Beverley Bell**

Beverley Bell is an associate professor in the School of Education at the University of Waikato, Hamilton, New Zealand. She has a background in science education conceptual change research for over 20 years, and her current research interests are in pedagogy, learning, assessment, and teacher education.

**Paul Black**

Paul Black is emeritus professor in the School of Education at King's College in London, UK. He worked as a physicist for 20 years before moving to science education. He has made contributions to curriculum development, and to research into learning and assessment, particularly for teachers' classroom assessments. He has served on advisory groups of the US National Research Council and as visiting professor at Stanford University.

**Edward Britton**

Edward Britton, is senior research associate in WestEd's Mathematics and Science Program, US. He contributed to the Third International Mathematics and Science Study and co-led an international comparison of high school exit examinations in science.

**Glenda Carter**

Glenda Carter is an associate professor of science education and the associate director of the Center for Mathematics and Science Education at North Carolina State University, US. Her research focuses on the use of language, gesture and tools as mediators of conceptual understanding. She is a member of the Friday Institute Mathematics and Science Collaboratory and the Middle Grades Academy.

**William Carlsen**

Bill is a professor of Science Education in Penn State's College of Education, US, and is director of the university's new Center for Science and the Schools. His current research focuses on the use of web-mediated peer review of original scientific research by high school students and preservice science teachers.

**Michael P. Clough**

Dr. Clough is an Associate Professor at Iowa State University, US where he directs the secondary science teacher education program and teaches courses addressing science learning and teaching and the nature of science and science education. His scholarly work examines learning and teaching the nature of science, laboratory learning and teaching, and the teacher's role in both.

**Charlene M. Czerniak**

Charlene M. Czerniak is a professor at The University of Toledo, US. She is the co-author of a methods textbook on Project-Based Science, and she has written numerous articles on teachers' beliefs, curriculum integration, teacher professional development, and science education reform.

**Onno De Jong**

Dr. Onno De Jong is an associate professor in chemical education at Utrecht University, The Netherlands. He has published on education in problem solving, models and modeling, and electrochemistry. His current research interests include the professional development of chemistry teachers.

**Reinders Duit**

Reinders Duit is a professor of physics education at the Leibniz-Institute for Science Education (IPN) in Kiel (Germany). His research interests include teaching and learning processes from conceptual change perspectives, quality development, teacher professional development and video-based studies on the practice of science instruction.

**Barry J. Fraser**

Barry J. Fraser is director of the Science and Mathematics Education Centre at Curtin University of Technology in Perth, Australia. He is author/editor of *Learning Environments Research: An International Journal*, *International Handbook of Science Education*, *Classroom Environment*, and *Educational Environments*. A past President of NARST,

he was 2003 recipient of that association's Distinguished Contributions to Science Education through Research Award.

### **Shawn M. Glynn**

Shawn M. Glynn is a professor of science education and educational psychology at the University of Georgia, US. His specialization is in the application of psychology to science education, particularly in the areas of cognition and motivation. His books include *The Psychology of Learning Science* and *Learning Science in the Schools*.

### **Chorng-Jee Guo**

Chorng-Jee Guo is a professor and the president of National Taitung University, Taitung, Taiwan. His research interests in science education are students' learning of science, science teaching strategies and materials, professional development of science teachers, and science education policy.

### **Paul Hart**

Paul Hart is a Professor of Science Education at University of Regina in Canada. He is executive editor of the *Journal of Environmental Education* and consulting editor for several journal in environmental education. He has published widely and is the recipient of several research awards including the Jeske Award from the North American Association for Environmental Education.

### **Peter W. Hewson**

Peter Hewson is a professor of science education at the University of Wisconsin-Madison, US. His primary interest is in conceptual change approaches to the learning and teaching of science, and the initial education and professional development of science teachers. He is also interested in fostering international collaborative research opportunities.

### **Avi Hofstein**

Avi Hofstein is Professor and Head of the Department of Science Teaching at the Weizmann Institute of Science, Israel. For more than 30 years he has engaged in science curriculum development, implementation, and evaluation. He holds a B.Sc. in chemistry, M.A. in education, and Ph.D. in science education.

### **M. Gail Jones**

M. Gail Jones is a professor of science education in the Department of Mathematics, Science and Technology Education at North Carolina State University, US, where she prepares middle and high school science teachers. In addition to an interest in teacher beliefs, her research interests include the impacts of high stakes testing policy, gender, and nanotechnology education.

### **Jane Butler Kahle**

Jane Butler Kahle, Condit Professor of Science Education, Miami University, US, is former director of the Elementary, Secondary, & Informal Education division at the US National Science Foundation. In 1991, Miami University awarded her an honorary L.H.D. degree. Her scholarship focuses on gender equity and systemic reform of education. She is a past president of NARST.

**Gregory J. Kelly**

Gregory Kelly is a professor of science education at Pennsylvania State University, US. He teaches courses on teaching and learning science, qualitative research methods, and uses of history, philosophy, sociology of science in science education. His research examines science learning, classroom discourse, and epistemology in science education.

**Thomas R. Koballa, Jr.**

Thomas R. Koballa, Jr. is a professor in the Department of Mathematics and Science Education at the University of Georgia, US. His research interests include the science-related attitudes of students and teachers and the induction experiences of beginning science teachers. He is a past President of NARST and co-author of *Science Instruction in the Middle and Secondary Schools*.

**Frances Lawrenz**

Dr. Lawrenz is Wallace Professor of Teaching and Learning in the Educational Psychology Department at the University of Minnesota, US. Her specialty is science education program evaluation. She has published extensively, received the university's highest award for teaching and has served as department chair and assistant vice president for research.

**Reuven Lazarowitz**

Reuven Lazarowitz is Emeritus Professor of Science Education in Biology, at the Israeli Institute of Technology, Technion, Haifa, Israel. His research interest is in the structure of high school biology curriculum; teaching and learning biology concepts and principles in individualized, cooperative small groups and computer-assisted learning settings. Recently he was involved in the national committee for developing learning units in the STS approach and educating teachers for teaching those units to the high school students who do not major in science and technology.

**John Leach**

John Leach is Professor of Science Education and Head of the School of Education at the University of Leeds, UK. His research interests include epistemic aspects of science learning and the use of insights from research in the practice of science teaching.

**Norman G. Lederman**

Norman G. Lederman is Chair and Professor of Mathematics and Science Education at the Illinois Institute of Technology, US. He is internationally known for his research and scholarship on the development of students' and teachers' conceptions of nature of science and scientific inquiry. He is a former President of NARST and of the Association for the Education of Teachers in Science (AETS). He has also served as Director of Teacher Education for the National Science Teachers Association (NSTA) and as Editor of *School Science and Mathematics*.

**Okhee Lee**

Okhee Lee is a professor in the School of Education, University of Miami, Florida, US. Her research involves language and culture in science education. One of her

current research projects implements instructional interventions to promote science learning and language development for elementary students from diverse languages and cultures.

### **J. John Loughran**

J. John Loughran is a professor in education and the Foundation Chair in Curriculum and Professional Practice in the Faculty of Education at Monash University in Australia. He has been actively involved in teacher education for the past decade. His research interests include science teacher education, teacher-as-researcher, and reflective practice.

### **Vincent N. Lunetta**

Vincent Lunetta is Professor Emeritus at Penn State University, US. He has received awards for scholarship and leadership in science education and given special attention to: teacher education; goals for science learning; the role of the laboratory, computer technologies, and simulation in learning and teaching; the development of conceptual procedural knowledge; international education; and education policy.

### **Aurolyn Luykx**

Aurolyn Luykx is an anthropologist specializing in ethnography of schooling, bilingual-intercultural education, and language planning and policy. Her book, *The Citizen Factory*, was published in 1999 by SUNY Press. She currently holds a joint appointment in the Departments of Sociology/Anthropology and Teacher Education at the University of Texas at El Paso, US.

### **Andrea K. Martin**

Andrea K. Martin is an adjunct professor in the Faculty of Education, Queen's University, Kingston, Ontario, Canada. Her areas of interest and scholarship include the development of teachers' knowledge, preservice teacher education, special education, and literacy development and interventions.

### **J. Randy McGinnis**

J. Randy McGinnis is professor of science education in the Science Teaching Center at the University of Maryland, College Park, US. His research and writing primarily concern science teacher education and equity. He has served on the executive boards of NARST and the Association for Science Teacher Education. He is co-editor of the *Journal of Research in Science Teaching*.

### **Elizabeth McKinley**

Dr. Elizabeth McKinley currently teaches research methodologies, curriculum and social issues at the University of Auckland, New Zealand. She researches and writes on indigenous people's educational issues, particularly with respect to Maori students in science education. She has had extensive experience teaching science in high schools and in bilingual (Maori/English) science curriculum development.

### **Hans Niedderer**

Hans Niedderer is a retired professor of physics education at the University of Bremen (Germany). His research interests include students' alternative conceptions, learning processes, and curriculum development. Currently he works as guest pro-

fessor at two Swedish universities in cooperation with the Swedish National Graduate School in Science and Technology Education Research (FoNTD).

### **J. Steve Oliver**

J. Steve Oliver is an associate professor in science education at the University of Georgia, US. His interest in rural education issues began during a childhood spent around the family farms. His current interests include secondary science teacher education as well as teacher knowledge and practices.

### **Nir Orion**

Dr. Nir Orion holds a professorship in the Weizmann Institute of Science in Israel where he heads the Earth Science and Environment Group of the Science Teaching Department. His activity covers all facets of science education: research, curriculum development, implementation, and teacher education from K-12. His main areas of activity are: Earth and Environmental Sciences; the outdoors as a learning environment; science for all; and teachers' professional change.

### **Léonie J. Rennie**

Dr Léonie Rennie is Professor of Science and Technology Education and Dean, Graduate Studies at Curtin University of Technology in Western Australia. Her research interests include adults' and children's learning in science and technology and the communication of science in a range of out-of-school contexts.

### **Douglas A. Roberts**

Doug Roberts, Professor Emeritus of the University of Calgary in Canada, began his science education career in 1957 as a high school science teacher in Pennsylvania. Doug has been a university faculty member at Harvard, Temple, Toronto (OISE), and Calgary. His research interests include science curriculum policy and the development of science teacher thinking.

### **Kathleen J. Roth**

After teaching middle school science and later completing a PhD in science education, Kathy became a teacher-researcher in elementary classrooms while also teaching teachers at Michigan State University. In 1999, Kathy became the director of the TIMSS video study of science teaching at LessonLab Research Institute in the US, where she currently supports and studies elementary teacher-researchers.

### **Tom Russell**

Tom Russell is a professor in the Faculty of Education at Queen's University, Kingston, Ontario, Canada. His research focuses on reflective practice and learning from experience in the context of learning to teach. He teaches preservice physics methods, supervises the preservice practicum, and teaches action research in the graduate program.

### **Kathryn Scantlebury**

Kathryn Scantlebury is an associate professor in the Department of Chemistry and Biochemistry and the Secondary Science Education Coordinator in the College of Arts & Sciences at the University of Delaware, US. Her research focuses on gender and equity issues in science education.

**Phil Scott**

Phil Scott is professor of science education at the University of Leeds, UK. His main research interests lie in drawing on research findings to plan and implement science instruction and analyzing language, teaching and learning in science classrooms. This research informs a wide range of professional development activities with science teachers.

**Horst Schecker**

Horst Schecker is a professor of physics education at the University of Bremen (Germany). His research interests include multimedia, learning processes in physics, and curriculum development. One of his current projects is about a standardized test of students' understanding of thermodynamics.

**Steven Schneider**

Steven Schneider, program director of mathematics, science and technology at WestEd, US, is principal investigator for the NSF-funded Center for Assessment and Evaluation of Student Learning (CAESL) and the National Assessment Governing Board's development project, 2009–2021 US National Assessment of Educational Progress Science Framework and Test Specification.

**Nancy Butler Songer**

Dr. Songer is a Professor of Science Education and Learning Technologies at the University of Michigan, US. Focusing on students in high-poverty urban settings, Songer's research: a) characterizes children's higher-order thinking in science, b) evaluates simple technologies used as cognitive tools, and c) develops assessment systems to provide developmental evidence of complex reasoning in science.

**Gregory P. Stefanich**

Dr. Gregory P. Stefanich is professor of science education and former Interim Head of the Department of Curriculum and Instruction at the University of Northern Iowa, US. He joined the faculty at the UNI in 1976. His research over the years has focused on special needs learners and science.

**Keith S. Taber**

Keith Taber taught science in schools, and a college, before joining the Faculty of Education at Cambridge University, UK. He has been a Teacher Fellow for the Royal Society of Chemistry, is Chair of the Society's Chemical Education Research Group; and serves as Associate Editor of *Chemistry Education: Research and Practice*.

**David Treagust**

David Treagust is Professor of Science Education at Curtin University in Perth, Western Australia and teaches courses in campus-based and international programs related to teaching and learning science. His research interests are related to understanding students' ideas about science concepts, and how these ideas can be used to enhance the design of curricula and improve teachers' classroom practice. He is past President of NARST and recipient of the association's 2006 Distinguished Contributions to Science Education through Research Award.
