# Preface

Although some have predicted the end of science (Horgan, 1996), the scientific enterprise thrives and scientists generate new knowledge at an incredible rate. (A recent report from the US National Science Foundation stated that over 92,000 scientific articles were published in 2001 in comparison with about 70,000 in 1991 (Hill, 2004).) Essential to the vibrancy of science, scientists continue to ask questions of the world. In the July 1, 2005 issue of the journal *Science*, the editor compiled responses from senior scientists and published the 125 questions that science “should have a good shot at answering” (Kennedy & Norman, 2005, p. 75) in the next 25 years, many from relatively young sciences such as neuroscience, genomics, biomedical science, geophysics, astrophysics, and bioengineering. According to Siegfried (2005), in that same journal issue:

When science runs out of questions, it would seem, science will come to an end. But there’s no real danger of that. The highway from ignorance to knowledge runs both ways: As knowledge accumulates, diminishing the ignorance of the past, new questions arise, expanding the areas of ignorance to explore. (p. 77).

For many years, science education researchers prided themselves on following research approaches and paradigms that approximated those of science. Thus, it is interesting to consider the similarities between science and science education. How does science education as a discipline compare? Our field has a much shorter history than that of the natural sciences. Our research has appeared in science education journals and books for fewer than 100 years. Yet we have generated a substantial body of knowledge during this time, knowledge from which new questions have emerged. Like the sciences, our questions are partly shaped by the society in which we live and partly by the research community in which we work. Research in science is guided by and builds upon prior research. However, in the science education community, researchers are often opportunistic, studying what is convenient to them rather than building on previous investigations. We believe that a handbook of research in a discipline such as science education provides a foundation upon which future research can be built.

The purpose of this volume is twofold. First, the authors look backward in time in an attempt to capture where science education has been and what we currently know. Secondly, the authors project into the future, positing research agendas for

---

The National Association for Research in Science Teaching (NARST) endorses the *Handbook of Research on Science Education* as an important and valuable synthesis of the current knowledge in the field of science education by leading individuals in the field.

various subfields in the discipline. When we invited authors to take part in the project, we asked that they tackle these two purposes:

We are asking authors to write an “integrative review” of the research in each topic area. Authors will pull together the existing research on the topic and work to understand the historical trends and patterns in that body of scholarship. Authors will describe how the issue is conceptualized within the literature, how methods and theories have shaped the outcomes of the research, and where the strengths, weaknesses, and gaps are in the literature. Reviews will end with implications for practice and future research derived from the review. (S. Abell & N. Lederman, personal communication, October 15, 2002)

This book is intended as a comprehensive research handbook for the field of science education. Two research handbooks in the field were produced in the previous decade. The first, edited by Gabel (1994), the *Handbook of Research on Science Teaching and Learning*, was published in cooperation with the National Science Teachers Association. It is now over 10 years old and no longer represents the scope of research in the field. The second, edited by Fraser and Tobin (1998), the *International Handbook of Science Education*, although international in its collection of authors, did not present a comprehensive review of the research in science education. Rather it was an in-depth sampling of the work of various researchers, demonstrating a slice in time of research in the field. Both of these volumes responded to the inadequacy of the single review chapters for science education contained in general education research handbooks such as those produced by the American Educational Research Association. The work represented in this volume is international and comprehensive in scope. It provides both veteran and emerging science education researchers with a coherent synthesis of the empirical and theoretical research concerning teaching and learning in science, and paves the way for future research.

## OVERVIEW OF THE BOOK

One of our first steps as editors was to map out our construction of the structure of the discipline of science education. We first created five organizing categories in which to place the research in the field: Science Learning; Culture, Gender, and Society and Science Learning; Science Teaching; Curriculum and Assessment; and Science Teacher Education. We thought that this organization would capture most, if not all, of the published science education research (although we were aware that no organizational scheme would achieve consensus among our colleagues). These organizers became the five major sections in this *Handbook*.

The more difficult step was deciding what chapters should appear within each section. The decisions we made were unique, based on our experiences as science educators and researchers. Our decisions certainly would not match the organization other researchers would impose on the field. Current trends and length restrictions led us to make strategic decisions on chapters to include or not to include. For example, given the recent importance of the literature on language and science, we included two chapters on language and science learning. However, as we envisioned, these chapters serve different purposes. The first, by William Carlsen, appears in the first section of the book, Science Learning. It is meant to be a theoretical overview

of language and learning and how such theory has informed science education research. The second chapter on language and science education research appears in the third section of the book, *Science Teaching*. That chapter, by Gregory Kelly (once Carlsen's doctoral student), reviews classroom-based research on discourse in science education. We also made strategic decisions on chapters not to include. For example, although research on college science teaching has increased in the past decade (demonstrated in part by a dedicated strand at the annual NARST meeting), we chose to include this research by science discipline instead of by grade level, along with subject-specific studies at middle and high school levels, in the *Science Teaching* section of the *Handbook*. However, we decided that the research on elementary science teaching was less science discipline-specific and more age-related, and therefore deserved its own chapter.

The organization of this *Handbook* highlights other recent trends in the field. For example, the second section of the book, *Culture, Gender, and Society*, acknowledges the contributions of research focused on context to understanding science learners. The chapters in this section demonstrate the importance of learners' gender, culture, and special needs, as well as the larger societal context (urban, rural, postcolonial), in learning science. In the final section of the book, *Science Teacher Education*, we have presented a comprehensive synthesis of the research in the area of science teacher education for the first time. Twenty years ago, few studies in science education focused on science teacher learning. Currently such research comprises the largest submission to the NARST annual meeting, necessitating the development of two separate dedicated strands. The chapters in this section are thus a unique contribution to the field.

As editors, we also influenced the direction of the book in other ways. Once we had a structure for the *Handbook* in place, we brainstormed authors for the various chapters. First and foremost, we wanted authors who were leading experts in their research area, and who had published a significant quality and/or quantity of research. As veteran science education researchers with a total of 40+ years in the field, and as past presidents of NARST, our collective expertise was a good place to begin the brainstorming. However, we recognized that our expertise was limited in certain areas of the field and was somewhat North American centric. Thus we also consulted other resources during the author selection process, including the NARST annual meeting programs of recent years, other conference proceedings, and the ERIC database. In addition to selecting high profile researchers, we tried to ensure that our selection represented the international and gender diversity that exists in our research community. We believe that the final list of authors indeed meets these selection criteria.

An additional task we faced as editors was to engage thoughtful reviewers in providing feedback to authors on the first drafts of chapter manuscripts. The peer review process is critical to maintaining quality in our work. The reviewers we selected, along with the editors, provided insight and made recommendations that improved the final chapters in many ways. Some authors also involved their own colleagues in the review processes. The reviewers are acknowledged in the chapters they reviewed. Through section and chapter organization, author selection, and review work, we crafted this *Handbook*. It represents our current construction of the structure of the discipline of science education.

## THEMATIC ELEMENTS

We have had the honor of interacting with many authors and reviewers to shape the contents of this book. We have had the privilege of reading all of the chapters and interpreting various themes that emerged from our reading. In this section we highlight three such themes.

One of the striking features of the field of science education as represented in the chapters in this *Handbook* is that it is influenced by the prevailing learning theory of the day. Few would argue that perspectives on learning have changed drastically over the past 100 years. Even the most superficial analysis indicates at least five “general families” of learning theory held dominance in educational matters over the past century—mental discipline, natural unfoldment, apperception, behaviorism, and cognitive science. These differing perspectives have influenced how science education researchers view learning, teaching, and the assessment of both.

A second theme of the research reviewed in this *Handbook* is that the predominance of various research methodologies change over time. Some of this fluctuation corresponds directly with changing views of learning. Early research on teaching and learning focused on the identification and exercise of various mental faculties as a direct result of the dominance of mental discipline theory. In the 1970s, process-product research methodologies clearly reflected the dominance of behavioristic learning theories. The emergence of qualitative methodologies mirrored the replacement of behaviorism with cognitive theories of learning.

A final theme that emerges from the *Handbook* chapters is that the teaching and learning of science is discipline-specific. What is considered effective instruction in a biology class is not the same as effective instruction in another class, science or otherwise. Teachers do not teach and learners do not learn biology in the same ways as they do physics or social science or humanities. This theme appears in the sections on science learners and learning, in the discipline-specific chapters on science teaching, and in the section on science teacher education. In that section, authors examine the notion of pedagogical content knowledge as a framework for science teacher education research. Lee Shulman, who invented this idea (1986), began his career as a science educator. He cautioned us not to allow the disappearance of subject matter from educational research. The existence of this *Handbook* is a testimony to the value of science subject matter in our research.

## THE FUTURE OF SCIENCE EDUCATION

Much like the authors in the July, 2005 issue of *Science* demonstrate that science is alive and well, the chapters in this *Handbook* illustrate the vitality of science education as a discipline. We have learned much about science learners and learning, and science teachers and teaching, over the past 80 or so years of research. According to the chapter authors, many questions remain open for investigation. Surely many other questions we have not yet thought to ask.

As we continue to ask and investigate questions in science education, we believe it is crucial to keep a few guidelines in mind.

1. The ultimate purpose of science education research is the improvement of science teaching and learning throughout the world. We must take care that the proximate causes of our research (e.g., achieving publications that count for tenure, writing conference papers so our universities will fund our travel, preparing new researchers, getting grant dollars) do not derail us from achieving our ultimate purpose. Thus we call for rigor in design, data collection, interpretation, and write up.
2. To achieve the ultimate purpose of improving science teaching and learning, our research must be grounded in the real world of students and teachers and school systems and society. Ours is an applied field, and we must ensure that our research makes sense in the real world. Our research must address, and attempt to answer, the questions and concerns of teachers. To have educational warrant, our research must answer questions of educational importance.
3. To achieve the ultimate purpose of improving science teaching and learning, we as researchers need to be open to new theoretical frameworks, research methodologies, and strategies, even as we embrace existing tried and true methods. We are long past the paradigm wars that dominated education research in the 1980s. Mixed methods research (Chatterji, 2004; Johnson & Onwuegbuzie, 2004) is a new paradigm ripe for application to science education settings. Longitudinal studies that employ mixed methods will be essential to understanding student and teacher learning over time. In addition, theoretical frameworks that embrace postmodern thinking will help us see the world in new ways.
4. Translating our research for teachers is an essential component of our work. If we write only for other researchers, we will never achieve this ultimate goal. Teachers and researchers often describe the gap between research and practice. It is our responsibility to translate our research so that practitioners and policy makers can ultimately decide whether what has been offered is of practical value. This *Handbook* is written for researchers. We leave it to others to undertake the important work of interpreting and transforming its contents for other stakeholders.

These guidelines, along with the research agendas suggested by chapter authors, can help our field advance. Although we are not quite ready to state the 125 questions that the science education community has a shot at answering in the upcoming 25 years, the guidelines and research agendas can help science education researchers fulfill the mission, reflected in the NARST slogan, to improve science teaching (and learning) through research. If we keep our eyes on this goal, then we will continue to raise new research questions that will diminish our current ignorance while expanding the areas of ignorance yet to be explored.

## Science Learning

# CHAPTER 1

---

## Perspectives on Science Learning

**Charles W. Anderson**

*Michigan State University*

The past two decades have been an exciting time for research on science learning. During this time, science educators have created or adapted an impressive array of new research practices and conceptual tools that we can use to analyze student learning in science classrooms and in other settings. The results of those analyses have given us new insights into science learning as it occurs in individual students and in social, cultural, historical, and institutional contexts.

### **INTRODUCTION: PERSPECTIVES AND RESEARCH TRADITIONS**

#### **Purposes of This Chapter**

The literature on science learning is diverse. It has been conducted by researchers from different cultural and intellectual backgrounds, using different methods, working in different settings. These researchers have based their work on different ideas about the nature of science, the purposes of science education, and the nature of science learning. Some aspects of this diversity are explicit and apparent to readers; for example, most research articles include descriptions of the settings and participants in the research and the methods used by the researchers. Other aspects of this diversity are harder to discern; authors can never fully reveal the assumptions that underlie their work or the intellectual influences that have shaped it.

This diversity of methods and viewpoints can make reading research on science education a frustrating experience. There seem to be no rules that everyone follows, no beliefs that everyone shares, no findings that everyone agrees on. Where is the order in this welter of confusing findings? How can we say that we are making progress in the field?

One way to find order and to see the progress in the literature on science learning is to recognize that within the broad field of science education there are groups of researchers who share common intellectual heritages and seek to build on one another's work. By recognizing the differences among those research traditions, we can see how researchers in each tradition are advancing knowledge as they understand it. We can also see how, in spite of their differences, researchers in all traditions are contributing to a collective effort that deepens and enriches our understanding of science learning.

In this chapter, I seek to provide a reader's guide that draws attention to the conceptual, methodological, and stylistic choices that the authors make in reporting research on science learning, and to how those choices are related to underlying beliefs about the nature and purposes of science education research. I have labeled these the *conceptual change tradition*, the *sociocultural tradition*, and the *critical tradition*. Rather than trying to provide historical overviews or general reviews of the literature in each tradition, I have chosen to focus on one exemplary article from each tradition, using quotations and commentary to discuss the authors' choices, the beliefs that underlie those choices, and the contributions that the tradition makes to our collective understanding of science learning.

In choosing to describe perspectives on student learning in terms of three research traditions, and in summarizing three individual articles to exemplify those traditions, I have oversimplified both the exemplary papers and the field in general. Representing research on science learning by focusing on three examples is a little like representing the visible spectrum by showing examples of the three primary colors. Subtlety and nuance are lost. Furthermore, the choice of three particular colors as primary is an accident of human physiology rather than a physical characteristic of light. Nevertheless, we continue to find the primary colors useful as we seek to understand color and color vision. I hope that these examples can be similarly useful. As with colors, there are very few pure examples of research within one of these traditions, both because the traditions themselves are multivoiced and because science educators are eclectic in their use of practices and conceptual tools from different traditions that will help them to achieve their research goals.

My choice of these three traditions is also idiosyncratic and historically situated. For example, I have included the extensive literature on uses of instructional technology in science education (e.g., Feurzeig & Roberts, 1999; Linn & Hsi, 2000; White & Frederiksen, 1998) in a broadly defined Conceptual Change tradition, though many researchers in both fields would consider the work in these fields as belonging to distinct traditions. Similarly, an author writing about perspectives on science learning in 1990 or in 2010 would probably identify traditions that are different from the ones I have chosen.

Thus the contrasts that I make among the traditions will not be very useful for classifying research studies, and I have not attempted to summarize research results. I hope, however, that by representing a range of perspectives and voices that researchers bring to the challenges of understanding and improving science learning, this chapter can help readers gain additional insights into the research itself. This chapter is not a substitute for reading research on science education, but an invitation that I hope will make the process of reading interesting and informative as we pursue our individual and collective goals in science education.

## Core Goals and Issues

Research on student learning in science can be broadly characterized as focusing on the development of *scientific literacy*. Scientific communities have developed knowledge and practices that are potentially valuable to members of the general public in their roles as workers, consumers, family members, and citizens. *Scientific literacy* is a term that can be used to designate the science-related knowledge, practices, and values that we hope students will acquire as they learn science.

For researchers in science education generally, scientific literacy includes a sense of empowerment or agency in two senses. The first of these I call *social agency*. Successful learners of science can gain respect for their knowledge, skills that enable them to do useful work, and access to jobs and to communities that would otherwise be closed to them. The second I call *agency in the material world*.<sup>1</sup> Successful learners of science can describe and measure the world around them with precision, predict and explain phenomena, and act effectively to influence natural and technological systems. Following Sharma and Anderson (2003), I also sometimes refer to these two kinds of agency as dialogues: learners' *dialogues with nature* and *dialogues with other people*.

Researchers in science education also generally agree on one central finding about current school practice: *Our institutions of formal education do not help most students to learn science with understanding*. This is a robust finding, encompassing both large-scale studies of science achievement (e.g., Blank & Langesen, 2001; Schmidt et al., 2001), as well as thousands of smaller studies conducted in a single classroom or a few classrooms. Given any reasonable definition of scientific literacy, the research shows that neither most students in schools nor most adults are achieving it. Furthermore, the benefits of science education are not evenly distributed. In the United States, for example, there is a large and persistent *achievement gap* that separates students by race, ethnicity, and social class (Blank & Langesen, 2001; Kim et al., 2001; see Chapter 8, this volume). Similar achievement gaps exist within and among countries worldwide. This leads to a two core questions that research on science learning should address:

1. Why don't students learn what we are trying to teach them?
2. Why does the achievement gap persist?

The importance of the three research traditions examined in this chapter lies largely in the provocative and useful responses that each tradition provides to these questions. The practices and theories developed through this research give us a deeper understanding of how students learn, why they fail to learn, and how we might create educational systems that are more responsive to their needs.

## Commonplaces and Contrasts

The next three sections of this chapter are devoted to an examination of the three traditions. Each section begins with a detailed examination of a single recently

---

1. I use the term *material world* to include the naturally occurring systems and phenomena that are studied by life, earth, and physical scientists, as well as technological systems created by humans.

published article that illustrates the perspectives and research methods typical of that tradition and exemplifies the kinds of insights into science learning that the tradition affords. Each section concludes with a more general look at the contributions that research in that tradition has made to our understanding of science learning, the influence of that research on policy and practice, and at the limitations of the tradition. Finally, the chapter concludes with some final thoughts on current issues and future progress in research on science learning.

As I compare and contrast the three articles and the traditions that they represent, I characterize each tradition in terms of five *commonplaces*—aspects of science learning that are explicitly or implicitly addressed by all research studies on science learning. These commonplaces are briefly described below and addressed in greater depth in the analyses of the research articles.

1. Intellectual history and related disciplines. All three traditions arise out of earlier work in science education and in related disciplines, such as psychology, sociology, linguistics, anthropology, and philosophy. The three traditions differ, though, in their intellectual roots and in the related disciplines that have most influenced them.
2. Ideas about the nature of science. Researchers in all three traditions share an understanding that our ideas about science learning and scientific literacy depend in part on our ideas about science. These traditions share an understanding that science is more than a body of knowledge or a set of methods for developing new knowledge. All three traditions share a view of science as a subculture with specialized language, values, and practices. The three traditions characterize science and scientific knowledge, though, in quite different ways, and those differences are reflected in their approaches to science learning.
3. Ideas about science learners and science learning. Researchers in all three traditions share a view of science learners as agents in their own right, who come to science learning with their own knowledge, language, beliefs, cultural practices, and roles in communities and power relationships. They recognize that learning arises out of the interactions between learners and the knowledge and practices they encounter in science classrooms. The three traditions differ, though, in their approaches to characterizing both learners and the process of science learning.
4. Research goals and methods. The most important research on student learning during this period has relied more on qualitative than on quantitative methods, and it has generally been conducted on a modest scale, focusing on individual learners, small groups, or learning in a few classrooms. The traditions differ, though, in the kinds of knowledge they seek to develop, in the degree to which they mix qualitative and quantitative methods, and in their methodological traditions and standards.
5. Ideas for improving science learning. All three traditions have convincing answers to the questions about the failures of formal science education above; they identify important barriers to successful learning that are rarely successfully addressed in school science. All three traditions have ideas about how schools and science teaching could be changed so that students would learn more successfully. The traditions, though, differ in the barriers to successful learning that they identify and in the suggestions that they develop for helping more students learn successfully.

## CONCEPTUAL CHANGE TRADITION: SCIENTIFIC LITERACY AS CONCEPTUAL UNDERSTANDING

Of the three research traditions, the conceptual change tradition is the one with the longest history and the most influence within the science education community. Like all of the research traditions, it encompasses a wide variety of perspectives and practices. Many of its methods and perspectives can be traced back to the developmental research of Jean Piaget (see Chapter 3, this volume). Piaget recognized the importance of children's thinking and developed the clinical interview as a method for investigating how children make sense of the world. Many of his investigations, especially early in his career, focused on children's understanding of scientific topics. Piaget's core interests, though, were developmental and psychological, so his research did not lead directly to the conceptual change tradition.

Conceptual change research emerged when investigators began to link Piaget's methods with ideas about the historical development of scientific knowledge, notably those of Kuhn (1970) and Toulmin (1961, 1972). Posner, Strike, Hewson, and Gertzog brought these strands together in a seminal article in 1982, suggesting that individual learners had "conceptual ecologies" like those used by Toulmin to describe scientific disciplines, and that learning in individuals resembled the complex process of theory change in science.

Since conceptual change research became prominent in the early 1980s, this tradition has generated an impressive amount of research worldwide. Reinders Duit's bibliography of conceptual change studies (Duit, 2004) covers more than 500 single-spaced pages. Conceptual change researchers have described alternative frameworks for every topic in the school curriculum (see, for example, Chapter 15 of *Benchmarks for Science Literacy*, American Association for the Advancement of Science [AAAS], 1993, or the reviews by Driver, Squires, Rushworth, & Wood-Robinson, 1994).

### An Example of Conceptual Change Research

One recent article that illustrates a number of important theories and practices is "Linking Phenomena with Competing Underlying Models: A Software Tool for Introducing Students to the Particulate Model of Matter," by Joseph Snir, Carol Smith, and Gila Raz (2003). This section summarizes the article and then discusses ways in which it exemplifies the perspectives and practices of research within this tradition.

Snir et al. (2003) addressed a problem in science learning that was well documented in previous conceptual change research and introduced in the first paragraph of their article:

The particulate model of matter is one of the central ideas in modern science. It is also a central subject in the middle and high school science curriculum. Yet, as is well known, this topic is very hard for students to learn and internalize. . . . We believe that understanding the particulate model of matter is difficult because it requires that students develop an understanding of two profoundly important, but counterintuitive, ideas. The first one is the idea of the *discontinuity of matter* and the second is the idea of an *explanatory model* as a metaconcept in science. (p. 795)

As is typical in conceptual change research, Snir et al. (2003) defined the learning problem in conceptual terms and focused on a specific scientific domain, in this

case theories about the nature of matter. Their focus on a specific scientific model or theory was also typical of conceptual change research. Their article was devoted to (a) helping readers to understand the depth and difficulty of this learning problem; (b) presenting a strategy for helping students achieve their learning goals; and (c) presenting and discussing data on student learning from two studies, one conducted in a laboratory and the other in a classroom setting. Their approach to each of these parts of the article is discussed below.

## Understanding the Learning Problem

Although the study focused on learning by middle-school students, the article barely mentioned middle-school students—or any students at all—in its first four pages. Instead, the article begins with a prolonged explication of the historical and philosophical significance of scientific models in general and the particulate model of matter in particular. The authors quoted the Nobel Prize-winning physicist Richard Feynman:

If, in some cataclysm, all the scientific knowledge were to be destroyed, and only one sentence passed on to the next generation of creatures, what statement would contain the most information in the fewest words? I believe it is the *atomic hypothesis* . . . that *all things are made of atoms—little particles that move around in perpetual motion, attracting each other when they are a little distance apart, but repelling upon being squeezed into one another*. In that one sentence, you will see, there is an *enormous* amount of information about the world, if just a little imagination and thinking are applied. (Feynman, Leighton, & Sands, 1963, Chapter 1, as cited in Snir et al., 2003, p. 795)

The authors then described the key features and multiple uses of particulate models of matter in current scientific practice, as well as the historical struggles of scientists to develop the particulate model in its current form. Thus the article begins with a description of how scientists' dialogues with nature led to the development of the particulate model, and how it continues to play a critical role in scientists' dialogues with nature today. The introduction continues with a discussion of "the general conception of an explanatory model," noting that scientific models are understood to be (a) not true descriptions of a system, (b) limited in scope, (c) evaluated according to their power to explain and predict observed phenomena, and (d) not unique—the same system can be modeled in more than one way. Thus the article begins with a careful explication of current scientific knowledge and practice as a goal for science education.

Snir et al. (2003) devoted the next five pages of their article to a detailed review of the research literature on attempts to teach students to use particulate models to reason about properties of materials and changes in materials. They made the case that Feynman's simply stated idea makes sense only in the context of a complicated conceptual ecology that students develop when they "make the transition from a tangible, observable continuous world to an abstract unseen one that consists of discrete particles at a microscopic level" (p. 802).

The authors argued that students could understand and use particulate models of matter only if they were building on some critical macroscopic understandings about matter (e.g., even bits of matter that are too small to weigh, have weight;

understanding of the relationships among volume, weight, and density) and on their development of some understandings about the nature and uses of models in general. They argued that previous attempts to teach middle-school students about particulate models of matter had generally tried to “take on too much too fast,” paying insufficient attention to some of these critical conceptual issues.

Thus, the educational challenges involve not only deciding what part of the particulate model to teach first and what prerequisite conceptions must be in place to create these conceptual puzzles, but also how to build students’ general understanding of what a model is. We believe the best approach is to involve students in explaining a series of phenomena and in evaluating the explanatory adequacy of alternative models. This approach gives students the opportunity to construct the particulate model slowly in their mind in response to puzzling but concrete phenomena (Snir et al., p. 803).

### **Presenting a Strategy for Helping Students Achieve Their Learning Goals**

The next 11 pages of the article are devoted to detailed presentation and discussion of a software tool that the authors developed to help students accomplish their learning goals. The tool presented simulations of three critical experiments, involving (a) mixing of water and alcohol (a puzzling phenomenon, inasmuch as the volume of the mixture is slightly less than the total volume of the separate liquids), (b) thermal expansion of an iron ball, and (c) the reaction of copper and sulfur—the critical observation being that copper and sulfur always combine in the same proportions regardless of the amounts of the reactants available.

The tool focused the students’ attention on key aspects of each phenomenon, then guided students through explanations of the phenomena based on four different models, a particulate model representing their learning goals and three alternative models designed to incorporate common student misconceptions. A series of screens guided students through the application of each model to each phenomenon, both illustrating how the model explained the phenomenon and comparing predictions of the model with actual experimental results. Only the particulate model consistently produced predictions aligned with the experimental results.

The authors summarized the key elements of the software (and implicitly the key elements of a strategy for conceptual change teaching about this topic) as follows:

1. It is designed to help students filter central facts from many experimental details.
2. It combines both tutorial and tool elements, while adjusting the mode to the nature of the learning. If one conceives of learning science on three levels—factual, conceptual, and metaconceptual (Snir, Smith, & Grosslight, 1993)—then we used the tutorial mode for the factual level and the tool mode for the conceptual and metaconceptual levels.
3. It allows students to compare, on the same screen, surface and model levels of description.
4. It acknowledges the existence of alternative models and students’ initial ideas.
5. It facilitates the introduction of model evaluation based on consistency with a range of facts, rather than simply one observation, as a central part of the curriculum. (p. 814)

## Research Methods, Results, and Conclusions

The next 10 pages of the article are devoted to presentation of data from two studies: a laboratory study in which nine American fifth- and sixth-grade students explained their thinking as they used the software and a classroom study in which 28 Israeli seventh-grade students used the software as part of a unit on matter.

In each study, the researchers carefully tracked the reasoning of individual students as revealed on pretests, posttests, and their performance as they were using the software. There were measures of retention in each study: students in the laboratory study were interviewed a week after they used the software; students in the classroom study took a delayed posttest the next year. The classroom study also included teaching about macroscopic conceptions of matter (e.g., identifying solids, liquids, and gases as matter; relationships among weight, volume, and density), demonstrations of the actual phenomena, and a control group of students who studied a similar curriculum without the software. The teachers of the experimental classes were the authors, Joseph Snir and Gilda Raz. In addition to the concepts that were the focus of this study (particulate models of matter and general understanding of models), the pretests and posttests included measures of students' macroscopic understanding of weight, volume, and density.

The results of these studies were complex, but some of the key conclusions were as follows:

1. Both the think-aloud data from students using the software and class discussions revealed that most (but not all) students engaged in the activities intended by the authors: comparing and evaluating models based on their ability to predict observed results of the experiments;
2. Focusing on seven key, tenets of the particulate nature of matter,

In the experimental group, we found that 30% of the students had a perfect understanding of these seven simple points, compared to none in the control group. If we allow students one error, we find that 47% of the experimental students understood at least six of the seven points compared to 22% of the control students. (Snir et al., 2003, p. 823)

3. Thirty percent of the students in the experimental group wrote open-ended responses indicating that what makes the particulate model a good model is its ability to explain a wide range of phenomena. In contrast, none of the students in the control group answered in this way (p. 823)
4. Finally, the data provided evidence that students' macroscopic and microscopic understandings of matter mutually support one another. Students who by the time of the delayed posttest showed that they had a strong macroscopic understanding of matter were the ones most likely to have internalized the assumptions of the particulate model. (p. 825)

Similarly, these students were also the ones who showed the best understanding of the nature of models in general.

The article concludes with an argument that the key features of the software were responsible for the successful learning of the students in the experimental classes, and that the successful learners had undergone a fundamental long-term change in the way they viewed matter and models of matter. Their new, stable understanding

included three mutually supporting components: an understanding of key macroscopic ideas about matter, understanding of key components of a particulate model of matter, and understanding of the nature and functions of models in general.

## General Characteristics of Conceptual Change Research

The results in the article by Snir et al. (2003) are more detailed and the arguments more subtle than I could portray in the brief summary above. I hope, however, that the brief summary is sufficient to illustrate some of the key characteristics that their research shares with other research in the conceptual change tradition. I discuss some of those characteristics in the following sections, then conclude with some thoughts on the power and limitations of conceptual change research.

## Characteristics of Conceptual Change Research

I discuss these characteristics in terms of the five commonplaces introduced at the beginning of this chapter. The first of these commonplaces, the intellectual history of the research tradition, is discussed briefly at the beginning of this section. The other four commonplaces—view of the nature of science, view of students and learning, methods, and implications for practice—are discussed briefly below.

*Science as a theoretical dialogue with nature.* Although conceptual change researchers recognize the importance of both aspects of scientific literacy discussed in the introduction—social agency and agency in the material world—they give primacy to agency in the material world. Snir et al. (2003) for example, characterized science as an ongoing theoretical dialogue with nature, in which scientists have developed successively more powerful models to account for a wider range of phenomena. For these authors and for other conceptual change researchers, the power of science lies both in its general use of model-based reasoning to understand nature and in the specific models that scientists have developed. Thus the task of science education is to include students in scientists' ongoing dialogue with nature and to give them access to the power of scientific ideas.

*Learners as rational but inexperienced thinkers and learning as conceptual change.* Like other conceptual change researchers, Snir et al. (2003) characterized the students who they worked with as coming into the research setting with their own ideas about matter. These ideas (labeled *misconceptions*, *naïve conceptions*, *alternative frameworks*, etc.) are less powerful and precise than scientific theories, but they generally work for the students' purposes and within the limits of their experience. Thus the task of the researchers is both to give students access to new experiences with the material world that are incompatible with students' naïve ideas—the three key experiments—and to help students see the power of the particulate model to account for these new experiences. This is a complex process of *conceptual change*; students learn with understanding only if they modify their conceptual ecologies to accommodate the more sophisticated scientific conceptions. Much of the detailed work of the conceptual change research program—the contents of

Duit's (2004) 500-page bibliography—has been mapping out the conceptual ecologies for specific topics and for students of different ages.

**Research methods for analyzing students' conceptions.** Snir et al. (2003) used methods typical of conceptual change research—written tests, clinical interviews, and think-aloud protocols of problem solving—to construct an argument about the understanding of the students before and after instruction. In the article and its supporting literature, they took great care to describe and defend the validity of their methods for assessing the specific beliefs of the students with respect to the scientific topic of study: the particulate nature of matter and the nature and uses of scientific models.

As significant as what they included in their research description is what the authors did *not* consider essential information. They provided no information about themselves and their intellectual or cultural backgrounds. Although they noted the age and nationalities of the students, they provided no other information about their cultural backgrounds or social class. They did not investigate the students' general experience or learning styles. In these respects, too, they were typical of conceptual change researchers. They took great care to investigate the conceptual ecologies of their informants around the scientific topics they studied and to situate their research in a scientific context, but neither they nor the reviewers of their research thought it necessary to report on the social or cultural contexts of their work.

**Teaching methods for conceptual change learning.** This article differs from much conceptual change research in that it focused on an instructional intervention. Although instructional studies are common in this research tradition, they are outnumbered by studies that document students' current conceptions and their responses to traditional science instruction. Those studies have almost inevitably found traditional instruction to be inadequate and have recommended instructional methods like those used by Snir et al. (2003). Their summary of the key characteristics of their software has great resonance within the conceptual change tradition, because it focuses only on the qualities that conceptual change researchers generally believe are essential for successful science learning—and missing from most science teaching. Their underlying belief is that successful student learning will be driven by situations of *conceptual conflict* like those that have driven historical advances in scientific communities, where students can see the contrast between their conceptions and alternative scientific conceptions and the superior power and precision of the scientific conceptions.

## **Power and Limitations of Conceptual Change Research**

One reason for the popularity of conceptual change research is that it has produced productive answers to the first of our two key questions: Students fail to learn what we try to teach them because they come to school with alternative conceptual frameworks that shape their perceptions and interpretations and that are not addressed by school science. This is a productive answer in part because it suggests a course of action: Identify the students' alternative frameworks and address them explicitly in

instruction. Furthermore, conceptual change researchers have developed conceptual and methodological tools that they can use to follow this course of action.

Another reason for the popularity of conceptual change research has been that it makes effective use of the intellectual resources of science educators. The primary qualifications for doing conceptual change research are knowledge and skills acquired through scientific training and educational experience. Scientific training teaches people to be attuned to rational and coherent theories as the content of discussions with professors and colleagues, so it prepares science educators to attune themselves to these kinds of meanings in students' language and thinking. Thus, conceptual change research has been a source of personal and professional growth for many scientists and science educators, opening up new dimensions of communication with students that lead to improved practices in science teaching and teacher education.

Conceptual change research has also had a substantial influence on educational policy. The authors of the U.S. national standards documents (AAAS, 1993; National Research Council, 1996) consulted conceptual change research findings in writing content benchmarks, and their recommendations for teaching practice were influenced by conceptual change research. Many textbooks now include lists of common misconceptions in their teacher's editions.

The evidence that conceptual change research can be used to improve teaching practice is sketchier than the evidence that students' alternative frameworks affect their learning, but still substantial. The article by Snir et al. (2003) is typical of much of this research in that it provides an "existence proof"—an example of successful teaching for understanding by individual teachers for a small number of students. These existence proofs show that under the right conditions many students can learn science with levels of understanding that are currently achieved by only a small elite. Furthermore, this article, like others in this tradition, emphasized the potential scalability of the teaching methods. Other teachers can be given access to the software tool, the demonstrations are easily replicable, and other students can be expected to have similar misconceptions.

There is little evidence, however, that these practices are spreading to large numbers of teachers, suggesting that there may be difficulties in taking these innovative to scale that are not addressed in the article. Some of those difficulties are inherent in any attempt to implement innovative practice on a large scale and are beyond the scope of this chapter (see, for example, Cohen & Hill, 2000; Elmore, 2002; Gamoran et al., 2003). There are questions that we could pose about the research itself. In the study by Snir et al. (2003), for example, a number of students did not achieve the learning goals. The authors reported that these were the students who had not previously mastered key macroscopic understanding of mass, volume, and density. But why did some students fail to master the prerequisite knowledge, especially in the classroom study where that knowledge was included in the instructional program? Was there some deeper source of difficulty that the conceptual change research methods did not discover?

These questions about a particular study are connected to questions about the larger conceptual change research program. For example, what might scientific literacy involve beyond conceptual understanding? A view of students as proto-scientists who understand the world on the basis of implicit theories is not the whole story. Conceptual change researchers generally recognize that scientific understanding is

more than just understanding core concepts, but their data collection methods and analytical tools focus on conceptual frameworks.

Furthermore, the theories and methods of conceptual change research have produced more productive answers to the first of the two key questions posed in the introduction than to the second (about the achievement gap between students of different races, cultures, or social classes). Although conceptual change research has been done in many countries, there is little evidence that students of different cultures or social classes have significantly different conceptual frameworks, or that conceptual differences are responsible for group differences in achievement. Conceptual change teaching can improve the learning of many students, but it shows little evidence of reducing the achievement gap. For tools and methods that help us to address these unanswered questions, we will need to look to other traditions.

### **SOCIOCULTURAL TRADITION: SCIENTIFIC LITERACY AS PARTICIPATION IN A DISCOURSE COMMUNITY**

The conceptual change tradition explains the failure of students to learn the science that they are taught in schools in terms of hidden conflicts—conflicts between scientific conceptual frameworks and the conceptual frameworks that students develop through their own experience. Sociocultural researchers are also concerned about hidden conflicts, but they see those conflicts in quite different terms.

Like conceptual change research, sociocultural research in science education brings together ideas and practices from several longstanding intellectual traditions. Both perspectives draw on developmental psychology, but on different branches in the field. Whereas conceptual change research used ideas and methods developed by Piaget, sociocultural research has depended more on the research of Lev Vygotsky and his followers (see Chapter 3, this volume). In contrast to Piaget's emphasis on how children learn from their encounters with the material world, Vygotsky focused on how children learn from their participation in activities with other people.

Sociocultural researchers also share with conceptual change researchers an interest in research on scientific communities and scientific practices. Again, however, their interests are different. Whereas conceptual change researchers focus on intellectual history and philosophy of science, sociocultural researchers focus more on analyses of the culture and language of scientific communities (e.g., Kelly, Carlsen, & Cunningham, 1993; Latour & Woolgar, 1979; Traweek, 1988). Sociocultural researchers in science education also base their research on anthropological studies of how people learn to use practices and resources from their intellectual and cultural contexts in their approaches to reasoning and problem solving (e.g., Cole, Gay, Glick, & Sharp, 1971; Lave & Wenger, 1991; Rogoff & Lave, 1984; Scribner & Cole, 1983). Finally, sociocultural researchers are influenced by sociocultural research that focuses on careful analysis of the language that people use in particular situations and its meaning in social and cultural context (e.g., Gee, 1991a, 1991b; Michaels, 1991; O'Connor & Michaels, 1993; Tannen, 1996).

Although these are longstanding lines of research, their application to problems of science education is more recent. The record of science education research

in the sociocultural tradition is substantial, but there is no 500-page bibliography like Duit's (2004). An article that illustrates the concerns and analytical methods of sociocultural research in science education is "Maestro, What is 'Quality'?: Language, Literacy, and Discourse in Project-Based Science" (Moje, Collazo, Carrillo, & Marx, 2001).

## **An Example of Sociocultural Research**

Moje et al. (2001) analyzed science teaching and learning in a bilingual seventh-grade classroom. In many ways this class exemplified the best of what our current science education system has to offer. "Maestro Tomas" was a well-qualified teacher who had close and supportive relationships with his students. The air quality and water quality units he used were developed by a team of highly qualified teachers, researchers, and curriculum developers, who were supporting Maestro Tomas as he taught the units (Krajcik, Blumenfeld, Marx, Bass, & Fredricks, 1998). In spite of these admirable aspects of the classroom, the authors saw reasons to doubt how effective the unit had been. Their paper included (a) an explanation of their theoretical approach, (b) the methods and the results of their research, and (c) a discussion of the implications of their research for science education.

## **Theoretical Approach**

The first five pages of the article are devoted to a literature review that describes the authors' theoretical approach. Like other sociocultural researchers, Moje et al. (2001) viewed conceptual frameworks as cultural products that are embedded within practices (such as explaining phenomena in the material world) and Discourses (Gee, 1996): "ways of knowing, doing, talking, reading, and writing, which are constructed and reproduced in social and cultural practice and interaction" (p. 470). Moje et al. argued that students in science classrooms are likely to experience not only conceptual conflict, but also conflict among multiple Discourses, each associated with its own community of practice, that intersect in science classrooms:

Although several different intersecting Discourses can be at work in any one classroom, at least three are particularly salient for this discussion: disciplinary or content area, classroom, and social or everyday Discourses. These Discourses represent distinct ways of knowing, doing, talking, reading, and writing, and yet they overlap and inform one another in important ways. For example, the Discourses of classroom instruction are informed by what teachers and student believe about the nature of knowledge in the discipline . . . Similarly, the ways that students take up classroom or disciplinary Discourses are shaped by the social or everyday Discourses they bring to the classroom. (p. 471)

## **Research Methods and Results**

Moje et al. (2001) used these ideas to analyze science teaching and learning in a seventh-grade classroom with students drawn from populations for which conceptual change teaching has generally been less successful. This is the longest section of the article—12 pages.

The teacher of the seventh-grade class, whom we call Maestro Tomas, was a native Spanish speaker of Dominican descent who had been reared in both the Dominican Republic and the United States. All but one student in the class of 32 were Latino or Latina, and some were relatively recent immigrants to the United States; 27 of these students demonstrated some level of proficiency in both Spanish and English. The remaining five students had very recently immigrated from Spanish-speaking countries, and so we identified them as Spanish-dominant, English language learners. (pp. 474–475)

Moje et al. (2001) observed Maestro Tomas and his students as they studied two project-based units, on air quality and water quality. Typically for sociocultural research, they relied on ethnographic data collection and analysis techniques:

Primary data sources included participant observation documented in field notes, formal and informal interviews with the teacher and students, and artifact collection, . . . student writings and curriculum work sheets. All classroom sessions were audio taped, and several were also videotaped. Another level of data collection included an electronic discussion of the analyses with Maestro Tomas. (p. 475)

The authors saw “competing Discourses” as a dominant theme that emerged from their analyses:

Our analyses of the Discursive demands of the curriculum enactment in this one classroom yielded a number of themes, but the dominant theme was one of competing Discourses. Each of the Discourses in the classroom had its own rules and expectations, usually implicit, and often in conflict. Maestro Tomas and his students had difficulty recognizing and orienting themselves to the demands and practices of these competing Discourses. Some of their difficulties arose from the nature of the curriculum itself, which encouraged students to contribute information in their everyday Discourses and included texts that presented information in a variety of Discourses, such as a fictional play in which the villains are the “awful eight pollutants.” Thus, the curriculum introduced competing Discourses, but privileged the scientific (via pre- and posttesting, writing assignments, and final projects). (p. 482)

For Moje et al. (2001) the problem was not so much that scientific Discourse was privileged as that the privileging was hidden: The curriculum neither explicitly compared Discourses nor made it clear that scientific discourse was the preferred mode of expression on assignments and tests.

While the use of different Discourses might be justified as a means of making the curriculum more engaging for students, one effect was that students saw fewer models of the privileged scientific Discourse than they otherwise might have. Neither was it always clear that this Discourse was meant to be privileged, nor were its rules and expectations made explicit. The effects of these ambiguities were apparent in the students’ work.

For example, Maestro Tomas asked students to respond—in English or Spanish—to this prompt midway through the study of air quality:

Imagine a factory opens in your neighborhood. Write a story about what would happen to the neighborhood and how would the air be affected.

The students responded to this kind of assignment enthusiastically, but they also responded in ways that would more appropriately be labeled creative writing rather than scientific or even informational writing. Of the 32 papers produced by students, all were

written as journal-like responses, suspense stories, and journal entries written by fictional characters; 23 were stories or fictional journal entries, whereas the other nine were straightforward responses to the question, written as if an entry in a journal. . . . In fact, despite Maestro Tomas's focus on writing and reading as informational tools, and despite the enthusiasm and creativity that students brought to the writing of these papers, only 11 of the 32 pieces incorporated terms or phrases drawn from the project work. (pp. 483–484)

## Discussion and Implications

To resolve these conflicts in ways that enable students to master scientific discourse, Moje et al. (2001) turned to the ideas of Kris Gutierrez and her colleagues about the creation of *congruent third spaces*:

Gutierrez et al. (1999) argued that the weaving together of counterscripts (what we have been calling everyday Discourses) with official scripts (or in this case, scientific Discourses) constructs a third space “in which alternative and competing discourses and positionings transform conflict and difference into rich zones of collaboration and learning.” (Gutierrez, Baquedano-Lopez, Alvarez, & Chiu, 1999, as cited in Moje et al., p. 487)

Moje et al. further suggested criteria for the successful creation of congruent third spaces and the ways in which Maestro Tomas and his students had fallen short of this ideal:

To develop congruent third spaces for language, literacy, and science learning in diverse classrooms, four characteristics of classroom interaction seem necessary: (a) drawing from students' everyday Discourses and knowledges, (b) developing students' awareness of those various Discourses and knowledges (cf. New London Group, 1996), (c) connecting these everyday knowledges and Discourses with the science discourse genre of science classrooms and of the science community, and (d) negotiating understanding of both Discourses and knowledges so that they not only inform the other, but also merge to construct a new kind of discourse and knowledge. Maestro Tomas and the written curriculum achieved the first step of constructing congruent third spaces for the development of scientific literacy, but needed to take that first step further. (p. 489)

## General Characteristics of Sociocultural Research

Although the brief summary of the article by Moje et al. (2001) does not do justice to the interest of their results or the complexity of their arguments, it does illustrate some of the key characteristics that their research shares with other research in the sociocultural tradition. I discuss some of those characteristics below, then conclude with some thoughts on the power and limitations of sociocultural research on science learning.

### Characteristics of Sociocultural Research

Many of the characteristics of sociocultural programs of research and development are apparent in the article by Moje et al. (2001). As in the section on conceptual change research, I use the commonplaces from the introduction—view of the nature

of science, view of students and learning, methods, and implications for practice—to characterize this research tradition and compare it with the conceptual change tradition.

*Science as a discourse community.* In contrast to conceptual change researchers' emphasis on scientists' dialogues with nature, sociocultural researchers focus primarily on scientists' dialogues with people. For Moje and other sociocultural researchers, scientists are participants in communities of practice with shared linguistic and social norms, values, and patterns of activity. Scientists' language and practices give them agency in both the social and material worlds. Thus, a primary task of science education is to help students control the linguistic and cultural resources that they need to participate in this privileged Discourse.

*Learning as control of multiple discourses.* Like other sociocultural researchers, Moje et al. (2001) portrayed students as participants in multiple communities of practice, each with its own language, values, and practices. Students entering school have not participated in scientific communities of practices, though some students come from home communities whose language and practices are much closer to scientific language and practice than others. Students learn science when they are able to adopt scientific language, values, and social norms for the purposes of participating in scientific practices, such as inquiry and application of scientific concepts.

Thus there are interesting parallels and differences between the arguments of Moje et al. (2001) and those of conceptual change researchers like Snir et al. (2003). Researchers in both traditions attribute students' difficulties in learning science to hidden conflicts. At this point, however, the arguments diverge. Rather than conceptual conflicts, Moje et al. saw conflicts among Discourses—"ways of knowing, doing, talking, reading, and writing, which are constructed and reproduced in social and cultural practice and interaction" (p. 470). In this situation, conceptual change teaching methods, which rely heavily on rational argument within a shared scientific Discourse, are not likely to be sufficient. Maestro Tomas and his students needed to find ways of resolving conflicts not only among conceptual frameworks, but also among values, social norms, and ways of using language.

*Research methods for analyzing learners' culture, language, and practices.* In contrast with Snir et al. (2003), who collected data in carefully controlled settings that would allow for a detailed analysis of students' conceptions, Moje et al. (2001) used more naturalistic methods, seeking to understand how Maestro Tomas and his students talked, wrote, and acted as they worked together. They sought to understand how these individuals operated within the social context of the classroom. Rather than conceptual knowledge, their analyses of learning focused on students' use of language, including choice of vocabulary and genre.

It is also interesting to note what these authors and their reviewers considered essential information about their methods. In contrast with Snir et al. (2003), Moje et al. (2001) informed readers about the linguistic and cultural backgrounds of each author, Maestro Tomas, and all of his students.

The research and development team was composed of two Latinas, two Latinos (one of whom was Maestro Tomas), and two European Americans, one male and one female. All

Latino and Latina members are fluent Spanish and English speakers, whereas the European American team members are monolingual. (Moje et al., p. 475)

They did not have formal instruments for structured data collection or detailed descriptions of their analytical methods. Thus, while the conceptual change researchers paid careful attention to the details of methods for data collection and analysis, the sociocultural researchers paid careful attention to the backgrounds, possible biases, and intellectual resources of the researchers themselves.

*Teaching methods for sociocultural learning.* Sociocultural researchers focus their attention on methods that help learners master language and culturally embedded practices, beginning with the problem of how teachers and students can communicate meaningfully across linguistic and cultural differences. Moje et al. (2001) focused on the development of congruent third spaces in classrooms, where everyday and scientific Discourses and knowledge can be negotiated and merged to create new understanding. Within these third spaces sociocultural conflicts can be resolved, and students from different home cultures can contribute intellectual resources to the classroom community. Although conceptual conflict is a commonly proposed mechanism for learning in the conceptual change tradition, many sociocultural researchers focus on *apprenticeship* as a metaphor for learning (e.g., Collins, Brown, & Newman, 1989; Lave & Wenger, 1991).

## Power and Limitations of Sociocultural Research

Although roots of the sociocultural research tradition extend back for decades, it is only in the last 10 years that its significance has been widely recognized by science educators. Compared with conceptual change research, sociocultural research has had less influence on science education policy and practice. This can be attributed partly to its relatively short history in the field, and partly to the methodological challenges that sociocultural research presents. It has been difficult to use sociocultural methods to collect quantitative data or to translate sociocultural ideas about teaching into prescriptions for reproducible practice. [Though, like conceptual change research, sociocultural research has produced “existence proofs” of excellent teaching based on sociocultural ideas. See, for example, Heath (1983, Chapter 9), O’Connor & Michaels (1993), and Rosebery, Warren, & Conant (1992)].

Furthermore, the ideas and methods of the sociocultural tradition are less familiar and more challenging to science educators than conceptual change ideas and methods. People who, like most science educators, have trained to be scientists or science teachers have had relatively little exposure to the linguistic and anthropological concepts that are central to sociocultural research. Education in the sciences emphasizes immersion in communities of scientific practice, but not awareness of the ways in which other communities of practice differ in cultural practices, values, and habits of mind that scientists take for granted. Thus, science educators must struggle to see hidden sociocultural conflicts and to make use of the cultural resources that children bring to science learning.

The struggle is worthwhile, however, because sociocultural research produces deep and compelling insights with respect to the two questions posed in the intro-

duction to this chapter. With respect to the first question, about why students fail to learn science, sociocultural research adds to and deepens the insights of conceptual change research. We can see that students in school must deal with hidden cultural conflicts as well as hidden conceptual conflicts. Furthermore, the methods of sociocultural research can reveal those conflicts in particular classrooms and show how they inhibit students' science learning.

With respect to the second question, about the origins and persistence of the achievement gap, sociocultural research produces compelling insights. This research tradition reveals the many ways in which scientific discourse communities are built around the language, values, and social norms of their (mostly European middle class) members. Similarly, schools privilege the language, values, and social norms of their (mostly European middle class) teachers. Thus middle-class European children enter school with significant advantages over children from other social and cultural backgrounds.

Sociocultural researchers recognize that these advantages have emotional as well as intellectual consequences and, more fundamentally, that science learning is an emotional as well as an intellectual process. Many sociocultural researchers (e.g., Kurth, Anderson, & Palincsar, 2002; Ogbu, 1992; Steele, 1992, 1999) have investigated the effects of the accumulated weight of cultural differences on students' willingness to keep trying to succeed in school. Research by sociocultural researchers on engagement and alienation helps us to understand how apparently simple unmotivated behavior has deep roots in students' cultural histories and personal development, as well as in the ways that schooling privileges other cultures and values at the expense of their own. Thus, sociocultural researchers transform the essential motivational problem of teaching from one of remedying motivational deficiencies to one of finding new and more productive ways of making use of the cultural resources that all children bring to school.

In summary, sociocultural researchers have developed analytical tools that they can apply to issues that conceptual change researchers relegate to craft. In particular, sociocultural research helps us to understand science learning as a linguistic, cultural, and emotional process, as well as a process of conceptual change.

### **CRITICAL TRADITION: SCIENTIFIC LITERACY AS EMPOWERMENT**

Researchers in the conceptual change and sociocultural traditions both attribute students' difficulties in learning science to hidden conflicts, either conceptual or cultural. Researchers in the critical tradition recognize the existence and importance of these conflicts, but they are centrally concerned with the ways in which these conflicts are shaped and how their outcomes are determined by power and ideology.

Critical researchers in science education are heirs to a long intellectual history of scholars who sought to show how dominant classes manipulated "truth" to their advantage, including scientific truth (e.g., Foucault, 1977; Scott, 1998). Feminist critics of science (e.g., Harding, 1991; Keller, 1985) have been especially influential among science educators. Other critical researchers in education have focused on how students in school who are not members of dominant classes have been marginalized and labeled "disadvantaged" or "at risk" (e.g., Delpit, 1995; Natriello, McDill, &

Pallas, 1990). In recent years, critical researchers in science education have combined these two strands to investigate specifically how some students are marginalized in our science education system. An article that illustrates the concerns and analytical methods of critical research in science education is “The Culture of Power and Science Education: Learning from Miguel,” by Angela Barton and Kimberly Yang (2000).

### **An Example of Critical Research**

Barton and Yang (2000) sought to understand and report on the life history and science learning of a young father, “Miguel,” who was living in a homeless shelter in New York City with his wife, “Marisol,” and their two children. Their article begins with a two-page vignette that describes the essential facts of Miguel’s case: He was a Puerto Rican high-school dropout who never took science in high school in spite of a continuing interest in nature. He later earned a high-school equivalency diploma and supported Marisol and their children by working as an industrial painter of fire trucks. When his company downsized, however, Miguel was not able to find new employment, so his family came to the homeless shelter where Barton and Yang met and interviewed him.

The authors sought to describe and explore the implications of Miguel’s life history and of the beliefs that he revealed in his interviews. After the opening vignette, their article includes a discussion of the culture of power in schools and in science education (three pages), a description of their research orientations and methods (one page), an interpretation of Miguel’s story (six pages), and a discussion of the implications of cases like Miguel’s for science education (four pages).

### **The Culture of Power**

Barton and Yang (2000) positioned themselves as advocates for Miguel and in opposition to the “culture of power” that has a pervasive influence on schools and school science:

The “culture of power” and its effects are part of nearly every institution in the United States, including the institution of schooling. . . . Delpit (1988) argues that without making the rules for the culture of power explicit, those who are not familiar with the culture of power will lack opportunities for upward mobility, be perceived as deficient, inferior, or disadvantaged, and be viewed as the cause of society’s problems. (pp. 873–874)

Like other researchers taking a critical perspective, Barton and Yang (2000) saw abundant evidence that the culture of power affects science education as well as other aspects of schooling:

Textbooks and other curricular materials often hide the people, tools, and social contexts involved in the construction of science. The result is often a fact-oriented science which appears decontextualized, objective, rational, and mechanistic (Brickhouse, 1994). Science labs and classrooms are typically structured hierarchically with the teacher and the text controlling what knowledge counts (Brickhouse, 1994). (Barton & Yang, p. 875)

## Research Methods and Interpretations

Barton and Yang's (2000) critical perspective was also apparent in their explanations and justifications of their research methods. They were explicit in describing their own backgrounds and perspectives:

As co-authors we come to this research from two different perspectives: One of us is an ethnic minority, the daughter of immigrants, bi-lingual, and raised on the west coast in a family that during her lifetime moved from "poor immigrant status" to upper-middle class professional. The other of us is a white, middle-class woman raised on the east coast with experience as a homeless individual in the same metropolitan area as the family presented in this paper. (p. 877)

For Barton and Yang (2000), ideas about the culture of power provided a critical lens for understanding Miguel's life story. Their case study of Miguel focused on "four key experiences in which culture, power, school, and science played out in Miguel's life: studying/doing herpetology, dropping out of school and school science, critiquing peer culture, and child rearing" (p. 878). Briefly, they reported the following:

***Studying/Doing herpetology.*** "Miguel often expressed a love of nature, and had for a while maintained his own black-market herpetology business, raising reptiles and selling them for a profit.

He was drawn to a way of explaining the world around him that went beyond books. The world—the turtles, rats, snakes, and other creatures he studied—was real life. However, the science to which Miguel referred was always outside of school, always a part of his own research into the world around him" (Barton & Yang, 2000, p. 878).

***Dropping out of school and science.*** Miguel's teachers and counselors placed him on a vocational track, never suggesting that taking a science course was even a possibility. In Miguel's school, science was clearly meant for people other than him. "In retrospect, Miguel believed these actions on the part of his teachers and his counselors only reinforced his belief that school science and scientific careers were not realistic options for youth from the 'hood'" (Barton & Yang, 2000, p. 879). In response, "Miguel dropped out of school when he was a junior, and when in his words, he had 'done all of the time [he] could handle'" (Barton & Yang, p. 879).

***Critiquing peer culture.*** Miguel's experiences led him to a complex understanding of the difficult relationships between his own culture and the culture of power. On the one hand, he recognized how the institutions of society had denied him opportunities. On the other hand, he recognized that the street culture in which he grew up, valuing "an image of toughness" and failing to look toward the future, had also prevented him from developing the knowledge and skills he needed to succeed. "As Miguel stated, 'Puerto Ricans are not respected in American culture, and in turn we [Puerto Ricans] make no effort to gain respect'" (Barton & Yang, 2000, p. 881).

***Child rearing.*** Miguel removed his daughter from an after-school program at the shelter and was reluctant to send her to a predominantly Puerto Rican public

school, stating that he “‘preferred to send [his] children to a school populated predominately by whites and run by whites.’ In his opinion, ‘they [Puerto Ricans] can learn from others because they are succeeding and we [Puerto Ricans] are not’” (Barton & Yang, 2000, p. 881).

## Discussion and Implications

Barton and Yang (2000) told a story of frustration and disappointment. They saw the reasons for Miguel’s frustration in the ability of “those in power [to] set the discursive norms and values, leaving those belonging to other cultural perspectives to be perceived as different and deficient” (p. 886). What can science educators learn from Miguel and his experiences? Barton and Yang suggested an answer, posing the question: “How might Miguel’s story and our understanding of the culture of power inform efforts to promote equitable science education reforms?” (p. 885).

We believe that part of the answer to this question lies in moving beyond the rhetoric of “science for all” to critically understanding how culture and power influence what creating an inclusive science community might mean. One way to ameliorate this situation is to examine what has been traditionally considered school science versus non-school science. The silencing of scientific knowledge that does not fall in the realm of recognized school science has resulted in exclusion of certain populations toward the formal learning of science (Eisenhart, Finkel, & Marion, 1996). (Barton and Yang, p. 886)

## General Characteristics of Critical Research

This brief summary of Barton and Yang’s (2000) article illustrates some of the key characteristics that their research shares with other research in the critical tradition. I discuss some of those characteristics in the following section, then conclude with some thoughts on the power and limitations of critical research on science learning.

### Characteristics of Critical Research

Many of the characteristics of critical programs of research and criticism are apparent in Barton and Yang’s (2000) article. As in the sections on conceptual change and sociocultural research, I use the commonplaces from the introduction—a view of the nature of science, a view of students and learning, methods, and implications for practice—to characterize this research tradition and compare it with the conceptual change tradition.

*Science as inherently ideological and institutional.* Researchers in all three traditions recognize that scientific truth is not absolute; scientists are inevitably limited by the perspectives and resources available to them. Conceptual change researchers see scientific truth as historically situated: Scientists of any generation are limited by the data available to them and the perspectives that they have inherited from their intellectual forbears. Sociocultural researchers see scientific truth as also culturally situated: Different cultures or subcultures decide what is true according to their own culturally specific standards and forms of argument. Critical researchers

see truth as the servant of power: Dominant classes of people arrange the “rules of the game” so that their knowledge and their ways of thinking and acting are seen as superior to those of other classes. Thus claims that scientific knowledge is objective or disinterested mask the ways in which scientific knowledge and practice serve the culture of power.

*Science learning as indoctrination or the development of critical consciousness.*

Critical researchers see students as participants in power relationships and institutions: Some students are given preferred access to the power of scientific knowledge and practice while others are excluded. They see current science education largely as a form of indoctrination: Students are taught to accept as truth knowledge that is designed to serve the interests of the powerful. They advocate an alternative kind of science learning—the development of critical literacy: Students need to learn not only how to participate in scientific communities but also to question and criticize the relationships between those communities and other powerful interests.

*Research methods for discovering and analyzing ideologies and power relationships.* Barton and Yang’s (2000) approach to describing their backgrounds, credentials, and research methods differs from the approaches of the other focus articles in ways that reveal differences in the beliefs of the authors about what counts as significant knowledge and how knowledge claims can be validated. The authors of the other two focus articles used the traditional “scientific” passive voice in describing their methods and described themselves in the third person. They sought to reassure readers that they had taken appropriate steps to avoid bias in their reporting. For Snir et al. (2003), this meant careful attention to instruments and methods. For Moje et al. (2001), it meant triangulating among multiple data sources and submitting their knowledge claims to extensive intersubjective verification.

In contrast, Barton and Yang (2000) described their research methods in less than one page, writing in the first person. They informed readers about their backgrounds and interests so that readers could decide for themselves how to interpret the case study. Their goal was not to generate independently verifiable knowledge claims; instead they aspired to “intersubjectively shared theoretical perspectives and life experiences” (p. 877).

Underlying Barton and Yang’s (2000) description of methods were different beliefs about the nature of the knowledge they produced and about their relationship with their informants, their readers, and social institutions. Critical researchers question whether “unbiased” or “fair-minded” knowledge is possible. They find bias to be inherent in our backgrounds and perspectives, so knowledge that claims to be unbiased typically serves the interests of powerful interests and institutions. Thus the fairest position researchers can take is to be honest about their perspectives, their biases, and whose interests they seek to serve.

*Teaching methods to achieve critical literacy.* Critical researchers have also developed ideas about how changes in the organization and ideology of schooling can be used to improve instruction, including changed power relationships in schools and the acceptance of knowledge that is currently outside the bounds of school science. They maintain that successful learning involves changes in powerful adults as well as powerless students. For examples of successful critical peda-

gogy, critical researchers often point to programs on the margins of the formal institutions of schooling, such as alternative schools or out-of-school programs like the one at the homeless shelter attended by Miguel's daughter (Barton, 1998) or the programs for disenfranchised poor started by Paulo Freire (1970/1993). Other critical researchers examine the practices of teachers in public schools, often minority teachers, who engage children in meaningful, important learning (e.g., Delpit, 1995; Ladson-Billings, 1994). A common theme that runs through all of these accounts of successful learning is that learners achieve critical literacy—the ability to see and criticize how power works to privilege some people and some forms of knowledge at the expense of others.

## Power and Limitations of Critical Research

Critical research has had less influence on policy and practice than the other traditions, in part because critical researchers openly question the premises on which policy is made, science teaching practice is based, and science achievement is measured. In particular, they challenge science educators to think about our own roles in maintaining injustice and inequality in our schools. Researchers in all three traditions proclaim their commitments to social justice and their desire to improve the science literacy of less successful students. The conceptual change and sociocultural traditions implicitly assume that these improvements can come at little or no cost to students who are currently successful in school (including the children of science educators). The critical tradition challenges that assumption. Critical researchers point out that the competition for positions of power and influence in society has always been a zero-sum game, with losers as well as winners. Are comfortable professionals like science educators willing to work for the fundamental changes in society that would really change the relationships among those of us who are more and less powerful?

Critical researchers would respond to the two key questions posed in the introduction, about the ineffectiveness of our science education system and the persistence of the achievement gap, by challenging their implicit premises. Is it not possible that the science education system is doing quite well what it was designed to do—to restrict access to the true power of scientific reasoning to a small elite? The remaining students are fed a thin gruel of “facts” presented in ways that reinforce the correctness of their inferior position in society. The hidden message is that the people who produce and distribute the facts are different—smarter and better qualified than the students could ever be. It is not quite right to say that the people who benefit from the culture of power, including teachers, professors, and science educators, are deliberately making this happen. However, we are acquiescing in a system that serves our interests and the interests of our powerful sponsors far better than it serves the interests of the powerless students entrusted to our care.

In summary, critical researchers have developed analytical tools that reveal the hidden workings of the culture of power in the institutions that society has made responsible for science education and in the knowledge that they teach. In particular, critical research helps us to understand the ways in which the achievement gap is not an unfortunate accident; it persists because it serves the interests of those who benefit from their preferred access to and control over scientific knowledge.

## CONCLUSION

Looking collectively at these three research traditions, where do we stand? We still must decide whether the glass—our understanding of how people learn science and how to improve science learning—is half full or half empty. On the half-empty side, it is clear that as a field we still have a lot to learn about science learning. Here are three important issues that are not fully addressed by the three focus articles or by the research traditions that they exemplify.

### Relationships among Traditions

One question that we face concerns what we can understand about science learning by looking collectively at research from the three traditions. Are these traditions, like subdisciplines of biology, looking in complementary ways at different subsystems? In that case, the collective insights from the three traditions provide us with a richer and deeper understanding of science learning than we could achieve from any one of the traditions alone—the whole is greater than the sum of its parts. Or, alternatively, are the three traditions more like contending political parties or schools of thought, each rejecting the ideas of the others and arguing for the superiority of its theories and methods? In that case, we have to choose one tradition while rejecting many of the claims of the others—the whole is less than the sum of its parts.

I see our current situation as being somewhere between these two alternatives. On the one hand, there are real and important conflicts among the traditions, particularly with respect to questions of epistemology and research method. For example, critical theorists see science education communities as facing a basic choice about whose interests we will serve with the knowledge that we produce. Will we produce knowledge that reflects the perspectives and serves the interests of the powerful or the powerless in our society?

While acknowledging the importance of this question, conceptual change and sociocultural researchers are more sanguine about the possibility of producing knowledge that transcends the interests and perspectives of its sponsors. For example, Shakespeare's art and Galileo's science gave us insights into the human condition and the material world that could not have been anticipated by their wealthy sponsors. Is it not possible that, in our modest ways, science educators could do the same? Conceptual change and sociocultural researchers are also concerned that critical researchers' stances of open advocacy and relative lack of concern about procedures for verification of knowledge claims will undermine long-term programs of knowledge building. Thus each tradition holds ideas about the nature of grounded knowledge and the research methods appropriate to achieving that knowledge that are considered to be deeply problematic by practitioners of the other traditions.

The differences in perspectives among the traditions run deep, as do the common interests and concerns that lead people to do research on science learning. Resolving these differences must ultimately be a communal effort. Individual researchers may achieve syntheses that they find personally satisfying, but those syntheses can bring science educators together around common perspectives only in so far as they are accepted by the communities of practice associated with the different traditions. We should never expect differences in perspective and method to be completely re-

solved, but there are reasons to hope that researchers in different traditions can become increasingly respectful of one another's insights and understanding of one another's methods.

### **Understanding Learners' "Dialogues with Nature"**

Sharma and Anderson (2003) characterized scientific communities as carrying on two simultaneous dialogues: a dialogue with nature in which scientists seek to create and understand new experiences with natural systems and phenomena, and a dialogue among people in which scientific communities submit the knowledge claims of their members to a process of collective validation. In studying science learning, all three of the research traditions discussed in this chapter have given us more insight into learners' dialogues among people than into learners' dialogues with nature. Our ideas and our language are strongly constrained by our individual and collective experiences with the material world, but none of the traditions has produced fully satisfactory accounts of the interactions among experience, individual cognition, and social communication.

### **Developing Prescriptions for Policy and Practice**

Research on learning has given us increasingly powerful analytical tools that improve our understanding of why educational institutions fail to engender scientific literacy in many students. As a field, we have been far less successful in translating that analytical power into practical results. We need to find better ways to use this understanding as a basis for design work in science teaching and teacher education—programs and strategies that move beyond existence proofs to help large numbers of science learners. We also need better ways of using our understanding to develop arguments that influence policies and resources for science education.

### **Putting the Issues in Perspective**

On the other hand, it is hard not to be impressed with the progress that our field has made in understanding science learning. As I write this, it has been over 25 years since I attended my first NARST Conference in 1979. The theme of that conference was "Paradigms for Research in Science Education." The three research paradigms discussed were (a) the behaviorist theory of Robert Gagne, (b) the verbal learning theory of David Ausubel, and (c) the developmental theory of Jean Piaget.

Looking back at these three theories, I can see the precursors to some of the theories that I have written about in this chapter, especially conceptual change. At the same time, I cannot help but be struck by how inadequate they look in comparison with the research described in this chapter. Those theories relied on thin, impoverished descriptions of scientific knowledge. They depended mostly on laboratory studies for their data; they largely lacked the analytical power to make sense of science learning in natural situations, inside or outside of school classrooms. They had little to say with respect to the two key questions about science learning posed at the beginning of this chapter. As a field, we have learned a lot since 1979, and we still have a lot to learn—all things considered, not a bad place to be.

## ACKNOWLEDGMENTS

Thanks to Fouad Abd-El-Khalick, David Jonassen, and Ron Marx, who reviewed this chapter.

# CHAPTER 2

---

## Student Conceptions and Conceptual Learning in Science

**Phil Scott**

**Hilary Asoko**

**John Leach**

*University of Leeds, United Kingdom*

Alice is a 14-year-old high school student, and in her science classes she has been taught quite a lot about the scientific concept of energy. Prior to these lessons Alice certainly used the word “energy” in her every day speech, whether in talking about “having no energy,” referring to the “high energy music” of her favorite band, or trying to reduce “energy consumption” to preserve the environment. During the lessons, Alice struggled to come to terms with some of the scientific ideas, which often seemed to go against common sense. Indeed, her teacher had warned that “this is always a difficult topic to get hold of.” Nevertheless, by the end of the teaching, Alice (who is a bright girl) was able to use the idea of energy in answering questions about batteries and bulbs, chemical reactions, and photosynthesis. However, she still struggled, for example, to see how the products of an exothermic chemical reaction could have the same mass as the reactants, even though “energy has been transferred to the surroundings,” and it didn’t make sense to her that a soda can on her desk “has gravitational potential energy,” even though it “just sits there.”

It is clear that Alice has learned something about the concept of energy. How might we conceptualize what has happened to Alice in these particular lessons? What do we mean when we say that Alice has “learned something about energy”? What factors act to influence her learning? What happens to Alice’s existing ideas about energy being consumed, in the face of her new learning? Why should she find some of the scientific energy ideas strange and difficult to understand?

There are many questions that might be posed about any such learning event. The aim of this chapter is to review the different approaches taken to characterizing science concept learning. We begin by providing a brief historical overview of

trends in the way in which research on conceptual learning has developed over the last 40 years or so. We then introduce the key features that have guided our structuring of the review, before presenting the detailed review itself. Given the sheer volume of literature addressing student conceptions and conceptual learning in science, it is not possible to be comprehensive in coverage. Rather, we have cited studies which, in our judgment, best illustrate the key features guiding our review, including work, where possible, that has been influential in various parts of the English-speaking world.

Although there are significant and fundamental differences among some of the approaches taken to conceptualizing science learning, it is also the case that other differences arise simply because different aspects of the learning process are being addressed. Bearing this point in mind, we believe that some approaches offer potentially complementary perspectives. We return to this theme in the concluding section, where we discuss the ways in which these ideas about learning might be drawn upon to illuminate and inform science teaching and learning in classroom settings.

### STARTING POINTS AND TRENDS IN CHARACTERIZING SCIENCE CONCEPT LEARNING

Perspectives on student concepts and conceptual learning in science have been heavily influenced by the seminal work of the Swiss genetic epistemologist Jean Piaget. This influence was particularly dominant during the 1960s and 1970s, as can be confirmed by looking through the citations of Piaget in papers published in the main science education journals of that period (see Erickson, 2000, p. 276). Piaget described an interactive learning process whereby an individual makes sense of the world through cognitive schemes, which are themselves modified as a result of the individual's actions on objects in the world. This model is summarized in the statement "L'intelligence organise le monde en s'organisant elle-même"<sup>1</sup> (Piaget, 1937). Piaget emphasized the significance of the child's social environment for knowledge development, claiming that: "Society is the supreme unit, and the individual can only achieve his inventions and intellectual constructions insofar as he is the seat of collective interactions that are naturally dependent, in level and value, on society as a whole" (Piaget, 1971, p. 368). Nonetheless, in most of Piaget's writing—and writing addressing the significance of Piagetian theorizing for science education—knowledge is portrayed as schemata in the individual's head, with little prominence being given to wider social aspects. The proposed mechanism for changes in intellectual organization as a result of interactions with the world (termed *adaptation*) involves the processes of assimilation and accommodation (Piaget, 1952). Assimilation is the process by which an individual interprets particular sensory information and in so doing includes that information in his/her existing cognitive structure. Accommodation is the process by which cognitive structure adapts in order to make sense of specific information. Assimilation and accommodation cannot be dissociated: whenever an individual interacts with sensory information, both assimilation and accommodation take place.

---

1. Intelligence organizes the world by organizing itself.

Although Piaget was primarily interested in development as a result of maturation, rather than learning as a result of instruction (Piaget, 1964), his empirical work addressed the development of children's knowledge about various aspects of the natural world, including life (Piaget, 1929); time (Piaget, 1946); and mass, weight, and volume (Piaget, 1930). Drawing upon this body of empirical work, an account of conceptual change based upon the development of content-independent logical structures was proposed (Piaget & Inhelder, 1956). Characteristic stages in the development of logical thinking were set out, based upon students' abilities to perform tasks involving skills such as conservation and seriation (the serial ordering of items). The concrete operational stage, for example, runs between approximately 2 and 12 years and is characterized by the development and coordination of conceptual schemes, including conservation, classification, and seriation. Children at the concrete operational stage are not capable of performing operations at a purely symbolic level, however; that competence is characteristic of the formal operational stage.

Piaget's work has influenced perspectives on student conceptions and conceptual learning in several ways. His account of how individuals come to know can be seen in much writing about students' conceptions, conceptual change, and personal constructivism through references to assimilation and accommodation. Piaget's methods for probing an individual's understanding, which involve an interviewer asking children questions without attempting to "lead" their responses (Piaget, 1929), have also been drawn upon in research on students' alternative conceptions. Furthermore, Piagetian stage theory has been drawn upon to inform science curriculum design and sequencing [e.g., *Science Curriculum Improvement Study* in the United States (Andersson, 1976) and *Cognitive Acceleration through Science Education* in Britain (Adey & Shayer, 1993)].

Various criticisms of the use of Piagetian theory in science education have been advanced. Carey (1985), Donaldson (1978), and Driver (1978) questioned the empirical basis on which claims for characteristic stages in logico-mathematical thinking were founded. Specific criticisms include the following: (a) tasks requiring identical logico-mathematical reasoning are made easier or more difficult by the degree of familiarity with the task's context (Donaldson); (b) tasks characteristic of a given stage can be performed by much younger children (Driver); and (c) the analysis used in Piagetian research is designed to validate existing theory rather than account for children's reasoning (Driver; Carey).

Although there has been a decline in the influence of Piagetian approaches since the 1970s, there remains a significant line of research on domain-general reasoning skills in science learning (e.g., Koslowski, 1996; Kuhn, 1991; Kuhn, Amsel, & O'Loughlin, 1988; Metz, 1997), as well as accounts of science learning that draw on Piaget's work (e.g., Adey & Shayer, 1993; Lawson, 1985; Shayer, 2003).

Perhaps the most significant break from the Piagetian account of conceptual learning in science can be traced back to the developmental psychology of David Ausubel (1968). Ausubel argued that the most significant influence on the learners' conceptual development is their existing conceptual knowledge in the target domain. During the early 1970s, a small number of empirical studies were conducted that accounted for students' science learning in terms of domain-specific factors, rather than explaining learning in terms of global logico-mathematical reasoning skills (e.g., Driver, 1973; McClosky, 1983; Viennot, 1979).

An empirical research program was subsequently developed (Novak, 1978), focusing upon the content of students' domain-specific reasoning (or students' alternative conceptions; Driver & Easley, 1978) about natural phenomena and involving researchers from around the world. Two particularly influential books in the development of research on pupils' alternative conceptions were *The Pupil as Scientist* by Rosalind Driver (1983) and *Learning in Science: The Implications of Children's Science*, edited by Roger Osborne and Peter Freyberg (1985). The latter provides an account of the work carried out by a group of researchers in the Learning in Science Project (LISP) at Waikato University, New Zealand. The "alternative conceptions" or "misconceptions" (Gilbert & Watts, 1983) movement gained further strength from a series of major international conferences organized by Joe Novak at Cornell University (Novak, 1987), and the number of publications in this field of science education research increased into the thousands (see, for example Bell, 1981; Driver, Guesne, & Tiberghien, 1985; Gunstone, 1987; Wandersee, Mintzes, & Novak, 1994). Helga Pfundt and Reinders Duit of the IPN in Kiel, Germany, developed a comprehensive bibliography, *Students' Alternative Frameworks and Science Education*, which is now in its fifth edition (Pfundt & Duit, 2000). All of the evidence suggests that there are strong commonalities in the alternative conceptions of students from different cultures, and, furthermore, these ideas about the natural world have a profound influence on what is learned as a result of science teaching, and some ideas are extremely resistant to change (Driver, 1989).

During the 1970s and 1980s, accounts of the *origins* of students' thinking about the natural world tended to be based upon a Piagetian view of the knower-known relationship, with knowledge portrayed in terms of entities in the individual's head, which developed through that individual's interactions with the material world. Such views of knowledge were later challenged (Matthews, 1992) on the grounds that they advanced an empiricist account of the generation of scientific knowledge, an argument that will be returned to later in the chapter. Furthermore, they failed to make any distinction between an individual's *beliefs* about the world and *knowledge* of the world that has been publicly warranted as reliable.

In recent years, the "discursive turn in psychology" (Harré & Gillett, 1994) has involved a shift in focus away from viewing meaning-making purely in terms of cognitive processes in the individual, toward an account of individuals as they function in social contexts. Central to this development has been the rediscovery of the work of Vygotsky and other Soviet psychologists of the sociocultural tradition.

Overall, we therefore see a trend in characterizing students' science concept learning, which takes us from the individually oriented perspectives of Piaget toward those sociocultural perspectives that bring together the individual with the social. In the following section we introduce the framework that we have drawn upon to structure our account of this development.

## STRUCTURING THE REVIEW

Given the range of approaches taken to conceptualizing science learning, we have found it helpful to identify two key features that we use as organizing dimensions in developing and presenting the review. The first dimension is taken from the influential paper by Anna Sfard (1998), in which she proposed two key metaphors for learning: the *acquisition* metaphor and the *participation* metaphor.

According to Sfard (1998), human learning has been conceived of since the dawn of civilization as an *acquisition* of something; in recent decades, “the idea of learning as gaining possession over some commodity has persisted in a wide spectrum of frameworks, from moderate to radical constructivism and then to interactionism and sociocultural theories” (p. 6). Gaining possession implies that something is stored or held somewhere. Sfard makes clear that it is *concepts* that are learned and then stored in the learner’s head: “Since the time of Piaget and Vygotsky, the growth of knowledge in the process of learning has been analysed in terms of concept development. Concepts are to be understood as basic units of knowledge that can be accumulated, gradually refined, and combined to form ever richer cognitive structures” (p. 5).

By way of contrast, Sfard (1998) saw the *participation* metaphor as offering a fundamentally different perspective on learning, in which “the learner should be viewed as a person interested in participation in certain kinds of activities rather than in accumulating private possessions” (p. 6). According to this perspective, “learning a subject is now conceived of as a process of becoming a member of a certain community” (p. 6).

In developing this review, we start with approaches to conceptualizing science concept learning that belong to the *acquisition* perspective and then move on to those that relate to *participation*. From the outset, it is important to recognize that the acquisition-participation dimension is *not* a continuum. The two metaphors offer fundamentally different perspectives on learning, or, as Sfard (1998) stated, “the acquisition/participation division is ontological in nature and draws on two radically different approaches to the fundamental question, ‘What is this thing called learning?’” (p. 7). The majority of approaches to conceptualizing science learning that we review here relate to the acquisition perspective.

The second dimension to be addressed involves the distinction between individual and social perspectives on learning. This takes us from a starting point where the main focus is on the *individual* learner and moves toward approaches where increased account is taken of various *social* aspects of the learning process and of knowledge itself.

## **SCIENCE CONCEPT LEARNING AS ACQUISITION: COGNITIVE APPROACHES**

Following the ideas set out in the previous section, we first consider those approaches that see science learning as involving a process of *acquisition* and focus on the *individual* in providing an account of that learning.

### **Learning as Conceptual Change**

Recognition that prior knowledge influences learning (Ausubel 1968), together with Piagetian ideas of accommodation and assimilation, and work from the philosophy of science (Kuhn, 1970; Lakatos, 1972) all underpinned a seminal paper by Posner, Strike, Hewson, and Gertzog (1982) on conceptual change in science learning. In the paper by Posner et al., the conditions needed for a major change in thinking within a scientific field (such as the shift from an Earth-centered to a Sun-centered model of the solar system) were considered analogous to the conditions needed to

bring about accommodation or conceptual change in individual learners. Posner et al. identified four conditions that must be met before such an accommodation can occur. These conditions are that a learner must first be *dissatisfied* with existing ideas and then that the new ideas must be seen as *intelligible*, *plausible*, and *fruitful*. Empirical evidence from students' learning about the special theory of relativity was then used to illustrate and exemplify this model of conceptual change learning. Though taking the view that learning is a rational activity, Posner et al. recognized that such accommodations might take considerable time, involving "much fumbling about, many false starts and mistakes, and frequent reversals of direction" (p. 223). The conditions of intelligibility, plausibility, and fruitfulness contribute to the status of an idea. During conceptual change the status of different ideas within a person's conceptual ecology (the range of ideas they hold) changes (Hewson, 1981; Hewson & Hennesey, 1992; Hewson & Lemberger, 2000). The implications of this model for teaching were outlined in the original paper and further discussed by Hewson, Beeth, and Thorley (1998). In addition, Scott, Asoko, and Driver (1992) outlined two broad approaches to conceptual change teaching. The first of these is based upon promoting cognitive conflict and follows from the model proposed by Posner et al., whereas in the second the learner's existing ideas are built upon and extended.

A significant point of confusion in this whole area of work concerns the different meanings that are attached to the term *conceptual change*. Sometimes *conceptual change* refers to the process of learning, and at other times it refers to the products. Furthermore, *conceptual change* sometimes refers to situations where one concept (seen as a unit of knowledge) is *exchanged* for another; sometimes where a concept is *modified* in some way, for example by differentiation into two; sometimes where the *relationship* between concepts changes; and sometimes where new concepts are *added* without loss of the original ideas. The interest in student misconceptions, or alternative conceptions, in the 1980s led to a focus on conceptual change as revolutionary, with new ideas replacing the original ones (through a process of exchange), rather than evolutionary and gradual, with the possibility of several views existing simultaneously (through a process of addition) and used in different contexts (see, for example, Sinatra, 2002).

## What Changes During Conceptual Change?

Posner et al.'s (1982) model of conceptual change focused on the *conditions* under which radical accommodations occur. Alongside this, the focus of much work in developmental cognitive psychology has been on *what* changes, exploring the performance of learners at different ages and attempting to explain this in terms of the ways in which concepts are mentally represented and related and the cognitive processes by which they are acquired and change.

One of the early proponents of domain-specific approaches, Susan Carey, proposed two forms of knowledge restructuring in learning, one similar to that demonstrated in the shift from novice to expert and one analogous to that of theory change in science. In the first, "weak" restructuring, the relations between concepts are changed. In the second, "strong" restructuring, the concepts themselves change (Carey, 1985), and this is regarded as difficult to achieve. Considerable attention has

been given to these latter situations where radical restructuring is needed, particularly in the context of learning physics concepts.

The idea that learning occurs as discrete concepts are formed and then linked into more complex conceptual structures has largely given way to a view that concepts are part of larger relational structures from the start. Vosniadou (1994), for example, argued that concepts are embedded into larger theoretical structures of two types, with the term *theoretical* being used to describe a relatively coherent explanatory structure. *Framework theories*, which develop from early infancy, consist of fundamental ontological and epistemological presuppositions. *Specific theories* are beliefs about the properties or behavior of objects, which arise from observation and/or are transmitted by the pervading culture. These specific theories are constrained by the assumptions of the underpinning framework theories. Specific and framework theories provide the basis for the generation of situation-specific mental models in response to the demands of a particular situation. Exploration of these mental models, for example in the context of the development of ideas about astronomical phenomena or force, provides insight into the underlying theoretical base. Conceptual change, according to this perspective, is thought to occur by enrichment or revision of a specific or a framework theory, a process that requires a gradual suspension of presuppositions and their revision or replacement with a different explanatory framework (Vosniadou & Ioannides, 1998). From this perspective, misconceptions are generated on the spot, during testing, from the deeply held framework theory, rather than being deeply held beliefs.

Following the seminal work of Keil (1979), ontological categorization is also seen as being of fundamental importance in the learning of science concepts. Chi (Chi, 1992; Chi, Slotta, & de Leeuw, 1994) argued that the meaning of a concept is determined by the ontological category to which it is assigned. Misconceptions thus arise when a concept is assigned to an inappropriate ontological category, for example, seeing the concept of "heat" as belonging to the category of "matter" instead of the category "process." Chi and Roscoe (2002) distinguished between the reassignment of concepts within levels of an ontological category and change, which requires a shift from one category to another, which is much more difficult.

DiSessa and Sherin (1998) pointed out some difficulties with the "standard" model of conceptual change. They argued that the notion of "concept" needs to be replaced by more carefully defined theoretical constructs within a knowledge system, which allow us to understand how that system functions. Focusing on the cognitive processes by which we gain information from the world, they proposed entities such as "co-ordination classes" and "phenomenological primitives," or p-prims. Co-ordination classes include cognitive strategies such as selecting and integrating information and are "systematically connected ways of getting information from the world" (p. 1171). Phenomenological primitives are described as abstractions from experience that need no explanation and form primitive schemata that constitute the basis of intuitive knowledge. For example, people usually expect that greater effort produces greater results and may apply this principle across a range of contexts. Intuitive "rules" such as these have also been identified by Stavy and co-workers (Stavy & Tirosh, 2000; Tirosh, Stavy, & Cohen, 1998). They believed that many of the alternative conceptions reported in the literature are, in fact, due to the use of rules such as *more of A-more of B*, which are relatively stable and resistant to change.

All of the above utilize some form of mental model, or system that develops and changes as a result of cognitive processes. The view that evolutionary pressures have led to the development of innate dispositions to interpret the world in particular ways was discussed by Matthews (2000), who also suggested that some conceptual structures can be triggered, rather than learned in the usual sense of the word. He considered, for example, that some of the p-prims, proposed by DiSessa, have the character of triggered concepts. Drawing on connectionist theories, he suggested that certain neural networks are designed to respond quickly and thus reinforce an initial bias. Conceptual change might then be viewed as a “process by which additional cognitive structures are built that, once firmly established, can over-ride rather than merge with, the functioning of competing innate structures” (p. 528). Such innate structures might correspond or give rise to the “naïve physics” and “naïve psychology” proposed by Carey (1985) or DiSessa’s naïve “sense of mechanism” (DiSessa & Sherin, 1998) and perhaps lie behind Vosniadou’s (1994) framework theories and Stavy’s intuitive rules (Stavy & Tirosh, 2000).

### **Beyond “Cold” Conceptual Change**

Although Posner et al. (1982) noted that motivational and affective variables were not unimportant in the learning process, the model of conceptual change they proposed was based on a view of learning as a rational activity. Pintrich, Marx, and Boyle (1993), in their critique of “cold” conceptual change models, proposed that the conditions of dissatisfaction with existing conceptions and the intelligibility, plausibility, and fruitfulness of the new, although necessary, are not sufficient to support conceptual change. Cognitive, motivational, and classroom contextual factors must also be taken into account as the individual student in the classroom is subject to influences from the broader social setting.

### **Cognitive Approaches: Summary and Implications**

The following fundamental insights about science concept learning are common to the majority of cognitive perspectives:

1. Individuals’ beliefs about the natural world are *constructed*, rather than *received*.
2. There are strong commonalities in how individuals appear to think about the natural world.
3. A person’s existing ideas about a given subject greatly influence his/her subsequent learning about that subject.

In addition, some have argued that there are more general aspects of reasoning, such as Piaget’s logico-mathematical reasoning skills, or the skills described by Kuhn et al. (1988), which influence the learner’s response to instruction.

These insights have significant implications for our understanding of how science concepts are taught and learned. The facts that scientific knowledge cannot be *transferred* during teaching, and that existing thinking influences learning outcomes,

offer a starting point to explaining why some aspects of science are difficult to learn. Furthermore, the research into students' thinking about aspects of the natural world has been drawn upon by science educators involved in the design and evaluation of teaching sequences (see, for example, Clement, 1993; Minstrell, 1992; Psillos & Méheut, 2004; Rowell & Dawson, 1985; Stavy & Berkowitz, 1980; Tiberghien, 2000; Viennot & Rainson, 1999) and in decisions about sequencing of ideas and age placement in the science curriculum (Driver, Leach, Scott, & Wood-Robinson, 1994). Science educators have also drawn upon research into more general aspects of students' scientific reasoning in developing teaching materials focused on the general reasoning skills of students (e.g., Adey & Shayer, 1993).

If the above points constitute a shared ground among cognitive perspectives, where do the points of difference lie? One area for debate concerns the existence and relative importance of domain-general and domain-specific aspects of reasoning in accounting for conceptual learning and conceptual change in science. Thinking back to the case of Alice, some of her difficulties with learning about energy might be explained, from a domain-specific perspective, in terms of the ontology of her existing concepts ("How come the mass hasn't changed when energy has been transferred to the surroundings?"). Instruction might therefore be designed to make it plausible that energy is not a substance, and to allow Alice to compare the scientific account of energy explicitly with her prior thinking.

From a domain-general perspective, Alice's difficulties might be accounted for in terms of the prevalence of abstract entities in the scientific account of energy and Alice's capacity to operate with those abstract entities. We are not aware of research that accounts for the teaching and learning of specific conceptual content from a domain-general perspective. Rather, the instructional solution might involve teaching thinking skills, or possibly not addressing the more abstract aspects of the energy concept until Alice has developed the appropriate thinking skills.

Another area of debate is the relative coordination or fragmentation of the elements of conceptual thinking in science learners. Are Alice's ideas about energy coordinated and coherent, or fragmented and lacking in logical coherence? Depending on the answer to this question, the challenge for Alice's science teacher might involve presenting a scientific account of energy and contrasting it explicitly with students' theories, or helping students to appreciate how a single, coherent theory can explain a wide range of phenomena.

In practice, however, there may be no simple, direct relationship between perspectives on learning and strategies for teaching (Millar, 1989), and Alice's teacher might well achieve similar success as a result of using several of the above strategies. It might therefore be the case that messages for practice lie at a more fundamental level, suggesting that teaching ought to provide opportunities to probe students' developing understanding in a formative way, allowing subsequent teaching to be responsive to students' learning. Insights about how to teach conceptual content in areas such as thermodynamics, chemical change, or plant nutrition will only arise through design research (Brown, 1992), where insights about domain-specific reasoning are drawn upon in the design of teaching materials, which are then tested and developed in a cyclical process (Lijnse, 1995). Such research does not in itself rest directly upon cognitive theory.

## SCIENCE CONCEPT LEARNING AS ACQUISITION: SOCIOCULTURAL AND SOCIAL CONSTRUCTIVIST PERSPECTIVES

At this point in the review we take a significant step in moving from approaches to characterizing science concept learning that focus on the individual, while recognizing the influence of the social context, to those that take the social context as an integral part of the learning process. In short, we move from cognitive to sociocultural and social constructivist approaches.

### Vygotskian Perspective on Learning

A fundamental theoretical reference point for sociocultural and social constructivist perspectives on learning was provided by Lev Semenovich Vygotsky (Vygotsky, 1934/1987). Central to Vygotsky's views is the idea that learning involves a passage from social contexts to individual understanding (Vygotsky, 1978). Thus, we first meet new ideas (new to us, at least) in social situations where those ideas are rehearsed between people, drawing on a range of modes of communication, such as talk, gesture, writing, visual images, and action. Vygotsky referred to these interactions as existing on the *social plane*. The social plane may be constituted by a teacher working with a class of students in school; it may involve a parent explaining something to a child. As ideas are explored during the social event, each participant is able to reflect on and make individual sense of what is being communicated. The words, gestures, and images used in the social exchanges provide the very tools needed for individual thinking. Thus, there is a transition from *social* to *individual* planes, whereby the social tools for communication become *internalized* and provide the means for individual thinking. It is no coincidence that Vygotsky's seminal book is titled *Thought and Language* (Vygotsky, 1962).

The *social* origins of learning are thus a fundamental and integral part of Vygotsky's account, and it is the job of the teacher to make scientific knowledge available on the social plane of the classroom, supporting students as they try to make sense of it. Vygotsky brought the activities of teaching and learning together through his concept of the Zone of Proximal Development or ZPD (Vygotsky, 1978). The ZPD provides a measure of the difference between what the student can achieve working alone and what can be done with assistance. The key point here is that the student's learning is conceived of as being directly connected to, and dependent upon, the supporting activity of the teacher on the social plane.

As well as drawing attention to the social origins of learning, Vygotsky also emphasized the role of the *individual* in the learning process. The process of internalization, as envisaged by Vygotsky, does not involve the simple transfer of ways of talking and thinking from social to personal planes. There must always be a step of personal sense making. Leontiev (1981), one of Vygotsky's contemporaries, made the point in stating that "the process of internalisation is not the transferral of an external activity to a pre-existing 'internal plane of consciousness.' It is the process in which this plane is formed" (p. 57). That is, individual learners must make sense of the talk, which surrounds them on the social plane, relating that talk in a dialogic way to their existing ideas and ways of thinking.

In this respect Vygotskian theory shares common ground with the constructivist perspectives outlined earlier, which emphasize that learners cannot be passive recipients of knowledge. It is perhaps with this point in mind that those contemporary approaches to conceptualizing science learning, which draw on Vygotskian *socio-cultural* theory, are often referred to as *social constructivist* perspectives.

## Social Constructivist Views of Learning Science

Vygotskian theory has been directly drawn upon by a number of researchers in their development of an account of science learning (see, for example, Driver et al., 1994; Hodson & Hodson, 1998; Howe, 1996; Leach & Scott, 2002, 2003; Mortimer & Scott, 2003; Scott, 1998; Wells, 1999).

Hodson and Hodson (1998), for example, outlined a social constructivist perspective on teaching and learning science, which was “based on the Vygotskian notion of enculturation” (p. 33). They argued that this perspective provides an alternative to personal constructivist accounts of learning (see also Osborne, 1996), which they claimed often imply “that students who construct their own understanding of the world are building *scientific* understanding” (p. 34; emphasis as in original). This point takes us back to the empiricist critique of constructivism outlined earlier. Thus Michael Matthews has argued that “constructivism is basically, and at best, a warmed up version of old-style empiricism” (Matthews, 1992, p. 5). One might question whether adherents to such an empiricist view of constructivism actually exist.

Central to the social constructivist response to charges of empiricism is the fundamental epistemological tenet that areas of knowledge such as science are developed within specific social communities. Thus, Driver et al. (1994) stated:

[I]f knowledge construction is seen solely as an individual process, then this is similar to what has traditionally been identified as discovery learning. If, however, learners are to be given access to the knowledge systems of science, the process of knowledge construction must go beyond personal empirical enquiry. Learners need to be given access not only to physical experiences but also to the concepts and models of conventional science. (p. 7)

The implications of this point are fundamental. The understandings of an individual, acquired, on the one hand, through the individual’s interactions with the material world, and, on the other, through being introduced to the concepts and models of conventional science, are ontologically different. The concepts and models of conventional science embody practices, conventions, and modes of expression that are socially and institutionally agreed upon. Because scientific knowledge is the product of the scientific community, it cannot be learned through interactions with the material world alone. Such differences between empiricist interpretations of personal constructivism and social constructivist accounts of learning were discussed by Leach and Scott (2003).

Following the ideas set out in the preceding sections, social constructivist accounts of learning can be deemed to be “social” in nature on two counts: first, in the sense of specifying the social origins of learning, through the interactions of the social plane, and second in recognizing the social context of the scientific community for the development of scientific knowledge.

## Learning Science as Learning the Social Language of Science

The view of scientific knowledge as a product of the scientific community maps onto Bakhtin's notion of *social languages*. For Bakhtin, a social language is "a discourse peculiar to a specific stratum of society (professional, age group etc.) within a given system at a given time" (Bakhtin, 1934/1981, p. 430). Thus science can be construed as the social language that has been developed within the scientific community. It is based on specific concepts such as energy, mass, and entropy; it involves the development of models that provide a simplified account of phenomena in the natural world; and it is characterized by key epistemological features such as the development of theories, which can be generally applied to a whole range of phenomena and situations. The social language of science is clearly different from that of geography or economics or literary criticism. Furthermore, the science that is taught in school focuses on particular concepts and models and is subject to social and political pressures, which are quite different from those of professional science (Tiberghien, 2000). From this point of view, learning science involves learning the social language of "school science" (Leach & Scott, 2002; Mortimer & Scott, 2003; see also Chapter 3, this volume).

James Wertsch (1991) suggested that the different social languages that we learn constitute the "tools" of a "mediational tool kit," which can be called upon for talking and thinking as the context demands. Furthermore, Wertsch suggested that "children do not stop using perspectives grounded in everyday concepts and questions after they master these [scientific] forms of discourse" (1991, p. 118). Thus, everyday, or spontaneous (Vygotsky, 1934/1987), ways of talking and thinking constitute an "everyday social language." Wertsch saw the learner developing disciplinary social languages alongside these everyday ways of talking and thinking. As such, this sociocultural perspective on learning clearly involves a process of conceptual *addition* (as introduced in the earlier section on cognitive science approaches) rather than replacement.

## Learning as Conceptual Addition/Replacement

This formulation of learning in terms of conceptual addition and replacement is rather more complex than these simple labels might suggest. For example, can it be the case that, in conceptual addition, everyday knowledge is left intact as the learner develops a new point of view based on a particular social language, such as school science?

There is a certain ambiguity in Vygotsky's (1987) views on the possible outcome of the learning process. In some cases he seemed to suggest that scientific perspectives (Vygotsky actually uses the term *scientific* in referring to disciplinary knowledge, which includes the natural sciences) are likely to transform everyday views: "The formal discipline of studying scientific concepts is manifested in the complete restructuring of the child's spontaneous concepts. This is why the scientific concept is of such extraordinary importance for the history of the child's mental development" (p. 236).

Elsewhere, Vygotsky suggested that even with the emergence of scientific concepts, people continue to have access to everyday concepts, which they often employ:

A child who has mastered the higher forms of thinking, a child who has mastered concepts, does not part with the more elementary forms of thinking. In quantitative terms these more elementary forms continue to predominate in many domains for a long time. As we noted earlier, even adults often fail to think in concepts. The adult's thinking is often carried out on the level of complexes, sometimes sinks to even more primitive levels. (p. 160)

So, we have a picture of scientific knowledge transforming everyday thinking on the one hand and everyday or elementary thinking being left behind on the other. It might be the case that the outcome of this meeting of social languages (everyday and school science) depends on the *context* of learning. For example, it might be argued that coming to understand a fundamental scientific principle such as the "conservation of substance" is likely to transform the thinking of the individual. It is difficult to believe that the learner will consciously revert to being a nonconservator and talk about simple everyday events in such a way (being prepared to accept, for example, that salt actually does disappear on dissolving in water). On the other hand, as one learns about air pressure, it is unlikely that air pressure explanations will replace everyday talk in terms of "sucking." Here it is likely that the individual will move between the two forms of explanation according to the perceived context of activity and application. Joan Solomon made a seminal contribution to the development of this perspective in science education with her work on "how children think in two domains" (see Solomon, 1983).

This general idea of a heterogeneity in ways of thinking (see Bachelard, 1940/1968; Berger & Luckmann, 1967; Tulviste, 1988/1991) has been developed in the context of science education in terms of a *conceptual profile* (Mortimer, 1995, 1998). The conceptual profile acknowledges the coexistence, for the individual, of different ways of conceptualizing physical phenomena in science. These different ways can range from approaches based on everyday knowledge (which might be informed by the immediate sense perception of the actual phenomenon) to sophisticated scientific ways (which might represent reality in purely symbolic models) and constitute different zones of an individual person's conceptual profile. As such, science learning can be characterized in terms of extending the zones of the individual learner's conceptual profile.

## Alternative Conceptions and Everyday Social Language

The sociocultural view of learning offers an interesting perspective on the origins and status of alternative conceptions or misconceptions. From the sociocultural point of view, an alternative conception, such as the idea of a plant drawing its food from the soil, is representative of an everyday way of talking and thinking about plants. This is the way in which ordinary people talk about such things, and in this respect there is a very real sense in which the *scientific* point of view (based on the concept of photosynthesis) offers the *alternative* perspective. Viewed in this way, it is

hardly surprising that the alternative conceptions or misconceptions identified by the science education community are “robust” and “difficult to change.” These are not the ephemeral outcomes of the solitary musings of children trying to make sense of the natural world around them, but the tools of an everyday language that continuously acts to socially define, and reinforce, our ways of talking and thinking.

### **Social Constructivist Approaches: Summary and Implications**

The following insights about science concept learning are common to social constructivist perspectives:

1. Learning scientific knowledge involves a passage from social to personal planes.
2. The process of learning is consequent upon individual sense-making by the learner.
3. Learning is mediated by various semiotic resources, the most important of which is language.
4. Learning science involves learning the social language of the scientific community, which must be introduced to the learner by a teacher or some other knowledgeable figure.

What perspective do these distinctive aspects of the social constructivist perspective take us to that is different from the interests and outcomes of the cognitive viewpoint? The most obvious development has been the increased attention, during the late 1980s and 1990s, to the role of the teacher and the ways in which teachers guide the discourse of the classroom to support the introduction of scientific knowledge and scientific ways of explaining (Edwards & Mercer, 1987; Mortimer & Scott, 2003; Ogborn, Kress, Martins, & McGillicuddy, 1996; Scott, 1998; van Zee & Minstrell, 1997). Through this kind of work, we have a much better grasp of the ways in which teachers make scientific knowledge available on the social plane of the classroom.

Whereas these approaches to *analyzing* teacher talk have been fruitful, we are less aware of work, informed by social constructivist perspectives, that addresses the issue of *designing* science instruction (see, for example, Hodson & Hodson, 1998; Leach & Scott, 2002). It also seems to be the case that the step of individual sense making, or internalization, has been given less attention, both theoretically and empirically in social constructivist studies.

And what about Alice and her learning the concept of energy? According to these views, Alice is learning a new social language, a new way of talking and thinking about the world. If some of the scientific ideas “that energy is not used up” appear implausible, it is because they *are* in relation to everyday ways of thinking. The obvious way to address this point is for the teacher to make clear that what is on offer is a new and powerful way of thinking and talking about the natural world—the scientific point of view. Furthermore, learning a scientific account of energy must involve an authoritative introduction of ideas by the teacher. Thereafter, Alice and her fellow students need the opportunity to talk and think with those conceptual tools for themselves.

## SCIENCE CONCEPT LEARNING AS PARTICIPATION

In this final section of the review we take the step from approaches to conceptualizing science concept learning that are based on acquisition to those that entail some form of participation.

### Situated Cognition

The metaphor of learning as participation has largely arisen through a perspective on learning known as *situated cognition* (see, for example, Brown, Collins, & Duguid, 1989; Lave & Wenger, 1991; Rogoff, 1990).

The pioneering work in this field focused on the use of mathematics in the workplace and in day-to-day life. For example, Scribner (1984) analyzed the arithmetical practices of people as they worked in a dairy factory, and Lave (1988) focused on the use of arithmetic in everyday shopping. These studies and others (see Hennessy, 1993, for a comprehensive review) have identified forms of arithmetic that are radically different from those taught in school. The skilled users of these everyday forms of arithmetic vary their problem-solving approaches depending on the specific situation, and problems that appear to be structurally identical are solved with different strategies. In this sense, the strategies are seen to be directly linked to context and thereby *situated* in nature.

According to the situated cognition perspective, learning is seen as a process of enculturation, or participation in socially organized practices, through which specialized skills are developed by learners as they engage in an apprenticeship in thinking (Rogoff, 1990) or in legitimate peripheral participation (Lave & Wenger, 1991). According to Collins, Brown, and Newman (1989), the key components of the apprenticeship process include modeling, coaching, scaffolding, fading, and encouraging learners to reflect on their own problem-solving strategies. This apprenticeship leads to the learner becoming involved in the *authentic* practices of a "community of practice" (Lave and Wenger, 1991). Brown, Collins, and Duguid (1989) argued: "Unfortunately, students are too often asked to use the tools of a discipline without being able to adopt its culture. To learn to use tools as practitioners use them, a student, like an apprentice, must enter that community and its culture" (p. 33). Roth (1995a) suggested that authentic practices involve activities "which have a large degree of resemblance with the activities in which core members of a community actually engage" (p. 29).

In the context of education, situated cognition perspectives have received a lot of attention, particularly in North America and particularly in relation to mathematics education (see, for example, Cobb, Wood, & Yackel, 1991; Cobb & Yackel, 1996; Lampert, 1990). According to Cobb and Bowers (1999), "A situated perspective on the mathematics classroom sees individual students as participating in and contributing to the development of the mathematical practices established by the classroom community" (p. 5).

Situated perspectives on learning have also been drawn upon as part of a theoretical justification for "inquiry-based" approaches to science teaching and learning (see, for example, Metz, 1998; Roth, 1995b). Roth (1995a) suggested that "situated

learning emphasizes learning through the engagement in authentic activities" (p. 29). He explained his use of the term "authentic" by suggesting that in classrooms focused on scientific activities, the students would (a) learn in contexts constituted in part by ill-defined problems; (b) experience uncertainties, ambiguities, and the social nature of scientific work and knowledge; (c) engage in learning (curriculum) that is predicated on, and driven by, their current knowledge state; (d) experience themselves as part of communities of inquiry in which knowledge, practices, resources, and discourse are shared; and (e) participate in classroom communities, in which they can draw on the expertise of more knowledgeable others (Roth, 1995a, p. 29; see also Wells, 1999).

Drawing explicitly upon these ideas, science instruction has been planned and implemented as the enculturation of students into practices such as field ecology (e.g., Roth & Bowen, 1995), environmental activism (e.g., Roth & Désautels, 2002), and basic scientific research (e.g., Ryder, Leach, & Driver, 1999). Although the practices described in these studies can be argued to be *authentic* in the sense that they refer to situations in which science is actually used, it is more difficult to argue that they are closely related to the everyday experience of most science learners. Furthermore, the authors' analyses of teaching focus more upon students' learning about various *practices* that involve science (the use of instrumentation and specific technical procedures, the construction of arguments, the social relationships of various communities) than upon the development of conceptual understanding by students.

## Learning Science, Learning to Talk Science

Lemke (1990) offered a different perspective on learning science through participation in his book, *Talking Science: Language, Learning and Values*. This "social semiotic" approach has been highly influential in drawing attention to the fundamental importance of language in science learning. The basic thesis that Lemke proposed is that learning science involves learning to talk science: "it means learning to communicate in the language of science and act as a member of the community of people who do so" (p. 1). Lemke questioned the value of cognitive theories of concept use based on mental processes "which we know nothing about" and suggested that "we may as well cut out the 'middleman' of *mental* concepts, and simply analyse conceptual systems in terms of the thematic patterns of language use and other forms of meaningful human action" (p. 122). Consistent with this point of view, Lemke suggested that scientific reasoning is learned "by talking to other members of our community, we practice it by talking to others, and we use it in talking to them, in talking to ourselves, and in writing and other forms of more complex activity (e.g., problem-solving, experimenting)" (p. 122; see also Chapter 3, this volume, for more on language and science learning).

## Multimodality: Extending Beyond Language

Although science classrooms are filled with the voices of teacher and students, it is clear that communication and learning in the classroom are achieved by more than just linguistic tools. Kress, Jewitt, Ogborn, and Tsatsarelis (2001) set out an approach to analyzing science teaching and learning, "in which the multiplicity of *modes of*

*communication* that are active in the classroom are given equally serious attention” (p. 1). Through this “multimodal” approach, Kress et al. were able to demonstrate how the meaning of what is spoken or written does not reside purely in language, by focusing on the ways in which teacher and students use a variety of semiotic modes, “actional, visual and linguistic resources” (p. 33), to represent and communicate ideas. One of their examples offers a detailed and vivid illustration of how a teacher orchestrates a range of modes of communication to introduce the idea of blood circulation. The image that sticks in the mind is the teacher moving fluently between a diagram on the board, a model of the human body, and his own body, gesturing toward each as he develops the verbal scientific narrative (see also Scott & Jewitt, 2003).

This multimodal account of learning sits firmly in the participation camp. “We believe that ‘acquisition’ is an inappropriate metaphor to describe the processes of learning: it implies a stable system which is statically acquired by an individual” (Kress et al., 2001, p. 28). Rather, learning is presented as a *process* of transformation in which “students are involved in the active ‘remaking’ of teachers’ (and others’) signs” (p. 27). In other words, learning involves the students in making sense of (and thereby transforming) the multimodal events that are unfolding around them in the science classroom.

In his more recent work, Lemke has developed the social semiotics perspective introduced in *Talking Science*, along similar multimodal lines, to investigate “how we make meaning using the cultural resources of systems of words, images, symbols and actions” (Lemke, 2003, “Languages and Concepts in Science” section). As part of this analysis, Lemke made the important point not only that it is the communicative activities of teacher and students in the classroom that are multimodal in character, but that science itself also involves the use of multiple semiotic systems: “Science does not speak of the world in the language of words alone, and in many cases it simply cannot do so. The natural language of science is a synergistic integration of words, diagrams, pictures, graphs, maps, equations, tables, charts, and other forms of visual and mathematical expression” (p. 3).

Science thus consists of: “the languages of visual representation, the languages of mathematical symbolism, and the languages of experimental operations” (p. 3). Following this perspective, Lemke argued that learning science must involve developing the ability “to use all of these languages in meaningful and appropriate ways, and, above all, to be able to functionally integrate them in the conduct of scientific activity” (p. 3).

## Participative Approaches: Summary and Implications

The following insights about learning are common to the participative approaches outlined above:

1. Learning is seen as a *process* of developing participation in the practices of a particular community.
2. The learner takes on the role of apprentice, whereas the teacher is seen as an expert participant.
3. That which is to be learned involves some aspect of practice or discourse.

Perhaps the biggest question to be raised in relation to the participative approaches concerns the issue of subject matter and the very aims of science education. For example, what does it mean to suggest that learning science should involve “participation in the practices of a scientific community”? What does it mean to suggest that students should “engage in the authentic practices of science”? To what extent is it possible to reconfigure the science classroom as a seat of authentic scientific practices? Is it reasonable to expect that the teacher can act as an expert practitioner within this scientific community of the classroom? What would be the aims of such an approach to science education? What would be learned?

Of course, we have already referred to examples of classroom practice where these kinds of questions have been addressed; it is clear that the kinds of investigative or inquiry-based activity suggested offer workable possibilities. But what about Alice and her quest to understand the scientific concept of energy? It stretches faith in participative methods to suggest that learning scientific concepts, the tools of science, might best be achieved through investigative methods. Here the social constructivist perspective seems to offer a more plausible and helpful way of framing possible instructional approaches.

### WHAT CAN WE SAY ABOUT SCIENCE CONCEPT LEARNING IN CLASSROOM SETTINGS?

We began this chapter with a brief sketch of one student, Alice, and her learning of the scientific account of energy during science lessons in school. We return to that scenario, for a final time, to consider the ways in which the different approaches to viewing science concept learning might be drawn upon to illuminate such a teaching and learning event, addressing some of the questions listed in the introduction to the chapter. Our view is that, given the complexity of what goes on in classrooms as students learn science, it is unrealistic to expect that one “grand” theory might capture all of the activity. In this respect we follow the lead of Sfard (1998) and others (see, for example, Mayer, 2002) in drawing upon what might be regarded as complementary perspectives on learning.

As a starting point, we take the social constructivist perspective, which we believe constitutes a helpful framing or “orienting” (Green, Dixon, & Gomes, 2003) theory in bringing together the social context for learning with the individual student’s response. Here the teacher occupies the pivotal role, between culture and students, in introducing the scientific social language. Given this overall framing, it is clear that learning scientific concepts is driven by teaching and that the students must engage in the act of personal sense-making during internalization.

Accepting the point of view that learning science involves learning the social language of “school science,” a legitimate question to ask is, why can learning some parts of science prove to be so *difficult*? Why is it, for example, that Alice struggled to come to terms with the school science account of “energy.” Why is it that the school science view often appears implausible to the learner, even if it is intelligible (Posner et al., 1982)? How can we develop and extend our *orienting* theoretical framework to address these questions?

One response relates to *differences* in social languages and is based on the idea that where there are significant differences between school science and everyday

accounts of a particular phenomenon, greater “learning demands” (Leach & Scott, 2002) are created for the student. How might such learning demands be appraised? Three possible ways in which differences between everyday and school science perspectives might arise have been identified (Leach & Scott). These relate to differences in the *conceptual tools* used, differences in the *epistemological underpinning* of those conceptual tools, and differences in the *ontology* on which those conceptual tools are based.

For example, in relation to plant nutrition, students commonly draw upon everyday notions of food as something that is ingested, in contrast to scientific accounts, which describe the synthesis of complex organic molecules within plants, from simple, inorganic precursors. In the case of energy, the scientific concept is essentially a mathematical accounting device (which can be used to predict the limits of possible outcomes to physical events), whereas the everyday concept is likely to involve references to human activity and notions of energy as something that “makes things happen.”

Other differences relate to the *epistemological underpinning* of the conceptual tools used. Thus, the ways of generating explanations using scientific models and theories that are taken for granted in school science are not part of the everyday social language of many learners (Driver, Leach, Millar, & Scott, 1996; Leach, Driver, Scott, & Wood-Robinson, 1996; Vosniadou, 1994). Whereas in scientific social languages, great importance is attached to developing a small number of models and theories, which can be generally applied to as broad a range of phenomena as possible, the same is not true for everyday social languages. Thus, in science, energy is an absolutely central concept, simply because it offers a generalizable way of thinking about virtually any phenomenon. In everyday contexts, where there is not the same attention to generalizability; the term *energy* might be used with different meanings in different contexts.

Learning demands may also result from differences in the *ontology* of the conceptual tools used (Chi, 1992; Chi, Slotta, & de Leeuw, 1994; Leach et al., 1996; Vosniadou, 1994). Thus, entities that are taken for granted as having a real existence in the realm of school science may not be similarly referred to in the everyday language of students. For example, there is evidence that many lower secondary school students learning about matter cycling in ecosystems do not think about atmospheric gases as a potential source of matter for the chemical processes of ecological systems (Leach et al.). There is a learning issue here that relates to the students’ basic commitments about the nature of matter—initially they do not consider gases to be substantive. With regard to the energy example, in scientific social languages energy is regarded as an abstract mathematical device, whereas in everyday contexts it is often referred to as being substantial in nature: *Coal contains energy; I’ve run out of energy.*

From this point of view, learning science involves coming to terms with the conceptual tools and associated epistemology and ontology of the scientific social language. If the differences between scientific and everyday ways of reasoning are great, then the topic in question appears difficult to learn (and to teach). The key point here is that the concept of learning demand is framed in terms of the differences between social languages *and* draws on aspects of the “individual cognition” literature in identifying the epistemological and ontological aspects of learning demand.

In the cognitive literature, ontological recategorization (for example) is presented as a mental process, possibly as a psychological barrier to learning a specific science concept. The account of ontological barriers to successful learning presented here, however, begins by recognizing that ontological differences exist between the *social languages* of everyday talk and school science. Any ontological recategorization required of learners therefore has its origins in social language, and we can begin to address these through systematic teaching.

One might argue that all of this adds up to the same thing, and in a sense it does. The systematic teaching still requires individual cognitive effort by the student if learning is to take place. Nevertheless, it might be helpful in thinking about teaching and learning science in classroom settings, to cast the issue in terms of the aspects of learning demand to be worked on by teacher and students. In this way, there is greater clarity about what it is that needs to be taught and learned in any topic area of school science.

This realization of what it is is extended still further by Lemke's (2003) social semiotic analysis. As outlined earlier, Lemke emphasized that learning school science involves developing the ability to integrate and use all of the semiotic resources of science, pulling together the languages of visual representation, mathematical symbolism, and experimental operations. Lemke was absolutely clear in stating that it is the responsibility of the teacher to show students "how to move back and forth among the different mathematical, visual, and operational representations" (p. 5).

All of these preceding points relate to achieving greater clarity about what it is that needs to be taught if students are to come to understand and to be able to use the social language of science with its distinctive conceptual tools, epistemological and ontological framing, and range of semiotic resources. Within this account, there are also half-exposed hints about the kinds of instructional approaches that might be taken in addressing these learning targets. There is clearly a central role for the teacher in introducing these new conceptual tools and helping the students to make links to their existing ways of thinking. This communicative aspect of the teaching role, focusing on both language-based and broader multimodal approaches, has been developed in detail elsewhere (Kress et al., 2001; Lemke, 1990; Mortimer & Scott, 2003; Ogborn et al., 1996; Scott, 1998). It must also be a priority for the students to begin to use these ideas for themselves and to start talking and thinking with the scientific social language(s) if they are to engage with them meaningfully.

In these ways, we can see how Sfard's conclusion that "one metaphor is not enough" (p. 10) might be addressed, in the context of teaching and learning science contexts, as elements of theory are drawn on from the camps of both acquisition and participation.

### **LOOKING AHEAD: FUTURE RESEARCH DIRECTIONS**

One measure of the extent to which science education research can be regarded as a progressive field of activity concerns the impact of that research on practice (see Fensham, 2004). The picture that is painted in this review points to areas of research on science concept learning where our knowledge is extensive. Thus, as a commu-

nity, we are familiar with students' typical alternative conceptions in a wide range of science topic areas; we are able to identify the main barriers to conceptual learning as scientific ideas are introduced against a backdrop of everyday ways of talking and thinking; we are aware of the ways in which learning involves both engaging in the social contexts of the classroom and steps of personal meaning making. The list can be further developed and, given the relatively short history of research in science education, is impressive in its extent. This body of knowledge is both broad and reliable and is based upon aspects of theory along with extensive empirical studies.

What remains far more problematic concerns the instructional approaches that might be taken to *advance* that learning. Put briefly, science education researchers are currently in the position where we can point with confidence to the likely conceptual starting points and challenges for students in any area of science learning, but we have rather less to say about how to shape instruction in order to help students come to terms with the scientific point of view. The challenge remains one of crossing the bridge from our insights on learning to making the link to reliable approaches to instruction.

Some argue that teaching is an idiosyncratic, highly personalised activity such that the very notions of best practice or an optimal instructional approach do not make sense. Although it is clear that teaching is a responsive activity and that to an extent it must therefore depend upon the circumstances prevailing in specific contexts (this class of children, at this time of the week, in this particular school, with this teacher), it might still be argued that some instructional approaches are likely to be more effective than others in supporting student learning. Why should this be the case? Possibly because the particular instructional approach is tightly linked to clear teaching objectives, or involves a motivating activity for the students, or challenges students' thinking in an engaging way, or allows students the opportunity to articulate their developing understandings.

Following this line of argument, the central challenge for science education researchers remains one of building upon insights about learning to develop robust guidelines (both science domain specific and general) to support instructional design. If such research activity is to have an impact upon practice in schools, then it needs to engage with the professional knowledge and expertise of practicing teachers and their priorities for professional development. This is a substantial project that has as its ultimate aim the exciting prospect of allowing students such as Alice to develop deeper insights into the power and elegance of scientific knowledge.

# CHAPTER 3

---

## Language and Science Learning

William S. Carlsen

*Pennsylvania State University*

In a 1998 contribution to the *International Handbook of Science Education*, Clive Sutton used the writings of Faraday, Boyle, Harvey, and others to compare the language found in historical documents with the ways in which science is represented in contemporary textbooks and classrooms. In Michael Faraday's letters to scientific contemporaries, Sutton found a voice that was personal and overtly persuasive, eschewing the third-person, "stick to the facts" register with which schoolchildren today are commonly taught to write laboratory reports. Drawing on science studies by Bazerman (1988), Lemke (1990), Medawar (1974), Shapin & Schaffer (1985), and others, Sutton (1998) recommended reduced emphasis in science education on language as a means of transmitting information and greater emphasis on language as an interpretive system of sense-making.

Only 5 years later, a survey of recent literature on language and science education demonstrates both the utility of Sutton's framework and the potential for its expansion. An overall healthy growth of that literature masks some interesting trends within that literature. Consider, for example, Figure 3.1, which plots the average annual publication rate of documents with keywords *Science Education*, *Language*, and either *Concept Formation* or *Culture*. Following a period of stability from about 1980 to 1995, publications related to *Concept Formation* have declined in number, while *Culture* has increased.<sup>1</sup> Trends like this reflect changes in the field regard-

---

1. For the sake of the narrative, I have simplified my description of the method in which the Figure 3.1 data were generated. The set described in the prose as (kw = "Science Education" AND "Language") is actually more accurately represented as ((kw = "Science Education" OR "Science Instruction" – (kw = "Programming" OR "Programing")) AND "Language"). Use of the longer specification eliminated almost all of the numerous studies of computer programming (or ERIC's earlier spelling, "programing"), few of which were concerned with language as a means of oral or written communication between teachers and students engaged in science teaching and learning. My choice of keywords (and their linking algebra) followed a quantitative analysis of all ERIC citations in the aforementioned set from 1975–2002 (the most recent year that is reasonably completely indexed) and from study of the frequency distributions by date of the first 10 keyword descriptors of each of the citations. However, the data in Figure 3.1 are offered for heuristic purposes only; this is not a statistical argument!

FIGURE 3-1. ERIC citation rates for publications with keywords *Science Education*, *Language*, and either *Culture* or *Concept Formation*, by date.

ing what it means to learn (and to teach) science. Following a shift in emphasis from learning as individual cognitive growth to learning as individual cognitive growth in social settings, research increasingly views language as more than just a social means to individual ends.

The first section of this chapter discusses the origins of much of this newer research, beginning with four schools of thought. The roots of these perspectives grow together in a number of ways, but they also emphasize different things. The second section of this chapter reviews recent research concerning language and science learning, building to a conceptual framework based on Sutton's earlier work. The reader should note that a detailed perspective on specific studies of spoken and written discourse in science classrooms is provided by Greg Kelly in Chapter 16. A comprehensive recent review of science literacy by Yore, Bisanz, and Hand (2003) deals more extensively than I do here with the important role of writing in science learning. My aim here is to propose a framework informed by theoretical issues that are historically significant or productively emerging in science education, without covering the same ground in the same way. To do this, I first identify some of the contributions of four productive contemporary approaches to studying the role of language in science learning: the Vygotskian perspective, conceptual change theory, sociolinguistics, and situated learning.

## ORIGINS OF CONTEMPORARY RESEARCH ON LANGUAGE AND LEARNING

### Vygotsky

Lev Vygotsky was a contemporary of the young Piaget and closely followed his work. He concurred with many, but not all, of Piaget's conclusions. Vygotsky's

most compelling contribution to science education is probably *Thought and Language* (1934/1986). Although the book says practically nothing about pedagogy, it has been productively probed for its educational implications, which are significant (Howe, 1996; Wertsch, 1985, 1991). Vygotsky distinguished between spontaneous and scientific thinking. Spontaneous concepts arise in a child's everyday experience and begin with egocentric speech, often in the company of others. Eventually, vocalized speech is internalized, evolving into inner speech. According to this view, spoken language precedes conceptualization in everyday life. Meaning actually follows speech.

According to Vygotsky, scientific thinking is special because new scientific concepts generally arise from work within a formal conceptual structure (which may be explicitly taught). Consequently, science learning is a process of moving from the linguistically abstract to the concrete, not vice versa. Children learn spontaneous concepts (e.g., what a bowl is) from their everyday experiences. Scientific concepts (e.g., what photosynthesis is) are often invisible, abstract, or otherwise inaccessible. One oft-overlooked instructional implication of this perspective is that some scientific concepts may never arise from hands-on experience, no matter how creative or time-consuming that experience may be.

Vygotsky's "zone of proximal development" (ZPD) has been used extensively by researchers and educators. The idea is appealing: The trajectory of future learning can be predicted by comparing a child's work alone with his or her work in the company of a more knowledgeable teacher or peer. Numerous studies have translated the ZPD concept into a pedagogical agenda: Engage learners in group tasks with others, on the grounds that the social setting will allow many students to stretch beyond the limits of their abilities, working alone.

Finally, in *Thought and Language*, Vygotsky noted that writing is linguistically distinct from and more demanding than speech. The developmental path of writing is more abstract, symbolic, and less likely to elicit (and be shaped by) feedback from others. A number of research and instructional projects have been built upon Vygotskian ideas, such as the Cognitive Acceleration through Science Education (CASE) project in Britain (Adey, 1999), research on elementary science instruction in Mexico (Candela, 1995), and the effects of computer-mediated communication in American science and math instruction (Charnitski & Harvey, 1999).

Some critics have charged that Vygotsky has been misappropriated for nefarious purposes like promoting sociocultural relativism, replacing formal instruction with useless hands-on experiences, and misinterpreting the ZPD as a bridge between everyday experience and scientific concepts. Vygotsky, argued Stuart Rowlands (2000), was an "out-and-out objectivist" who believed that theory precedes practice in science. Everyday experiences may be necessary for scientific concepts to develop, but they do not cause that development. Scientific ideas ascend from the abstract to the concrete (Rowlands, 2000; Rowlands, Graham, & Berry, 1999). In science there is always a critical need for formal instruction.

## Conceptual Change Theory

Conceptual change theory (CCT) has long been an important paradigm in science education research. Building from work by Piaget (1929/1969) and Thomas Kuhn

(1970), the team of Posner, Strike, Hewson, and Gertzog (1982) outlined a model of science learning that accounts for the resistance of misconceptions to change and that foregrounds the interaction between individuals and the scientific communities (and theoretical perspectives) to which they are acculturated. From a sociolinguistic perspective, CCT is itself a fruitful research program; that is, it stimulates the generation of interesting questions. For example, Lavoie (1999) documented the positive effects of adding a prediction/discussion phase to the beginning of a learning cycle in secondary biology. Among the features of his experimental treatment was an insistence that students make their predictions explicit and that they publicly debate, modify, and reevaluate those predictions. The genesis of these steps from CCT is clear.

Constructivism has largely supplanted CCT in the science education research vernacular, despite the problem of its many different meanings. Nevertheless, CCT remains a viable theory and may prove—for social, philosophical, and methodological reasons—to be more long-lived. Fundamentally, constructivism is about individuals creating individual meanings, sometimes in social settings. Conceptual change theory emphasizes the congruence of individual understandings with public, often established, knowledge (see also Chapter 2, this volume). CCT also foregrounds the importance of epistemic communities (Kelly, 1997).

As Vygotsky's work is becoming more widely known, researchers and educators are seeking ways to extend CCT from the intramental to the intermental plane. Using an analysis of a chemistry lesson, Mortimer and Machado (2000), for example, discussed the evolution of their understandings of cognitive conflict (an individual, Piagetian construct) to one of public, discursive conflict, resolved dialogically. In recent years, the emphasis of many studies of conceptual development in science education has shifted from the investigation of individuals' cognitive schemata to studies of interactive discourse and the co-construction of concepts in natural language. This has required finding tools and methods better suited for documenting and analyzing the dynamics of spoken language in classrooms. This brings us to a third major approach to studying how language and learning are related: the sociolinguistic perspective.

## Social Semiotics and Sociocultural Considerations

Lemke's *Talking Science* (1990), a field guide to analyzing the content of classroom discourse, clearly demonstrates the need to consider the context of spoken language. Although this principle is a sociolinguistic fundamental, Lemke drew most directly on what he labeled "social semiotics." Here and in later works (e.g., Lemke, 2001), he argued that meaning is derived in part from the cultures in which talk takes place, and that meaning-making is impeded when culture clashes arise between disciplinary cultures, as well as between more conventional social/economic/political/ethnic cultures. In fact, the science classroom sits on the border between competing cultures, such as the scientific community, which values open inquiry and disagreement, and the formal school community, which generally prefers quiet obedience. Lemke and others found that sociologies of science also offer useful tools for understanding the social work of scientists, from which implications for classroom practice can be drawn (Kelly, Carlsen, & Cunningham, 1993; Roth, 1995a).

We learn to communicate in different ways in different settings. Children who begin school without having been socialized to conventional forms of school communication may experience communicative failures that are interpreted as lack of aptitude or intelligence (Heath, 1983). Studies of language minority students demonstrate how the routine communicative expectations of majority teachers can be misinterpreted because of lack of teachers' understanding of the cultural norms and practices in their students' out-of-school lives (Au & Mason, 1983; Erickson & Mohatt, 1982). Our *discourse* consists of the words, gestures, and other signs that we use; our *Discourse* consists of all of the other things that help us make sense of language: "Different ways of thinking, acting, interacting, valuing, feeling, believing, and using symbols, tools, and objects" (Gee, 1999, p. 13). Learning may be easier when teachers strive for instructional congruence between the academic culture and the culture(s) of their students, modifying subject matter by using students' language and cultural experiences (Lee & Fradd, 1998).

Provocative but less thoroughly explored, cultural practices and language may be exploitable in addressing students' scientific misconceptions. Hewson and Hamlyn (1984) discovered that southern African Sotho and Tswana teens speak languages that predispose them to kinetic (particulate) rather than caloric (substance) views of heat. Potentially, this linguistic and cultural resource might help them avoid common misconceptions. Although later studies of Sotho college entrants could not corroborate this phenomenon (Lubben, Netshisaulu, & Campbell, 1999), further studies of the interaction of nonmajority language and science learning opportunities would be worthwhile.

Hogan and Corey (2001) provided an excellent example of classroom research from a sociocultural perspective. In addition to *Talking Science*, Groisman, Shapiro, and Willinsky (1991) offer a gentle introduction to the use of semiotics in science education research.

## Situated Learning and Communities of Practice

Clearly, the concepts of situated learning, legitimate peripherality, cognitive apprenticeships, and communities of practice are having an important impact on science education research. Studies by Lave, Wenger, and others have given educational researchers much to think about and work with, even though the bulk of their work has been done in nonschool settings (Chaiklin & Lave, 1993; Lave & Wenger, 1992; Wenger, 1998). Studies of cognition in situ—of craftwork, midwifery, and other jobs—reveal how novices learn complex skills through participation in real work, initially as peripheral participants. One of the most exciting aspects of this literature is its suggestions that learning is not a process of internalizing knowledge, that it is not promoted by social activity; learning is social activity.

Wenger (1998) portrayed a claims-processing office as an environment in which work, interaction, and learning are inextricably linked. "Issues about language," Lave and Wenger (1992) wrote, "may well have more to do with legitimacy of participation . . . than they do with knowledge transmission. . . . Learning to become a legitimate participant in a community involves learning how to talk (and be silent) in the manner of full participants" (p. 105).

In some cultures and for many crafts, conventional didactic instruction would be culturally inappropriate (Jordan, 1989) and less suitable than the traditional apprenticeship model.

Roth (1995b) applied many of these ideas in his analysis of science classroom practices. Of particular interest are his demonstrations of the transformation of gestures, inscriptions, and other phenomena in shaping concepts in the public sphere, a paralinguistic process evocative of Vygotsky. In the laboratory setting, gestures, for example, may function less as evidence of conceptual understanding than as a tool for co-constructing concepts with one's laboratory partners (Roth, 2001). The utility of viewing science learning in a social fashion has also been demonstrated in studies of adult learners. For example, in an ethnographic study that took place over several years, Bowen and Roth (2002) identified the different contributions to the education of ecologists that take place in formal and informal settings, and demonstrated the importance of stories and other informal communications in shaping novices' understandings. They also argued that storytelling contributes to social cohesion in scientific communities. In other words, not only do communities of practice provide a context and a means for learning science through language, but informal language—often superficially off-task—functions to help create functioning communities. The model of apprenticeship embedded in Lave's work can also be used productively to study the learning of novice teachers in settings where they coteach, and studies conducted with this lens have the potential to inform teacher education, viewing the learning of novice and experts as reciprocal (Roth & Tobin, 2001).

## TOWARD A REVISED FRAMEWORK FOR THE ROLE OF LANGUAGE IN SCIENCE EDUCATION

My goal in this section is to extend and update Sutton's 1998 framework concerning the role and function of language in science teaching and learning, focusing on four features: (a) what a speaker appears to be doing, (b) what listeners think that they are doing, (c) how language is thought to work in learning, and (d) how language is thought to work in scientific discovery.

### What a Speaker Appears to Be Doing

*Controlling discourse.* Although of course students often speak and write, traditional teaching is characterized by an asymmetry of conversational rights that favors the teacher. Teacher questions, for example, both reflect a teacher's authority and reinforce it (Carlsen, 1991a). Questions assert sociolinguistic power (Mishler, 1978), and when teachers find themselves discussing unfamiliar subject matter, they may rely upon questioning to prevent the topic of discussion from wandering into uncomfortable territory (Carlsen, 1991b). This creates what Driver (1983) labeled as the science teachers' dilemma: teaching science as a process of inquiry and as an accepted body of knowledge poses a constant linguistic challenge. Driver wrote, "On the one hand pupils are expected to explore a phenomenon for themselves, collect data and make inferences based upon it; on the other hand this process is intended to lead to the currently accepted law or principle" (p. 3). We expect teachers

to invite students to construct meaning, but we hold them accountable for the construction of the right meaning.

Fortunately, most students cooperate in the most common patterns of classroom discourse, such as variations on the Initiation-Response-Evaluation (IRE) triad that have been described by Mehan (1979), Lemke, and many others. Viewed as a language game (Wittgenstein, 1967), the IRE is both a mechanism of control and a cultural tool (Wertsch, 1991). Unfortunately, even well-intentioned control of the direction of science talk may result in a conflation of the teacher's authority as an expert with her authority as the person in charge (Carlsen, 1997; Russell, 1983; Toulmin, 1958). The resulting discourse may suggest to students that the nature of science is more certain and less susceptible to challenge than it really is. There are other cognitive hazards. Wilson (1999) cautioned: "[If] engagement in epistemic tasks in discourse is important in the construction of abstract declarative knowledge and conceptual understanding, then students may face disadvantages in classrooms in which discursive practices are teacher controlled and dominated by extensive triadic dialogue about knowledge claims provided for students by the teacher or the text" (p. 1080).

In more open-ended project-based science work, students may not understand the rules, and both order and learning may suffer. There are hazards to unguided discovery (Rogoff, 1994), but teachers who know how to play language games can transform original student moves and open them to extension, elaboration, or critique (Polman & Pea, 2001). But it is a balancing act. Hogan, Nastasi, and Pressley (1999) found that teacher-directed discourse was most effective in promoting higher-order reasoning and higher-quality explanations, but discussions among students were more generative and exploratory. Other work on the balance between restricting or expanding control has been informed by Vygotsky's ZPD concept (e.g., Blanton, Westbrook, & Carter, 2001).

*Creating opportunities for meaning-making.* On a more constructive note, teachers facilitate linguistic meaning-making in many ways. Kelly and his collaborators documented the work of a science non-expert teaching science to third graders. Instead of closing down the conversation, the teacher successfully modeled and directed scientific discourse, leading her students to define science in their local context (Crawford, Kelly, & Brown, 2000).

To become a member of a community (e.g., science classroom or research laboratory) who acts in socially appropriate ways (e.g., one who adheres to genre conventions when speaking and writing), one must first understand the social practices of a community, that is, what counts as a valid description, explanation, inference, etc. (p. 626).

The research group found similar practices in a high school physics classroom: a teacher framing activities and coordinating sociocultural practices, thus leading his students to appropriate scientific discourse (Kelly & Chen, 1999). Coherent and jointly constructed discourse resulted in the creation of public, sociolinguistic meaning.

Of course, local meaning is not the same as scientific fact: Gravity cannot be dismissed through a classroom conversation. Science is epistemologically distinct in its empirical approaches, its forms of argument, and the demonstrable productivity of concepts and theories that would never arise spontaneously in a school setting

(quantum physics, for example). Recalling Vygotsky, scientific concepts often grow from the abstract to the concrete. They are useful because they are decontextualized (Rowlands, 2000). Approached from a different direction, scientific experiments yield facts through social processes of inscription, translation, and the ultimate removal of “weasel words” that relate the empirical *who, what, when, where, and how* (Latour & Woolgar, 1986). The approaches are different, but the outcomes are the same: useful facts stripped from the particulars of their construction.

## What Listeners Think They Are Doing

In inquiry-oriented classrooms, students often work in groups, and their work can be viewed as contributing to the solution of shared problems. Students can learn science and *about* science when their communication takes place through online discussions (Hoadley & Linn, 2000), computer-mediated peer review (Trautmann et al., 2003), and other modalities, but group work usually takes place face to face. Without the teacher present, the rules of the language game are altered, and the new rules must be understood by all in order to make progress. Communicative competence entails knowing how to take turns without the teacher’s direction, how to hold (and yield) the floor, and how to make sense to (and of) others. These tasks are inevitably complicated by speaker differences of gender, culture, ethnicity, and so on (Philips, 1972).

The substance of science talk can be evaluated in a number of ways. Geddis (1998), for example, developed a multidimensional method for gauging the quality of discourse. High-quality discourse includes practices like giving reasons for assertions and demonstrating intellectual independence from the teacher’s authority. Hogan (1999) identified metacognition as an essential element in group inquiry and conducted a study in which students in experimental classes received training in metacognition and cognitive strategies for group work. The intervention resulted in improvements in students’ knowledge about metacognition and collaborative reasoning, but no difference was found in the experimental and control groups’ actual collaborative behaviors. Nevertheless, the success of metacognitive strategies in individual students’ learning suggests that further work along these lines may be valuable.

Epistemological beliefs may not change easily. In one study, 4 weeks of substantive inquiry about evolution produced little shift in students’ epistemological frameworks, which were found to be unstable and ill-defined. The investigators in that study advocated explicit epistemic discourse coupled with inquiry (Sandoval & Morrison, 2003).

In a study of college engineering students, Kittleson and Southerland (2004) found that concept negotiation was rare, even when the instructor structured the task to promote that process. Clearly, success in channeling student discourse into productive knowledge construction is a pedagogical goal that demands much more work.

## How Language Works in Learning

**Making meaning.** The Sapir-Whorf hypothesis (Whorf, 1956), now largely discredited, proposed that language shapes human cognition in profound ways, so that a person’s native language would shape how she perceived the world. Today it is

commonly assumed by linguists that our brains are wired for language (although the details remain in dispute, such as Chomsky's (1972) theory of a universal grammar). Why then is culture—and the signifying systems that culture embodies—so important in meaning-making? From a sociocultural perspective, learning involves appropriating and using intellectual and practical tools. Much of what a student learns comes not from direct experience, but from texts that are organized to tell a disciplinary story. "From a sociocultural perspective, the use of texts as the prime vehicle for communicating knowledge can be seen as a further step in the adoption of experience-distant accounting practices for understanding the world" (Säljö, 1998, p. 49). Human knowledge is discursive in nature, reproduced through language and artifacts in social institutions like schools.

The knowledge produced within these discourses does not remain inside the heads of individuals. . . . Rather, knowledge emerges as properties of tools and socially organized practices in which individuals participate, and which by necessity are ideological in nature—without values there can be no knowledge. . . . Knowledge is fundamentally argumentative in nature; it moves the world rather than reflects it. (Säljö, p. 53)

Wong and Pugh (2001) observed that we promote the teaching of concepts rather than facts because concepts are more integrative and thus more powerful in science. Cognitive perspectives emphasize thinking; sociocognitive perspectives highlight the role of language in stimulating and supporting thinking. John Dewey emphasized ideas rather than concepts, and being, the combination of cognition and action:

Dewey's emphasis on being, rather than cognition, reveals an epistemological stance that locates meaning neither in the mind of the learner nor in the surrounding environment. Instead, meaning is a transactive phenomenon: it exists only in the situation created in interaction between person and world. . . . To some readers, ideas and concepts may seem synonymous and we admit that Dewey's use of the term *idea* (along with other terms), although precise, is often confusing. To begin, concepts are something that students learn: To understand is to have an accurate representation of it and to be able to apply it appropriately. The goal of conceptually oriented teaching is the construction of accurate, meaningful representations. By contrast, ideas are something that seizes students and transforms them. The goal of ideas-based teaching is to help students to be taken by an idea and to live with it, to be with it in their world. (Wong & Pugh, pp. 324–325)

Of course, meaning-making is not the only function of language in the classroom. Discourse has two distinct functions in science education: generating meaning (its generative function) and conveying meaning (its authoritative function) (McDonald & Abell, 2002; Mortimer & Machado, 2000).

**Representing knowledge.** A number of researchers have studied how knowledge is represented in science education settings and have developed tools that provide insights into how language functions in learning. For example, in a cross-cultural study of English and Asian-speaking children, Curtis and Millar (1988) developed a method for representing students' knowledge about scientific concepts by classifying ideas generated in a writing task. Concept mapping in diverse forms remains a popular tool for representing the relationships among concepts (Fisher, Wandersee, & Moody, 2000), and the use of concept maps has been facilitated by

several different computer tools. Semantic networks, ideational networks, and other graphical diagrams have been found to be useful diagnostically and to stimulate science talk with language minority students (Anderson, Randle, & Covotsos, 2001; Duran, Dugan, & Weffer, 1998).

Building upon work on situated learning and the sociology of science, Roth (1995a) described a number of cases of both individual and collaborative knowledge construction. The assignment of group work and the use of conscription devices such as concept maps helped create conditions in which “students had to negotiate the meanings of concept labels or future courses of action. During these negotiations they externalized and objectivized their understandings so that they were open not only to public scrutiny but also to critical self-reflection. In this process, students negotiated prior understandings and invented new and not-yet-experienced connections between concepts” (p. 267).

In related studies, Roth and his colleagues described the semiotic significance of graphs as signs representing objects and processes (Roth, Bowen, & Masciotra, 2002), as well as the role of gestures and rough-draft talk, which they believe support the subsequent evolution of more structured talk, iconic objects, and eventually abstract communication tools, including symbols and writing (Roth & Lawless, 2002). “Gestures are a medium on which language can piggyback in its development” (Roth & Welzel, 2001). The authors suggested that, because gestures frequently are used to refer to materials in the laboratory, students should not be sent home to write laboratory reports until they have had the opportunity to discuss the complex conceptual issues explored in the teaching laboratory.

## **Cultural Considerations**

The interaction of culture, language, and schooling has been a productive focus of research in a number of disciplines. A great deal is known, for example, about how and why differences between the cultures and languages of school and home can be problematic for students (Au & Mason, 1983; Shultz, Erickson, & Florio, 1982). Even among speakers of the same language, problems may arise if the home register does not match the privileged formal register of schools (Bernstein, 1961). The dynamics of communication between linguistic and ethnic minority and majority speakers continues to be an active and interesting area of work (see, e.g., Moje, Collazo, Carrillo, & Marx, 2001; Stoddart, Pinal, Latzke, & Canaday, 2002). Lee’s (1999) study of south Florida children’s attributions of Hurricane Andrew demonstrated gender, socioeconomic, and ethnicity effects, not only with respect to what the children knew, but also where they got their information. Lee and Fradd (1996) emphasized that although culture may sometimes contribute to misconceptions, and that scientific practices like questioning and public skepticism may clash with some cultural norms, culture also provides metaphors and other linguistic resources that we are only beginning to understand.

## **Writing**

Although my comments have focused primarily on spoken language, there is a growing literature on how writing functions in the development of knowledge. For

example, Keys has shown how collaborative writing can enhance students' constructions of scientific concepts (Keys, 1994, 1999) and the quality of their reasoning (Keys, 1995). She and her colleagues developed a Science Writing Heuristic as an alternative to the traditional laboratory report and reported that it promotes students' generation of assertions from data; making connections among procedures, data, evidence, and claims; and metacognition (Keys, Hand, Prain, & Collins, 1999). Positive outcomes from interventions using diverse types of writing tasks have been reported, although the students themselves may not see writing as a tool for knowledge development (Prain & Hand, 1999).

Talking and writing yield different outcomes because of their different natures. Rivard and Straw (2000) noted:

Talk is important for sharing, clarifying, and distributing scientific ideas among peers, while asking questions, hypothesizing, explaining, and formulating ideas together all appear to be important mechanisms during discussions. The use of writing appears to be important for refining and consolidating new ideas with prior knowledge. These two modalities appear to be dialectical: talk is social, divergent, and generative, whereas writing is personal, convergent, and reflective. (p. 588)

Both are important for doing science in classrooms: just as it is through the public processes of formal science that objectivity is pursued, via intersubjective means.

## How Language Works in Science

Language is central to science. It is the medium through which claims are made and challenged, empirical methods and data are recorded, and the story of inquiry unfolds. Language is not just a vehicle for transmitting scientific information; the history of science reveals that analogies, for example, are a powerful conceptual resource for scientific discovery and understanding (Dörries, 2002). Scientific language is rich with specialized terms that have metaphorical origins (Sutton, 1992).

Compared with students, scientists, not surprisingly, hold much more sophisticated understandings about how to make knowledge claims from data. They are more likely to prioritize rhetorically the relationship between empirical evidence and conclusions, and they attribute this ability to their earlier socialization to science. In contrast, middle-school science students rely more upon their personal views to evaluate claims (Hogan & Maglienti, 2001). Nevertheless, scientists generally believe that the writing process involves knowledge telling, not knowledge building. Their writing tends to be narrowly focused on a specific genre, target audience, and approach (Yore, Hand, & Prain, 2002).

The experimental article is a specialized genre with an interesting history. For example, the detachment and emotionlessness of the form may have helped to reduce factionalism in science (Bazerman, 1988). Scientific writing is lexically dense because it is replete with colorful, invented words that reduce complex processes to singular identities (Halliday & Martin, 1993) (e.g., *photosynthesis* or *cellular automaton*). Also commonly invented are scientific discoveries, which are often reconstructed after the dust settles, fixed in time retrospectively by a scientific community (Branigan, 1981; Woolgar, 1976). But the more startling the claim, the more likely it is that there will be dust to settle. Discursive consensus in science is not as clean or as

common as is generally believed. Intellectual divergence is normal, and the interpretations of scientists may vary with their own sociocultural context (Mulkey, 1991).

Nevertheless, it would be an unusual scientific research manuscript that began with a personal statement about the investigator's gender, race, religion, or ethnicity. The official registers of science do not document an investigator's personal and social values, beliefs, and commitments, because, after all, facts speak for themselves. The status of science is attributable in part to persistent myths. As Helen Longino (1990) noted, science achieves objectivity through social means. We ought to be willing to talk about it. Furthermore, students of science need those opportunities as well. Longino (2002) offered four criteria for effective scientific discourse: (a) public venues for the critical review of methods, facts, and the interpretation of data; (b) an expectation of uptake—that investigators will respond to the substance of public criticism; (c) the existence of public standards for evaluating claims, such as the criterion that claims refer specifically to data in ways that can be generally understood; and (d) that discourse occurs in a context of tempered intellectual equality—one that recognizes inevitable differences in participants' knowledge without denying the less knowledgeable opportunities to challenge.

## CONCLUSION AND IMPLICATIONS

Table 3.1 updates and extends Sutton's (1998) framework. To his two articulations of the role of language—1. a system for transmitting information, and 2. an interpretive system for making sense of experience—I have added a third column: a tool for participation in communities of practice. This third perspective reflects a contemporary emphasis on learning as a social accomplishment. Formal science is much more than Scientist A convincing Scientist B that X is true. Scientist A's conception of X is almost always the product of extensive work in a local community of practice (such as a lab group), and the proposed definition of X may have emerged there from a complex iteration of experiments, inscriptions, translations, conversations, arguments, informal talks, feedback from peers outside the group, methodological training, new experiments, etc. (see Knorr-Cetina, 1983). At the broader disciplinary level, Scientist A and Scientist B probably share assumptions and understandings that are not recognized by others. Scientist C (and her group) may be exploring the same scientific terrain with very different tools and assumptions, leading to very different conclusions. Eventually, an agonistic struggle is likely, but as Longino (1990) notes, that is the point of science. It is in the expectation and practice of public argument that science progresses. Conflict is not only permissible, it is necessary. This does not mean that science is nothing more than mob psychology. Usually arguments must be based on observable phenomena, but what counts as an observation is something we agree to agree about.

An important problem for researchers using sociocultural tools—at least in the United States—is that we are working in an era of accountability, and political forces demand “objective” measures of student learning and educational productivity. Today's emphasis on individual standardized testing is based on an assumption that learning is an individual accomplishment. One implication of a sociocultural perspective is that we need to develop better tools for evaluating learning in complex social environments. Affordable new tools for video recording and analysis

**TABLE 3.1.**  
**Changing Perspectives on the Role of Language in Science and Science Teaching**

Characteristic*	Role of Language		
	<i>A system for transmitting information (Sutton, 1998)</i>	<i>An interpretive system for making sense of experience (Sutton, 1998)</i>	<i>A tool for participation in communities of practice</i>
1 What the speaker or writer appears to be doing.	Describing, telling, reporting.	Persuading, suggesting, exploring, figuring.	Contributing to the solution of a shared problem.
2 What listeners or readers think that they are doing.	Receiving, noting, accumulating.	Making sense of another person's intended meaning.	Contributing to the solution of a shared problem.
3 How language is thought to work in learning.	Clear transmission from teacher to learner; importance of teacher's speech.	Re-expression of ideas by learner; importance of learner's speech.	Achievement of a shared understanding. Learning and language as social accomplishments.
4 How language is thought to work in scientific discovery.	We find a fact, label it, and report it to others. Words stand for things.	Our choices of words influence how we and others see things: highlighting some features and ignoring others.	Language is used to persuade, and "discovery" is often constructed only retrospectively.

\*Note. "Characteristic" labels and the next two columns are based on Sutton (1998).

offer great potential for helping researchers study language as an educational outcome, not just a means. However, few science education researchers have had formal training in sociolinguistics; after all, their undergraduate training tends to occur in the sciences. It would benefit our community to support the development of graduate training programs that teach future researchers skills to work with linguistic data.

A related implication is that we need to publicly challenge the prevailing view of learning as an individual accomplishment. We must challenge that view with policymakers and parents as well as within our own research community. Strategically, support for the development of social methods of assessment is likely to require convincing the public of the social nature of real science and demonstrating that the attrition of talent from the scientific work force is in part the result of practices that represent science as the individual accomplishment of unambiguous understandings.

New tools notwithstanding, collecting data in the form of natural language is extraordinarily time-consuming and expensive. Because our community lacks useful standards for the collection, transcription, analysis, cataloging, and use of sociolinguistic data, data collected in one study are unlikely to be used again. Compounding this problem, university institutional review boards today often seek assurances that the use of video recording in precollege classrooms is minimized and that recordings are locked away or destroyed after research is conducted. The development

of standards for sociolinguistic analysis in science education would be a useful effort. These standards should certainly be informed by standards in related fields. However, our needs are likely to be unique, given the gestures and other signs, texts and inscriptions, specialized tools, and shifting group composition that characterize science learning environments. We are likely to be best served by systems that could be used responsibly by researchers who have not had extensive training in linguistics. As part of such an initiative, it would be useful to develop conventions for metadata production and cataloging (e.g., through the Open Archives Initiative, [www.openarchives.org](http://www.openarchives.org)), as well as mechanisms for protecting human subjects without the necessity of locking data away from other researchers. A corpus of such data would be useful in both future research and for training new researchers.

# CHAPTER 4

---

## Attitudinal and Motivational Constructs in Science Learning

Thomas R. Koballa, Jr.

Shawn M. Glynn

*University of Georgia*

This chapter examines the attitudinal and motivational constructs that are closely linked to science learning. First, we present a rationale for the study of attitudes and motivation in the context of science learning. We then discuss the history of attitude research in science education, define constructs prominent in this research, and review recent attitude research findings. We review research methods and instruments, students' attitudes toward science and factors that influence them, and interventions to change students' attitudes. Next, we focus on motivation, highlighting the historical background of theoretical orientations and discussing research on constructs of particular relevance to science education researchers. We conclude our chapter by offering recommendations for future research involving attitudinal and motivational constructs, noting implications for policy and practice.

At this point, we wish to acknowledge that it is impossible within the scope of this chapter to evaluate every significant study in the field of science education that addresses attitudinal or motivational constructs. Our goal is to provide the reader with an overview of the role these constructs play in science learning through strategic sampling of the relevant research.

Throughout this chapter we use the term *construct* to mean a scientific concept that represents a hypothesized psychological function (Snow, Corno, & Jackson, 1996). Attitudinal and motivational constructs are used to account for and infer patterns of science-related thinking, emotion, and action. They tend to be relatively enduring within a person, but have the potential to change. According to Snow et al. (1996), a construct identifies a unique dimension on which all persons differ by degree and should be represented by more than one kind of data.

Effective science instruction has the potential to improve attitudes toward science and heighten the motivation to learn science. Hands-on science activities, lab-

oratory work, field study, and inquiry-oriented lessons tend to have these goals. Attitudinal and motivational constructs may also serve useful purposes in the context of science program evaluation and national comparisons. Of course, science instruction that is purposely developed to influence attitudes and motives may be construed as indoctrination (Koballa, 1992), raising ethical questions in some circumstances. In addition, there are attitudinal and motivational constructs that may be considered as both entry characteristics and outcomes of science instruction (Bloom, 1976). For example, motivation to enroll in elective science courses and positive attitudes toward chemistry are just as likely to be considered important instructional outcomes as they are determinants of whether a person will engage in certain science learning experiences.

An important reason for examining attitudinal and motivational constructs in science education is to understand the ways in which they affect student learning in the cognitive arena. Pintrich, Marx, and Boyle (1993) described attitudinal and motivational constructs as moderators of a learner's conceptual change and suggest that they may influence science learning in the short term and over longer periods of time. Researchers have studied these relationships intensively as individual learner differences and caution against forming expected "straightforward monotone relations" between such constructs and cognitive learning (Snow et al., 1996, p. 246). Furthermore, these relationships are influenced by contextual factors, including classroom organization, teacher authority, the nature of classroom academic tasks, and evaluation structure (Pintrich et al., 1993). These contextual factors may serve to strengthen the relations between attitudinal and motivational constructs and science learning as well as to weaken them.

Attitudinal and motivational constructs also are associated with students' actions that are considered precursors to science learning and achievement. Often, attitudes and motives are considered predictors of students' science-related decisions that affect learning, such as attending class, reading textbook assignments, and completing homework. However, the influence of attitudes and motives on science learning and achievement has tended to be difficult to document through research.

Finally, attitude and motivation are constructs of the affective domain. And although the affective dimensions of science learning have long been recognized as important, they have received much less attention by researchers than have the cognitive dimensions. Reasons for this imbalance include the "archetypal image of science itself," where reason is separated from feeling, and the "long-standing cognitive tradition" of science education research (Alsop & Watts, 2003, p. 1044). A contemporary view is that the "affective dimension is not just a simple catalyst, but a necessary condition for learning to occur" (Perrier & Nsengiyumva, 2003, p. 1124). Attitude and motivation are indeed the most critically important constructs of the affective domain in science education.

## ATTITUDES

Attitudinal constructs have been part of the science education literature for more than a century; however, the interest in students' science-related attitudes among researchers and practitioners has waxed and waned over the years. According to Jones (1998), waxing interest in any research topic may result from factors ranging

from convenient research paradigms and new measurement instruments to prestige of the investigator, funding priorities, and theoretical power. Waning interest, on the other hand, may result from redirection to other emerging research areas, achieving solutions to previous research problems, and research activity reaching an empirical plateau. Factors such as these have caused research on students' science-related attitudes to wax and wane.

## Historical Background and Theoretical Orientations

John Dewey's philosophy served as an early inspiration for attitude research in science education. Dewey (1916) underscored the need for teaching scientific attitudes as an important aspect of educating reflective thinkers in the inaugural issue of the journal *General Science Quarterly*, which later became *Science Education*. He believed that science instruction should foster such mental attitudes as intellectual integrity, interest in testing opinions and beliefs, and open-mindedness rather than communicate a fixed body of information (Dewey, 1934). Many agreed with Dewey's thinking about scientific attitudes and translated it into practice. An early effort by Weller (1933) involved the development and use of a true-false scale to determine whether scientific attitudes could be taught. Others developed scales to measure elements of scientific attitude (Koslow & Nay, 1976) and sought to determine whether scientific attitudes can be changed by instruction (Charen, 1966).

Pioneering work on attitude measurement (Likert, 1932; Thurstone, 1928) and theoretical ideas about attitude and its relationship to behavior (Sherif, Sherif, & Nebergall, 1965) were major influences on science attitude research. In the 1960s, research on students' attitudes toward science, scientists, and science learning appeared regularly in the science education literature (e.g., Weinstock, 1967). Science educators began to distinguish "attitudes toward science" from "scientific attitudes," also called *scientific attributes*. This new label stems from the notion that scientific attitudes, such as open-mindedness, embody the attributes of scientists that are considered desirable in students (Koballa & Crawley, 1985).

The 1970s and 1980s saw a proliferation of research on students' attitudes toward science; however, research interest in scientific attitudes waned. This shift in interest from scientific attitudes to attitudes toward science was attributed to the understanding that learning about the modes of thinking associated with scientific attitudes does not mean that students will adopt them as their own (Schibeci, 1984). In other words, students may hold favorable or unfavorable attitudes toward these scientific attitudes. Attitudes came to be viewed as both the facilitators and products of science learning and research efforts focused on documenting student attitudes and their relationship to science achievement. Highlighting the research of this period was the learning theory-based program led by Shrigley (1983) that addressed the influence of persuasive messages on science attitudes and the development of Likert-type attitude scales.

Attitude research in science education began to wane in the 1990s, in part because attitude researchers seemed to reach an empirical plateau. Many studies produced results that provided little direction for improving classroom practice or advancing research in the field. For example, some studies showed favorable effects of activity-oriented instruction on students' attitudes toward science, whereas others

did not (see Simpson, Koballa, Oliver, & Crawley, 1994). A second reason for the decline is that the research paradigms in social psychology and educational psychology that had influenced attitude research in science education shifted from a behavioral to a more cognitive orientation (Richardson, 1996). This shift in theoretical orientation saw attitudes aligned with affect, or feeling and belief with cognition, as exemplified in studies based on Ajzen & Fishbein's (1980) theory of reasoned action (see Crawley & Koballa, 1994). With the separation of attitudes from cognition, and the emergence of beliefs as a construct thought to explain the actions of learners, attitudes became less important.

Research on students' science-related attitudes is again receiving increased attention. The disturbing decreases in science course enrollments at the secondary and post-secondary levels, particularly in Western countries, the disdain expressed by many students for school science, and the promise of new research methods have prompted renewed interest in attitude research (Osborne, Simon, & Collins, 2003). Exemplifying this renewed interest is the special issue on affect edited by Alsop and Watts (2003) in the *International Journal of Science Education*, which included three articles that address aspects of students' attitudes.

## Attitudinal Constructs

Unfortunately, issues of definition and meaning have hampered the advancement of attitude research in science education. School science is typically the focus of investigations, but often this is not made clear in reports of science attitude research. Osborne, Driver, and Simon (1998) contend that attitude researchers should consider the elements of science in society, school science, and scientific careers separately, defining them carefully. But attitude has been defined in many ways and has, unfortunately, often been used interchangeably with terms such as *interest*, *value*, *motivation*, and *opinion*. This confusion is unnecessary because quite specific definitions appear in the attitude literature (e.g., Ramsden, 1998; Schibeci, 1984; Shrigley, Koballa, & Simpson, 1988).

An attitude is "a general and enduring positive or negative feeling about some person, object, or issue" (Petty & Cacioppo, 1981, p. 7). *I love science*, *I hate my science teacher*, and *Science experiments are wonderful!* reflect attitudes because they express general positive or negative feelings about something. This definition distinguishes attitude from related terms such as *value*, *belief*, and *opinion*. Values are more complex and broader than attitudes and are more enduring (Trenholm, 1989). Examples of values are equality, justice, and symmetry in nature. Beliefs are often described as the cognitive basis for attitudes (Ajzen & Fishbein, 1980); they provide information about a person, object, or issue that may be used in forming an attitude. *Science is fun*, *My science teacher is smart*, and *Animal dissection should be banned* all reflect beliefs. Opinions are cast as verbal expressions of attitudes and historically have been used to represent not only attitudes but also the constructs of cognition, evaluation, and behavior (Shrigley, Koballa, & Simpson, 1988). When considered in relation to one another, a person will have far fewer values than attitudes or beliefs and many more beliefs than attitudes.

The relationship between attitude, belief, and behavior was presented in a causal model in research based on the theory of reasoned action (e.g., Crawley & Black,

1992). Attitude is the overall evaluation of a highly specific behavior that is defined in terms of action, target, context, and time. The overall evaluation of the behavior, called *attitude toward the behavior* (AB), is the affective component of the model. Attitude toward the behavior is a significant determinant of intention to engage in the behavior, the conative component of the model, called *behavioral intention* (BI). Personal beliefs, the cognitive element of the model, are the determinants of attitude. According to Simpson et al. (1994): "Each belief about the behavior links the behavior with a specific attribute (a characteristic, outcome, or event). The strength of the link between an attribute and the object (called behavioral belief, *b*) is weighted by the attribute's subjective evaluation (called outcome evaluation, *e*) through the expectancy value theorem" (p. 222). The summed product of each salient belief by its associated evaluation is the cognitive or belief-based estimate of attitude, called attitude toward the behavior (AB).

Feeling and emotion are other constructs considered in science education attitude research. According to Teixeira dos Santos and Mortimer (2003), "the word *feeling* is used to characterize the mental experience of an emotion, and the word *emotion* is used to describe the organic reactions to external stimuli" (p. 1197). Basing their definitions of these terms in the work of Damasio (1994), these researchers explain that while feelings cannot be observed, the emotions that prompt feeling are observable. The emotional states of science students and teachers that are detectable through observation of body posture, body movement, and contraction of facial musculature include anger, annoyance, joy, and satisfaction. *Mood* is the term used to describe a long-term emotional climate (Damasio, 1994; Teixeira dos Santos & Mortimer, 2003).

Reaching a universal agreement on definitions of attitude and its related terms is unlikely to occur in the near future and may even be undesirable. It is for this reason that Snow et al. (1996) recommended that it is "important not to belabor definitions unduly, even while seeking common agreement on some convenient and useful terminology" (p. 247). We suggest that science educators heed this recommendation when conducting and interpreting attitude research.

## Research Methods and Instruments

The methodological approaches used in studying students' science-related attitudes are increasing in their variety. While most studies continue to make use of self-report instruments that provide quantitative measures of attitude, investigators are also employing student drawings, personal interviews, and physiological expression as indicators of attitudes. Furthermore, the research methods reveal different levels of emotiveness, ranging from "the detached, statistical analysis of attitudes to the personalized, emotionally charged account[s] of teaching and learning" (Alsop & Watts, 2003, p. 1044). In this regard, it comes as no surprise that the various methodological approaches employed in the research reflect, and in a sense are limited by, the strategies used to collect and interpret attitudinal data. For example, Siegel and Ranney (2003) used quantitative modeling and Rasch analysis to develop and test the usefulness of the *Changes in Attitudes about the Relevance of Science* (CARS) questionnaire. In contrast, the ethnographic approaches highlighted in the research of Palmer (1997) and Pilburn and Baker (1993) used interviews and researchers' field

notes. In the study by Teixeira dos Santos and Mortimer (2003), which is anchored in work of Damasio (1994) on emotions and feelings, videotapes of lessons were used to attend to such details as personal posture, gestures, and facial expressions in constructing understandings of emotion and attitudes. Stretching the methodological envelope of science attitude research are studies like that reported by Perrier and Nsengiyumva (2003). Basing their work on trauma recovery therapy, these researchers used data gleaned from photographs and the contents of personal diaries to construct a vivid description of the influence of inquiry-based science activities on the attitudes of orphans in war-ravaged Rwanda.

## Attitude Instruments

The self-report instruments used in much of the research address one or more dimensions of attitude. An example of a unidimensional instrument is the *Attitude Toward Science Scale* (Francis & Greer, 1999), which has only 20 items and purports to measure secondary students' attitude toward science. A second example is the *Changes in Attitudes about the Relevance of Science* questionnaire (Siegel & Ranney, 2003), which includes three equally balanced versions to overcome problems associated with assessing students' attitudes over multiple intervals. In comparison, the scale developed by Pell and Jarvis (2001) includes subscales that measure the five dimensions of *liking science*, *independent investigator*, *science enthusiasm*, *the social context of science*, and *science as a difficult subject*. Excluding instrument development influenced by the theoretical work of Ajzen and Fishbein (1980), science attitude instruments typically address the evaluative or affective component of attitude and do not distinguish among the cognitive, affective, and conative components that constitute the attitude trilogy. Some of these instruments (e.g., West, Hailes, & Sammons, 1997) that have been designed for young children make use of smiley faces rather than words, in an effort to better capture the children's expressions of attitude. We present summary data for a sampling of recently developed attitude instruments in Table 4.1.

Instrument reliability and validity are important qualities of attitude scales. Content analysis, exploratory factor analyses, item analyses, correlations between subscales, correlations between attitude scale scores and the number of science-related subjects studied, and student interviews are among the tests and procedures used by researchers to explain the reliability and validity of their instruments (Francis & Greer, 1999; Pell & Jarvis, 2001; Siegel & Ranney, 2003). It is recognized that attitude scale construction is a multistep process that may take more than a year to complete (Bennett, Rollnick, Green, & White, 2001). In addition, instrument reliability and validity need to be reestablished when an instrument is modified or used with a population that is different from the one for which it was originally developed. Unfortunately, attitude instruments are sometimes selected for use without adequate attention to reliability and validity (e.g., Terry & Baird, 1997).

There are two limitations commonly associated with science attitude scales: (a) the limited amount of information yielded about the respondents' attitudes and (b) the inclusion of items generated by researchers who do not share the mindset of the respondents (Pilburn & Baker, 1993). These limitations have been addressed in several ways by science education researchers. One strategy involves scale

**TABLE 4.1.**  
**Summary Data for Sample Attitude Instruments**

<i>Developers and instrument focus</i>	<i>Instrument format</i>	<i>Sample items</i>
Thompson and Mintzes's (2002) Shark Attitude Inventory measures the attitudes toward sharks of fifth-grade students through senior citizens.	Five-point Likert scale, with response options ranging from <i>strongly agree</i> to <i>strongly disagree</i> across four subscales.	I would like to touch a shark. Sharks should not be protected if protecting them makes shark fishermen lose money.
Francis and Greer (1999) developed an instrument to measure secondary school students' attitudes towards science.	A 20-item unidimensional instrument arranged for scoring on a 3-point Likert scale, with <i>not certain</i> as the midpoint response.	Science has ruined the environment. Studying science gives me great pleasure.
Pell and Jarvis's (2001) instrument assesses the attitudes to science of 5- to 11-year-old children.	Five-point "smiley" face Likert scoring scheme across five attitude subscales that include only positively worded items.	How do you feel about . . . Doing science experiments. Watching the teacher do an experiment.
Bennett, Rollnick, Green, and White's (2001) instrument measures university students' attitudes toward the study of chemistry.	Patterned after Aikenhead and Ryan's VOSTS, the multiple-choice items include response options that combine evaluation and explanation.	I like it when the lecturer gives us small tasks to do in lecture. A. I AGREE with this statement because it improves my understanding. E. I DISAGREE with this statement because it increases the noise and wastes time. X. None of the above statements reflect my view, which is . . .
The Parkinson, Hendley, Tanner, and Stable (1998) questionnaire was developed to assess the attitudes toward science of age 13 pupils in England and Wales.	Statements generated by pupils were selected for inclusion on the 34-item scale. Scoring is based on a 4-point Likert scale.	I like doing experiments in science lessons. More time should be spent on science at school.
Siegel and Ranney's (2003) Changes in Attitude about the Relevance of Science (CARS) questionnaire was designed for use with adolescents.	Three versions for repeated measures were developed. Scoring for each 20-item version is based on a 5-point Likert scale with an additional <i>don't understand</i> response option.	Science helps me to make sensible decisions. The things I do in science have nothing to do with the real world.

construction in which researchers solicit input from a sample of respondents. Crawley and Koballa (1992) questioned a representative sample of Hispanic-American students and used the students' responses to construct a scale to assess attitudes toward chemistry enrollment. Along similar lines, Bennett et al. (2001) and Ellis, Killip, and Bennett (2000) solicited student input in developing multiple-choice attitude scale items. Guided by work on the *Views on Science-Technology-Society* instrument (Aikenhead & Ryan, 1992), they used data from students to construct four or more statements for each scale item that are expressions of agreement or disagreement with the item and reasons for agreeing or disagreeing. For example, for the scale item *Scientists do a wide variety of jobs*, sample statements are: "I AGREE because they do jobs ranging from designing new medicines to being astronauts," and "I DISAGREE because scientists tend to concentrate on one thing" (Ellis et al., 2000, p. 25).

## Drawing

Finson (2002) reviewed efforts since 1957 to use drawings to gather information about one aspect of students' attitudes toward science, perceptions of scientists. The image that school students hold of scientists tends to be stereotypical and rather negative, with scientists most often depicted as men with unkempt hair, wearing glasses and white lab coats, and working alone in laboratories. He concluded that Chamber's *Draw-a-Scientist Test* and the more recently developed *Draw-a-Scientist Checklist* are reliable and valid instruments for gathering data about students' perceptions of scientists and recommends that interviewing students about their drawings can enhance researchers' interpretations of students' perceptions. Finson also cautioned researchers about assuming that a student's drawing provides the definitive image of his or her perception of a scientist because students may hold multiple images of scientists that differ depending on context and recent exposure.

## Interview

Other researchers have turned to student interviews as a way to overcome the limitations associated with attitude scales and to augment the data provided by the scales. In an effort to determine more about the meaning associated with students' images of scientists, Palmer (1997) interviewed upper elementary and high school students about their understandings of scientists and their work in an environmental context. From an analysis of 125 interviews, he concluded that students hold both private perceptions and stereotyped images of scientists and their work. The findings of Palmer's study suggest that drawings may not encourage students to express the full range of their perceptions about scientists. Pilburn and Baker (1993) also interviewed students with the use of a semi-structured protocol and employed a qualitative data analysis approach to gauge students' attitudes. Students were questioned about their attitudes toward science and school, academic and career goals, and what improvements they would make to science class if they were the teacher. By changing the wording of questions to suit the age of their student participants and following initial student responses with additional probing questions, Pilburn and Baker gathered attitude data from students in kindergarten through

grade 12. They concluded from their work that student interviews provide useful information about students' attitudes toward science.

### **Attitudes and What Influences Them**

Despite the limitations associated with attitude scales and other techniques used to gather attitudinal data, what they reveal provides valuable insight into students' science attitudes. A number of studies reported that although children at the primary level hold positive feelings about science, attitude scores decline as students progress through the grades (George, 2000; Jurd, 2001; Osborne et al., 1998; Reid & Skryabina, 2002). This decline, which is particularly evident in the middle school and high school years, is likely related in some way to the types of science courses in which the students are enrolled and the science self-concept that they develop as a result of these courses (George, 2000). However, it is also possible that the decline is a result of students' inability to separate their attitudes toward science from their attitudes toward school. Morrell and Lederman's (1998) investigation of the relationship between students' attitudes toward school and attitudes toward classroom science revealed a weak relationship between the two attitudes. Their findings led them to conclude that students' less-than-favorable attitudes toward science are not part of a bigger school-related attitude problem and that attitudes toward science could not be improved by addressing students' attitudes toward school. Also, in contrast to the findings of the other studies previously discussed, Morrell and Lederman found no evidence of declining attitudes toward science for older students.

### **Gender**

Despite more than two decades of attention to issues of gender equity in science education, differences between girls and boys still persist regarding attitudes toward science. The findings of several recent studies indicate that the differences develop during the elementary school years (Andre, Whigham, Hendrickson, & Chambers, 1999; Jones, Howe, & Rua, 2000). Consistent with previous findings (e.g., Weinburgh, 1995), these studies report that girls tend to have less favorable attitudes toward science than boys, and that girls' science-related interests are more focused on the biological than physical sciences. Dawson (2000) reported similar trends in a study of primary-age boys and girls in Australia and concluded that little has changed in two decades. In contrast, Andre et al. (1999) found no differences between girls and boys in their liking of life science or physical science. However, their comparison of students' preferences for school subjects revealed that, in the elementary grades, girls prefer reading and language arts over physical science. Their findings led them to speculate that the attitudinal differences often detected between boys and girls are not a result of girls liking physical science less than boys, but their liking reading more.

Differences between boys and girls also extend to the stereotypic images that they hold of science and scientists. Boys and girls view science as a male-dominated school subject and consider science to be a male profession (Andre et al., 1999). Students in Taiwan, as is the case in other countries, are influenced by the stereotypic images of science and scientists that are often depicted in the popular media. How-

ever, the impact of these stereotypes on students' interest in a science career seems to decline as students advance in school, with girls more so than boys open to the idea of women working as scientists (She, 1998). One possible interpretation of this finding is that students hold both private perceptions of scientists and their work in addition to the public stereotypes (Palmer, 1997).

Explanations for these gender differences include both physiological and sociological functions. More credence is given to sociological factors, as indicated by the widespread support for broad-based intervention programs such as EQUALS and *Family Science* that target the science attitudes and experiences of girls. The most frequently given sociological reasons for why girls have less positive attitudes toward science than do boys include the differential cultural expectations placed on girls and boys by parents, teachers, and peers, and the different experiences in science, both in school and out of it, provided to boys and girls (Jones et al., 2000; She, 1998).

### **Achievement and Science-Related Decisions**

A study of Australian students using data collected as part of the Third International Mathematics and Science Study (TIMSS) revealed that attitudes toward science have a strong effect on achievement (Webster & Fisher, 2000). Attitudes were found not to predict physics achievement (Willson, Ackerman, & Malave, 2000) and to be related directly to the science achievement of American students (Singh, Granville, & Dika, 2002). The narrow interpretation of attitude applied in many studies might explain the weak relationships found between attitude and achievement (Rennie & Punch, 1991), as might the narrow definitions of achievement. Research in this area still tends to corroborate Fraser's (1982) position that improving science attitudes will not necessarily lead to science achievement gains.

The influence of attitudes on students' decisions such as enrolling in elective science courses and pursuing careers in science was also examined in recent studies. The attractiveness of careers in science and higher education courses, the relevance of courses for future study and careers, self-confidence in science, and science interests are among the factors found to influence students' science course-taking and career decisions (Robertson, 2000; Woolnough & Guo, 1997). Based on a review of earlier studies that produced similar findings, Shrigley (1990) concluded that only under certain conditions should attitudes be expected to predict learners' science-related decisions. These conditions include: (a) when attitude and the decision are measured at the same level of specificity; (b) when social context and individual differences, including cognitive ones, are considered; and (c) when the person's intentions regarding the decision are known. Each of Shrigley's conditions was addressed in Butler's (1999) study, in which he sought to identify the determinants of students' intentions to perform both laboratory and non-laboratory science learning tasks in grades 4 through 8. Butler found that the students' attitudes toward the behavior were better predictors of their intentions to perform both laboratory and non-laboratory science learning tasks than either attitudes toward science or subjective norm, the element of Ajzen and Fishbein's (1980) model that measures social support for engaging in the behavior. A limitation of Butler's study was that the students' actual behaviors were not observed.

## Attitude Change Interventions

Activity-based practical work (Thompson & Soyibo, 2002), learning cycle classes (Cavallo & Laubach, 2001), formally teaching ethical issues (Choi & Cho, 2002), jigsaw cooperative learning groups (De Baz, 2001), student- and teacher-constructed self-teaching resources (McManus, Dunn, & Denig, 2003), video technologies (Escalada & Zollman, 1998; Harwood & McMahon, 1997), inquiry-based summer camps (Gibson & Chase, 2002), and computer-assisted instruction (Soyibo & Hudson, 2000) are among the attitude change interventions evaluated in recent years. Other interventions targeted the attitudes toward sciences of girls and minorities and their continuation in the science pipeline. These included after-school science programs and residential summer science camps as well as year-long science courses that emphasize hands-on and performance-based learning experiences (Ferreira, 2002; Freedman, 2002; Haussler & Hoffmann, 2002; Jayaratne, Thomas, & Trautmann, 2003; Jovanovic & Dreves, 1998; Phillips, Barrow, & Chandrasekhar, 2002).

Overall, the interventions were well planned and quite complex and incorporated a host of activities believed to enhance attitudes toward science and commitment to the study of science. The results of these studies point to the success of some interventions, particularly those that engage learners in hands-on science activities and that stress the relevance of science through issue-based experiences (e.g., Haussler & Hoffman, 2002; Perrier & Nsengiyumva, 2003; Siegel & Ranney, 2003).

## MOTIVATION

As we turn to a discussion of the role of motivation in learning science, it is important to recognize that attitudes influence motivation, which in turn influences learning, and ultimately behavior. This sequence is relevant to investigating learning in many science contexts, although the relationships among these variables can be more complex and interactive than this basic sequence suggests.

It is also important to recognize that motivation has not been manipulated or assessed as frequently as attitudes by science education researchers, although historically science education research on learning has been significantly influenced by the theoretical orientations that researchers have adopted toward motivation. As science education researchers respond to current national initiatives to foster students' science achievement, the emphasis placed on motivation has been increasing, as reflected in recent articles with titles such as "Skill and will: The role of motivation and cognition in the learning of college chemistry" (Zusho & Pintrich, 2003, p. 1081). Ten years ago, in the *Handbook of Research on Science Teaching and Learning* (Gabel, 1994), the word *attitude* appeared in more than 45 subject index listings and sub-listings, whereas the word *motivation* appeared only three times. The inclusion of *motivation* in the present *Handbook* in a chapter with attitudes attests to greater value being placed on the role that motivation plays in science learning.

A discussion of motivation should begin with a definition. Motivation is an internal state that arouses, directs, and sustains students' behavior. The study of motivation by science education researchers attempts to explain why students strive for particular goals when learning science, how intensively they strive, how long they strive, and what feelings and emotions characterize them in this process.

In this section, we discuss the research orientations and constructs that play important roles in learning science. One feature of motivation research has been the creation of many motivational constructs. Unfortunately, the constructs are often unclear in their definitions and functions, as Schunk (2000) observed:

The field of motivation is beset with a lack of clear definition of motivational constructs and specification of their operation within larger theoretical frameworks. These problems have implications for interpretation of research results and applications to practice. . . . At times educational researchers—perhaps unwittingly—have behaved like Humpty Dumpty by renaming or defining motivational constructs to fit their theoretical models and research methodologies with insufficient attention paid to extant conceptualizations. (p. 116)

Our goal is to provide an overview of current motivation research in learning science that stresses the most widely accepted and empirically supported findings about student motivation. Cognizant of the conceptual clarity issue raised by Schunk and others (e.g., Pintrich, 2003), we have endeavored to describe, in as straightforward a fashion as possible, the orientations and constructs that are of particular relevance to science education researchers. The broad theoretical orientations that researchers adopt, either explicitly or implicitly, influence the assumptions they make about the more specific constructs they study. This point is important because researchers with different theoretical orientations often study the same constructs. They may even define them similarly but interpret them differently.

## Historical Background and Theoretical Orientations

Historically, science education researchers have adopted four orientations to motivation when studying learning. We refer to these orientations as *behavioral*, *humanistic*, *cognitive*, and *social*. Although these orientations are described separately, it should be kept in mind that many science education researchers adopt aspects of more than one orientation when studying learning, with hybrids resulting, such as a *cognitive-social* orientation (Pintrich, 2003). In addition, the orientations researchers adopt often are determined by the particular topic they are studying.

Science education researchers with a behavioral orientation to motivation focus on concepts such as *incentive* and *reinforcement*. An incentive is something that makes a behavior more or less likely to occur. For example, the promise of a field trip to a quarry to study rock strata could serve as an incentive for students to perform well on a geology test. Participation in the trip itself could be the reinforcement.

Researchers have identified potential problems associated with the use of incentives and reinforcements to shape behavior in a science classroom. One major problem is that the students may not develop *intrinsic motivation* to learn. In some conditions, when students are offered incentives for doing tasks they naturally find motivating, their desire to perform the tasks can decrease (Cameron & Pierce, 2002; Deci, Koestner, & Ryan, 1999). External incentives also can focus students' attention on the incentives as ends in themselves, rather than serve as a kind of feedback on the progress students are making.

Science education researchers with a humanistic orientation to motivation emphasize students' capacity for personal growth, their freedom to choose their des-

tiny, and their desire to achieve and excel. Humanists have used various constructs to express students' need to reach their potential. Maslow (1968, 1970) described this need as *self-actualization*. Maslow proposed that everyone has a hierarchy of needs: physiological, safety, love and belongingness, esteem, intellectual achievement, aesthetic appreciation, and self-actualization. When basic needs are satisfied, the motivation to fulfill them decreases and the motivation to fulfill the higher-level ones increases. Building upon Maslow's theory, humanists currently investigate students' *actualizing tendency* (Rogers & Freiberg, 1994) and *self-determination* (Deci, Vallerand, Pelletier, & Ryan, 1991).

When science education researchers adopt a cognitive orientation to motivation, they emphasize students' goals, plans, expectations, and attributions (Glynn & Duit, 1995; Glynn, Yeany, & Britton, 1991; Schunk, 1996). An *attribution* is an explanation for the cause of a particular behavior (Weiner, 1986, 1990, 1992). When students respond to instructional events, they are viewed as responding to their attributions about these events. For example, students' motivation to achieve in a particular college biology class could be undermined by the students' attribution (true or false) that all students are receiving high grades because the instructor's grading criteria are lax.

Science education researchers with a social orientation to motivation emphasize students' identities and their interpersonal relationships in the communities that exist inside and outside of school. Students' identities are formed in their communities, and a great deal of science can be learned, both intentionally and incidentally, in them. To maintain their membership in their communities, students are motivated to learn the attitudes, values, and behaviors of those communities (Lave & Wenger, 1991). The process of *modeling* is central to the learning that takes place in those communities (Greeno, Collins, & Resnick, 1996). Science classrooms, museums, nature centers, aquariums, and even websites are being conceptualized as *learning communities*. One template for conceptualizing a science-learning community was developed by Scardamalia and Bereiter (1996), who used a computer system called *Computer-Supported Intentional Learning Environment* (CSILE) to prompt students to collaborate by posing questions and hypotheses and discussing findings. Brown and Campione (1996) developed another template that made innovative science research projects central to a classroom community.

## Motivational Constructs

According to Brophy (1987), *motivation to learn* is "a student tendency to find academic activities meaningful and worthwhile and to try to derive the intended academic benefits from them" (pp. 205–206). What motivates students to learn science? We answered this question by closely examining the disparate body of research that Schunk (2000) alluded to, integrating the findings, and identifying relevant methods and instruments for the constructs. We noted that the constructs of *arousal*, *anxiety*, *interest*, and *curiosity* all have been found to play important roles, particularly in the creation of *intrinsic motivation*. We also noted that the extent to which science students are intrinsically motivated was found to be influenced by how *self-determined* they are, by their *goal-directed behavior*, by their *self-regulation*, by their *self-efficacy*, and by the *expectations* that teachers have of them.

## Arousal and Anxiety

Arousal, defined as a student's level of alertness and activation (Anderson, 1990), plays an important role in initiating and regulating motivation. Arousal is a state of physical and psychological readiness for action. Too little arousal in students leads to inactivity, boredom, daydreaming, and even sleeping, and too much of it leads to *anxiety*, defined as a "general uneasiness, a sense of foreboding, a feeling of tension" (Hansen, 1977, p. 91). All students experience anxiety from time to time. Some anxiety is good in that it helps motivate science learning. Too little, however, debilitates performance, and so does too much (Cassady & Johnson, 2002).

Most researchers conceptualize anxiety as both a *state*, temporarily associated with a situation such as a science test, and a *trait*, enduringly associated with the individual. As measured by the *State-Trait Anxiety Inventory* (Spielberger, 1983), state anxiety is defined as an unpleasant emotional arousal in response to situations that are perceived as threatening. Trait anxiety, on the other hand, implies the existence of stable individual differences in the tendency to respond with state anxiety in the anticipation of threatening situations.

## Interest and Curiosity

The terms *interest* and *curiosity* are often used interchangeably in the science education literature. A student who is interested or curious about a science topic has a readiness to pursue it. A student's interest in a science topic or activity is "specific, develops over time, is relatively stable, and is associated with personal significance, positive emotions, high value, and increased knowledge" (Wade, 2001, p. 245). This particular kind of interest is known as *individual* or *personal*; it should be distinguished from *situational* interest that is evoked by things in the environment that create a momentary interest. When students do poorly in science and other areas, what is the most common reason? "Lack of interest" was rated highest by more than 200 middle school students studied by Vispoel and Austin (1995). In some cases, ratings of low interest can be ego-protective—students wish to attribute their poor performance to an external, uncontrollable variable. When students do well, what is the reason? Vispoel and Austin found that middle school students rated effort highest, but interest next highest, in explaining successes. These findings indicate that students perceive interest to be a very important factor in their achievement.

According to Pintrich and Schunk (1996), interest or curiosity is "elicited by activities that present students with information or ideas that are discrepant from their present knowledge or beliefs and that appear surprising or incongruous" (p. 277). This does not mean, however, that the more discrepant the better. Researchers have found that students are most interested in science concepts and phenomena that are moderately novel to them and moderately complex (Berlyne, 1966). When students are very familiar with something, they may ignore it, and when they are unfamiliar with something, particularly if it is complex, they may not find it relevant or meaningful.

One of the most effective means of making science concepts relevant and meaningful to students is the use of analogies during instruction (Glynn & Takahashi, 1998). For example, Paris and Glynn (2004) found that elaborate analogies increased

students' interest in the concepts covered in science texts, as well as their understanding of those concepts. This finding suggests that elaborate analogies can play an important role in strategically regulating students' motivation. The analogies likely do this by establishing in students a sense of self-relevancy, or personal involvement. In the Paris and Glynn study, most of the students indicated that a text with analogies was interesting because it compared an abstract science concept to something more familiar to them. A typical comment was: "I know about photography, so it was more interesting when the eye was compared to a camera."

## **Intrinsic and Extrinsic Motivation**

Motivation to perform an activity for its own sake is intrinsic, whereas motivation to perform it as a means to an end is extrinsic (Pintrich & Schunk, 1996). Intrinsic motivation derives from arousal, interest, and curiosity. Intrinsic motivation taps into the natural human tendency to pursue interests and exercise capabilities (Deci, 1996; Reeve, 1996; Ryan & Deci, 2000). Typically, students who are intrinsically motivated to learn a science concept do not require physical rewards, because the process itself is inherently motivating. On the other hand, when students learn concepts only to earn grades or avoid detention, their motivation is primarily external (Mazlo et al., 2002). Students who are intrinsically motivated to perform a task often experience *flow*, a feeling of enjoyment that occurs when they have developed a sense of mastery and are concentrating intensely on the task at hand (Csikszentmihalyi, 2000). For example, *flow* describes the preoccupation that some students develop with a science fair project to the exclusion of other activities in their lives.

The distinction between intrinsic and extrinsic motivation is difficult to make in some instances. When studying motivational patterns in sixth-grade science classrooms, Lee and Brophy (1996) found it useful to distinguish among students' motives in multiple ways. Students are often motivated to perform tasks for both intrinsic and extrinsic reasons. The student who constructs the science fair project may enjoy the process, particularly because the student selected the topic, but may also be motivated by the prospect of receiving a prize, an award ribbon, or entry into a higher-level science fair.

## **Self-Determination**

Self-determination is the ability to have choices and some degree of control in what we do and how we do it (Deci et al., 1991; Reeve, Hamm, & Nix, 2003). Most people strive to be in charge of their own behavior—to be captains of their own ships. Most people are unhappy when they feel they have lost control, either to another person or to the environment. Deci (1996), in his theory of self-determination, suggested that students in particular need to feel competent and independent. He explained that intrinsically motivated activities promote feelings of competence and independence, whereas extrinsically motivated activities can undermine these feelings. Deci has found that students with self-determined motivation are more likely to achieve at a high level and to be well adjusted emotionally.

When science students have the opportunity to help design their educational activities, they are more likely to benefit from them. According to Garner (1998), "It

is through this self determination, measured though it might be, that wise teachers allow each of their students to guide them to what the students find particularly enjoyable and worth learning" (p. 236). This advice is based on studies such as that by Rainey (1965), who found that high school science students who were allowed to organize their own experiments exhibited greater interest and diligence than students who were required to follow rote directions.

When students lack self-determination, it is difficult for them to feel intrinsically motivated. When they come to believe that their performance in science is mostly uncontrollable, they have developed a failure syndrome or *learned helplessness* (Seligman, 1975). Students who develop learned helplessness are reluctant to engage in science learning. They believe they will fail, so they do not even try. Because they believe they will fail, these students do not practice and improve their science skills and abilities, so they develop cognitive deficiencies. Students with learned helplessness also have emotional problems such as depression and anxiety.

## Goal-Directed Behavior

A science objective or outcome that students pursue is a *goal*, and the process of pursuing it is referred to as *goal-directed behavior*, an important component of *goal theory* (Pintrich & Schunk, 1996). Goal theory builds upon an earlier *expectancy-value theory of achievement motivation* (Atkinson & Raynor, 1978), which posited that behavior is determined by how much students value a particular goal and their expectation of attaining that goal as a result of performing certain behaviors. When students endeavor to identify a substance as the objective of a chemistry lab, they are engaged in goal-directed behavior. Researchers have found that the very act of setting a goal is beneficial to students because it helps them to focus their attention, organize their efforts, persist longer, and develop new strategies (Covington, 2000; Linnenbrink & Pintrich, 2002; Locke & Latham, 1990, 2002; Midgley, Kaplan, & Middleton, 2001; Wentzel, 2000). In classrooms where students and teachers share the goals of student understanding and independent thinking, rather than the memorization and rote recall of science facts, students have higher motivation to learn (Glynn, Muth, & Britton, 1990; Nolen, 2003; Nolen & Haladyna, 1990). Recognizing this, Nicholls (1992) recommends that students be viewed as educational theorists who actively interpret and influence the classroom environment.

Science education researchers often distinguish between *learning goals* (also known as *mastery goals* or *task goals*) and *performance goals* (also known as *ego goals*). Students with learning goals focus on the challenge and mastery of a science task (Meece, Blumenfeld, & Hoyle, 1988). They are not concerned about how many mistakes they make or how they appear to others. These students are primarily interested in mastering the task and task-related strategies. They view mistakes as learning opportunities and do not hesitate to ask others for feedback and help. They are not afraid of failing, because failing does not threaten their sense of self-esteem. As a result, they set reasonably challenging goals, they take risks, and they respond to failure appropriately. When they succeed, they generally attribute it to their own effort. They assume responsibility for learning. They generally perform well in com-

petitive situations, learn fast, and exhibit self-confidence and enthusiasm. They want to acquire mastery, often in an apprenticeship relationship. Students with learning goals are more likely to trust their teachers and adopt the goals set by their teachers as their own. They are also likely to work harder.

Meece et al. (1988) found that students with learning goals were more actively involved in science activities than students with performance goals because the latter were preoccupied with gaining social status, pleasing teachers, and avoiding extra work. Students with performance goals frequently compare their grades with others and choose tasks that are easy for them so they can maximize their grade. They work hard only on graded tasks and are often reluctant to help others achieve (Stipek, 1996). Their self-esteem is based on the external evaluation of their performance, so their esteem can be as fleeting as their last grade on a biology test. They take very few risks and restrict themselves to those skills with which they are most comfortable. If they do not receive positive external evaluations, they often develop ego-protective mechanisms such as procrastination or apathy.

In a study that examined more than 200 middle school students' motivation goals, Meece and Jones (1994) found students tended to feel greater confidence and mastery when science lessons were taught in small groups rather than in large ones. They also found that boys reported greater confidence in their science abilities than girls. More recent studies with middle school and high school students (Britner & Pajares, 2002; DeBacker & Nelson, 1999; Stake & Mares, 2001) suggest that the confidence of girls relative to that of boys is influenced by how science is being taught.

## Self-Regulation

Goal setting is an important aspect of *self-regulated learning* (Schunk & Zimmerman, 1997). Students who are self-regulating know what they want to accomplish when they learn science—they bring appropriate strategies to bear and continually monitor their progress toward their goals. According to Neber and Schommer-Aikins (2002), self-regulated learning can be thought of as a cognitive activity consisting of two components, regulatory strategy use (for planning and monitoring) and cognitive strategy use (for organizing and elaborating). These components are often measured by subscales of the *Motivated Learning Strategies Questionnaire* (Pintrich & DeGroot, 1990), with items such as *In class, I ask myself questions to make sure I know what I have been studying* and *When I am studying a topic, I try to make the material fit together*.

Students' perceptions of *control* are relevant to their self-regulation and motivation to learn science. When students feel they are in control of their learning, they select more challenging tasks, they expend more effort, and they work longer on assignments (Anderman & Young, 1994; Schunk, 1996; Weiner, 1992). Students who feel they are in control are more likely to pick themselves up when they fail, attributing their failure to controllable, internal causes such as a lack of preparation. These students are adaptive and will adopt strategies to increase the likelihood of their success in the future. In contrast, students who typically feel that they are not in control of their learning focus increasingly on their own limitations and become apathetic about learning science.

## Self-Efficacy

Before defining self-efficacy, it is easier to define what it is not. It is not self-concept, nor is it self-esteem (Bong & Clark, 1999). Self-concept is a more general construct that includes self-efficacy. Self-concept refers to global ideas about one's identity and one's role relations to others. According to Bong and Skaalvik (2003), "self-efficacy acts as an active precursor of self-concept development" and "self-concept is colloquially defined as a composite view of oneself" (pp. 1–2). Self-esteem is also a more general construct, and self-efficacy contributes to it. Self-esteem refers to the value one places on himself or herself. In contrast, self-efficacy is not a general personality trait or quality. It makes no sense to speak of a generally "self-efficacious" student.

Bandura (1997) defined self-efficacy as "beliefs in one's capabilities to organize and execute the courses of action required to produce given attainments" (p. 3). When science teachers use the term, they refer to the evaluation that a student makes about his or her personal competence to succeed in a field of science. For example, a student may have high self-efficacy with respect to knowledge and skills in biology, but low self-efficacy with respect to knowledge and skills in physics. In other words, self-efficacy is domain specific—and potentially task specific in a domain. Students' judgments of their self-efficacy in particular areas of science have been found to predict their performance in these areas. For example, Zusho and Pintrich (2003) found that students' self-efficacy was found to be the best predictor of grades in an introductory college chemistry course, even after controlling for prior achievement. Similarly, Joo, Bong, and Choi (2000) found that students' self-efficacy predicted their written test performance in a biology course. In their study, self-efficacy was assessed with questionnaire items similar to this one: "What grade (A through F) do you anticipate earning at the end of the term in biology?" Other questionnaires, such as the *Perceptions of Science Classes Survey* (Kardash & Wallace, 2001, p. 202), have been designed to assess self-efficacy for general science, with items such as "I have a good understanding of basic concepts in science." Given the domain-specific nature of self-efficacy, it may be that questionnaires that address a particular field of science will prove more useful than ones that address science in general.

According to Bandura (1997), a student's sense of self-efficacy is derived from sources such as mastery experiences, vicarious experiences, and social persuasion. Mastery experiences are students' actual experiences, and these have the greatest impact on their sense of efficacy in an area. Successes increase efficacy, and failures lower it. Vicarious experiences, according to Bandura, are those associated with the observation of others ("models") such as teachers, parents, peers, or characters in films (such as "Indiana Jones, archeologist"). The more that students identify with the model, the greater the model's influence on them. Social persuasion, particularly when it comes from a source that students respect, can also influence students and induce them to try harder in science. Social persuasion can reinforce students' self-efficacy in science when they have suffered a temporary setback.

## Expectations and Strategies

The effect of teachers' expectations on student performance is called the *Pygmalion effect* (Rosenthal & Jacobson, 1968), named after a mythological king who created a

statue and then made it come to life. Research findings on the Pygmalion effect have been mixed but generally support the view that the effect does occur and that teachers' expectations can influence student performance in science and other areas (Smith, Jussim, & Eccles, 1999). Science teachers' expectations of students, and the strategies based on these expectations, play an important role in increasing or reducing students' motivation. Researchers have found that teachers who have high expectations of students give cues and prompts that communicate to them their belief that the students can perform well (Good & Brophy, 1997; Rop, 2003). If teachers have high expectations of students, they are less likely to accept poor answers from them, and they are more likely to praise them for good answers. Teachers with low expectations of students are more likely to provide them with inconsistent feedback, sometimes praising inadequate answers, sometimes criticizing them, and sometimes ignoring them (Good & Brophy, 1997). Sometimes, if many teachers in a school adopt low expectations of the students there, a culture of low expectations can permeate the school (Weinstein, Madison, & Kuklinski, 1995).

## RECOMMENDATIONS FOR FUTURE RESEARCH

The role of attitudes and motivation in learning science is a rich area for future research. As views of learning become increasingly constructivistic, it is more important than ever that researchers adopt a comprehensive view of learners that includes affective characteristics. The research reviewed in this chapter clearly shows that science learning cannot be explained solely by examination of cognitive factors. Learners' attitudes and motivation should be taken into account in explanations of science learning. Theoretical orientations and models describing meaningful relationships among affective constructs and cognition are becoming more evident in the research on science learning (Glynn & Koballa, 2007).

The research indicates that the principal means for assessing students' attitudes continues to be scales that produce quantitative scores. Instrument reliability and validity should be considered when one is choosing or modifying scales for use. We recommend that quantitative data gathered with the use of attitude scales be coupled with other forms of data, such as that collected via individual and group interviews, student drawings, log books, and photographs, to provide a more informed understanding of students' attitudes. Equally important, researchers should not be overly concerned with definitions of attitude and related constructs, but strive to seek common agreement for terms useful in their own studies. We found Teixeira dos Santos and Mortimer's (2003) use of personal posture, gesture, and voice intonation as evidence of emotion to be innovative and encourage further exploration of other physiological indicators of attitude. Building on this work, future research may include the examination of facial muscle patterns detectable through electromyographic recordings as evidence of learners' science-related attitudes (see Cacioppo & Petty, 1979).

Theoretical frameworks have not always guided attitude research in science education (Ramsden, 1998). Prominent in past research are the guiding frameworks of Hovland's learning theory approach and Fishbein and Ajzen's theories of reasoned action and planned behavior (Simpson et al., 1994). More recent attitude research has found theoretical grounding in Damasio's (1994) work on emotion and feeling

and the psychotherapy of trauma recovery (Winnicott, 1970), which emphasizes the importance of play and community as elements of the learning process. These frameworks will provide guidance for continued research into the design of interventions to affect attitudes. In addition, psychologists' work on implicit attitudes (see Dovidio, Kawakami, & Beach, 2001) and the differentiated role of beliefs and attitudes in guiding behavior (called the mismatch model; see Millar & Tesser, 1992) may also contribute to the theoretical foundations for future attitude research in science education. It is clear from the research we have reviewed that diversity in theoretical orientation will lead to the use of more and different methodological approaches to investigate learners' science-related attitudes.

With respect to the role of motivation in learning science, a future direction for research is to investigate how different theoretical orientations and constructs relate to one another, rather than create new orientations and constructs simply to be innovative. *Synthesis* and *integration* should be the keywords of future motivational research in science learning (Pintrich, 2003). There is great need to clarify this area of research by examining the similar roles that orientations and constructs can play in fostering science learning (Glynn & Koballa, 2007).

We recommend that motivation researchers avoid simple categorizations such as high versus low anxiety, intrinsic versus extrinsic motivation, and learning versus performance goals. Instead, they should adopt broader perspectives that serve to synthesize orientations and constructs. For example, rather than conceptualize students as having either learning goals *or* performance, researchers should conceptualize students as having a variety of goals, depending upon the context, and endeavor to explain the relationship between students' goals and other motivational constructs such as self-determination and self-efficacy.

## IMPLICATIONS FOR POLICY AND PRACTICE

Although there are certainly positive consequences of current federal initiatives designed to promote student achievement in science and other areas, there are negative ones as well. Because of an increased and often inappropriate emphasis on standardized testing, students are at increased risk of developing poor attitudes and low motivation in the area of science. Science education policy makers must come to understand that although high-stakes testing may serve to inspire some students to achieve at high levels, it serves as a deterrent to learning for many more. They are encouraged to adopt a view of learning in which "affect surrounds cognition," recognizing that "if children are not comfortable or joyful they will not learn, irrespective of how well pedagogical practices are designed" (Alsop & Watts, 2003, p. 1046). Acting from this informed view of science learning, policy makers should press state departments of education and local schools to specifically address affective elements of learning in their science curricula and associated assessment programs. Science learning experiences that are fun and personally fulfilling are likely to foster positive attitudes and heightened motivation toward science learning and lead to improved achievement. Attention to student attitudes and motivation in science curricula will prompt policy makers to become advocates for assessing affective outcomes of learning. Professional learning opportunities should be provided for teachers that will help prepare them to encourage unmotivated science students.

The research on science-related attitudes also has implications for professional practice. Teachers should consider strategies for improving students' attitudes as possible ways to increase enrollment in noncompulsory science courses and enhancing science achievement (Osborne, Simon, & Collins, 2003). Approaches to positively affecting student attitudes include instruction that emphasizes active learning and the relevance of science to daily life. When endeavoring to improve students' attitudes, teachers should consider their own cultural expectations. For example, teachers may unwittingly contribute to the persistent attitudinal differences between boys and girls. Teachers should recognize that students' enjoyment of science may be as important an outcome of school science in the long run as their scores on standardized tests.

Numerous instruments are available to assess the influence of instruction on students' science-related attitudes. When using an available measure, we recommend that teachers recognize that learners are not always willing and able to divulge their true feelings. We also encourage teachers to use interviews, photographs, and student drawings as alternatives to the use of scales and to supplement data gathered with the use of scales.

The research on motivational constructs also has many implications for practice in science education. Some of the most important of these involve the construct of self-determination, because science teachers wish to help students become independent, life-long learners. Science teachers can promote students' self-determination by providing them with appropriate challenges and feedback, by giving them leadership opportunities, by fostering students' relationships with peers and their parents, by creating a positive classroom environment, and by providing them with a role in classroom governance. The result will be greater student interest, sense of competence, creativity, learning, and preference for challenges (Matthews, 1991; Ryan & Grolnick, 1986; Williams, Wiener, Markakis, Reeve, & Deci, 1993).

Effective science teachers know students' self-determination leads to successful learning only when it is accompanied by high self-efficacy. If students have high self-efficacy in science, they will set higher goals, persist longer, expend greater effort, and endeavor to find increasingly better strategies. If students have low efficacy, they will tend to give up easily when science learning becomes difficult (Zimmerman, 2000). Students will increase their self-efficacy and improve their achievement if they adopt short-term goals to judge their progress, use specific learning strategies such as summarizing to help them focus their attention, and receive rewards based on their performance and not just their participation.

In conclusion, in this chapter we have examined the attitudinal and motivational constructs that influence science learning. We have reviewed the research conducted on these constructs, emphasizing the methods and instruments used, and the theoretical orientations in which the constructs are embedded. In addition, we have made specific recommendations for future research on these constructs and drawn implications for policy and practice.

We strongly encourage new and seasoned researchers to advance what is known about how attitudes influence motivation and how motivation influences science learning, and ultimately behavior. Ideally, all students of science should develop positive attitudes that motivate them to achieve at high levels. Their achievement should be reflected not only in their understanding of science and their development of scientific skills, but in their appreciation of the world around them. Ideally,

students of science should learn to use their knowledge and skills to become caretakers of the world, preserving it and enhancing it for generations to come. We encourage science educators, who wish to help students achieve such goals, to embark on programs of research that focus upon how to best foster the growth of students' positive attitudes and their intrinsic motivation to learn science.

## ACKNOWLEDGMENTS

# CHAPTER 5

---

## Classroom Learning Environments

**Barry J. Fraser**

*Curtin University of Technology, Australia*

Because students spend approximately 20,000 hours in classrooms by the time that they graduate from university (Fraser, 2001), their reaction to their teaching-learning experiences are of considerable importance. However, despite the obvious importance of what goes on in school and university classrooms, teachers and researchers have relied heavily and sometimes exclusively on the assessment of academic achievement and other learning outcomes. Although no one would dispute the worth of achievement, it cannot give a complete picture of the educational process.

Although classroom environment is a subtle concept, it can be assessed and studied. A considerable amount of work has been undertaken in many countries in developing methods for investigating how teachers and students perceive the environments in which they work. Remarkable progress has been made over several decades in conceptualizing, assessing, and researching the classroom environment.

Researchers have carried out many dozens of studies of the relationship between student achievement and the quality of the classroom learning environment (Fraser, 1998a). These studies have been carried out in numerous different countries with tens of thousands of students. The consistent and overwhelming evidence from these studies is that the classroom environment strongly influences student outcomes. Therefore, teachers should not feel that it is a waste of time for them to devote time and energy to improving their classroom environments. The research shows that attention to the classroom environment is likely to pay off in terms of improving student outcomes.

A milestone in the historical development of the field of learning environments occurred over 30 years ago when Herbert Walberg and Rudolf Moos began seminal independent programs of research (Fraser, 1986; Fraser & Walberg, 1991; Moos, 1974). In turn, the pioneering work of Walberg and Moos built upon the ideas of Lewin (1936) and Murray (1938), presented several decades before. Lewin's field theory recognized that both the environment and its interaction with personal characteristics of the individual are potent determinants of human behavior. Lewin's

formula,  $B = f(P, E)$ , stressed the need for new research strategies in which behavior is considered to be a function of the person and the environment.

Drawing on Murray's work, Stern (1970) formulated a theory of person-environment congruence in which complementary combinations of personal needs and environmental press enhance student outcomes. The Getzels and Thelen (1960) model for the class as a social system holds that, in school classes, personality needs, role expectations, and classroom climate interact to predict group behavior, including learning outcomes.

Psychosocial learning environment has been incorporated as one factor in a multifactor psychological model of educational productivity (Walberg, 1981). This theory, which is based on an economic model of agricultural, industrial, and national productivity, holds that learning is a multiplicative, diminishing-returns function of student age, ability, and motivation; of quality and quantity of instructions; and of the psychosocial environments of the home, the classroom, the peer group, and the mass media. Because the function is multiplicative, it can be argued in principle that any factor at a zero point will result in zero learning; thus either zero motivation or zero time for instruction will result in zero learning. Moreover, it will do less good to raise a factor that already is high than to improve a factor that currently is the main constraint to learning. Empirical probes of the educational productivity model were made by carrying out extensive research syntheses involving the correlations of learning with the factors in the model (Fraser, Walberg, Welch, & Hattie, 1987) and secondary analyses of large data bases collected as part of the National Assessment of Educational Progress (Walberg, Fraser, & Welch, 1986). Classroom and school environment was found to be a strong predictor of both achievement and attitudes even when a comprehensive set of other factors was held constant.

The field of learning environments has undergone remarkable growth, diversification, and internationalization during the past 30 years (Fraser, 1998a). A striking feature of this field is the availability of a variety of economical, valid, and widely applicable questionnaires that have been developed and used for assessing students' perceptions of classroom environment (Fraser, 1998b). Although learning environment research originated in Western countries, African (Fisher & Fraser, 2003) and especially Asian researchers (Fraser, 2002; Goh & Khine, 2002) have made many major and distinctive contributions in the last decade. For example, some of the main questionnaires that were developed in the West have been adapted (sometimes involving translation into another language) and cross-validated for use in numerous other countries.

This chapter provides access to past research on classroom learning environments and to instruments that have proved valid and useful in international contexts. The chapter begins by describing historically important learning environment questionnaires as well as contemporary instruments. In order to illustrate the application of learning environment assessments, another section is devoted to reviewing past research in six areas: (a) associations between student outcomes and environment; (b) evaluation of educational innovations; (c) differences between student and teacher perceptions of actual and preferred environment; (d) determinants of classroom environment; (e) use of qualitative research methods; and (f) cross-national studies. The chapter's concluding section provides a look forward to the next generation of learning environment research.

## QUESTIONNAIRES FOR ASSESSING CLASSROOM ENVIRONMENT

Because few fields of educational research can boast the existence of such a rich array of validated and robust instruments, this section describes four contemporary instruments that have been used in both Western and non-Western countries: the Questionnaire on Teacher Interaction (QTI); the Science Laboratory Environment Inventory (SLEI); the Constructivist Learning Environment Survey (CLES); and the What Is Happening In this Class? (WIHIC) questionnaire. Before we discuss each of these instruments, some historically important questionnaires are briefly considered.

### Historically Important Questionnaires

The Learning Environment Inventory (LEI) and Classroom Environment Scale (CES) were developed in the United States in the late 1960s. The initial development of the LEI began in conjunction with evaluation and research related to Harvard Project Physics (Walberg & Anderson, 1968). The CES (Moos & Trickett, 1987) grew out of a comprehensive program of research involving perceptual measures of a variety of human environments, including psychiatric hospitals, prisons, university residences, and work milieus (Moos, 1974).

The LEI was used in the Hindi language in a large study involving approximately 3,000 tenth-grade students in 83 science and 67 social studies classes (Walberg, Singh, & Rasher, 1977). Student perceptions on the LEI accounted for a significant increment in achievement variance beyond that attributable to general ability. In Indonesia, Paige (1979) used the CES and three scales selected from the LEI to reveal that individual modernity was enhanced in classrooms perceived as having greater task orientation, competition, and difficulty and less order and organization, whereas achievement was enhanced in classes higher in speed and lower in order and organization. Hirata and Sako (1998) used an instrument in the Japanese language that incorporated scales from the CES. Factor analysis of the responses of 635 students suggested a four-factor structure for this questionnaire (consisting of Teacher Control, Sense of Isolation, Order and Discipline, and Affiliation).

The My Class Inventory (MCI) is a simplified form of the LEI for use among children aged 8–12 years (Fisher & Fraser, 1981). In Singapore, Goh, Young, and Fraser (1995) changed the MCI's original Yes-No response format to a three-point response format (Seldom, Sometimes, and Most of the Time) in a modified version of the MCI that includes a Task Orientation scale. Goh et al. found the modified MCI to be valid and useful in research applications with 1,512 elementary-school students in 39 classes. In Brunei Darussalam, Majeed, Fraser, and Aldridge (2002) used the original version of the MCI with 1,565 middle-school students in 81 classes in 15 government secondary schools. When the Satisfaction scale was used as an attitudinal outcome variable instead of as a measure of classroom environment, Majeed et al. found strong support for a three-factor structure for the MCI consisting of three of the four *a priori* scales, namely, Cohesiveness, Difficulty, and Competitiveness.

## Questionnaire on Teacher Interaction (QTI)

Research that originated in the Netherlands focused on the nature and quality of interpersonal relationships between teachers and students (Wubbels & Brekelmans, 1998; Wubbels & Levy, 1993). Drawing upon a theoretical model of proximity (cooperation-opposition) and influence (dominance-submission), the QTI was developed to assess student perceptions of the eight behavior aspects listed in Table 5.1. Research with the QTI has been completed at various grade levels in the United States (Wubbels & Levy) and Australia (Fisher, Henderson, & Fraser, 1995).

Goh pioneered the use of the QTI in a simplified form in Singapore with a sample of 1,512 elementary-school students in 13 schools (Goh & Fraser, 1996, 1998,

**TABLE 5.1**  
**Scale Names, Response Alternatives, and Sample Items for Four Commonly-Used Classroom Environment Instruments**

<i>Instrument</i>	<i>Scale names</i>	<i>Response alternatives</i>	<i>Sample items</i>
Questionnaire on Teacher Interaction (QTI)	Leadership Helping/Friendly Understanding Student Responsibility/ Freedom Uncertain Dissatisfied Admonishing Strict Behaviour	Five point (Never- Always)	"She/he gives us a lot of free time." (Student Responsibility) "She/he gets angry." (Admonishing)
Science Laboratory Environment Inventory (SLEI)	Student Cohesiveness Open-Endedness Integration Rule Clarity Material Environment	Almost Never Seldom Sometimes Often Very Often	"I use the theory from my regular science class sessions during laboratory activities." (Integration) "We know the results that we are supposed to get before we commence a laboratory activity." (Open-Endedness)
Constructivist Learning Environments Survey (CLES)	Personal Relevance Uncertainty Critical Voice Shared Control Student Negotiation	Almost Never Seldom Sometimes Often Very Often	"I help the teacher to decide what activities I do." (Shared Control) "Other students ask me to explain my ideas." (Student Negotiation)
What Is Happening In this Class? (WIHIC)	Student Cohesiveness Teacher Support Involvement Investigation Task Orientation Cooperation Equity	Almost Never Seldom Sometimes Often Very Often	"I discuss ideas in class." (Involvement) "I work with other students on projects in this class." (Cooperation)

2000). This study cross-validated the QTI for use in a new country and found it to be useful in several research applications. Scott and Fisher (2004) translated the QTI into Standard Malay and cross-validated it with 3,104 elementary science students in 136 classes in Brunei Darussalam. An English version of the QTI was cross-validated for secondary schools in Brunei Darussalam for samples of 1188 science students (Khine & Fisher, 2002) and 644 chemistry students (Riah & Fraser, 1998). In Korea, Kim, Fisher, and Fraser (2000) validated a Korean-language version of the QTI among 543 Grade 8 students in 12 schools, and Lee and Fraser (2001a) provided further cross-validation information for the QTI with a sample of 440 Grade 10 and 11 science students. In Indonesia, Soerjaningsih, Fraser, and Aldridge (2001b) translated the QTI into the Indonesian language and cross-validated it with a sample of 422 university students in 12 classes. For example, Fisher, Fraser, and Rickards' (1997) study with a sample of 3,994 high school science and mathematics students revealed that the Cronbach alpha reliability ranged from 0.63 to 0.88 for different QTI scales at the student level of analysis.

### **Science Laboratory Environment Inventory (SLEI)**

Because of the importance of laboratory settings in science education, an instrument specifically suited to assessing the environment of science laboratory classes at the senior high school or higher education levels was developed (Fraser, Giddings, & McRobbie, 1995; Fraser & McRobbie, 1995). The SLEI has the five seven-item scales in Table 5.1. The SLEI was field tested and validated simultaneously with a sample of 5,447 students in 269 classes in six different countries (United States, Canada, England, Israel, Australia, and Nigeria) and cross-validated with Australian students (Fisher, Henderson, & Fraser, 1997; Fraser & McRobbie). For example, based on a sample of 3,727 senior high school students from five countries, the Cronbach alpha reliability ranged from 0.70 to 0.83 for different scales when the student was used as the unit of analysis (Fraser et al., 1995).

The SLEI was further cross-validated and found to be useful in research involving both its original English form and translated versions. The validity of the English version of the SLEI was established in Singapore by A. F. L. Wong and Fraser's (1995, 1996) study of 1,592 Grade 10 chemistry students in 56 classes in 28 schools. Also, Riah and Fraser (1998) cross-validated the English version of the SLEI with 644 Grade 10 chemistry students in Brunei Darussalam.

A noteworthy program of research involving a Korean-language version of the SLEI was initiated by Kim and built upon by Lee (Kim & Kim, 1995, 1996; Kim & Lee, 1997; Lee & Fraser, 2001b; Lee, Fraser, & Fisher, 2003). For example, Lee and Fraser reported strong factorial validity for a Korean version of the SLEI and replicated several patterns from previous research in Western countries (e.g., low Open-Endedness scores and significant associations with students' attitudes).

### **Constructivist Learning Environment Survey (CLES)**

The CLES (Taylor, Fraser, & Fisher, 1997) was developed to assist researchers and teachers to assess the degree to which a particular classroom's environment is consistent with a constructivist epistemology, and to help teachers to reflect on their

epistemological assumptions and reshape their teaching practice. The CLES has 36 items, which fall into the five scales shown in Table 5.1.

In South Africa, Sebela, Fraser, and Aldridge (2003) cross-validated the CLES among 1,864 learners in 43 intermediate and senior classes, and they used it to provide feedback that successfully guided teachers in action research aimed at promoting constructivist teaching and learning. In Texas, Dryden and Fraser (1998) cross-validated the CLES among a sample of 1,600 students in 120 Grade 9–12 science classes, and they used it to evaluate the success of an urban systemic reform initiative aimed at promoting constructivist teaching and learning. Also in Texas, Nix, Fraser, and Ledbetter (2003) cross-validated the CLES among 1,079 students in 59 classes and used it to evaluate an integrated science learning environment that bridged traditionally separate classroom, field trip, and instructional technology milieus.

Kim, Fisher, and Fraser (1999) translated the CLES into the Korean language and administered it to 1,083 science students in 24 classes in 12 schools. The original five-factor structure was replicated for the Korean-language version of both an actual and a preferred form of the CLES. Similarly, Lee and Fraser (2001a) replicated the five-factor structure of a Korean-language version of the CLES among 440 Grade 10 and 11 science students in 13 classes. Furthermore, the CLES was translated into Chinese for use in Taiwan (Aldridge, Fraser, Taylor, & Chen, 2000). In this cross-national study, the original English version was administered to 1,081 science students in 50 classes in Australia, and the new Chinese version was administered to 1,879 science students in 50 classes in Taiwan. The same five-factor structure emerged for the CLES in the two countries. Scale reliabilities (Cronbach alpha coefficients) ranged from 0.87 to 0.97 for the Australian sample and from 0.79 to 0.98 for the Taiwanese sample, with the class mean as the unit of analysis.

## **What Is Happening In this Class? (WIHIC) Questionnaire**

The WIHIC questionnaire combines modified versions of salient scales from a wide range of existing questionnaires with additional scales that accommodate contemporary educational concerns (e.g., equity and constructivism). The original 90-item nine-scale version was refined both by statistical analysis of data from 355 junior high school science students and by extensive interviewing of students about their views of their classroom environments in general, the wording and salience of individual items, and their questionnaire responses (Fraser, Fisher, & McRobbie, 1996). Analysis of data from an Australian sample of 1,081 students in 50 classes (Aldridge & Fraser, 2000) led to a final form of the WIHIC containing the seven eight-item scales in Table 5.1. The WIHIC items are listed in an article by Aldridge, Fraser, and Huang (1999).

Although the WIHIC is a relatively recent instrument, its adoption around the world has been frequent, and already it has been translated into several other languages and cross-validated:

1. Zandvliet and Fraser (2004) used the WIHIC among 81 classes of senior high school students in Canadian and Australian internet classes, whereas Lightburn and Fraser (2002) and Robinson and Fraser (2003) used the WIHIC in teacher-researcher studies in Florida.

2. An English version was cross-validated in Brunei Darussalam with samples of 644 Grade 10 chemistry students (Riah & Fraser, 1998) and 1,188 Form 5 science students (Khine & Fisher, 2001). In Singapore, Fraser and Chionh (2000) reported strong validity and reliability for both an actual and a preferred form of the WIHIC when it was responded to by a sample of 2,310 students in 75 senior high school classes.
3. A Chinese version of the WIHIC was developed for use in Taiwan and cross-validated with a sample of 1,879 junior high school students in 50 classes (Aldridge & Fraser, 2000; Aldridge et al., 1999).
4. The WIHIC was translated into the Korean language and validated with a sample of 543 Grade 8 students in 12 schools (Kim et al., 2000).
5. The WIHIC was translated into the Indonesian language and used with both high school and university students. The validity and usefulness of the WIHIC were established for samples of 594 high school students in 18 classes (Adolphe, Fraser, & Aldridge, 2003), 2,498 university students in 50 classes (Margianti, Fraser, & Aldridge, 2001a, 2001b), and 422 students in 12 classes (Soerjaningsih, Fraser, & Aldridge, 2001a).

Dorman (2003) used confirmatory factor analysis with data collected by administration of the WIHIC to 3980 high school students in Australia, Britain, and Canada. The *a priori* factor structure of the WIHIC was supported and was found to be invariant across country, grade level, and student gender. Alpha reliability coefficients for this sample ranged from 0.76 to 0.85 for different WIHIC scales at the student level of analysis.

The WIHIC has formed the foundation for the development of learning environment questionnaires that incorporate many of the WIHIC's dimensions, but encompass new dimensions that are of particular relevance to the specific study at hand. For example, in Canada, Raaflaub and Fraser (2002) used a modified version of the WIHIC in their investigation involving 1,173 science and mathematics students in 73 classrooms in which laptop computers were used. In Australia, Aldridge and Fraser (2003) added three new dimensions (Differentiation, Computer Usage, and Young Adult Ethos) to the WIHIC to form the Technology-Rich Outcomes-Focused Learning Environment Inventory (TROFLEI) in their study of 1,035 students in 80 classes in an innovative senior high school that provides a technology-rich and outcomes-focused learning environment. In South Africa, Seopa, Laugksch, Aldridge, and Fraser (2003) used the WIHIC as a basis for developing the Outcomes-Based Learning Environment Questionnaire (OBLEQ), which they used with 2,638 Grade 8 science students in 50 classes in 50 schools in Limpopo Province. In Texas, Sinclair and Fraser (2002) modified the WIHIC for use in a study aimed at changing classroom environments among a sample of 745 urban middle-school science students in 43 classes.

## RESEARCH INVOLVING CLASSROOM ENVIRONMENT INSTRUMENTS

In order to illustrate some of the many and varied applications of classroom environment instruments in science education research, this section considers six types

of past research which focused on: (a) associations between student outcomes and environment; (b) evaluation of educational innovations; (c) differences between student and teacher perceptions of actual and preferred environment; (d) determinants of classroom environment; (e) use of qualitative research methods; and (f) cross-national studies.

### **Associations between Student Outcomes and Environment**

The strongest tradition in past classroom environment research has involved investigation of associations between students' cognitive and affective learning outcomes and their perceptions of psychosocial characteristics of their classrooms. Fraser's (1994) tabulation of 40 past studies in science education showed that associations between outcome measures and classroom environment perceptions have been replicated for a variety of cognitive and affective outcome measures, a variety of classroom environment instruments and a variety of samples (ranging across numerous countries and grade levels). For example, a meta-analysis encompassing 17,805 students from four nations revealed that student achievement was consistently higher in classes that were more organized, cohesive, and goal-directed and had less friction (Haertel, Walberg, & Haertel, 1981).

McRobbie and Fraser (1993) extended learning environment research to science laboratory class settings in an investigation of associations between student outcomes and classroom environment. The sample consisted of 1,594 senior high school chemistry students in 92 classes. The Science Laboratory Environment Inventory (SLEI) was used to assess Student Cohesiveness, Open-Endedness, Integration, Rule Clarity, and Material Environments in the laboratory class. Student outcomes encompassed two inquiry skills assessed with the Test of Enquiry Skills (TOES) (Fraser, 1979b) and four attitude measures based partly on the Test of Science Related Attitudes (TOSRA) (Fraser, 1981). Simple, multiple, and canonical analyses were conducted separately for two units of analysis (student scores and class means) and separately with and without control for general ability. Past research was replicated in that the nature of the science laboratory classroom environment accounted for appreciable proportions of the variance in both cognitive and affective outcomes beyond that attributable to general ability. Science educators wishing to enhance student outcomes in science laboratory settings are likely to find useful the result that both cognitive and attitude outcomes were enhanced in laboratory classes in which the laboratory activities were integrated with the work in non-laboratory classes.

Fraser (2002) noted that Asian researchers have undertaken a wide variety of valuable studies of associations between student outcomes and students' perceptions of their classroom learning environment. These studies also covered a wide range of environment instruments, student outcomes, school subjects, and grade levels. Whereas some studies involved English-language versions of questionnaires, other studies involved learning environment questionnaires translated into various Asian languages. These studies involved samples from Singapore (Goh & Fraser, 1998; Teh & Fraser, 1995; A. F. L. Wong & Fraser, 1996), Brunei (Majeed et al., 2002; Scott & Fisher, 2004), Korea (Kim et al., 1999, 2000; Lee et al., 2003), and Indonesia (Margianti et al., 2001a).

Many past learning environment studies have employed techniques such as multiple regression analysis, but few have used multilevel analysis (Bryk & Raudenbush, 1992), which takes cognizance of the hierarchical nature of classroom settings (i.e., students within intact classes are more homogeneous than a random sample of students). However, two studies in Singapore compared the results from multiple regression analysis with those from an analysis involving the hierarchical linear model. In a study by A. F. L. Wong, Young, and Fraser (1997) involving 1,592 Grade 10 students in 56 chemistry classes in Singapore, associations were investigated between three student attitude measures and a modified version of the SLEI. In Goh's study with 1,512 Grade 5 students in 39 classes in Singapore, scores on modified versions of the MCI and QTI were related to student achievement and attitudes. Most of the statistically significant results from the multiple regression analyses were replicated in the HLM analyses, as well as being consistent in direction (Goh & Fraser, 1998; Goh et al., 1995).

Some research into outcome-environment associations involved the use of more than one classroom environment questionnaire in the same study, so that commonality analysis could be used to ascertain the unique and joint contributions made by each questionnaire to the variance in student outcomes. In Singapore, Goh and Fraser (1998) used the MCI and QTI in a study involving the achievement and attitudes of 1,512 elementary-school students. The MCI and the QTI each uniquely accounted for an appreciable proportion of the variance in achievement, but not in attitudes. Much of the total variance in attitude scores was common to the two questionnaires. A conclusion from this study was that it is useful to include the MCI and QTI together in future studies of achievement, but not of attitudes. Similarly, when Korean-language versions of the SLEI, QTI, and CLES were used in a study of science students' attitudes in Korea, generally, each classroom environment instrument accounted for variance in student outcome measures independent of that accounted for by the other instrument (Lee & Fraser, 2001a, 2001b; Lee et al., 2003).

## Evaluation of Educational Innovations

Classroom environment instruments can be used as a valuable source of process criteria in the evaluation of educational innovations. For example, in an early evaluation of the Australian Science Education Project (ASEP), ASEP students perceived their classrooms as being more satisfying and individualized and having a better material environment relative to a comparison group (Fraser, 1979a). In Singapore, Teh used his own classroom environment instrument as a source of dependent variables in evaluating computer-assisted learning (Fraser & Teh, 1994; Teh & Fraser, 1994). Compared with a control group, a group of students using microPROLOG-based computer-assisted learning had much higher scores for achievement (3.5 standard deviations), attitudes (1.4 standard deviations), and classroom environment (1.0–1.9 standard deviations).

Oh and Yager (2004) used the CLES with 136 Grade 11 earth science students involved in two longitudinal action research studies in Korea aimed at implementing constructivist instructional approaches. Not only was it found that students' perceptions on the CLES became more positive over time, but also that changes in the CLES scale of Personal Relevance were associated with improvements in student attitudes to science. In another study, the CLES was used among 70 Korean high school teach-

ers who attended professional development programs at the University of Iowa to monitor changes in constructivist philosophies (Cho, Yager, Park, & Seo, 1997).

Classroom environment dimensions also have been used as criteria of effectiveness in evaluating the use of laptop computers in Canadian science and mathematics classrooms (Raaflaub & Fraser, 2002), a technology-rich and outcomes-focused school in Australia (Aldridge & Fraser, 2003), the use of anthropometric activities in science teaching in the United States (Lightburn & Fraser, 2002), and the success of outcomes-based education in South Africa (Aldridge, Laugksch, Fraser, & Seopa, 2005). For example, Aldridge and Fraser's (2003) longitudinal study revealed that, over time, the implementation of an outcomes-focused, technology-rich learning environment led to more positive student perceptions of Student Cohesiveness, Task Orientation, Investigation, Cooperation, and Young Adult Ethos, but less classroom Differentiation. Despite the potential value of evaluating educational innovations and new curricula in terms of their impact on transforming the classroom learning environment, only a relatively small number of such studies have been carried out around the world.

### **Differences between Student and Teacher Perceptions of Actual and Preferred Environment**

An investigation of differences between students and teachers in their perceptions of the same actual classroom environment and of differences between the actual environment and that preferred by students or teachers was reported by Fisher and Fraser (1983). Students preferred a more positive classroom environment than was actually present for all five environment dimensions of Personalization, Participation, Independence, Investigation, and Differentiation. Also, teachers perceived a more positive classroom environment than did their students in the same classrooms on the four of the dimensions of Personalization, Participation, Investigation, and Differentiation. The pattern in which students prefer a more positive classroom learning environment than the one perceived as being currently present has been replicated with the use of the WIHIC and QTI among Singaporean high school students (Fraser & Chionh, 2000; A. F. L. Wong & Fraser, 1996) and the WIHIC among 2,498 university students in Indonesia (Margianti et al., 2001b).

### **Determinants of Classroom Environment**

Classroom environment dimensions have been used as criterion variables in research aimed at identifying how the classroom environment varies with such factors as teacher personality, class size, grade level, subject matter, the nature of the school-level environment, and the type of school (Fraser, 1994). Hirata and Sako (1998) found differences between the classroom environment perceptions of at-risk students (delinquent and non-attendees) and normal students in Japan. In Brunei, Khine and Fisher (2002) reported cultural differences in students' classroom environment perceptions depending on whether the teacher was Asian or Western. In Korea, Lee and Fraser (2001a, 2001b) and Lee et al. (2003) reported the use of the SLEI, CLES, and QTI in the investigation of differences between streams (science-oriented, humanities-oriented) in the student-perceived learning environment. For

the first four QTI scales, the clear pattern was that the humanities stream students had less favorable perceptions than did the other two streams. Science-oriented stream students perceived their classrooms more favorably than the humanities stream students did, but less favorably than the science-independent stream students did. Overall, cooperative behaviors were more frequently displayed in the science-independent stream than in the other two streams. In contrast, opposition behaviors were less frequently displayed in the science-independent streams than in the other two streams.

Undoubtedly, the determinant of classroom environment that has been most extensively researched is student gender. Generally within-class comparisons of students' perceptions reveal that females typically have more favorable views of their classroom learning environment than do males. These studies of gender differences have encompassed numerous countries, including Singapore (Fraser & Chionh, 2000; Goh & Fraser, 1998; Khoo & Fraser, 1998; Quek, Wong, & Fraser, 2005; A. F. L. Wong & Fraser, 1996), Brunei (Khine & Fisher, 2001, 2002; Riah & Fraser, 1998), Indonesia (Margianti et al., 2001a, 2001b), and Korea (Kim et al., 2000).

### **Use of Qualitative Research Methods**

Significant progress has been made in using qualitative methods in learning environment research and in combining quantitative and qualitative methods within the same study of classroom environments (Fraser & Tobin, 1991; Tobin & Fraser, 1998). For example, Fraser's (1999) multilevel study of the learning environment incorporated a teacher-researcher perspective as well as the perspectives of six university-based researchers. The research commenced with an interpretive study of a Grade 10 teacher's classroom at a school, which provided a challenging learning environment in that many students were from working-class backgrounds, some were experiencing problems at home, and others spoke English as a second language. Qualitative methods included several of the researchers visiting this class each time that it met over five weeks, using student diaries, and interviewing the teacher-researcher, students, school administrators, and parents. A video camera recorded activities for later analysis. Field notes were written during and soon after each observation, and during team meetings that took place three times per week. The qualitative component of the study was complemented by a quantitative component involving the use of a classroom environment questionnaire.

The qualitative information helped the researchers to provide consistent and plausible accounts of the profile of this teacher's scores on a classroom environment instrument to which her students responded. For example, the high level of perceived Personal Relevance in this teacher's class was consistent with her practice of devoting one science period a week to things that were personally relevant to students. Relatively high scores on the Critical Voice scale were consistent with observations that this teacher encouraged students to voice their opinions and suggest alternatives (Tobin & Fraser, 1998).

One of the most salient aspects of the learning environment in this study was Teacher Support. This teacher's class perceived higher levels of Teacher Support than did students in other Grade 10 classes at this school. This teacher had several features in common with the types of students whom she was teaching. She had not been a motivated learner at school and knew that students' life histories often made

it difficult for them to concentrate on learning as a high priority. She was aware that social problems afflicted many students, and she was determined to make a difference in their lives. Consequently, she planned to enact the curriculum to facilitate transformative goals. She had considerable empathy for her students, was concerned with their well-being as citizens, and perceived science as an opportunity to develop their life skills. Learning to be communicative and cooperative was a high-priority goal. Getting to know her students was a priority, and meeting them at the door seemed important because it permitted brief individual interactions with almost every student. For these reasons, it was quite plausible that Teacher Support scores were high (Tobin & Fraser, 1998).

Fraser (2002) noted that the use of quantitative methods has tended to dominate Asian research into learning environments. But there are some notable exceptions in which qualitative methods have been used to advantage. Quite a few Asian studies have used qualitative methods in a minor way, such as in interviews of a small group of students aimed at checking the suitability of a learning environment questionnaire and modifying it before its use in a large-scale study (e.g., Khine, 2001; Margianti et al., 2001a, 2001b; Soerjaningsih et al., 2001a, 2001b). Lee's study in Korea included a strong quantitative component involving the administration of the SLEI, CLES, and QTI to 439 students in 13 classes (four classes from the humanities stream, four classes from the science-oriented stream, and five classes from the science-independent stream; Lee & Fraser, 2001a, 2001b; Lee et al., 2003). However, two or three students from each class were selected for face-to-face interviews in the humanities stream and the science-oriented stream. In the case of students in the science-oriented stream, interviews were conducted via e-mail to overcome practical constraints. All of the face-to-face interviews were audiotaped and later transcribed in Korean and translated into English. When the Korean transcriptions were completed, they were shown to the students for member checking. Furthermore, one class from each stream was selected for observation. While the researcher was observing, whenever possible she wrote down any salient events that occurred in the classroom. Some photographs were also taken. Field notes were made and translated into English in order to transfer the images into English. Overall, the findings from interviews and observations replicated the findings obtained with the learning environment surveys.

During observations, the researcher noted that, in classes in the science-independent stream in Korea, teachers appeared more receptive to students' talking and the lessons involved mainly group activities. Students' cooperation was natural and did not require explicit intervention from the teacher. Interviews also indicated that students from the science-independent stream were more likely to interact actively with their teachers than were students from the other two streams. It would appear that the stream in which students study influences their perceptions of their science classes.

This Korean study suggested that teacher-student interactions in senior high school science classrooms reflect the general image of the youth-elder relationship in society of "directing teachers and obeying students." It is also noteworthy that each stream's unique nature in terms of teacher-student relationships did not go beyond this societal norm.

In Hong Kong, qualitative methods involving open-ended questions were used to explore students' perceptions of the learning environment in Grade 9 classrooms

(N. Y. Wong, 1993, 1996). This researcher found that many students identified the teacher as the most crucial element in a positive classroom learning environment. These teachers were found to keep order and discipline while creating an atmosphere that was not boring or solemn. They also interacted with students in ways that could be considered friendly and showed concern for the students.

## Cross-National Studies

Educational research that crosses national boundaries offers much promise for generating new insights for at least two reasons (Fraser, 1997). First, there usually is greater variation in variables of interest (e.g., teaching methods, student attitudes) in a sample drawn from multiple countries than from a single country sample. Second, the taken-for-granted familiar educational practices, beliefs, and attitudes in one country can be exposed, made "strange," and questioned when research involves two countries. In a cross-national study, six Australian and seven Taiwanese researchers worked together on a study of learning environments (Aldridge, Fraser, & Huang, 1999; Aldridge, Fraser, Taylor, & Chen, 2000; She & Fisher, 2000). The WIHIC and CLES were administered to 50 junior high school science classes in Taiwan (1,879 students) and Australia (1,081 students). An English version of the questionnaires was translated into Chinese, followed by an independent back translation of the Chinese version into English again by team members who were not involved in the original translation (Aldridge et al., 2000).

Qualitative data, involving interviews with teachers and students and classroom observations, were collected to complement the quantitative information and to clarify reasons for patterns and differences in the means in each country. Data from the questionnaires guided the collection of qualitative data. Student responses to individual items were used to form an interview schedule to clarify whether items had been interpreted consistently by students and to help to explain differences in questionnaire scale means between countries. Classrooms were selected for observations on the basis of the questionnaire data, and specific scales formed the focus for observations in these classrooms. The qualitative data provided valuable insights into the perceptions of students in each of the countries, helped to explain some of the differences in the means between countries, and highlighted the need for caution in the interpretation of differences between the questionnaire results from two countries with cultural differences (Aldridge, Fraser, & Huang, 1999; Aldridge et al., 2000).

Another cross-national study of learning environments was conducted in the United States, Australia, the Netherlands, Slovakia, Singapore, and Brunei by den Broek et al. (2003). This study, involving 5,292 students in 243 classes, was intended only to test the cross-national validity of the QTI in terms of the two-dimensional circumplex model of interpersonal behavior on which the QTI is based. Researchers found that the empirical scale locations differed from the theoretical positions hypothesized by the model and that scale positions in the circumplex differed between countries. The authors concluded that the QTI cannot be compared between countries and that further research is needed to determine whether the QTI is cross-culturally valid.

In contrast to these findings in den Broek and colleagues' cross-national validation of the QTI, Dorman (2003) reported strong support for the cross-national valid-

ity of the WIHIC when used with a sample of 3,980 students in Australia, Britain, and Canada.

Researchers from Singapore and Australia also have carried out a cross-national study of secondary science classes (Fisher, Goh, Wong, & Rickards, 1997). The QTI was administered to students and teachers from a sample of 20 classes from 10 schools each in Australia and Singapore. Australian teachers were perceived as giving more responsibility and freedom to their students than was the case for the Singapore sample, whereas teachers in Singapore were perceived as being stricter than their Australian counterparts. These differences are not surprising, given the different cultural backgrounds and education systems in the two countries. Most recently, Adolphe et al. (2003) conducted a cross-national study of science classroom environments and student attitudes among 1,161 science students in 36 classes in private coeducational schools in Indonesia and Australia.

## CONCLUSION

The history of the first two decades of learning environments research in Western countries shows a strong emphasis on the use of a variety of validated and robust questionnaires that assess students' perceptions of their classroom learning environment (Fraser, 1998a). The past decade of research into learning environments in non-Western countries shows a very similar pattern. Researchers have completed numerous impressive studies that have cross-validated the main contemporary classroom environment questionnaires that were originally developed in English (SLEI, CLES, WIHIC) and Dutch (QTI). Not only have these questionnaires been validated for use in English in countries such as Singapore and Brunei, but researchers also have undertaken painstaking translations and have validated these questionnaires in the African, Chinese, Indonesian, Korean, and Malay languages. These researchers have laid a solid foundation for future learning environment research internationally by making readily accessible a selection of valid, reliable, and widely applicable questionnaires for researchers and teachers to use in a range of languages for a variety of purposes.

On the basis on the research reviewed in this chapter, the following generalizations and implications for improving science education can be drawn:

1. Because measures of learning outcomes alone cannot provide a complete picture of the educational process, assessments of the learning environment should also be used to provide information about subtle but important aspects of classroom life.
2. Because teachers and students have systematically different perceptions of the learning environments of the same classrooms (the "rose-colored glasses" phenomenon), feedback from students about classrooms should be collected in the evaluation of preservice teachers during field experience and during investigation of professional development programs.
3. Science teachers should strive to create "productive" learning environments as identified by research. Cognitive and affective outcomes are likely to be enhanced in classroom environments characterized by greater organization, cohesiveness, and goal direction and by less friction. In laboratory classroom

environments specifically, greater integration between practical work and the theoretical components of a course tends to lead to improved student outcomes.

4. The evaluation of innovations and new curricula should include classroom environment instruments to provide economical, valid, and reliable process measures of effectiveness.
5. Teachers should use assessments of their students' perceptions of actual and preferred classroom environments to monitor and guide attempts to improve classrooms. The broad range of instruments available enables science teachers to select a questionnaire or particular scales to fit personal circumstances.

In the future, there will be scope for researchers to make internationally significant contributions to the field by developing new questionnaires that tap the nuances and uniqueness of classrooms in particular countries, and/or which focus on the various information technology-rich learning environments (e.g., web-based, online learning) that are currently sweeping education worldwide (Khine & Fisher, 2003). Similarly, there is scope to adapt currently widely used paper-and-pencil questionnaires to online formats.

The most common line of past learning environment research has involved investigating associations between students' outcomes and their classroom environment perceptions. This impressive series of studies has been carried out in many countries in a variety of subject areas (science, mathematics, geography, English, and computing), at various grade levels (elementary, secondary, and higher education), and using numerous student outcome measures (achievement, attitudes, self-efficacy) and different learning environment questionnaires. Overall, these studies provide consistent support for the existence of associations between the nature of the classroom environment and a variety of valued student outcomes. These findings hold hope for improving student outcomes through the creation of the types of classroom environments that are empirically linked to favorable student outcomes.

Feedback information based on student or teacher perceptions of actual and preferred environments has been employed in a five-step procedure as a basis for reflection upon, discussion of, and systematic attempts to improve classroom environments (Sinclair & Fraser, 2002; Thorp, Burden, & Fraser, 1994; Yarrow, Millwater, & Fraser, 1997). The five steps involve (a) *assessment* of actual and preferred classroom environments; (b) *feedback* of results, including identification of aspects of classroom environments for which there are large discrepancies between actual and preferred scores; (c) *reflection and discussion*; (d) *intervention*; and (e) *reassessment* of classroom environment. Surprisingly, this important practical benefit has not yet been widely realized in science education in any country.

Whereas the use of questionnaires in learning environment research has been prolific, studies that include qualitative methods such as interview and observation have been somewhat less common. Although studies demonstrate the benefits of combining qualitative and quantitative methods in learning environment research (Tobin & Fraser, 1998), it is desirable for future learning environment research to make greater use of qualitative methods. For example, qualitative data can help researchers to make more meaningful interpretations of questionnaire data that can take into account various background, cultural, and situational variables. Although

learning environment questionnaires are valuable for illuminating particular constructs and patterns, their use can also obscure other important constructs and patterns that could be revealed through qualitative methods. Researchers can also use narrative stories to portray archetypes of science classroom environments.

There is scope for researchers to adopt, adapt, or create new theoretical frames to guide the next generation of learning environment studies. For example, this could build upon Roth's (1999) advice against conceptualizing the environment as being independent of the person, and on his use of life-world analysis as a new theoretical underpinning. Roth, Tobin, and Zimmermann (2002) broke with past traditions by taking researchers into the front lines of the daily work of schools, thereby assisting in bringing about change. They proposed co-teaching as an equitable inquiry into teaching and learning processes in which all members of a classroom community participate—including students, teachers, student teachers, researchers, and supervisors. Roth and colleagues articulate co-teaching in terms of activity theory and the associated first-person methodology for doing research on learning environments that is relevant to practice.

The next generation of learning environment studies also could benefit from advances in methods of data analysis. Rasch analysis has been used to permit valid comparison of different cohorts of over 8000 science and mathematics students who responded to learning environment scales during different years of a systemic reform effort in Ohio (Scantlebury, Boone, Butler Kahle, & Fraser, 2001). In research on systemic reform, there are several important measurement problems in need of solution. For example, if we are interested in improvements in achievement or attitudes at the same grade level over several years as reform is implemented, there is a potential problem: that our samples for different years are unlikely to be strictly comparable. Similarly, changes made to evaluation instruments during the lifetime of a reform initiative can make it difficult to attribute changes to the reform rather than simply to modifications in an instrument. Finally, because all students seldom answer all items on a test or questionnaire, we need a method of calculating a valid score for each student based on the subset of items answered. Item response theory, or the Rasch model, provides a solution to all of these measurement problems.

Dorman (2003), taking advantage of relatively recent advances in techniques for validating learning environment questionnaires, has demonstrated the value of using confirmatory factor analysis within a covariance matrix framework. Using a sample of 3,980 high-school students from Australia, Britain, and Canada, Dorman found strong support for the *a priori* structure of the WIHIC and demonstrated the factorial invariance of model parameters across three countries, three grade levels, and gender. In the first use of multitrait-multimethod methodology in learning environment research, a study by Aldridge, Dorman, and Fraser (2004) involving 1,249 students used the 10 scales of the Technology-Rich Outcomes-Focused Learning Environment Inventory (TROFLEI) as traits and the two forms of the instrument (actual and preferred) as methods. Findings supported the sound psychometric properties of the actual and preferred forms of the TROFLEI.

In investigating outcome-environment associations, Goh et al. (1995) have illustrated how multilevel analysis can take cognizance of the hierarchical nature of classroom environment data in their study involving over 1,500 Singaporean students. Because classroom environment data typically are derived from students in intact classes, they are inherently hierarchical. Ignoring this nested struc-

ture can give rise to problems of aggregation bias (within-group homogeneity) and imprecision.

This chapter encourages others to use learning environment assessments for a variety of research and practical purposes. Given the ready availability of questionnaires, the importance of the classroom environment, the influence of the classroom environment on student outcomes, and the value of environment assessments in guiding educational improvement, it seems very important that researchers and teachers more often include the classroom environment in evaluations of educational effectiveness. Although educators around the world pay much greater attention to student achievement than to the learning environment, research on the classroom environment should not be buried under a pile of achievement tests.

# CHAPTER 6

---

## Learning Science Outside of School

Léonie J. Rennie

*Curtin University of Technology, Australia*

Unfortunately, there has been a tendency in this country to equate the term *education* with what happens in the schools or, at most, with what happens in schools, colleges, and universities. This leaves out other agencies and influences that, for better or worse and to greater and lesser degrees, may have a great impact on the knowledge, skill, understanding, appreciation, and judgment of our people: television, radio, motion pictures, the nontextbook press, the family, the back-alley gang, the teachers of private lessons, fairs and expositions, industry (through its greatly expanded training programs), the military, and the *museum*. (S. Anderson, 1968, p. 115, emphasis in original)

Fortunately, even as S. Anderson penned his chapter in 1968, a revolution had begun. Equating education with what happens in schools ignored two facts: Most people spend less of their lives in school than out of it, and they continue to learn throughout their lifetime in many places other than educational institutions. In the past, out-of-school learning for most individuals was associated with making a living and family care. Now, with more time for leisure in our society, we have the luxury of learning for interest rather than necessity, for satisfying our curiosity and enjoying ourselves. Recognizing the educational value of out-of-school learning is part of a revolution because there are so many opportunities to learn.

This chapter is about the learning of science through those out-of-school “agencies and influences” that, as S. Anderson (1968) stated, “impact on the knowledge, skill, understanding, appreciation, and judgment of our people” (p. 115). The chapter begins with an exploration of the dimensions and characteristics of such learning and so constructs a framework for the review. The subsequent overview of the research literature in the field is divided into three sections: Museums, Community and Government Organizations, and Media. Implications are then drawn for research, educational practice, and policy.

## WHAT IS MEANT BY LEARNING SCIENCE OUTSIDE OF SCHOOL?

Learning that occurs outside of school or other educational institutions has many different names: informal learning; nonformal learning; informal education; free-choice learning; learning in out-of-school contexts, settings, or environments. The term *informal* invariably refers to out-of-school contexts; for example, Crane, Nicholson, Chen, and Bitgood (1994) wrote: "Informal science learning refers to activities that occur outside the school setting, are not developed primarily for school use, are not developed to be part of an ongoing school curriculum, and are characterized as voluntary as opposed to mandatory participation as part of a credited school experience" (p. 3).

Juxtaposition of the words *informal* and *learning* has been challenged because it implies a qualitative difference between informal learning compared with formal learning. Is there a difference? In 2003, the Informal Science Education Ad Hoc Committee of the Board of the National Association for Research in Science Teaching (NARST) published a policy statement developed from a program of discussion and input from NARST members. The Committee agreed that

Learning rarely if ever occurs and develops from a single experience. Rather, learning in general, and science learning in particular, is cumulative, emerging over time through myriad human experiences, including but not limited to experiences in museums and schools; while watching television, reading newspapers and books, conversing with friends and family; and increasingly frequently, through interactions with the Internet. The experiences children and adults have in these various situations dynamically interact to influence the ways individuals construct scientific knowledge, attitudes, behaviors, and understanding. In this view, learning is an organic, dynamic, never-ending, and holistic phenomenon of constructing personal meaning. This broad view of learning recognizes that much of what people come to know about the world, including the world of science content and process, derives from real-world experiences within a diversity of appropriate physical and social contexts, motivated by an intrinsic desire to learn. (Dierking, Falk, Rennie, Anderson, & Ellenbogen, 2003, p. 109)

If learning is an ongoing, cumulative process that occurs from experience in a range of settings, it does not make sense to try to distinguish it as formal or informal. As Walton (2000) suggested, "in the absence of physiological evidence to the contrary, all that can be said is that the learning which takes place in [science centers] is the same as learning that takes place anywhere else" (p. 50). Nevertheless, in order to mark out the boundaries for this chapter, it is helpful to distinguish between the formal and informal contexts where learning opportunities arise. Hein (1998) provided a simple distinction: "the terms 'formal' and 'informal' [refer to] a description of settings and the presence or absence of a formal curriculum" (p. 7). There are certain consistent qualitative differences in the nature of formal and informal settings or environments. For example, Falk, Koran, and Dierking (1986) compared "dimensions in which museum learning is distinct from school learning" (p. 504), but made it clear that the distinction was between the settings or contexts for learning, not between different kinds of learning. Also with a focus on museums, Bitgood (1988) compared formal and informal learning, but he discussed differences in learning en-

vironments and gave no indication that the learning was different; rather the context was different. Similarly, Wellington (1990, 1998) described the features of formal and informal learning in science in terms of differences in the settings.

These authors characterized the informal, out-of-school learning environment as one where (a) both attendance and involvement are voluntary or free-choice, rather than compulsory or coercive; (b) the curriculum has an underlying structure that is open, offers choices to learners, and tends not to be didactic; (c) the activities are nonevaluative and noncompetitive, rather than assessed and graded; and (d) the social interaction is among groups heterogeneous with regard to age, rather than constrained between same-age peers and formalized with the teacher as the main adult. In sum, compared with formal school environments, learning outside of school is learner-led and intrinsically motivated, rather than teacher-led and extrinsically motivated. Oliver Sacks (2001) identified these features as he reflected on how he learned about science in London in the late 1940s:

My school . . . had no science and hence little interest for me—our curriculum, at this point, was based solely on the classics. But this did not matter, for it was my own reading in the [public] library that provided my real education, and I divided my spare time, when I was not with Uncle Dave, between the library and the wonders of the South Kensington museums, which were crucial for me throughout my boyhood and adolescence. The museums, especially, allowed me to wander in my own way, at leisure, going from one cabinet to another, one exhibit to another, without being forced to follow any curriculum, to attend lessons, to take exams or compete. There was something passive, and forced upon one, about sitting in school, whereas museums—and the zoo, and the botanical garden at Kew—made me want to go out into the world and explore for myself, be a rock hound, a plant collector, a zoologist or paleontologist. (p. 57)

Besides the library, museums, zoo, and botanical garden as sources for his science learning, Sacks referred to Uncle Dave. He made much of his learning from family members, drawing attention (as did Bitgood, 1988; Falk et al., 1986; and Wellington, 1998) to the social dimension of learning outside of school. In essence, however, it is the element of volition—the freedom to choose—that characterizes the learning opportunities in out-of-school contexts. The NARST Ad Hoc Committee decided that whatever term is used to refer to learning in out-of-school contexts (and they recommended *not* using *informal*), it means “learning that is self-motivated, voluntary, guided by the learner’s needs and interests, learning that is engaged in throughout his or her life” (Dierking et al., 2003, p. 109).

Science educators have strongly supported sources of out-of-school learning as important and effective complements to the science curriculum. For example, in the United States, Bybee (2001) argued that the National Science Education Standards (NSES; National Research Council, 1996) could serve as a bridge between formal and free-choice settings, stating, “the free-choice learning community must be included in any view of achieving scientific literacy” (p. 45). Others, like Hodder (1997) in New Zealand and Wellington (1998) in the United Kingdom, pointed out how science museums could contribute to the achievement of their respective national curriculum. The U.S. National Science Teachers Association (NSTA) adopted a Position Statement on Informal Science Education in 1998 (NSTA, 1998) outlining the benefits offered because it “complements, supplements, deepens, and enhances classroom

science studies" (p. 30). Clearly, out-of-school learning is considered to be an important part of learning science, but what is the evidence that supports this belief?

## **RESEARCH ON LEARNING SCIENCE OUTSIDE OF SCHOOL**

Three important characteristics of learning are embodied in the description of learning quoted from the NARST Ad Hoc Committee (Dierking et al., 2003). First, learning is a personal process; second, it is contextualized; and third, it takes time. Some educational and psychological theories advanced about learning have not recognized these characteristics, but it turns out that they are especially significant to understanding and investigating learning outside of school. Many practitioners and researchers in out-of-school contexts now use theories of learning based in constructivist ideas (e.g., Driver & Bell, 1986; Duit & Treagust, 1998; in the museum context, see D. Anderson, Lucas, & Ginns, 2003; Hein, 1998; Roschelle, 1995) and sociocultural theory, with roots in the work of theorists such as Vygotsky (1978) and others (see also J. S. Brown, Collins, & Duguid, 1989; Lave & Wenger, 1991; Resnick, Levine, & Teasley, 1991; in the museum context, see Matusov & Rogoff, 1995; Schauble, Leinhardt, & Martin, 1997). These perspectives are not discussed here, but they are all consistent with the nature of learning as personalized, contextualized, and cumulative. These characteristics deserve some attention because of their implications for research (see Rennie & Johnston, 2004, for a more complete discussion).

### **Learning Is a Personal Process**

Because learning is a personal process, it is different for each person. Learning involves the making of mental associations or links between new and previously acquired ideas. These changes in mental structures, or new ways of thinking about things, cause a person to react to objects or events or people in new ways. Learning results from the interpretation of experience, so for learning to occur, an individual must engage in some mental, physical, or social activity. It involves where a learner is, how that learner chooses to interact, and the nature of that interaction. The implications of this are clear: people's life circumstances, their needs, interests, and motivations determine what is attended to and what is learned. People are different, and the freedom of out-of-school contexts allows them to behave in different ways and experience different learning outcomes.

Researching learning in out-of-school contexts must take account of these implications in at least two ways. First, the learner must be central to the data-gathering process in order to capture the personal nature of learning. Photographs and videotapes of visitors using exhibits have been used to stimulate recall of their thoughts and experiences. Innovative variations in the traditional interviews and questionnaires, such as Personal Meaning Mapping (Falk, Moussouri, & Coulson, 1998), are being used to explore the diversity of learners' thinking and ideas. New digital technologies, such as wireless microphones with minidisks, facilitate recording of learners' verbal activities (e.g., Leinhardt, Knutson, & Crowley, 2003). Second, the unpredictable and varied nature of free-choice learning ensures multiple outcomes from

any learning experience. Ways to measure both the expected and unexpected outcomes must be sought to get a holistic picture of what is learned and how.

## Learning Is Contextualized

Although learning is a personalized process, it is rarely done alone. People are social beings. If not interacting with other people, a person usually interacts with socially constructed things, such as artifacts, language, and other socially shared and understood symbols and conventions. As Schauble et al. (1997) pointed out, “[M]eaning emerges in the interplay between individuals acting in social contexts and the mediators—including tools, talk, activity structures, signs, and symbol systems—that are employed in those contexts. Individuals both shape and are shaped by these mediators” (p. 4).

Learning is socially contextualized and shaped by the physical features of the places where meaning is made and learning occurs, an important point in terms of the rich, physical variety of out-of-school settings. Falk and Dierking (1992) formulated a framework, the Interactive Experience Model, for thinking about learning in and from these settings that tried to accommodate much of the diversity and complexity surrounding learning. More recently they built upon and refined this model, recasting it as the Contextual Model of Learning (Falk & Dierking, 2000). This model posits three contexts of importance in these settings: the Personal Context, alluded to already, concerns what individuals bring to their experience. The Sociocultural Context refers to interactions they have with other people in their social group, with staff or other unrelated groups, as well as the social and cultural features inherent in the artifacts and exhibits. The Physical Context refers to the physical surroundings. The interaction among these three contexts determines the nature and outcomes of a person’s learning experience.

The Contextual Model of Learning also identified 12 critical suites of factors representing elements of the three contexts (cf. Falk & Dierking, 2000). Each factor is equally important. For convenience, they distinguish three separate contexts, but it is important to keep in mind that these contexts are not really separate, or even separable. Within the Personal Context, there are four factors: motivation and expectations; prior knowledge and experience; prior interests and beliefs; and choice and control. The Sociocultural Context includes within-group social mediation; facilitated mediation by others; and cultural background and upbringing. Factors within the Physical Context include advance organizers to content; orientation to the physical space; architecture and large-scale environmental design; design of exhibits and content of labels; and subsequent reinforcing events and experiences outside the museum. Together these 12 factors describe and emphasize the complexity of learning in museums and other out-of-school contexts.

These three contexts, and the factors inherent within them, are equally important influences on learning in any out-of-school setting. Because of this complexity, investigation of the nature of such learning requires a range of research designs and measurement techniques. Research in museums and other out-of-school settings is now guided by mixed-method research designs (Greene, Caracelli, & Graham, 1989), attention to methodological and data triangulation (Mathison, 1988; Soren, 1995), and approaches grounded in constructivist (e.g., D. Anderson et al., 2003; D. Anderson,

Lucas, Ginns, & Dierking, 2000; Falk et al., 1998; Gilbert & Priest, 1997; Stockmayer & Gilbert, 2002) and sociocultural (e.g., Ash, 2003; Crowley & Callanan, 1998; Crowley, Callanan, et al., 2001; Leinhardt, Crowley, & Knutson, 2002; Leinhardt et al., 2003) perspectives. The ability to preserve the context of learning is critical to success (Lucas, McManus, & Thomas, 1986). The presence of a researcher or equipment to record observations may change the nature of that context and interfere with the learning experience or inadvertently cue the learner to respond in certain ways. Such reactivity is a serious issue for the researcher to consider when designing the research. Furthermore, there is an inferential gap between observing behaviors believed to indicate learning and concluding that learning has occurred, and ways must be found to bridge that gap without compromising the visitors' experience through intervention. Some researchers (e.g., Barriault, 1999; Borun, Chambers, & Cleghorn, 1996; Griffin, 1999) have proposed noninterventionist observational frameworks to identify behaviors that result in learning. Gammon (2002) produced a comprehensive synthesis of these, backed by research at the Science Museum. However, more work is needed to determine how these frameworks might be used most effectively.

### **Learning Takes Time**

When people find themselves in new contexts, they remember knowledge and understanding gained from previous experiences and use these recollections to make meaning of their present situation. Learning occurs when people reconstruct meaning and understanding, leading to a different way of thinking, perhaps, or a different way of responding to an idea or event. Learning that occurs today depends on yesterday's learning and is the foundation for tomorrow's learning. The cumulative, iterative process of learning emphasizes the importance of time. The Contextual Model of Learning described earlier (Falk & Dierking, 2000) included time, recognizing more fully, as Falk and Dierking pointed out in 1992, that people learn from the museum experience when they "assimilate events and observations in mental categories of personal significance and character determined by the events in their lives before and after the museum visit" (p. 123). Thus learning takes time, and this makes it difficult to measure, particularly inasmuch as some learning opportunities, such as a visit to a museum, are transient events. Yet memories of them remain and can contribute to later learning (D. Anderson, 2003; Dierking, 2002; Falk & Dierking, 1997; Stockmayer & Gilbert, 2002). Longitudinal studies, examining appropriate variables before, during, and after the learning opportunities are needed to document such learning over time.

### **Out-of-School Contexts for Learning Science**

The opening quotation from S. Anderson (1968) listed a number of agencies and influences that facilitate learning outside of school. Lewenstein (2001) provided a more recent, but understandably similar, list of producers of science information for the public. These include government, museums, the mass media, community organizations, industry, and various nongovernment organizations and nonprofit foundations, which together have a broad range of programs and activities that directly, or indirectly, provide opportunities for learning about science throughout one's life-

time. Space prohibits an exhaustive review of each category in this chapter, so they are clustered into three sections. First, museums and related topics are given most attention because the cumulative body of research in that context provides many lessons generalizable to learning in other out-of-school contexts. In the second and third sections, relevant research on learning science from community and government organizations and the media is reviewed briefly to establish the key features of these agencies. Although prominence is given to research on school-age children, other research is included because it is important to appreciate that these settings are places that people use to support their science learning across a lifetime, often within family or all-adult groups.

## LEARNING SCIENCE IN AND FROM MUSEUMS

Museums and similar institutions have always had an educational role, although the first museums, the “cabinets of curiosities” of the seventeenth and eighteenth centuries, were simply private collections, privately displayed (McManus, 1992). Even so, it is difficult to imagine that a visitor who viewed such collections of rare or unfamiliar specimens and artifacts would fail to be intrigued and to experience at least a little learning. Over several centuries, museums have developed and proliferated to a range of forms, some quite removed from the traditional natural history museums that characterized the first public institutions. Now places such as science centers, aquaria, art galleries, environmental interpretative centers, zoos, botanical gardens, planetaria, and others are included under the generic term *museum*. The definition in the Statutes of the International Council of Museums (ICOM, 2001) captures this diversity: “A museum is a non-profit making, permanent institution in the service of society and its development, and open to the public, which acquires, conserves, researches, communicates, and exhibits, for purposes of study, education and enjoyment, material evidence of people and their environment” (1974-Section II, Article 3).

In this chapter the term *museum* is used in a generic way to include the diverse range of institutions that fit the ICOM definition.

Several authors have traced the development of museums with a focus on science education (Hein, 1998; Koster, 1999; McManus, 1992; Melber & Abraham, 2002; Roberts, 1997; Schiele & Koster, 2000; Weil, 1999). Over the last four decades, the educational role of museums has become increasingly explicit. For example, the first of the three key concepts underlying the American Association of Museums’ (1992) report, *Excellence and Equity*, was stated as follows: “The educational role of museums is at the core of their service to the public. This assertion must be clearly stated in every museum’s mission and central to every museum’s activities” (p. 8). This report emphasized the public dimension of museums and the need for both excellence (maintaining intellectual rigor) and equity (including a “broader selection of our diverse society”). From Ontario, Carter (1990) reported that community museums must formulate an interpretation and education policy to remain eligible for government funding. In Britain, the Department for Culture, Media and Sport’s (2000) document, *Learning Power of Museums*, emphasized that “museums need to embrace education as a core objective in the development of mission statements, policies and action plans; similarly formal recognition of the unique educational

role of museums must be reflected in the educational community's policies, plans and mission statements" (pp. 8–9). The latter part of this statement recognized the two-way commitment to education between museums and their communities, as evidenced by the British government's funding initiative to "exploit" the "learning power of museums" (p. 25).

Despite these mandates for education, in some institutions, particularly collection-based institutions such as natural history museums and zoos, there remains conflict between the dual roles of the traditional museums: research on the collections and education for the visitor (Melber & Abraham, 2002; Roberts, 1997). Koster (1999) referred to a "wide spectrum of museum philosophies [in which] the two end states seem to be (1) a curator-driven, collection-based museum with a passive stance on public programs, and (2) an audience-driven, educationally active museum that positions itself as a relevant community resource" (p. 287). Accountability pressures are moving many museums toward the second end state, a move that enhances the museum's ability to serve as a source of educational, social, and cultural change (Scott, 2003). Roberts (1997) provided an insightful analysis of the tensions created in this move, describing it as a "paradigm shift, from knowledge to knowledges, from science to narrative" (p. 3). Without doubt, such a move is transformative, because as educators become involved in exhibit development, they change the public face of the museum.

## Museums and Learning: Demolishing Myths

Given that education is a recognized role of museums, do people learn from visits to museums? The unequivocal answer is yes. This does not mean that all museums are equally effective. Clearly they cannot be. Every visit does not result in immediate learning, but the potential for learning is available. There has always been some disagreement about the educational effectiveness of places like museums, disagreement that seems to be underpinned by three myths about learning in museums: (a) that playing and learning cannot occur at the same time; (b) that if learning occurs, it must happen at the museum; and (c) that what people learn is predictable and therefore easily measurable. These myths can easily be demolished based on what we know about learning in and from these settings.

***Myth 1: Playing and learning cannot occur at the same time.*** Play has a large research literature, with roots in anthropology, ethology, psychology, and sociology, as well as education. Commonly agreed characteristics of play are that it is enjoyable, intrinsically motivated, spontaneous, and voluntary, and it involves active exploration and engagement (Garvey, 1991; Mann, 1996; Sylva, Bruner, & Genova, 1976). Furthermore, play has been linked with creativity, solving problems, learning language and social skills, and other cognitive and social outcomes (Klugman & Smilansky, 1990; Smilansky, 1968).

In the museum context, Diamond (1996) reviewed the relationship between play and learning and concluded that museum experiences can encourage play from which learning occurs. Earlier, Hutt (1970, 1981) had distinguished between young children's exploratory activities, or investigation, and other activities that

she referred to as play: "The implicit question in the child's mind during investigation seems to be 'What can this *object* do?' whereas in play it is 'What can *I* do with this object?'" (1970, p. 70, emphasis in original). Hutt's work suggested that not all playing is learning, but that much learning is associated with play. Rennie and McClafferty (1998, 2002) paraphrased Hutt's two questions as "What can this *exhibit* do?" and "What can *I* do with this exhibit?" to analyze how 3- to 7-year-old children used science center exhibits. They found that children whose play with exhibits was exploratory and investigative demonstrated higher levels of cognitive understanding than those whose play was repetitive or involved fantasy or pretense. However, symbolic or fantasy play, especially involving sociodramatic activities (when children play with others), has an important role in developing creativity and social skills (Smilansky, 1968). Clearly, playing and learning are not mutually exclusive; for children, some forms of play are, in fact, essential for learning.

Closely allied to play for older children (and even adults) is Hawkins's (1965) idea of "messing about in science." Writing for teachers, Hawkins explained how, when children are given materials and equipment and allowed to explore, test, probe, and experiment without instructions, they understood much more (and were more motivated) than if they were led immediately into formally structured investigations. Science centers are delightful places for "messing about" and the play behavior it encourages. As Semper (1990) pointed out, "Play is a serious matter in science education" (p. 6).

Science centers have been subject to the criticism that they entertain but fail to educate. Shortland (1987) famously wrote: "When education and entertainment are brought together under the same roof, education will be the loser" (p. 213). In his article, "Do science museums educate or just entertain?," Shields (1993) gathered a range of views from people employed in the science center industry, and although no one disagreed that playing and fun were important, they all had perspectives that included learning outcomes. There are strong research findings that support these perspectives. In a study conducted at the Smithsonian Institution's National Museum of Natural History, Falk et al. (1998) discovered that two motivations—education and entertainment—were given as reasons for visiting the museum by virtually all visitors and, contrary to popular belief, there was no evidence that visitors came to *either* learn or have fun, but almost without exception, visitors came to *both* learn and have fun. Individuals who self-selected to go to the museum were seeking a learning-oriented entertainment experience. As one visitor stated, "We expect to enjoy ourselves and learn new things" (p. 117).

Museum floor staff (attendants, docents, explainers, interpreters) are competent observers of visitors. Research using focus groups of museum floor staff (Rennie & Johnston, 1997), science center explainers (Johnston & Rennie, 1995), and visitors to each institution found remarkable congruence between their perceptions. Staff were adamant that both education and entertainment occurred, and visitors agreed. Griffin (1998) designed school visits that were specifically planned to match the ways in which family groups use museums. Her findings confirmed that by enabling students to have purpose, choice, and ownership of their learning processes, they enjoyed visiting museums "because they were learning *and* having fun" (p. 661, emphasis in original).

***Myth 2: If learning occurs, it must happen at the museum.*** It is not difficult to discount this myth, given that learning is cumulative, not a series of isolated events. Early researchers who decided what the outcome of a visit should be and tried to measure it at the end of a visit frequently failed. They concluded that no learning occurred, without considering that the visit might simply have produced a readiness to learn at a later time. Some longitudinal studies (Falk, Scott, Dierking, Rennie, & Jones, 2004; Medved & Oatley, 2000; J. Stevenson, 1991) indicated that not only do visitors remember their visit experience, but in many cases they report quite outcomes some time after the visit that are different from those they report at the time of the visit, providing evidence that related learning has continued to occur. Furthermore, this learning is personalized. D. Anderson's research (Anderson et al., 2000) examined concept maps about magnetism and electricity drawn by 11- to 12-year-olds prior to their visit to a science center, after the visit, and again after some post-visit activities in the classroom. Detailed case studies of 12 children revealed that all had constructed knowledge about these topics as a result of their visit experience and the post-visit activities. Importantly, this knowledge was built in the context of the prior knowledge and understanding children brought to these experiences and thus was highly individualized.

***Myth 3: What people learn is predictable and therefore easily measurable.*** Longitudinal studies invariably find evidence that different people learn different things. Falk and Dierking (2000) described the experiences of two women who visited a museum together and, despite doing similar things, recounted entirely different experiences. Interviews conducted five months later revealed that their museum visit had lingering influences on their subsequent activities, and again, these influences and their outcomes were quite dissimilar. Such differences are easily explained in terms of the personal context of the visit—although they were good friends, these women had different interests and motivations, and these personal differences ensured uniquely individual outcomes from the museum visit.

The experiences of these women expose the misconceptions in this third myth. People's learning is not predictable, because people are not predictable. They do not all learn the same things in the same way, because they come with different expectations and prior experiences, and the personal circumstances of their visit are different. For example, D. Anderson (Anderson et al., 2003) observed that children's learning varied from a subtle change to a recontextualizing or strengthening of something already known about electricity and magnetism, and sometimes the experience fostered personal theory building. These variations in learning not only seemed to depend upon children's prior knowledge and experience, but also embodied their personal approach to learning. Each child's knowledge was constructed and developed from a rich variety of related learning experiences that included interactions with parents and other people in enrichment and extracurricular activities; experiences at home such as reading books, watching television programs, and playing with and disassembling electric and motor-driven toys; as well as school- and museum-based experiences. Similarly, Stocklmayer and Gilbert (2002) found that adults' experiences in using exhibits were influenced by what they remembered from prior experiences, and because these memories were personally unique, so were the outcomes.

Because outcomes are personal and diverse, they are unpredictable and very difficult to measure. Much research that failed to find evidence of learning from the museum visit suffered from narrowly defined outcome measures, usually focused on some specific cognitive learning. Hence they missed the variety of affective, social, psychomotor, and other cognitive learning that occurred, which was often peripheral to the targeted outcomes, and often unexpected by exhibition designers.

Demolishing the three myths returns the focus to the nature of learning in free-choice settings. Understanding what is learned and how it is learned requires researchers to take into account the personalized, contextualized, and cumulative nature of learning. Not surprisingly, such research is challenging.

## Research into Learning from Museum Visits

Research into learning from museum visits has a long history. Hein (1998) referred to a study at the Liverpool Museum in 1884, but the field did not begin to blossom until the 1960s. In the 1920s and 1930s, Robinson (1928) and Melton and his colleagues (e.g., Melton, Feldman, & Mason, 1936/1988) carried out significant research in the United States. These were carefully designed studies, examining the influence of variables such as exhibit design on visitors' learning by using quantitative approaches that featured tracking of visitors, plotting their movement, timing their actions, and formally testing their learning. Hein contrasted these early studies with the 1940s research of Wittlin (as cited in Hein, 1998), whose more qualitative approach to data collection and reporting placed less emphasis on establishing the validity and generalizability of the findings and more emphasis on the context. Wittlin focused on what visitors did and said in interviews, enabling her to obtain visitors' personal perspectives about the museum and its exhibits.

In the 1960s, visitor studies in museums tended to focus on the evaluation of exhibits and exhibitions, taking advantage of the developments in educational evaluation that accompanied the post-Sputnik science curriculum programs. Concepts such as summative and formative evaluation (Scriven, 1967) soon gained currency in the evaluation of exhibitions in museums and were supplemented by front-end evaluation (to aid in the planning of new exhibitions) and remedial evaluation (modifying the exhibit after installation). Screven (1986, 1990) and Miles and his colleagues (Alt & Shaw, 1984; Miles, 1986; Miles, Alt, Gosling, Lewis, & Tout, 1988; Miles & Tout, 1979/1994) provided insightful commentaries about evaluation research into exhibits and their effectiveness.

These evaluation studies relied upon data collected about visitors' behavior and learning in museums. In the 1970s and 1980s, their findings were built upon and extended by educational research that focused on the visitors themselves. The significance of this accumulating body of knowledge to the museum industry was recognized when, from the late 1980s, the Association of Science-Technology Centers (ASTC) began to publish a series on "What Research Says about Learning" in its newsletter.

Research into visitors' learning borrowed methodology from research into learning in schools, and consequently research designs were consistent with the educational thinking of the day. Thus the early work of Melton et al. (1936/1988), who employed pretest-posttest, control-group designs to measure carefully considered

cognitive outcomes from children's museum experiences, was exemplary for its time. In 1949, Wittlin (as cited in Hein, 1998) stated her view that reliable results were possible only if they were based on controlled experiments, but her qualitative and visitor-focused reporting implied that there was some loosening in the definition of outcomes as more attention was paid to the visitors' perspectives. Surveys, observational studies, and pen-and-paper tests of knowledge continued to dominate research into the 1980s, but it was becoming increasingly urgent to recognize the active, rather than the passive, role of the visitor in the museum.

Alt and Shaw (1984) argued that "exhibits should be designed to meet the needs of visitors rather than trying to 'force' visitors to view exhibits developed largely without regard to their needs" (p. 25). This required a different approach to exhibit design, and Alt and Shaw described two studies that culminated in the visitors' view of the ideal museum exhibit. Wolf (1980) used naturalistic strategies in his evaluation studies in the Indianapolis Children's Museum. He believed that naturalistic evaluation, with its "broad, holistic view," and being "more interpretative than judgmental" in its attempts "to capture what actually occurs in museum settings" (p. 40), was a more effective way to investigate the impact on visitors. Wolf argued that there should be a focus on visitors' "current and spontaneous activities, behaviors, and expressions rather than a narrow set of pre-specified behaviors" (p. 40). These views made it clear that many evaluation measures provided ineffective recognition of the broad nature of the outcomes of museum visits. Outcomes other than cognitive had to be considered. Roberts (1989) urged that more attention be given to the affective domain, encouraging researchers to find ways of capturing "the elusive qualities of affect" (p. 6). McManus (1993) pointed out that the distinction between cognition and affect is artificial and presented evidence from her work in the Birmingham Museum of Science and Industry that "knowledge-building, meta-cognition and affect were intertwined" (p. 113).

By the 1990s, theories of learning had changed through the influence of constructivist ideas about learning and sociocultural theory, as mentioned earlier, and research in museums reflected those changes. Uzzell (1993), for example, described how, in only 15 years, visitor studies undertaken by Surrey University had moved from a behavioral to a cognitive, then to a sociocognitive focus to reflect the active constructions and interpretations made by the visitor, and the social and educational context in which they occur. Falk and Dierking (1995) provided perspectives on these theoretical changes and their implications for research. There is a substantial body of research literature, including a number of major reviews of science learning in museums and other avenues of free-choice learning (Crane et al., 1994; Falk, 2001; Falk & Dierking, 1992, 2000; Hofstein & Rosenfeld, 1996; Lucas, 1983; Ramey-Gassert, 1997; Ramey-Gassert, Walberg, & Walberg, 1994; Rennie & McClafferty, 1995, 1996), and several special issues of journals, including the *International Journal of Science Education* (Lucas, 1991), *Journal of Research in Science Teaching* (Rennie & Feher, 2003), and two issues of *Science Education* (Dierking, Ellenbogen, & Falk, 2004; Dierking & Martin, 1997). Now, in the middle of the 2000s, research on visitors' learning is an active, vibrant field. A summary of this research is presented in five parts: science museums and science centers; aquaria, botanical gardens, zoos, and interpretative centers; field trips; family visits; and museum-school-community programs.

## Science Museums and Science Centers

Science museums and science centers are of particular interest to this review because of their explicit endeavor to portray science<sup>1</sup> and their popularity as venues for field trips and family outings. These institutions vary enormously in history, content, and purpose. McManus (1992) described the historical background to this variety, pointing out that it was not until the 1960s and 1970s that the old, established “first-generation” museums, focused on collections, research, and authoritative information, began to remodel their exhibitions to enhance communication with their visitors. The “second-generation” museums, mainly those of science and industry, were also well established and had the purpose of promoting the wonder of science as well as a training role. Their working models and hands-on elements enabled an active, communicative approach to education. The more recent “third-generation” museums were created by the move from exhibits based around objects to exhibits built to display ideas. McManus described two strands of these third-generation science museums: the thematic but non-object-based exhibitions of larger concepts, such as space, evolution, or health, and the “decontextualized scattering of interactive exhibits” (p. 164) in science centers, each exemplifying its own science concept and usually unrelated to the adjacent exhibits. The two strands often coexist in today’s science centers, with the permanent, “decontextualized” exhibits rotating in the available space and themed exhibitions housed in an area dedicated to traveling displays.

Interactive exhibits, purpose-built to display some scientific and/or technological concept(s), are an important component of science centers. They are undeniably popular, so much so that “interactives,” as they tend to be called, are increasingly incorporated into displays in first- and second-generation museums. Interactive exhibits are more than hands-on exhibits that visitors can touch. Touch tables in museums provide sensory experiences, feeling the difference between kangaroo fur and horse hair, for example, but involve action rather than interaction. As McLean (1993) pointed out, “interactivity is about being reciprocal” (p. 92): when the visitor does something, the exhibit offers feedback and invites further interaction. McLean described interactive exhibits as “those in which visitors can conduct activities, gather evidence, select options, form conclusions, test skills, provide input, and actually alter a situation based on the input” (p. 93). Oppenheimer’s (1968) vision for the Exploratorium was driven by these aspects of interactivity. He argued for “an environment in which people can become familiar with the details of science and technology and begin to gain some understanding by controlling and watching the behavior of laboratory apparatus and machinery” (p. 206).

Of course, the fact that an exhibit is interactive does not ensure that people will learn from it. Building good exhibits, interactive or not, requires knowing the intended audience, knowing the possibilities of the venue, and knowing what makes an exhibit work, its strengths and limitations (Allen, 2004; Kennedy, 1994; McLean, 1993). Perry (1989) synthesized several theoretical positions to develop and test a

---

1. Science museums and especially museums of science and industry portray technology as well, but as the difference is not often recognized in research and rarely differentiated in the minds of the visitors, it will not be considered further (see Gilbert, 2001, for an expansion of this issue).

model for exhibit design that was attractive to visitors and both educational and enjoyable. Successful exhibits are intrinsically motivating, she argued, when they provide visitors with opportunities to experience (a) curiosity, or surprise and intrigue; (b) confidence and feelings of competence; (c) challenge, something to work toward; (d) control, a sense of self-determination; (e) play and enjoyment; and (f) communication through meaningful social interaction.

Semper (1990) provided a complementary perspective by exploring four themes in educational theory that he found relevant to the learning activity in science museums. He described (a) curiosity or intrinsically motivated learning, to which he argued too little attention has been given (see also Csiksentmihályi & Hermanson, 1995); (b) multiple modes of learning (that is, there are inviting avenues for people who learn in different ways; see also Gardner, 1993; Serrell, 1990); (c) the importance of play and exploration in the learning process (see Hawkins, 1965); and (d) the existence of different views and levels of knowledge about science and how the world works, which effective exhibits can challenge by providing entry at a variety of cognitive levels. Research confirms that visitors' understanding of the science behind the concepts or phenomena displayed depends, for example, upon how the phenomena are modeled and the range of experimentation and explanation possible (Gilbert, 2001), particularly the analogical nature of the exhibit (Falcão et al., 2004; Stocklmayer & Gilbert, 2002). In a practical way, the levels of complexity in the interactive elements of the exhibit can enhance or inhibit visitors' success in grasping the concept (Allen & Gutwill, 2004). Based on a decade of research, Allen (2004) suggested that successful exhibits should have "immediate apprehendability [*sic*]" (p. S20), be conceptually coherent, and cater to a diversity of learners.

The widespread use of media in museums deserves mention. Videotapes are common, and, on average, they attract about one-third of visitors. Yet, people tend to watch less than half of the content (Serrell, 2002). Videotapes are best used to extend visitors' experiences, to provide background context to exhibits, or to show animal or physical behavior unlikely to be witnessed by visitors (such as frogs catching prey and feeding; Allen, 2004). Computer exhibits, with their interactive touch screens, are attractive, and visitors expect a lot from them in terms of speed and excitement (Gammon, 1999). However, they are difficult to use in social groups of peers or families. They are now commonplace and rank low on visitors' preferences (Adams, Luke, & Moussouri, 2004), as stand-alone exhibits, computers can effectively present simulation games or scenarios where alternative choices lead to different outcomes (e.g., Falk et al., 2004).

Science centers are very popular,<sup>2</sup> and several comprehensive reviews of research and perspectives about science centers (McManus, 1992; Pedretti, 2002; Rennie, 2001; Rennie & McClafferty, 1996) have drawn attention to their role in communicating science. As remarked earlier, science centers have been criticized for promoting fun and enjoyment rather than education in science, but more serious criticisms were first made by Champagne (1975). After 6 hours at the Ontario Science Center with his family, he suggested that the science center failed to meet its

---

2. In 2001 ASTC estimated that there were over 158 million visits, including 47 million schoolchildren on field trips, to 445 ASTC-member science centers in 43 countries (ASTC, n.d.).

obligations to science in four ways. First, the real meaning of science was obscured—the bright and flashing displays were exciting, but no questions were asked or answers given about the important problems of the world. Second, the demonstrations contained “sloppy science”—poorly worded explanations, for example, that failed to trace the consequences of science and technological inventions and connect them with the quality of life. Third, the ethical dimensions of science and technology decisions were entirely ignored. Finally, Champagne argued that science was dishonestly portrayed as easy and unproblematic, omitting reference to the fallibility of humans and their attempts to achieve integrity in results.

If we believe that science centers should communicate an understanding of science as a genuine human endeavor, these are significant flaws, and they are not easily addressed, as shown by continued criticism (Fara, 1994; Parkyn, 1993; Ravest, 1993; Wymer, 1991) and some research evidence. Rennie and Williams (2002), for example, found that after their science center visit, some visitors were more likely to think that science was infallible and could solve all problems, consistent with Champagne’s (1975) final criticism. Bradburne (2000) and his colleague, Wake, found three weaknesses in science center exhibits: they communicate principles, not processes; most fail to communicate scientific thought, focusing on conclusions rather than the journey, which includes false leads and often failures; and they mask the complex links between science and technology because they are decontextualized. Bradburne’s answer was to find ways to present science as a process. One result was *Mine Games*, an exhibition at Science World in Vancouver that put the visitor at the center of social debate on science, technology, and society. According to Bradburne, “the visitors seemed ready, willing, and able to take that responsibility” (p. 45).

*Mine Games* is one of a genre of issues-based science exhibitions that deliberately forefront the intersections between science, technology, and society, and, to some extent, they address the challenges offered by the critics mentioned earlier. Pedretti and her colleagues researched how these exhibitions affected school visitors, finding that in focused class programs, both *Mine Games* (Pedretti, 1999) and *A Question of Truth* at the Ontario Science Center (Pedretti & Forbes, 2000) resulted in shifts in students’ perspectives about the nature of science and how it sits in the sociocultural context of real lives. Adult visitors also were affected by *A Question of Truth* (Pedretti, Macdonald, Gitari, & McLaughlin, 2001; Pedretti & Soren, 2003), and they showed support for this type of exhibition. Pedretti (2004) concluded that these exhibitions enhance learning through four factors—they personalize the subject matter, evoke emotion, stimulate dialogue and debate, and promote reflexivity.

Although such exhibitions may have positive effects on the public audience, they can also be subjected to strong criticism. Molella (1999) described the backlash against *Science in American Life*, an exhibition at the National Museum of American History, which explored critical intersections between science, technology, and society through a series of historic case studies. Despite its public success, scientists felt the exhibition blurred the image of science as a pure endeavor. Molella attributed these feelings to the political climate of the day (see also Friedman, 1995). Mounting such exhibitions involves risk, but then, so does science.

## **Aquaria, Botanical Gardens, Zoos, and Interpretive Centers**

Whereas science center exhibits are designed to display mainly physical science concepts (many dealing only with Newtonian physics), the living exhibits in aquaria, botanic gardens, zoos, and interpretive centers provide visitors with opportunities to explore biological science. Visitors differ in their responses to living things compared with preserved specimens. For example, Tunnicliffe (Tunnicliffe, 1996; Tunnicliffe, Lucas, & Osborne, 1997) found that, at the Natural History Museum, the specimens' lack of visible behavior encouraged visitors to construct their own narrative, by naming the animals, recalling knowledge about them, and commenting on structure and appearance. At the London zoo, visitors made similar comments, but often they had to locate the animal before observation could begin, and then they talked about its behavior. In both venues, Tunnicliffe found remarkable similarity in the conversations among school and family groups (Tunnicliffe et al., 1997), suggesting that much more might be done by teachers and by the institutions themselves to extend learning. Later, a comprehensive study with visitors, staff, and school groups at a New Zealand zoo (Tofield, Coll, Vyle, & Bolstad, 2003) confirmed that easily visible and active animals attracted the most attention from visitors. Furthermore, learning was enhanced considerably by pre- and post-visit activities.

Institutions housing living specimens are well placed to convey ecological and environmental messages. The zoo in the Tofield et al. (2003) study, for example, reflected its mission's emphasis on conservation education with signs conveying two types of message—information about the animals, and information about environmental and conservation matters. Adelman, Falk, and James (2000) found that visitors' experiences at the National Aquarium of Baltimore enriched their conservation-related experience, awareness, and knowledge. These positive changes persisted over time, especially with respect to the complex balance between the needs of people and nature. However, there was no evidence of increased conservation behavior, which these authors attributed to a lack of suitable reinforcing experiences.

Brody, Tomkiewicz, and Graves (2002) reported on the development of visitors' understanding of the rare geothermal and biological features of a geyser in Yellowstone National Park. Using pre- and post-visit interviews, they found that visitors constructed new knowledge and values from their prior conceptions, their experience with the environment, discussion among fellow visitors, and use of the site brochure. Values related to the beauty of this extreme environment, the need for preservation and conservation, and the commercial potential of the biotechnological use of the microorganisms. Brody et al. pointed out that effective educational programs must be cognizant of modern theories of learning, as well as the public's existing understanding of ecological concepts.

## **Learning Science from Field Trips**

Most young people experience museums on field trips; in fact, school groups are a major audience for museums. Museum educators develop activities to link with the relevant school curricula to enable teachers to plan effective visits. Different programs are offered for different parts or levels of the curriculum or for particular

exhibitions. Museums also offer programs that cater for the needs of special groups, for example, the gifted (Melber, 2003), those with disabilities (Tam, Nassivera, Rousseau, & Vreeland, 2000), and adolescents, historically “the missing audience” in museums (Lemerise, 1995). Despite these efforts, Jamison (1998) reported that many teachers are unaware of the resources and support available.

Teachers arrange field trips for a variety of reasons: to supplement or complement part of the curriculum, as an enrichment experience to see things that cannot be offered in school, or sometimes as a reward for their class, with no firm educational purpose in mind (Gottfried, 1980; Griffin & Symington, 1997; Jamison, 1998; Michie, 1998; Rennie, 1994). Sørensen and Kofod (2003) described (a) the “day out” tour, with no preparation and no follow-up; (b) the “classroom” tour, where students follow a docent or teacher around the venue and often do a worksheet; (c) the “inspiration” tour, when children explore the exhibits on their own to obtain ideas for their work back at school; and (d) the “learning resource” tour, when the visit is part of the work at school with before- and after-visit activities.<sup>3</sup> Sørensen and Kofod found that, although 80% of the 81 elementary teachers responding to their survey reported that their class visit to the Experimentarium in Denmark was related to their school science, it was clear from other patterns of responses that only about 30% of visits could be classified as “learning resource” tours and 10% as “inspiration” tours. A third of teachers regarded the visit as a social event, and nearly a quarter did no pre-visit preparation. Nearly all teachers indicated that they talked about the visit in class afterward, but in less than 10% of classes did students write, draw, or report about the visit. These findings confirm other research—the minority of field trips are integrated with work back at school (D. Anderson et al., 2000; Griffin & Symington, 1997; Rennie & McClafferty, 1995).

Not surprisingly, different kinds of visits have different outcomes. Clear and compelling findings have emerged from a great deal of research about field trips (see reviews by Bitgood, 1991; Griffin, 2004; Mason, 1980; Prather, 1989; Rennie & McClafferty, 1995; Rickinson et al., 2004). Their educational effectiveness depends on how well they complement the science curriculum at school. This means that, to a large extent, their success is in the hands of teachers. Early advice intended to help teachers organize effective field trips given by museum educators (e.g., Barrett, 1965; Beardsley, 1975) emphasized that planning before the trip and “recapitulation” afterward were almost as important as the trip itself. Research has confirmed this advice. In terms of planning, Rennie and McClafferty (2001) reminded teachers to ask themselves why they were going, to ensure that the field trip was planned to meet its purpose. These authors drew attention to both teacher and student preparation. They stressed the need for teachers to visit the intended venue and take advantage of the in-service courses, curriculum resources, and advice available from the education officers and the venue’s website. Student preparation serves two purposes. First, students need orientation about the venue, so they know what to expect in terms of what they will see, their physical comfort, and the time allocated for educational tasks and for their own exploration. Second, they

---

3. Sørensen and Kofod (2003) also described a partnership between the Experimentarium and a nearby school, where students visit the science center, choose a project based on the exhibits, and pursue it to completion with follow-up visits. Such partnerships are unusual but have great potential for learning.

need advance organizers for the learning objectives of the field trip so they can be self-directed in terms of achieving them during the field trip and by working toward the requirements of post-visit activities. Griffin and Symington (1997) urged teachers to include students in the planning process so they have a sense of commitment to the objectives to be achieved.

The field-trip venue is not a school classroom. The social and physical contexts, and hence the learning, are quite different. Teachers can take advantage of the new environment by helping students to orientate themselves at the venue, then allowing them sufficient time to complete structured tasks and pursue their own interests. Encouraging students to work in small groups capitalizes on the social dimension of the visit and enables them to share the responsibilities associated with learning. Group, rather than individual, worksheets are thus more effective records of students' explorations (Rennie & McClafferty, 1995). Toward the end of the visit, teachers should encourage students to regroup and ensure they have the information they need for follow-up activities. Back at school, the field trip experiences need to be revisited and built on to maximize the learning. Research still has the least to say about this aspect of field trips, but its significance has been established (D. Anderson et al., 2000; Tofield et al., 2003).

How teachers integrate the field trip with science at school depends in part on the learning objectives. Orion's (1989) high-school geology course based on field trips provides an exemplar for teachers who need to combine considerable content with first-hand experience with the subject, in this case, the geology of Israel. Astin, Fisher, and Taylor (2002) gave examples of class visits used to complete a compulsory component in a new physics course in Britain. In both cases, it is clear that prior to a field trip, the teacher must investigate the location and devise preparatory and summary activities around the field trip itself.

## **The Role of Docents**

Docents, explainers, or education staff are available to assist school groups at many venues. Their roles may vary from leading structured tours to merely responding to questions, and teachers need to consider the role they wish docents to play during their visit. Naturally, students' patterns of behavior are quite different when they are instructed by a docent than when they are not, as Birney (1988) demonstrated in her study at a zoo and a museum in Los Angeles. When students were led by a docent, their passivity and inattention were high; when students were free to explore, these responses were replaced with activity and interaction with exhibits and peers, behaviors more likely to be associated with learning. Similarly, Cox-Petersen, Marsh, Kisiel, and Melber (2003) found that the docent-guided tours in a natural history museum in California were lecture-oriented. Although students, who were given objects to examine and some time to explore the halls, enjoyed their visit, learning outcomes were limited. More effective, inquiry-oriented, learner-centered tours led by docents (Cox-Petersen et al., 2003) or teachers (Griffin & Symington, 1997) combine initial orientation with students then moving off in small groups to pursue their own explorations. Effective guides (docents, teachers, or accompanying adults) encourage visitors to actively explore and reflect, rather than simply direct them to the "right" answer.

Despite their significant benefits, field trips can be expensive and difficult to organize. There are administrative hurdles, insurance issues, and, especially at the high school level, the need to juggle timetables (Michie, 1998; Rickinson et al., 2004; Tofield et al., 2003), so it makes sense to maximize their value by ensuring that enjoyment and education both win on the day.

## Learning in Family Visits to Museums

Children visit museums in family groups, an ideal situation for play, talk, and learning from each other. Families are the most common museum-visiting group (Falk, 1998; Falk & Dierking, 1992; McManus, 1992), so it is not surprising that their behavior has been well studied. Early researchers focused on what families did in museums (e.g., Diamond, 1986; Dierking & Falk, 1994; Hilke & Balling, 1985; McManus, 1992, 1994) and constructed a general model of family visiting behavior that is still current (Kelly, Savage, Griffin, & Tonkin, 2004). Typical teaching-learning behaviors include parents acting as exhibit interpreters for children, by pointing, asking questions, and modeling exploratory behavior. Such actions might be expected to facilitate learning, especially for young children, who are likely to spend more time at an exhibit when an adult is also present (Crowley & Callanan, 1998; Crowley & Galco, 2001; Puchner, Rapoport, & Gaskins, 1997; Rennie & McClafferty, 2002).

Family behavior varies with the age of the children; older children may be left to explore alone or with their peers, and some parents are content to watch even young children rather than interact with them (C. Brown, 1995). Recognition that different patterns of behavior occurred at different types of exhibits prompted Borun and her colleagues (Borun et al., 1996; Borun, Chambers, Dritsas, & Johnson, 1997; Borun & Dritsas, 1997) to design “family-friendly” exhibits to encourage the kinds of behaviors believed to promote learning.

Recently, researchers have moved beyond observational “time and tracking” studies (Ellenbogen, Luke, & Dierking, 2004) and adopted a range of innovative methods for data collection in keeping with a sociocultural perspective on family learning. For example, paying closer attention to the nature of the conversations between parents and children in museums has revealed how parents scaffold children’s scientific thinking (Ash, 2003; Crowley & Galco, 2001). This research has shown that parents help children select and process relevant evidence, generate more evidence, and provide explanations (Crowley et al., 2001).<sup>4</sup>

Because families remain together before and after the visit, investigation of their learning must take a longitudinal perspective. Some researchers have asked families to recall discussions and activities subsequent to their museum visit, then tried to construct how and what learning occurred. Ellenbogen (2002) obtained much information as she worked on her dissertation research. In the role of participant observer, she not only accompanied four families on their regular museum visits, but spent time in their home before and after the visits. She concluded that frameworks

---

4. How parents scaffold children’s scientific thinking may be more easily studied in a science center than in the home, where the researcher would be more intrusive. Similarly, Feher and Diamond (1990) argued that science centers can be used as laboratories to study the way children learn by choice, rather than when they are constrained by expectations in the classroom.

for measuring family learning in museums (e.g., Borun et al., 1996) were constricted by the museum's agenda for assessing learning and insensitive to the variety and depth of learning conversation that actually occurred. Ellenbogen's research across multiple learning environments revealed that families who used museums frequently had their own complex motivations and agendas into which they fitted the museum visit. In this way, museums were used as tools for family members to negotiate and establish their identity as a family of learners, but on their own terms, rather than on those of the museum. Thus, the museum provided the context for learning, rather than the content. Occasional family visitors may not make the same use of their museum experience because their personal contexts and visit agendas are different, and they would be less familiar with the physical environment. However, there is evidence that families who have not traditionally used museums to meet their free-choice learning needs can learn to use these settings in personally meaningful ways that result in heightened interest and engagement in science (Dierking & Falk, 2003).

A decade ago, McManus (1992) described family members as a "coordinated hunter-gatherer team actively foraging in the museum to satisfy their curiosity about topics and objects that interest them" (p. 176). We still see this behavior pattern in museums, but the adoption of new and alternative research strategies that document the role of the museum in family life while retaining the family as the central focus of the research has resulted in a better understanding of the family as a learning institution. This learning institution utilizes the free-choice learning resources of an extensive community infrastructure, of which museums are an important part (Ellenbogen et al., 2004). Children's learning in a family context is a significant factor in their learning about science.

### **Other Museum-School-Community Links**

Museums make a significant contribution to science education through their work with schools, teachers, and the community. The School in the Exploratorium (SITE) was one of the earliest formal links between a science center and schools. Established in 1972, it involved weekly visits for 5 or 8 weeks by fourth, fifth, and sixth graders for an extended program of "hands-on" science (Silver, 1978). By 1987, the program included a range of curriculum development and teacher professional development programs. St. John (1987) found considerable success in extended teacher change. For example, about one-third of participants said they continued to use SITE materials extensively, and 80–90% of teachers expressed improved science understanding, interest, and comfort in teaching science. Today, beyond SITE, the Exploratorium is a major provider of programs for teaching and learning, with "10,000 teachers from 37 states annually participating in Exploratorium-designed workshops" (Exploratorium, n.d.), although not all are held at the Exploratorium.

Inverness Research Associates (1996) listed 12 different kinds of programs in "informal science education institutions" (including science centers, natural history museums, aquaria, botanic gardens, planetaria, and nature centers), 5 of which were related specifically to teacher development, and others related to curriculum, materials development, and support outreach; structured and educationally supported field trips (not including regular, teacher-led field trips); preservice teacher connec-

tions; national science education programs (e.g., Challenger Centers); and local educational partnerships. At that time, Inverness Research Associates estimated that 11% of all teachers of science in the United States participated in such in-service activities each year. Programs continue to grow. Based on their 2002 survey, the Institute of Museum and Library Services (n.d.) estimated that nearly 11,000 museums in the United States provided more than 18 million hours of K–12 educational programming, spending over \$1 billion in 2001–2002. A few examples will give a flavor of these activities.

Torri (1997) described a typical partnership between a museum and a nearby school to enhance K–8 science instruction. Teachers visited the museum for introduction to the programs; there were follow-up class visits and use of museum resources, some specifically written for teachers' needs. Torri stated that teachers appreciated the additional support, and the partnership was a successful innovation. Kelly, Stetson, and Powell-Mikel (2002) reported a partnership between a museum and university that benefited early childhood and elementary preservice teachers. Observation of, and working with, children visiting the museum's hands-on science facility improved the preservice teachers' understanding of young learners' abilities. In post-course surveys, the preservice teachers commented positively about their own improved confidence in science and mathematics.

Paris, Yambor, and Packard (1998) described a comprehensive museum-school-university partnership for a 6-week biology program for grades 3–5. This program was based on current research on learning with carefully designed strategies to promote intrinsic motivation and self-regulated learning. Children attended classes in the university's laboratory, used living exhibits and materials from the museum, and carried out other activities and projects, culminating in a family biology night. The children's classroom teachers were integrally involved, and university students assisted children in the laboratory as part of their own course. The program was thoroughly evaluated, showing positive increases in children's attitudes to science, problem-solving, and knowledge retention. Qualitative findings from teacher interviews and child case studies substantiated the enthusiasm of both, and the university students made similar reports. Paris et al. noted the benefits of matching the program to the state curriculum and its structuring in terms of learning theory and urged similar partnership programs.

Although not directly associated with schools, programs for volunteer exhibit interpreters provide young people with opportunities to learn about science and about people learning science, providing an ideal background for careers in teaching and science. Both the Ontario Science Center and the Exploratorium have had such programs since their inception in 1969; research with young people shows that they become better learners and educators (Nyhof-Young, 1996) and gain enduring skills in self-confidence, communication, and science learning (Diamond, St. John, Cleary, & Librero, 1987).

Museum outreach is closely related to, and often an extension of, links to schools. Many museums run programs off-site at venues such as schools, libraries, community halls, shopping centers, fairs, and festivals. D. Martin (1996) gathered descriptions of a variety of outreach programs ranging from Ulster Museum's Science Discovery Bus to Riksstutställningar's traveling garbage museum in Sweden, to art courses by telephone from the Metropolitan Museum of Art for homebound residents of New York City, to Harborough Museum's prison outreach. Martin suggested

that “outreach has become fundamental to the process of changing the role of museums within their communities, establishing relationships with new audiences, and turning museums from inward facing to outward facing organizations” (p. 38).

The opportunities provided by outreach programs are especially appreciated in remote and rural areas, where adults and children have no access to museums or similar organizations. In Australia, Garnett (2003) surveyed 63 museum-sponsored and private outreach providers of education and awareness programs in science, mathematics, engineering, and technology. Returns from 57 providers reported contacts with 421,360 students during 2002. Garnett conducted a case study in one town in each Australian state and one territory, and 207 surveys were returned from schools that had recently participated in an outreach program. The findings suggested that these programs increased students’ interest and skills levels, and that presenters benefited students and teachers by demonstrating new approaches, content, techniques, and resources. Garnett concluded that provision in remote areas fell well short of need, with programs reaching only one in four children. Two-thirds of providers offered supporting websites and teacher resources, one-third offered student resources and teacher workshops, and more than half also offered programs/exhibitions for the general public during their tours. These outreach programs are now the major providers of professional development for teachers of science outside major cities, but Garnett found that teachers in only 42 of the 207 schools believed they had access to professional development sufficient for their needs.

Rennie and Williams (2000) evaluated the impact of an Australian traveling science show. Their data included interviews with 82 teachers at 47 schools at the time of the show, 325 interviews and exit surveys from adult visitors to associated public exhibitions, and telephone interviews with 48 teachers between 4 and 8 weeks after the science show visit. The results from the teachers were similar to the findings from field trips. Very few teachers prepared their class for the visit, but about half followed up afterward by discussing what happened and what children thought about the visit. The conclusions that can be drawn are consistent with those made earlier. Although all participants were very positive about the experience, it is unlikely that the potential of these incursions into schools were fully realized in terms of students’ learning of science. Most providers (and certainly this traveling science show) supply information to teachers, especially via their website, to enable them to prepare for the visit by choosing shows that can be built into their teaching program and to plan follow-up activities (a resource pack was left at the school for this purpose). Most teachers do not do these things, and for many students it is likely that the major benefit of their experience is the memory of enjoyable science activities, which may or may not be relevant to their future science activities.

Clearly, museum-school-community programs are valued, or they would not be continued, but their effectiveness is assumed rather than demonstrated. This can be attributed, at least in part, to a desire to put time, funds, and effort into the program rather than its evaluation. Despite the availability of good advice, most evaluation is usually limited to feedback sheets and head counts of participants. Self-evaluation of outreach programs is difficult, as Matarasso (1996) pointed out, because there is always a vested interest in demonstrating success. Matarasso suggested that clearly stated aims of the program should be agreed on, and indicators of their being met decided, before data gathering begins. This helps to focus the evaluation and enables it to demonstrate the outcomes. The Paris et al. (1998) and Rennie and

Williams (2000) studies were designed in this way and contributed some empirical evidence to support the potential of such programs to promote better science learning for students at school and community members at large.

## LEARNING SCIENCE FROM COMMUNITY AND GOVERNMENT ORGANIZATIONS

This section considers programs that offer voluntary activities to groups of young people. Such programs are characterized by diversity. Some have a national base, such as 4-H, but others are genuinely community-based, operating in a defined geographical area. They may be offered as single events, annually, or as a regular program. Some are offered as extracurricular activities in schools, others are completely separate. An idea of their number and diversity can be obtained from a sample of what is available in Australia, a large country with a relatively small population.

The Australian Science Teachers Association's (ASTA) website (<http://www.asta.edu.au/st2003/alpha-list.html>) in 2003 listed 146 separate activities, competitions, programs, and events aimed at students and science teachers, sponsored or organized by a range of professional science-related associations, universities, industries, and other nongovernment organizations. These ranged from science poetry competitions, science fairs, summer schools, and work-experience placements to teacher and student awards. The annual National Science Week was not included in this list. That major event, which receives significant government funding, coordinates about 500 separate official events and activities. Rennie and ASTA (2003) analyzed the 2001 National Science Week event calendar and found that 40% were public lectures, forums, or debates; 20% school activities or competitions; 15% special exhibitions in museums or displays in public places; 5% open days/nights at science venues or to show science in industry; 5% tours or excursions; and a range of other awards, presentations, conferences, on-line activities, science theater, and so on. However, a comprehensive search for effective evaluation of the outcomes of these activities failed to provide anything beyond data for attendance/participation and subjective or self-reported assessment of the public's response.

On a broader level, the Australian government supports public science awareness-raising activities through the Science and Technology Awareness Program (STAP), replaced in 2001 by the National Innovation Awareness Strategy (NIAS). STAP and NIAS have been important sources of funding for projects aimed not only at increasing awareness of science and technology, but promoting understanding and a positive attitude toward science and technology among the Australian people. However, Gascoigne and Metcalfe (2001) noted that evaluations of STAP were positive about its role and activities but did not provide information about the effectiveness of its programs. They drew attention to the need for impact evaluation, rarely a design feature of such programs, both in Australia and internationally.

### Community-Based Programs

Community-based programs are usually flexible in time and topics. They offer science-related activities at variable cognitive levels and often for a range of age groups, allowing cross-age mentoring. Although most programs are not specifically

aligned to the school curricula, Nicholson, Weiss, and Campbell (1994) explained that many of them grew from a deliberate attempt to complement what was perceived as dull, teacher-directed science at school with innovative, hands-on, inquiry activities. Many such programs target minority groups and/or girls with the purpose of promoting their interest and participation in science.<sup>5</sup> Nicholson et al. described three categories of programs: discovery programs aimed at making science (and mathematics) interesting, thus changing attitudes and inspiring self-confidence in doing science, such as Operation SMART and Hands On Science Outreach; short-term, usually residential, science camps, providing intensive immersion in science aimed at changing attitudes and increasing participation in science; and longer term career programs, with regular participation allowing continued contact between participants and mentors.

Hands On Science Outreach (HOSO) is a good example of a community-based program because it has a long history and there has been some evaluation of its effects. HOSO was established as a local community after-school experiment in the United States in 1980 to provide a regular, recreational science option for preschool and elementary-school children (Katz, 2000). Children work in small groups with a trained adult helper (usually a parent) to engage in pleasurable, hands-on science activities in a personally supportive environment. Activity guides are provided for home use in a family situation. HOSO has grown rapidly and has received a National Science Foundation (NSF) grant to expand. HOSO's activities are consistent with the National Science Education Standards (Katz & McGinnis, 1999), and its topics are representative of the major disciplines outlined by the Standards. Katz (2000) reported several evaluations of HOSO. Participating children made significant gains in knowledge and understanding about science and perceptions of scientific activity, but long-term effects were not measured. Katz (1996) used focus groups and case studies in research with the adult leaders, finding that HOSO provided them with learning, enjoyment, and specific personal benefits.

Community-based programs are difficult to evaluate, especially their long-term effects. The evolution of programs with time and the difficulty of tracking past participants are two of the research challenges common to other out-of-school contexts. Eccles and Templeman (2002) recounted a thorough analysis and evaluation of after-school programs for youth (although with aims other than science) and concluded, with caution, that there were positive effects. More comprehensive evaluation is needed for such science-based programs to judge their effects in both the short and long term, and to examine the reasons for them. For the moment, our understanding is best informed by the findings described in the previous section, particularly for field trips, families, and museum-school-community links.

## LEARNING SCIENCE FROM THE MEDIA

The media include all print and electronic means of communication to the public. Some publications and programs have explicit educational aims, ranging from *Sesame*

---

5. Examples include the Girls at the Center project (<http://sln.fi.edu/tfi/programs/gac.html>) linked with the Franklin Institute Science Museums and Girl Scouts of the United States and activities in Britain sponsored by sciZmic (<http://www.scizmic.net>).

*Street* to publicly funded and coordinated media campaigns for health promotion (to quit smoking, for example). Others, such as fictional stories in print or on television, have entertainment as their prime purpose. Nevertheless, all can provide learning experiences related to science.

How can we discern the learning impact of media on young people? Much research on learning from the media is based on how these avenues of communication are used in classrooms, or on the impact of particular programs, rather than on what people learn from the media in a free-choice environment. School-directed use of media, such as textbooks, television, and the Internet (including their use for homework) is not the focus here; rather it is the use of media for personal interest and information. In this section, most attention is given to television because of its pervasiveness. Print media and the Internet are also mentioned, but there is little research on their contribution to young people's learning of science in out-of-school contexts.

## Print Media

Turney (1999) distinguished several genres of popular science in print: biography and autobiography both reveal much about the thinking of scientists and the way science works; sources of self-help provide information about topics of interest or relevance to the reader; dictionaries or primers for scientific literacy; and publications for intellectual entertainment that are often based on controversial issues. From a different perspective, Goldman and Bisanz (2002) described three roles for communicating scientific information: communicating among scientists, disseminating information generated by the scientific community, and formal education in science. The second is relevant here. Goldman and Bisanz divided this role into public awareness, including the press, news, advertisements, public service messages, and science fiction; and public understanding and informal learning, which includes Turney's genres and informational websites.

All of these are read by some young people, and research on the effects of reading such publications in a free-choice environment is confounded by just that; young people are *choosing* to read them. Already the personal context is positive, and although reading might be a solitary activity, most readers will share and talk over their reading with like-minded friends. Because they are already knowledgeable about the topic, interested readers find it easier to connect new information with old than does a person who is new to the topic (Goldman & Bisanz, 2002; Tremayne & Dunwoody, 2001). Given this, it is easy to imagine that reading for interest results in learning.

What research can reveal, however, is what kind of learning may occur. Most studies have been done in formal settings, often with university students, but some results are generalizable. Many public awareness communications are brief to engage the reader, but brevity risks ambiguity and oversimplification of the issues. Goldman and Bisanz's (2002) synthesis of research suggests that students have limited ability to judge the scientific status of an argument and tend not to adopt a critical stance. Of course, this varies with background knowledge, but it places the onus on journalists (and scientists) to portray science fairly to their readers. Rennie (1998) analyzed three examples and argued that this is not done well.

## Computers and the Internet

Science on the Internet can range from one person's idea (or ideology) to the large and comprehensive websites of public organizations, such as the BBC, NASA, and so on. Museums have their own websites and were among the first to recognize their educational potential (Streten, 2000). As they are expected to provide authoritative information, museum websites, together with those of government agencies, science publishers, and universities, are often recommended as web-based educational resources (e.g., Bodzin & Cates, 2002; Smith, 1999; S. Stevenson, 2001). Unlike print media, websites can be updated rapidly and hence provide the public with readily accessible information on complex and controversial scientific topics (Byrne et al., 2002; Hawkey, 2001).

Museum websites are popular. Rennie and McClafferty (1996) reported that in the week beginning December 10, 1995, the Exploratorium website had 188,381 accesses. Eight years later, in the week beginning December 7, 2003, it had 800,059 page views, 8,602,363 hits, and 39,896 Mb of data transfer (R. Hipschman, personal communication, March 21, 2004). Although many hits were seeking visitor information, such as opening hours, etc., most were seeking educational or science-related information.<sup>6</sup> There is extensive documentation of the use of websites, but little about the learning from them. Semper (2002) wrote that "the World Wide Web and museums were made for each other" (p. 13), but, he argued, a research agenda must be developed and implemented to understand both the online audience and how the websites can support learning.

Semper, Wanner, and Jackson (2000) set out to develop a means of evaluating three online resources: (a) a step-by-step instructional sequence for dissecting a cow's eye; (b) a general informational topic on the science of cycling; and (c) flights of inspiration, based on a museum collection. Their analyses and interpretation of viewing logs and an online survey of viewers found that, for each site, 60% or more of the users were adults. The cow's eye dissection was the most popular for high school students and was used mostly in an explicitly educational setting. Cycling was the resource hit most often out of interest. Semper et al. discussed the value of the different data sources they used, which revealed previously invisible users. More research will result in further information about the learning that occurs.

Museums have embraced digital and mobile technologies with the main goal of increasing access to the collections by presenting information about exhibits and educational programs on the web (Bradburne, 2001; Institute of Museum and Library Services, 2002). They have created successful "virtual field trips" (Bradford & Rice, 1996) for virtual visitors to explore, but this may be a double-edged sword. To retain their real visitors, M. Anderson (1999) pointed out, "museums will be forced to confront the fact that the competition for leisure time demands a more aggressive case for the experience of the original" (p. 131).

---

6. The Exploratorium was the 2004 Webby Award Winner for science, an honor presented by the International Academy for Digital Arts and Sciences (2004) for achievement in technological creativity and individual achievement.

## Television

Television is the most pervasive medium worldwide. Unlike books or the Internet, where the user actively chooses to read or interact, television viewing is often passive. Chen (1994) pointed out in his review of research in the field of “television and informal science education” that, despite the very high level of national funding for educational programs, there was a paucity of systematic research, and most of it was focused on NSF-funded science programs provided by the Children’s Television Workshop. Some years later, Wright et al., (2001) reached the same conclusion—very little attention has been paid to the educational value of children’s television viewing. Most of the challenges to research in out-of-school contexts mentioned earlier are evident in evaluation of the learning effects of television. Viewers differ in their personal and home contexts, and finding appropriate samples from which research findings may be generalized is a challenge. Data collection from people in their usual viewing context creates other problems—how does the researcher deal with channel changing, for example? Longitudinal impact studies are difficult because there are so many intervening variables. Chen (1994) also noted that summative or impact evaluation is historically absent, and the producers of most television projects do not regard it as a priority.

Chen’s (1994) search uncovered only eight studies of children’s or adolescents’ television watching in relation to science, and four for adults. Overall, programs on science and nature were appealing and ranked high for learning potential. The findings suggested an association between watching these programs and family support and heightened interest in the subject matter and desire to read in the area. Although Chen reviewed some comprehensive studies, he concluded there was not yet a field of research and argued for a greater commitment to summative evaluation.

Some research on children’s television viewing has been done by people employed in the field. Fisch, Yotive, Brown, Garner, and Chen (1997) found that although elementary school children rated two cartoon series (*Cro*—an educational program, and *The Flintstones*—a noneducational program) as having high appeal, they did not distinguish between them in terms of their educational content. Fisch et al. concluded that educational programs were more likely to be successful if they also were entertaining. Mares, Cantor, and Steinbach (1999) explored the potential of television to foster children’s interest in science. Under controlled viewing conditions, fifth-grade students watched versions of programs that varied in terms of whether and how science was presented. Children learned more when the science was shown in context than when it was not. A second study in fourth- and fifth-grade classrooms suggested that greater exposure to a program resulted in more positive attitudes to science, but it seemed that children who were more interested in science were more likely to watch the same program at home as well as at school.

Longitudinal studies of children’s television watching reported by Wright et al. (2001) deserve attention for their careful research design, although they did not focus on science. Two cohorts of children, aged 2 and 4 years, were studied for 3 years with the use of a combination of mother interviews, home environment visits, school readiness tests, and periodic telephone calls to document children’s activities for the previous day. Statistical controls were used for some extraneous variables, and the findings suggested that children who viewed more educational pro-

gramming had an advantage in school readiness compared with those who watched entertainment programs. Another study involved recontacting high school students who, 10 years earlier, had their home television viewing habits studied as 5-year-olds. Wright et al. found that the more 5-year-old children watched informative programs, the more likely they were as adolescents to have overall high grades, including in science. They attributed this to a more positive attitude toward learning. There is some relationship between these findings and earlier ones by Gibson and Francis (1993), who found teenagers' attitudes toward science to be negatively correlated with watching "soap operas" but positively correlated with watching "current awareness programs."

Long and Steinke (1996) analyzed the portrayal of science in children's educational programs and identified a variety of different images. They found that "images of science as truth, as fun, and as part of everyday life were quite evident" (p. 14). Long and Steinke inferred that viewers were encouraged to value science and the scientific community, but there was no empirical evidence to back this claim. Dhingra (2003) selected segments of network news, documentary, drama, and magazine-format science television programming to investigate how high school students understood the nature of science from these program genres. Students perceived the news and drama formats to convey uncertainty in science knowledge, whereas the documentary and magazine format conveyed an image of science as facts. Dhingra pointed out that different segments from these genres may have produced different responses, but she demonstrated that students' responses varied, and that they thought about what they had seen and made connections to other experiences in their lives, including at school.

Advertising is a ubiquitous feature of television, and the makers of advertisements are adept at finding ways to make viewers take notice of them. McSharry and Jones (2002) asked, "What better way to advertise science-based advances to the public than by television?" (p. 489). They identified 18 categories of advertisements on terrestrial (i.e., not satellite) television, of which 14 could be described as science-based, including a variety of domestic products like paints and cleaning products, and mapped them against the Science National Curriculum in England. A public survey of 196 people revealed that young people (7- to 16-year-olds) watched more science programs than adults, but all age groups watched much less science than was available (in the sample period, this was 7.21% of all programming). Furthermore, few recognized advertisements that were science-based, choosing an average of less than 4 from 14 choices. Health-care products were best recognized (by 64% of respondents), followed by food (41%). McSharry and Jones pointed out that advertisements may constitute the main exposure to science on television and urged educators to use advertising as a way to make science education relevant to children.

Television advertising, combined with other media, such as radio and print, can make a measurable difference in knowledge about an issue. Gillilan, Werner, Olson, and Adams (1996) found that after a 3-month campaign on radio, television, and in-store advertising, at least 65,000 citizens of Salt Lake City had heard of precycling (reduction of garbage by choosing goods with minimal or recyclable packaging). However, there was no evidence of behavioral change. Similarly, there is some evidence from a longitudinal study conducted by three telephone surveys that a health promotion program increased nutrition knowledge, but possible change in health-related behaviors was not measured (Chew, Palmer, & Kim, 1995). These studies

were carried out with adults, and learning and behavioral change are more likely to occur when the topic has an impact on one's personal life (see, for example, Layton, Jenkins, Macgill, & Davey, 1993). The same may well apply to school-age children.

Television and other means of visual communication are changing rapidly. Old programs do not go away—instead they are repackaged into videotapes, videodiscs, CD-ROMS, DVDs, online networks, and so on. Film and television have been revolutionized by digital technology and the increasing sophistication of computer animation. Science programming has changed accordingly. Rayl (1999) suggested that “an uneasy alliance has existed between science and television” (p. 8), partly because of a historic difficulty in communicating science to the lay public. He suggested that science's increasing need for public funding has resulted in the making of expensive, high-quality programs that try to present real science and scientists, such as *Life Beyond Earth*. A genre of television programs, such as *Walking with Dinosaurs* and *Walking with Beasts*, tells stories in documentary style about digitally created prehistoric animals. These series are expensive to make (*Walking with Beasts* cost €11 million), are usually produced by a consortium, and are immensely popular (European Research News Centre, 2002). However, critics have suggested that for the sake of drama, fact and fiction are blurred in such programs, and it is not made clear to viewers what is fact and what is assumption (McKie, 2001). Furthermore, opportunities are missed to capitalize on showing how science deals with uncertainties (Rose, 2001). Separating science from fiction in television and film can be a fruitful discussion topic in science classrooms (Allday, 2003).

Bennett (1997), then head of BBC Science, warned that although production methods were sophisticated, the understanding of qualitative evaluation methods was not. More reliance was placed on robust quantitative information about viewers' habits and demographics. Like museums, television competes for “visitors” (their viewers). Bennett described how the BBC had become more audience-focused in its program provision. She provided an illustrated history of science coverage on British television, concluding that “while it was once possible to criticize science programming as deferential and portraying a universally positive view of science, this is no longer the case. In the 1990s, some of the key features of science coverage on television are the search for relevance, a focus on the impact of breakthroughs and discoveries; and a concentration on process and the narrative when covering science in documentary format” (p. 63).

Nevertheless, Bennett argued, the challenges continue: how to tap the curiosity of the audience, increase the relevance of programming, exploit the increasing interactivity of television, and retain the ability to give a sense of excitement about science.

## IMPLICATIONS FOR RESEARCH, EDUCATIONAL PRACTICE, AND POLICY

This chapter began with an exploration of the meaning of learning science in out-of-school settings. Our current understanding, underpinned by constructivist and sociocultural perspectives, suggests that learning is an ongoing, personal process, shaped by the context of the learning experience. Effective learning occurs when a person is motivated to participate in the learning experience, the context is socially

and physically supportive, and the linking of new learning into the person's mental structures is facilitated. These factors must be kept in mind when one considers learning in any setting, including schools, and in drawing implications for research, practice, and policy.

### **Implications for Research into Learning Outside of School**

Recognizing that learning is personal, contextualized, and takes time provides a framework for interpreting the research findings we have reported here and providing directions for the future. It is easy to understand why early research, with narrow views of learning, produced inconclusive and partial results. Research in out-of-school settings is difficult because of the free-choice nature of the learning experience and the need to retain its context. This makes it difficult to generalize research results to other contexts and settings, and in many areas research is sparse and will probably remain so for some time. The 12 factors of the Contextual Learning Model described earlier in this chapter (Falk & Dierking, 2000) are potentially useful in this regard. Together, these 12 factors describe and emphasize the complexity of learning in museums and other out-of-school contexts. Taking account of all of them simultaneously is a nearly impossible research task. More realistically, researchers tend to tackle one or more of the factors, remain cognizant of the others, and gradually build up a holistic picture of learning outside of school.

The NARST Ad Hoc Committee set the future research agenda for learning science in out-of-school contexts (Dierking et al., 2003; Rennie, Feher, Dierking, & Falk, 2003). Six areas were suggested for extending and enhancing research in out-of-school settings. First, to accommodate the personal, self-motivated, and voluntary nature of learning, research must examine the precursors to the actual engagement in learning as well as the learning itself. Second, the physical setting must be considered by taking into account the context where learning takes place. Third, research must continue to explore the social and cultural mediating factors in the learning experience. Fourth, longitudinal research designs are required to take account of the cumulative nature of learning. Fifth, research designs must be broadened to investigate the process of learning as well as the products. Finally, innovative approaches are needed to expand the range of methods and analyses used in research. Pursuing these avenues, particularly in non-museum settings, will expand our understanding of learning outside of school.

### **Implications for Practice and Policy**

Out-of-school contexts are undeniable sources of learning for young people, and yet there seems to be little overlap there with what happens in school. Although, for the purpose of this chapter, agencies for learning outside of school have been discussed separately, they are not separate. Rather, they merge into one continuous experience in the out-of-school environment. Korpan, Bisanz, Bisanz, Boehme, and Lynch (1997) were surprised at Canadian students' high level of involvement in science-related activities outside of school and argued that teachers should not ignore

it. In the United States, Dhingra (2003) urged educators to recognize that students bring with them into the classroom television-mediated understandings about science. In England, Mayoh and Knutton (1997) observed science lessons and noted that out-of-school experiences were mentioned, on average, only once or twice a lesson, and that teachers rarely built on experiences volunteered by students. And in Botswana, Koosimile (2004) found a similar situation. In both developed and developing countries, it seems that teachers place emphasis on science concepts rather than on what students know about science and how they experience it in their everyday lives. Yet there are clear benefits for learning when teachers make use of their students' out-of-school experiences, not the least of which is capitalizing on students' interests.

The challenge for educators and policy makers is to forge closer links between formal science education and out-of-school learning. They are, as Bybee (2001) pointed out, "two components of one inclusive education system" (p. 49). Instead of quarantining school science from life outside of schools, we need to bring them together in mutually supportive ways. This review has touched on some avenues for improvement.

First, teachers can maximize the opportunities to learn from the wealth of resources available beyond the classroom door. For example, teachers can capitalize on popular media by bringing them into their classes. Freudenrich (2000) described how he uses science fiction novels, films, and television programs extensively in his physics class to motivate and maintain the interest of his students. Brake and Thornton (2003) prepared their science and science fiction degree course in a Welsh university as "a way of examining the relationship between science, technology and society" (p. 32).

Second, the evidence for learning from well-structured field trips is so strong that they should be integral to each year's science program. Research on field trips consistently concludes that effective field trips complement the in-school curriculum. Guidelines discussed earlier focused on the need for teachers to plan jointly with students and venue staff, incorporate pre-visit instruction, conduct a flexible but focused visit where students have independence and responsibility, and make use of organized, post-visit reflection. This structure has the best chance of effecting learning because it exploits the personal, contextual, and cumulative nature of learning. Furthermore, school administrators should ensure that teachers have adequate time to plan field trips, and that organizational and timetable barriers are minimized.

Third, preservice teacher education can be enhanced by experiences outside of the lecture rooms. Thirunarayanan (1997) found that preservice teachers benefited from something as simple as investigating the learning potential of a community-based science resource. In Taiwan, Chin (2004) built a semester-long course around museum visits and associated lesson planning by preservice science teachers. Participants learned science content and ways to teach it and became more willing to use a variety of resources and became aware of the importance of using different ways to assess learning outcomes. Museums are places where learning through inquiry is natural (Bybee, 2001). Especially for elementary school teachers, whose science background is often limited, they provide opportunities to learn science and to learn how to teach science in ways consistent with temporary science curricula

(Ault & Herrick, 1991; Kelly, 2000; Kelly et al., 2002). These experiences can help new teachers to feel confident and thus do more to blur the boundary between the classroom and the outside world.

Fourth, the interface between museum programs and the science curriculum is dynamic, and museum educators and interpreters, many of whom are volunteers, need support to “keep up” with educational change. Science curricula in many countries over the last decade have moved from a content focus to active inquiry, with desired outcomes much broader than increased knowledge. For example, Cox-Petersen et al. (2003) discussed the mismatch between the inquiry approach espoused by the National Science Education Standards and lecture-centered, docent-led tours. They proposed an alternative tour that focused more on inquiry learning, even in traditional galleries. Bybee and Legro (1997) pointed out the importance of museum educators using the Standards to build collaborative partnerships to improve science education, and provided examples of how this might be done. Museums, too, have recognized the opportunities provided by the new curricula to contribute to learning in science and the concomitant need to ensure appropriate training for museum professionals (Cordell, 2000; Diamond, 2000; Yorath, 1995). Lederman and Niess (1998) provided an educator’s view of the urgent need for such training.

Fifth, out-of-school agencies must not shirk their role in educating community members about controversial social and scientific issues, such as global sustainability, genetically modified products, biotechnology, and so on. Pedretti’s (2004) analysis of critical science exhibitions demonstrated that people’s understanding of such issues can be increased, yet there remains reluctance to engage with them. From a scientist’s point of view, Rose (2001) was critical of the media’s role in purveying science:

Science and technology permeate every aspect of our lives. Yet the media—BBC and newspapers alike—tend to put them into a separate box, labeled ‘Science’ with a capital S, parked somewhere beyond the [C. P.] Snow-line. Of course we need our dedicated programs, but if we are ever to move towards a sense of the natural and social sciences and the humanities as part of a seamless cultural web, we need to open that box and spread its contents around. (p. 118)

In order to spread those contents effectively, ways must be found to situate science in its sociocultural context—a challenge indeed for the creators of museum exhibitions, media presentations, and other out-of-school programs.

This chapter began with a plea from S. Anderson (1968) to recognize the influence of those nonschool agencies that educate our communities. These agencies form part of what has been described as the community infrastructure for science learning (Falk, 2001). Together they provide an enormous infrastructure, but not a cohesive one, with links among individual components ephemeral and ad hoc, rather than consistent and institutionalized (Luke, Camp, Dierking, & Pearce, 2001). Nevertheless, there are powerful learning opportunities available, but these diverse and pervasive sources of science learning remain, on the whole, under-researched and under-used in science teaching. Educators in schools and universities cannot ignore them while the research gets done. Instead, the value of learning science outside of school should be recognized and its benefits harnessed to complement our formal educational programs.

## ACKNOWLEDGMENTS

## Science Education and Student Diversity: Race/Ethnicity, Language, Culture, and Socioeconomic Status

**Okhee Lee**

*University of Miami*

**Aurolyn Luykx**

*University of Texas, El Paso*

Knowledge about science and technology is increasingly important in today's world. Aside from the growing number of professions that require a working familiarity with scientific concepts and high-tech tools, the future of our society hangs in the balance of decisions that must be made on the basis of scientific knowledge. Yet, the increasing diversity of the school-aged population, coupled with differential science performance among demographic groups, makes the goal of "science for all" a challenge for many nations.

Reform-oriented instructional practices hold the promise of more meaningful science learning but have yet to be widely implemented. All too often, teachers' knowledge of science and/or student diversity is insufficient to guide students from diverse backgrounds toward meaningful science learning. Limited resources often force a trade-off between providing modified instruction that takes student diversity into account and reinforcing general standards to raise the quality of instruction for mainstream students (often to the detriment of other student groups). In this way, the trend toward standardization of curricula and assessment may work against educational equity (McNeil, 2000), although efforts are made to promote both goals simultaneously (Delpit, 2003).

Standardized measures of science achievement have revealed significant gaps among students of diverse racial/ethnic and socioeconomic backgrounds. Although achievement gaps have diminished in recent decades, the gains are often disappointingly small relative to the inequities that persist (see the description below). If we start from the assumption that high academic achievement is potentially attainable by most children, then achievement gaps are a product of the learning opportunities available to different groups of students and the degree to which circumstances permit them to take advantage of those opportunities. The questions that this poses for researchers and educators are: What constitutes equitable learning opportunities, how do they vary for different student populations, and how can they be provided in a context of limited resources and conflicting educational priorities?

This chapter addresses key issues concerning student diversity and equity in science education, with a focus on how science achievement<sup>1</sup> relates to various factors or mechanisms. The chapter begins with conceptions of student diversity and science achievement gaps as two key constructs in this field of study. Next, it summarizes major findings in the literature with regard to the relation of science achievement gaps to curriculum, instruction, assessment, teacher education, school organization, educational policies, and students' home and community environments. Finally, it proposes an agenda for future research.

Although this chapter addresses student diversity in general, it highlights race/ethnicity, language, culture, and socioeconomic status (SES). The other chapters in this section of the *Handbook* address specific student populations that have traditionally been underserved by the education system, including girls, students in rural and inner-city settings, and students with special needs. The research studies considered for this chapter were carried out predominantly within the United States, although some studies conducted abroad (but published in English) are also considered.<sup>2</sup> This chapter includes studies published since 1982, in consideration of the document "Science for All Americans" (American Association for the Advancement of Science [AAAS], 1989), the release of which was a landmark for U.S. science education reform. The period between 1982 and 2003 spans the period from the years leading up to this document and to more than a decade after its release. In addition, the chapter considers primarily peer-reviewed journal articles that provide clear statements of research questions, clear descriptions of research methods, convincing links between the evidence presented and the research questions, and valid conclusions based on the results (Shavelson & Towne, 2002).

---

1. U.S. science educators and researchers generally support the goals of school science laid out in science education standards documents (AAAS, 1989, 1993; NRC, 1996): to enable students to develop an understanding of key science concepts, conduct scientific inquiry and reasoning, engage in scientific discourse, and cultivate scientific habits of mind. We acknowledge the concerns, expressed by various scholars, that science education reform in general and standards documents in particular espouse an assimilationist perspective by defining science and science achievement in terms of the Western modern science tradition, with little consideration of alternative views of science and ways of knowing from diverse backgrounds (Eisenhart, Finkel, & Marion, 1996; Lee, 1999a; Lynch, 2000; Rodriguez, 1997). However, engaging in this debate is beyond the scope of this chapter.

2. The decision to focus on the U.S. context is due to: (a) a wide range of student diversity in different countries; (b) various political, racial/ethnic, cultural, linguistic, and socioeconomic contexts in society at large and the educational systems in particular in different countries; and (c) a vast body of literature on this topic in different countries and in different languages. Despite such variations, major issues discussed about the U.S. context in this chapter have implications for issues of student diversity in other countries to the extent that non-mainstream students are marginalized from the mainstream in their societies.

## STUDENT DIVERSITY

A focus on student diversity presumes that choices made with regard to curriculum, instructional practices, assessment, and school organization affect different student populations differently. Therefore, differing science outcomes may be as much a product of the ways in which policies and schools define, delimit, and manage student diversity as they are of diversity itself. Regardless of the origin or nature of students' marginalization, academic success often depends on assimilation into mainstream norms. Thus, the educational success of immigrant or U.S.-born racial/ethnic minority students depends to a large degree on acquiring the standard language and shared culture of mainstream U.S. society. For example, traditional science instruction generally assumes that students have access to certain educational resources at home and requires students living in poverty to adopt learning habits that require a certain level of economic stability.

The interplay of race/ethnicity, culture, language, and social class is complex. On the one hand, it is difficult methodologically to separate out the influences of different variables, which may cut across populations in ways that are not easily untangled (for example, when ethnic groups are internally stratified by class). On the other hand, these variables are not entirely separable, conceptually speaking; language is an important element of ethnicity, culture is partly determined by social class, and so on. Racial/ethnic identities and language proficiencies are less bounded than implied by commonly used demographic categories; they may vary within a single household or even with regard to a single individual, depending on the situation. Furthermore, although a shared language, culture, and racial background are important components of a collective ethnic identity, the relative importance of each component varies widely from one group to another.

Social theorists have proposed concepts such as "languaculture" (Agar, 1996), "class cultures" (Bourdieu, 1984), "social class dialects" (Labov, 1966), and even "Ebonics" to capture the inevitable intertwining of race/ethnicity, language, culture, and social class. Especially with regard to native speakers of non-standard dialects of English (e.g., African-American and some Hispanic and Native American populations), the influences of these different variables on student outcomes are more often conflated than systematically analyzed.

Throughout this chapter, the terms *mainstream* and *non-mainstream* are used with reference to students. Similar to contemporary usage of the term *minority* by social scientists, *mainstream* is understood to refer not to numerical majority, but rather to social prestige, institutionalized privilege, and normative power. Thus, in classroom settings, mainstream students (i.e., in the United States those who are White, middle or upper class, and native speakers of standard English) are more likely than non-mainstream students to encounter ways of talking, thinking, and interacting that are continuous with the skills and expectations they bring from home, a situation that constitutes an academic advantage for students of the former group.<sup>3</sup> These group-level phenomena may not apply to particular individuals or

---

3. The focus on non-mainstream students should not obscure the fact that the culture and language of mainstream students play no less a role in their educational experience. Furthermore, the mainstream language and culture can no longer be assumed to be representative of most students' experience, especially in inner-city schools or large urban school districts where non-mainstream students tend to be concentrated.

may be offset by other factors within the group, such as the vast range of proficiency levels in both the home language and English, immigration history, acculturation to mainstream society, educational levels of parents, and family/community attitudes toward education in general and science education in particular. Recognizing overall differences between groups does not justify limiting one's expectations of individual students, but does provide a framework for interpreting observed patterns and processes that occur with differing frequency among different groups (Gutierrez & Rogoff, 2003).

Varying usages of terminology often reflect different theoretical stances or disciplinary traditions. The lack of consensus around designations for different categories of students reflects the rapidly changing demographic makeup of the country, the changing political connotations of different terms, and the specific aspects of identity that researchers and/or subjects may wish to emphasize. Although this sometimes causes difficulty with regard to comparability of studies, the lack of a standard terminology to describe the overlapping dimensions of student diversity is a valid reflection of the fluid, multiply determined, and historically situated nature of identity, and the ways in which such designations are used to stake out particular claims about the location and nature of social boundaries. Although much of the science education literature (especially those studies based on quantitative analysis of student outcome data) tends to treat such categories as discrete and unproblematic, this should be understood as a necessary fiction that makes possible the management of large data sets, thus revealing "the big picture" with regard to student diversity and science achievement. In reality, the number of students whose personal circumstances cross and confound such categorical boundaries is greater than ever, and will no doubt continue to increase as those boundaries become more flexible and porous.

Terminology can be problematic in any synthesis, because some researchers use particular terms with special meanings and others invent their own terms to express specifically intended meanings. In this chapter, terms are used as they appeared in the studies in order to represent the original intentions of the researchers, to the extent that this does not confuse or conflate the ways these terms are typically used in the literature.

## ACHIEVEMENT GAPS

Science outcomes are defined in broad terms that include not only achievement scores on standardized tests but also meaningful learning of classroom tasks, affect (attitudes, interest, motivation), course enrollments, high school completion, higher education, and career choices. Racial/ethnic, gender, and class disparities are evident in nearly all of these areas, suggesting that the nation's schools have far to go in terms of providing an equitable science education to all students. In the current U.S. policy context, which stresses "structured English immersion" for English language learners (or ELL students) and severely limits content area instruction in languages other than English, English proficiency becomes a *de facto* prerequisite for science learning. In this sense, acquisition of oral and written English, although not a "science outcome" *per se*, plays a large role in determining science outcomes as they are commonly measured.

## Ideological and Methodological Limitations

Description of science achievement gaps must be interpreted within the context of ideological and methodological limitations in the current knowledge base. In the ideological sense, Rodriguez (1998a) argued that failure to disaggregate science achievement data may create or reinforce stereotypes about certain groups. He also addressed achievement gaps in terms of social justice in the education system at large. Contrary to the notion of meritocracy—whereby academic achievement is viewed as a direct reflection of students' ability and effort—his analysis of achievement data suggests that the educational system is structured so as to benefit those groups already in power. The students most adversely affected by the meritocracy myth come from the fastest-growing ethnic groups. According to Rodriguez, to promote participation and achievement of non-mainstream students in science, the meritocracy myth needs to be exposed and addressed.

In the methodological sense, achievement is typically measured by standardized tests administered with national and international student samples. These databases provide overall achievement results by ethnicity, SES, and gender, but contain limited information with regard to disaggregation of results, such as socioeconomic strata within ethnic groups or subgroups within broad ethnic categories (Rodriguez, 1998a). This lack of information hinders researchers' and policy makers' ability to gain insight into the causes of science achievement gaps among specific student groups. Furthermore, in the United States, ELL students were excluded from most large-scale assessments until recently. Although the 2000 National Assessment of Educational Progress [NAEP] report card was the first (since the NAEP's inception in 1969) to analyze assessment accommodations in science, the results did not disaggregate students with disabilities from limited English proficient students (O'Sullivan, Lauko, Grigg, Qian, & Zhang, 2003).

## Gaps in Science Outcomes

The long-term trend assessments of U.S. students in science, as measured by the NAEP, indicate that the average score for students of every age level and race/ethnicity has increased slightly since the 1970s (Campbell, Hombo, & Mazzeo, 2000). Achievement gaps by race/ethnicity on the NAEP are gradually narrowing; the scores of Black and Hispanic students have improved since the 1970s at a slightly faster rate than the scores of White non-Hispanic students. Nevertheless, Black and Hispanic students' scores remain well below those of White students, and the gaps persist across the three age levels.

Furthermore, the growth rates of African American and Hispanic students are so minimal that (with the exception of Hispanic males) their 12th-grade achievement level still fell well below the initial 8th-grade achievement of Whites and Asian Americans (Muller, Stage, & Kinzie, 2001). Although the long-term trend assessments of NAEP science achievement by SES are not available, the 1996 and 2000 results indicate that students who were eligible for the free/reduced price lunch program performed well below those who were not eligible (O'Sullivan et al., 2003).

Rodriguez (1998a) conducted a systematic analysis of trends in science achievement by ethnicity, SES, and gender, using national databases including the National

Assessment of Educational Progress (NAEP), the National Education Longitudinal Study (NELS), the American College Test (ACT), the Scholastic Aptitude Test (SAT), and Advanced Placement (AP) exams. The results indicated improvement for all student groups in science achievement and participation, but wide gaps persisted between Anglo-European students and students from African and Latino groups (to use Rodriguez's terms). In addition, patterns of achievement gaps were alarmingly congruent over time and across studies with respect to race/ethnicity, SES, gender, and grade level.

Attitudes toward science vary among racial/ethnic groups, but this variation is not always consistent with the variation in science achievement results. In a study of four major ethnic groups of elementary, middle, and high school students in Hawaii, Greenfield (1996) reported that Filipino Americans and native Hawaiians had lower achievement and less positive attitudes toward science than Caucasian and Japanese American students. In contrast, researchers from the U.S. mainland reported that non-mainstream students have positive attitudes toward science and aspire to science careers, but have limited exposure and access to the knowledge necessary to realize this aspiration (Atwater, Wiggins, & Gardner, 1995; Rakow, 1985).

Other indicators of science outcomes include science course enrollment, college major, and career choice. Overall, minority racial/ethnic groups made gains with regard to enrollments in high school science courses, as well as bachelors', master's, and doctoral degrees awarded in science and engineering fields, but gaps persist (National Science Foundation [NSF], 2002; Oakes, 1990).

## KEY FINDINGS ON STUDENT DIVERSITY AND SCIENCE OUTCOMES

Research on diversity and equity in science education is a new and developing area. Most has been published since the mid-1990s, perhaps spurred in the United States by the emphasis on the dual goals of excellence and equity laid out in *Science for All Americans* and *Benchmarks for Science Literacy* (American Association for the Advancement of Science [AAAS], 1989, 1993) and the *National Science Education Standards* (National Research Council [NRC], 1996). Prominent science education journals have increased their coverage of science-and-diversity-related topics; the *Journal of Research in Science Teaching* and *Science Education* each produced a number of special issues in recent years.

Studies have been conducted from a wide range of theoretical and disciplinary frames, including cognitive science, sociolinguistics, and sociocultural and sociopolitical perspectives. They have utilized a variety of research methods, ranging from experimental designs, to surveys, case studies, and critical ethnography. The majority of studies are small-scale descriptive studies by individual researchers. There are only a small number of intervention-based studies, and relatively few of these are on a large scale. Experimental studies are rare, relative to the many studies using qualitative methods. We found no meta-analysis of statistical research studies in the literature.

Below, we summarize key findings and selected references on issues of student diversity in science education (see Lee & Luykx, 2006, for more detailed descriptions of individual studies). Although our focus is on student diversity and science

outcomes, most of the studies we reviewed did not include concrete information about student outcomes in their results. Notably absent are quantitative achievement results.

## Science Curriculum

One strand of the debate over science education among diverse student groups has focused on epistemological questions, such as what counts as science? and what are scientific ways of knowing? The definition of science constitutes “a *de facto* ‘gate-keeping’ device for determining what can be included in a school science curriculum and what cannot” (Snively & Corsiglia, 2001, p. 6; also see Hodson, 1993; Loving, 1997; Stanley & Brickhouse, 1994). A full and nuanced account of the debate over what counts as science is beyond the scope of this chapter. While recognizing the existence of multiple views of science, we focus here on school science as defined in U.S. standards documents—the systematic search for empirical explanations of natural phenomena (AAAS, 1989, 1993; NRC, 1996).

Although appropriate instructional materials are essential for effective instruction, high-quality materials that meet current science education standards are difficult to find (NSF, 1996). In attempting to make science accessible to all students, the NSF (1998) emphasizes “culturally and gender relevant curriculum materials” that recognize “[diverse] cultural perspectives and contributions so that through example and instruction, the contributions of all groups to science will be understood and valued” (p. 29). However, efforts to develop such materials present challenges to science educators. On the one hand, they require a knowledge base of examples, analogies, and beliefs from a range of different cultures, related to specific science topics and scientific practices. Even when culturally relevant materials are developed and prove effective, their effectiveness may be limited to the particular group for which they are designed. On the other hand, materials developed for wide use, particularly those that can be accessed electronically, may be implemented across various settings. However, local adaptations are essential for such materials to be used effectively, which in turn requires expertise on the part of teachers.

The small body of literature on science curricula for diverse student groups indicates that (a) most materials currently used in U.S. classrooms are not culturally relevant to non-mainstream students and (b) cultural diversity is not adequately represented in textbooks and materials (Barba, 1993; Eide & Heikkinen, 1998; Ninnis, 2000). Materials that do incorporate experiences, examples, analogies, and values from specific cultural and linguistic groups foster higher science achievement, more positive attitudes toward science, and enhanced cultural identity among non-mainstream students (Aikenhead, 1997; Matthews & Smith, 1994).

In addition to text-based curriculum materials described above, several studies developed interactive computer-based curriculum materials. In contrast to culturally relevant materials that are designed for specific cultural groups, computer-based materials (accompanied by web-based technology) are intended for large-scale implementation, although local adaptations are necessary for effective use across educational settings. The results show the positive impact of inquiry-based, technology-rich learning environments on student outcomes as measured by standardized achievement tests in large urban school districts (Rivet & Krajcik, 2004; Songer, Lee, & McDonald, 2003).

## Science Learning and Instruction

There is a rather extensive literature on science learning and instruction with non-mainstream students. The studies address a wide range of topics and employ various theoretical perspectives and research methods. This research is summarized below with regard to (a) culturally congruent instruction, (b) cognitively based instruction to promote scientific reasoning and argumentation, (c) the sociopolitical process of learning and instruction, and (d) science learning and instruction with ELL students.

### *Culturally Congruent Instruction*

The literature on science education's relation to students' worldviews (Allen & Crawley, 1998; Cobern, 1996; Lee, 1999b) and culturally specific communication and interactional patterns (see the review by Atwater, 1994) indicates that the culture of Western science is foreign to many students (both mainstream and non-mainstream), and that the challenges of science learning may be greater for students whose cultural traditions are discontinuous with the "ways of knowing" characteristic of Western science and science instruction. The challenge for these students is "to study a Western scientific way of knowing and at the same time respect and access the ideas, beliefs, and values of non-Western cultures" (Snively & Corsiglia, 2001, p. 24).

Teachers need to be aware of a variety of cultural experiences in order to understand how different students may approach science learning (Moje, Collazo, Carillo, & Marx, 2001). Teachers also need to use cultural artifacts, examples, analogies, and community resources that are familiar to students in order to make science relevant and intelligible to them (Barba, 1993). Lee and Fradd (1998; see also Lee, 2002, 2003) proposed the notion of "instructional congruence," which highlights the importance of developing *congruence* not only between students' cultural expectations and the norms of classroom interaction, but also between academic disciplines and students' linguistic and cultural experiences. It also emphasizes the role of *instruction* (or educational interventions), as teachers explore the relationship between academic disciplines and students' cultural and linguistic knowledge, and devise ways to link the two.

Effective science instruction should enable students to cross cultural borders between their home cultures and the culture of science (Aikenhead & Jegede, 1999; Costa, 1995). According to the multicultural education literature, school knowledge represents the "culture of power," that is, the dominant society (Delpit, 1988; Reyes, 1992). The cultural norms governing classroom discourse are largely implicit and tacit, and thus are not easily accessible to students who have not learned them at home. For students who are not from the culture of power, teachers need to initially provide explicit instruction about that culture's rules and norms and gradually lead students to take greater initiative and responsibility for their own learning.

### *Cognitively Based Instruction*

An emerging body of literature argues that the ways of knowing and talking characteristic of children from outside the cultural and linguistic mainstream are generally continuous with the ways of knowing and talking characteristic of scien-

tific communities. The Chèche Konnen Project has promoted collaborative scientific inquiry among language minority and low-SES students in order to help them use language, think, and act as members of a science learning community (Ballenger, 1997; Rosebery, Warren, & Conant, 1992; Warren, Ballenger, Ogonowski, Rosebery, & Hudicourt-Barnes, 2001). When presented with meaningful science learning opportunities, these children employ sense-making practices—deep questions, vigorous argumentation, situated guesswork, embedded imagining, multiple perspectives, and innovative uses of everyday words to construct new meanings—that intersect in potentially productive ways with scientific practices. As students engage in scientific inquiry, teachers can identify intersections between students' everyday knowledge and scientific practices and use these intersections as the basis for instructional practices. The results indicate that low-income immigrant students or those with limited science experience are capable of scientific inquiry, reasoning, and argumentation.

### *Sociopolitical Process of Learning and Instruction*

As an outgrowth of critical studies of schooling, a small number of studies have examined science learning as a sociopolitical process (Calabrese Barton, 1998, 2001; Rodriguez & Berryman, 2002). This literature is distinguished from that discussed above in several ways. First, it questions the relevance of science to students who have traditionally been underserved by the education system and argues that science education should begin with the intellectual capital of the learner and his/her lived experiences, not with externally imposed standards. In this way, it attempts to invert the power structure of schooling and its oppressive effects on these students. Second, it addresses issues of poverty, as well as cultural and linguistic diversity, from a critical perspective that focuses on the unequal distribution of social resources and the school's role in the reproduction of social hierarchy. Third, the researchers generally employ ethnographic methods and ground their analyses in the political, cultural, and economic history of the groups under study.

Several studies have found that science instruction often reinforces power structures that privilege mainstream students and that other students actively resist school science (Gilbert & Yerrick, 2001; Seiler, 2001; Tobin, 2000). The studies describe mistrust of schooling, of science instruction, and of science teachers among those students who have traditionally been disenfranchised and marginalized by schooling in general and science education in particular. This mistrust is exacerbated when science teachers do not expect students to succeed in science, thus presenting a serious barrier to achievement. Inquiry-based instruction is particularly trust-intensive, inasmuch as science inquiry demands skepticism, patience, and a tolerance for uncertainty and ambiguity, all of which require a certain level of trust between teacher and students (Sconiers & Rosiek, 2000). The researchers argue that building trusting and caring relationships between teachers and students is necessary in order for students to take intellectual risks, which are in turn necessary in order to develop deep understandings of science content and practices.

### *Science Learning and Instruction with ELL Students*

A number of studies have focused on the role of language in ELL students' science learning in either bilingual or mainstreamed classrooms. Research within

the United States has, unsurprisingly, focused on Spanish speakers (Duran, Dugan, & Weffer, 1998; Torres & Zeidler, 2002), whereas research in other parts of the English-speaking world has focused on students from a broad range of language communities, both immigrant and indigenous (Curtis & Millar, 1988; Kearsy & Tuner, 1999; Tobin & McRobbie, 1996). Some of the latter studies go beyond examination of language use in the classroom to consider the social, cultural, and demographic dynamics of students' language communities. Overall, the research suggests that students' limited proficiency in English constrains their science achievement when instruction and assessment are undertaken exclusively or predominantly in English.

In order to keep up with their English-speaking peers, ELL students need to develop English language and literacy skills in the context of content area instruction (August & Hakuta, 1997). Ideally, content areas should provide a meaningful context for English language and literacy development, while students' developing English skills provide the medium for engagement with academic content (Lee & Fradd, 1998). As more U.S. states adopt immersion approaches to English to Speakers of Other Languages (ESOL) instruction, ELL students must confront the demands of academic learning through a yet-unmastered language. Furthermore, teachers often lack the knowledge and the institutional support needed to address the complex educational needs of ELL students.

Recently, several studies have examined the impact of instructional interventions to promote ELL students' English language and literacy development simultaneously with science learning (Amaral, Garrison, & Klentschy, 2002; Merino & Hammond, 2001). These studies have focused on hands-on and inquiry-based science instruction, which enables ELL students to develop scientific understanding, engage in inquiry, and construct shared meanings more actively than does traditional textbook-based instruction. By engaging in science inquiry, ELL students develop English grammar and vocabulary as well as familiarity with scientific genres of writing. Furthermore, inquiry-based science instruction provides both authentic, communicative language activities and hands-on, contextualized exploration of natural phenomena, while promoting students' communication of their understanding in a variety of formats, including written, oral, gestural, and graphic (Lee & Fradd, 1998; Rosebery et al., 1992). Overall, the results indicate students' active engagement in science classroom tasks and improved achievement on standardized tests of science and literacy.

## **Assessment**

Research on science assessment (both large-scale and classroom) with non-mainstream students is extremely limited, for various reasons. Because assessment of ELL students tends to concentrate on basic skills in literacy and numeracy, other subjects such as science tend to be ignored. Because science is often not part of large-scale or statewide assessments, and usually does not count toward accountability measures even when it is tested, research on science assessment and accommodations with diverse student groups is sparse. Given these limitations, it is unclear whether new assessment technologies and innovations present more hopes or obstacles to non-mainstream students.

### *Science Assessment with Culturally Diverse Groups*

One way to promote valid and equitable assessment is to make science assessments relevant to the knowledge and experiences that students of diverse backgrounds acquire in their home and community environments (Solano-Flores & Nelson-Barber, 2001). This approach, which advocates tailoring assessments to specific student populations, contrasts with efforts to avoid cultural bias by making assessments as culturally “neutral” as possible. Solano-Flores and Trumbull (2003) argued that it is difficult to remove cultural bias from assessment practices because tests are inevitably cultural devices and that a more equitable and realistic approach is to consider students’ cultural beliefs and practices throughout the assessment process. However, this requires more knowledge about the cultural backgrounds of specific student groups than teachers and test developers usually have access to.

Another way to promote equitable assessment is to identify more effective formats for assessing student achievement. Advocates of alternative (or performance) assessments have argued that traditional multiple-choice tests fail to measure non-mainstream students’ knowledge, abilities, and skills (Ruiz-Primo & Shavelson, 1996). An important issue in using alternative assessments is their fairness to different student groups—“the likelihood of any assessment allowing students to show what they understand about the construct being tested” (Lawrenz, Huffman, & Welch, 2001, p. 280). Given the limited research on alternative science assessments with non-mainstream students, both advocates and critics have based their claims on inferences and insights drawn from related research endeavors, rather than on empirical studies that address the topic directly (see the discussion in Lee, 1999a). Furthermore, existing studies in science education show contradictory results (Klein et al., 1997; Lawrenz et al., 2001).

### *Science Assessment with ELL Students*

Assessment of ELL students is complicated by issues such as which students to include in accountability systems, what constitutes fair and effective assessment accommodations (Abedi, 2004), and how to assess content knowledge separately from English proficiency or general literacy (Shaw, 1997). Research on these issues with regard to school science is very limited. Although efforts to ensure valid and equitable assessment of ELL students generally focus on eliminating specific linguistic effects as a way to ensure test validity, Solano-Flores and Trumbull (2003) argued that consideration of students’ home languages should guide the entire assessment process, including test development, test review, test use, and test interpretation.

Regarding assessment of students with disabilities (SD) and limited English proficiency (LEP), the 2000 NAEP report is the first since its inception in 1969 to display two different sets of results: “accommodations-permitted” and “accommodations-not-permitted” (O’Sullivan et al., 2003). Accommodations included, but were not limited to, one-on-one testing, small-group testing, access to bilingual dictionaries, extended time, reading aloud of directions, and recording of students’ answers by someone else. At grade 4, the accommodations-permitted results, which included slightly more SD and LEP students because of the availability of accommodations, were 2 points lower than the accommodations-not-permitted results, and this difference was statistically significant. At grades 8 and 12, there was no statistically significant difference between the two sets of results. Because of the small numbers of

SD and LEP students who were assessed at each grade level, with or without accommodations, the results were not disaggregated by SD or LEP separately.

## **Teacher Education**

Teachers need not come from the same racial/ethnic backgrounds as their students in order to teach effectively (Ladson-Billings, 1995). Given the increasing student diversity even within individual classrooms, matching teachers with students of similar backgrounds is often not feasible. But when teachers of any background are unaware of the cultural and linguistic knowledge that their students bring to the classroom (Gay, 2002; Villegas & Lucas, 2002), or when they lack opportunities to reflect upon how students' minority or immigrant status may affect their educational experience (Cochran-Smith, 1995), there is clearly a need for teacher education that specifically addresses teachers' beliefs and practices with regard to student diversity as it relates to subject areas. Teachers must be equipped with knowledge of (a) academic content and processes, (b) ways in which academic content and processes may articulate with students' own linguistic and cultural knowledge, (c) pedagogical strategies appropriate to multicultural settings, and (d) awareness of how traditional curriculum and pedagogy have functioned to marginalize certain groups of students and limit their learning opportunities.

### *Teacher Preparation*

Most prospective science teachers enter their teacher preparation programs with beliefs that undermine the goal of equitable education for all students and graduate without fundamentally changing these beliefs (Bryan & Atwater, 2002). A sparse but emerging literature indicates the challenges and difficulties in making fundamental or transformative changes in the beliefs and practices of prospective U.S. science teachers (who are mostly from White, monolingual English, middle-class backgrounds) with regard to student diversity (Bianchini, Johnston, Oram, & Cavazos, 2003; Luft, Bragg, & Peters, 1999; Tobin, Roth, & Zimmerman, 2001; Yerrick & Hoving, 2003). Even when changes in teacher beliefs and practices occur, such changes are demanding and slow.

Rodriguez (1998b) proposed a conception of multicultural education as integrating a political theory of social justice with a pedagogical theory of social constructivism. This approach aims to enable prospective teachers to teach for both student diversity (via culturally inclusive and socially relevant pedagogy) and scientific understanding (via critically engaging and intellectually meaningful pedagogy). The results showed promise in terms of assisting prospective teachers to critically examine their prior beliefs about what it means to be a successful science teacher. Most became aware of the importance of creating science classrooms where all students are provided with opportunities for successful learning. However, several teachers demonstrated a strong resistance to both ideological and pedagogical change.

### *Teacher Professional Development*

Research on professional development indicates that teachers need to engage in reform-oriented practices themselves in order to be able to provide effective science

instruction for their students. However, affecting changes in teachers' knowledge, beliefs, and practices in science instruction is an arduous process (Knapp, 1997). Despite the critical need for professional development of science teachers working with diverse student groups, the literature is extremely limited. A small body of studies reports the positive impact of professional development on change in teachers' knowledge, beliefs, and practices and ultimately science achievement and attitudes of non-mainstream students (Kahle, Meece, & Scantlebury, 2000).

Several studies revealed both advantages and limitations of school-wide professional development initiatives in science (Blumenfeld, Fishman, Krajcik, & Marx, 2000; Gamoran et al., 2003). On one hand, collective participation of all teachers from the same school or grade level in professional development activities allows them to develop common goals, share instructional materials or assessment tools, and exchange ideas and experiences arising from a common context. On the other hand, unlike programs composed of volunteer teachers seeking opportunities for professional growth, school-wide implementation inevitably includes teachers who are not interested in or even resist participation. Additionally, the intensity of professional development activities may be compromised because of various constraints on urban schools. Despite these hurdles, school-wide professional development can provide valuable insights for large-scale implementation (Luykx, Cuevas, Lambert, & Lee, 2005).

### *Teacher Education with ELL Students*

Teachers of ELL students are charged with promoting students' English language and literacy development as well as academic achievement in subject areas. This may require subject-specific instructional strategies that go beyond the general preparation in ESOL or bilingual education that many teachers receive. Unfortunately, a majority of teachers working with ELL students do not feel adequately prepared to meet their students' learning needs (National Center for Education Statistics, 1999). Most teachers also assume that ELL students must acquire English before learning subject matter, though this approach almost inevitably leads such students to fall behind their English-speaking peers (August & Hakuta, 1997).

Professional development to promote science along with English language and literacy development involves teacher knowledge, beliefs, and practices in multiple areas (Wong-Fillmore & Snow, 2002). In addition to ensuring that ELL students acquire the language skills necessary for social communication in English, teachers need to promote development of both general and content-specific academic language. Furthermore, teachers must be able to view language within a human development perspective. Such an understanding would enable them to formulate developmentally appropriate expectations about language comprehension and production over the course of students' learning of English. The amalgamation of these knowledge sources should result in teaching practices that (a) engage students of all levels of English proficiency in learning academic language, (b) allow students to display learning in multiple modes, (c) provide learning activities that have multiple points of entry for students of differing levels of English proficiency, and (d) ensure that students participate in a manner that allows for maximum language development at their own level.

We found no study involving preservice science teachers of ELL students in the literature. A limited body of research indicates that professional development efforts

have a positive impact on helping practicing teachers examine their beliefs and improve their practices in integrating science with literacy for ELL students (Amaral et al., 2002; Hart & Lee, 2003; Lee, 2004; Stoddart, Pinal, Latzke, & Canaday, 2002).

## **School Organization and Educational Policies**

Policies are interpreted and mediated by educational actors at every level of their implementation, to the extent that they are sometimes implemented in ways that are directly contrary to their presumed goals. School organization, in turn, is influenced by policies mandated by the state and the school district. The literature highlights features of school organization or restructuring that influence science teaching for students from non-mainstream backgrounds (Oakes, 1990). The majority of the studies in this limited literature focus on urban education (see also Chapter 13, this volume).

### *School Organization*

One area of research has examined the effect of tracking or ability grouping on science learning opportunities and achievement among diverse student groups (see an extensive review of the literature in Oakes, 1990). In theory, such practices separate the academically stronger from the academically weaker students; in practice, this often means segregating students by SES, racial/ethnic origin, or degree of English proficiency. Educational scholars are in general agreement that tracking or ability grouping creates a cycle of restricted opportunities, diminished outcomes, and exacerbated inequalities for students from poor and non-mainstream backgrounds; nevertheless, it remains a common practice in schools throughout the nation.

School restructuring efforts (which often address tracking, among other issues) can narrow SES and race/ethnicity-based science achievement gaps. Valerie Lee and colleagues conducted a series of studies to examine how the structure of high schools affects student learning (Lee & Smith, 1993, 1995; Lee, Smith, Croninger, & Robert, 1997). The results indicated that in schools that engaged in practices consistent with the restructuring movement, student engagement and achievement were significantly higher (i.e., schools were more effective) and differences in engagement and achievement among students from different SES backgrounds were reduced (i.e., schools were more equitable). These schools had a strong academic focus, all students took a highly academic curriculum with limited tracking options, and teachers had strong professional communities emphasizing the quality of instruction.

Spillane, Diamond, Walker, Halverson, and Jita (2001) examined how the school leadership (administrators and lead teachers in science) at one urban elementary school successfully identified and activated resources for leading change in science education. Gamoran and associates (2003) examined how teachers from elementary through high school in six school districts across the nation taught mathematics and science for understanding with diverse student groups. Both studies emphasized that strategic use of resources (human, intellectual, social, and financial) and “distributed leadership” (i.e., administrators and teacher leaders support and sustain the professional community) are essential to bringing about change in school policies and practices.

### *Educational Policies*

All of the studies in the limited literature about policies addressing student diversity in science education focus on U.S. urban contexts. Although educational policies influence all districts and all schools, consequences are especially critical in urban schools because of the sheer number of students attending them, the array and scope of the obstacles they face, and the institutional precariousness under which they operate.

After almost a decade of high-stakes testing in reading, writing, and mathematics, school systems are now moving to include science and social studies as well. As states increasingly embrace accountability measures, high-stakes testing influences instructional practices both in subject areas being tested and in those that are not tested. When science is not part of accountability measures, it is taught minimally in the elementary grades (Knapp & Plecki, 2001; Spillane et al., 2001). When science is part of accountability measures, teachers are pressured to mold their teaching practices to the demands of high-stakes testing, sometimes leading to unintended and harmful consequences (Settlage & Meadows, 2002).

Several studies have examined systemic reform to improve science education in U.S. urban schools (see also Chapter 31, this volume). Knapp and Plecki (2001) provided a conceptual framework for renewing urban science teaching. Kahle (1998) developed an "equity metric" to monitor the progress of educational reform over time. Hewson, Kahle, Scantlebury, and Davies (2001) and Rodriguez (2001) borrowed Kahle's equity metric to assess the progress toward equity of two urban middle schools and an urban school district, respectively. Finally, Kim and colleagues (2001) examined the impact of the NSF-supported Urban Systemic Initiatives (USI) on teacher education, classroom practices, and student achievement in mathematics and science. The results indicated noteworthy gains in science achievement with non-mainstream students and strengthening of the infrastructure to sustain achievement gains.

Whereas systemic reform efforts continued from the 1990s to the present, strategies for scaling up of educational innovations have emerged more recently. Systemic reform involves restructuring various components of an educational system in interactive ways, whereas scaling up focuses on implementing effective educational innovations on a large scale. In the climate of standards-based instruction and accountability, scaling up is increasingly called for to bring about system-wide improvements (Elmore, 1996). However, scaling up compromises conceptual rigor and fidelity of implementation, because of the demands and constraints imposed by educational policies, local institutional conditions, and individual teacher practices (Coburn, 2003). Furthermore, scaling-up efforts in multilingual, multicultural, or urban contexts involve numerous challenges, due to fundamental conflicts and inconsistencies in educational policies and practices as well as lack of resources and funding. For example, Blumenfeld et al. (2000) and Fishman, Marx, Blumenfeld, Krajcik, and Soloway (2004) described the difficulties involved in scaling up technology innovations for science education in a large urban school district. They suggested that issues of scalability and sustainability be addressed in technology innovations, so that such innovations can be used widely in K-12 schools to foster deep thinking and learning.

## School Science and Home/Community Connection

Several studies have examined the influences of families and home environments on students' science achievement. A challenge facing many schools, especially those serving diverse student populations, is the lack of connection between schools and students' homes and communities. This may lead to student disengagement from schooling that they see as irrelevant and meaningless to their lives beyond school. Yet, students bring to the science classrooms "funds of knowledge" from their communities that can serve as resources for science learning (Moll, 1992; Vélez-Ibáñez & Greenberg, 1988).

There is clear evidence that family support (e.g., homework supervision, learning materials and resources, and parent's educational background) influences children's achievement, attitudes, and aspirations in science (Peng & Hill, 1994). Smith and Hausafus (1998) reported that low SES, ethnic minority students whose parents communicated and enforced high expectations for science and mathematics achievement had higher test scores than similar students with less supportive parents. This result is important in the sense that such support does not require parental knowledge of science and mathematics, areas in which parents often feel inadequate.

Several studies reported the positive impacts of intervention programs to help students recognize the meaning and relevance of science and connect school science to their homes and communities. Bouillion and Gomez (2001) explored a form of "connected science," in which real-world problems (i.e., current, unresolved, and of consequence) and school-community partnerships were used as contextual scaffolds for bridging students' community-based knowledge and school-based knowledge. Hammond (2001) reported collaborative efforts in which mentor and preservice teachers worked together with immigrant students and their families and utilized the funds of knowledge that these students and their families brought to the science learning contexts. Rahm (2002) described an inner-city youth gardening program and the kinds of learning opportunities it supported. The results indicate that the intervention fostered inner-city students' active participation in science-related activities in informal settings.

The research program led by Calabrese Barton has examined science teaching and learning with urban homeless children who are most at risk for receiving an inequitable education (Calabrese Barton, 1998, 2001; Fusco, 2001). Grounded in post-modern feminism, the research program employs critical ethnography, conceived of as a methodology that emerges collaboratively from the lives of the researcher and the researched and centers on the political commitment to the struggle for liberation (Calabrese Barton, 2001). This view of "science for all" challenges the traditional paradigm whereby science lies at the center as a target to be reached by students at the margins and offers a paradigm of inclusion whereby students' experiences and identities remain in tension with the study of the world.

## RESEARCH AGENDA

Considering that research on diversity and equity in science education is a relatively new and emerging field, there are multiple directions that future research might pursue. Virtually all of the areas discussed in this chapter require further investigation. However, it is necessary to prioritize in order to produce research out-

comes that are rigorous, cumulative, and useful to educational practice. The suggestions below reflect those areas of research that have shown promise in establishing a robust knowledge base, as well as others in which research is limited despite the urgent need for a knowledge base.

## **Student Diversity**

Although the studies mentioned here were selected because of their focus on diversity and equity, many do not address these issues in sufficient depth or complexity. Future research needs to conceptualize the interrelated effects of race/ethnicity, culture, language, and SES on students' science learning in more nuanced ways. Although the intersections among the multiple strands that make up student (and teacher) identities are being theorized in increasingly sophisticated ways, as are the social forces, processes, and practices that shape students' educational experiences (Levinson, Foley, & Holland, 1996), these new perspectives have rarely been applied to the area of school science.

Studies need to combine cognitive, cultural, sociolinguistic, and sociopolitical perspectives on science learning, rather than focus on one aspect to the exclusion of others. This will require multidisciplinary efforts that bring together research traditions that have too often been developed in opposition or isolation from one another.

With ELL students, future research needs to consider science learning/achievement, literacy development, and English proficiency as conceptually distinct but interrelated, and to operationalize the complex interplay of multiple variables in methodologically rigorous research designs. Science educators and researchers also need to engage more deeply the broad scholarship on classroom discourse, second language acquisition, and literacy development (see Chapters 4 and 17, this volume). Though this literature has seldom addressed school science directly, its potential contribution to science education is considerable.

## **Science Achievement**

Another area ripe for investigation involves conceptions and measurement of science achievement. Some research programs emphasize students' agency and empowerment with regard to science, rather than more commonly recognized outcome measures based on academic achievement. These conceptions vary widely from one research program to another and tend to differ from classroom assessment practices, which continue to emphasize memorization of facts. Although science educators (researchers, teachers, policymakers, and others) share the dual goals of improving science achievement and eliminating achievement gaps, existing research programs often do not address student outcomes, especially with quantitative achievement data. Although such data should not be the sole currency of educational research, they can provide an additional perspective that confirms or complicates narrative descriptions about other types of student outcomes, which are common in many research studies.

Lack of emphasis on science in current educational policies presents a unique set of issues. On the one hand, there are few assessment instruments that are widely

used in science. This obliges researchers to develop their own assessment instruments, often around authentic or performance assessments that are aligned with the goals of the research. Such instruments may be well tailored to the goals of a specific research project, but limit comparability across studies. On the other hand, the limited range of standardized tests in science makes it difficult to develop a cumulative knowledge base about student achievement in specific science disciplines or topics.

More research is also needed to examine the effectiveness of educational innovations on achievement gaps among different student groups. Such research should consider disaggregation of achievement results for the intersections of different demographic categories, as well as subgroups within categories. Longitudinal analysis of student achievement across several grade levels or beyond the K–12 years is conspicuously absent from the current literature. Finally, future research should attempt to establish (causal) relationships among educational innovations, learning processes, and student outcomes.

### **Diversity of Student Experiences in Relation to Science Curriculum and Pedagogy**

A major area of future research should be the cultural and linguistic experiences that students from diverse backgrounds bring to the science classroom, and the articulation of these experiences with science disciplines (Lee & Fradd, 1998; Warren et al., 2001). Future research should aim to identify those cultural and linguistic experiences that can serve as intellectual resources for science learning, as well as those beliefs and practices that may be discontinuous with the specific demands of science disciplines. This will require a balanced view of non-mainstream students' intellectual resources as well as the challenges they face in learning science.

An expanded knowledge base around students' non-school experiences related to science could offer a stronger foundation for science curriculum and instruction. Students of all backgrounds should be provided with academically challenging learning opportunities that allow them to explore and construct meanings based on their own linguistic and cultural experiences. At the same time, some students may need more explicit guidance in articulating their linguistic and cultural experiences with scientific knowledge and practices. Teachers (and curriculum designers) need to be aware of students' differing needs when deciding how much explicit instruction they should provide and to what extent students can assume responsibility for their own learning (Fradd & Lee, 1999; Lee, 2002). The proper balance of teacher-centered and student-centered activities may depend on the degrees and types of continuity or discontinuity between science disciplines and students' backgrounds, the extent of students' experience with science disciplines, and the level of cognitive difficulty of science tasks. Further research could examine what is involved in explicit instruction, when and how to provide it, and how to determine appropriate scaffolding for specific tasks and students.

Another area for future research concerns the demands involved in learning science through inquiry. Although current U.S. reforms in science education emphasize inquiry as the core of science teaching and learning (NRC, 1996, 2000), inquiry presents challenges to all students (and many teachers), inasmuch as it requires a critical stance, scientific skepticism, a tolerance for uncertainty and ambiguity, and

patience. These challenges are greater for students whose homes and communities do not encourage inquiry practices, or for those who have been historically disenfranchised by the social institutions of science and do not see the relevance of science to their daily lives or to their future (Gilbert & Yerrick, 2001; Seiler, 2001; Tobin, 2000). Recent research emphasizes the importance of role models, trust, and personal connections between teachers and students as the starting point for non-mainstream students' participation in science inquiry (Sconiers & Rosiek, 2000). Future research may identify essential aspects of inquiry-based teaching and learning, and how these articulate with the experiences of diverse student groups.

## Teacher Education

The literature is replete with accounts of the difficulties that science teachers (who are mostly from mainstream backgrounds) experience in teaching students from non-mainstream backgrounds (see the discussion about teacher education above; also see Bryan & Atwater, 2002, and Lee & Luykx, 2006, for comprehensive reviews of the literature). Some teachers have low expectations for such students and blame students or their families for academic failure, but even those teachers who are committed to promoting equity face challenges related to student diversity in their teaching. These problems will be exacerbated as diversity within the teaching population fails to keep pace with increasing diversity among students (Jorgenson, 2000).

Teachers may not need to share the language and culture of their students in order to teach effectively; however, effective teachers should have an understanding of students' language and culture and the ability to articulate their students' experiences with science in ways that are meaningful and relevant to students as well as scientifically accurate. Some teachers may lack the cultural knowledge necessary to identify students' learning resources, but even teachers with the relevant cultural knowledge may not recognize it as such or may be unsure of how to relate their students' experiences to science (Lee, 2004). Future research may address how to design teacher education programs to enable preservice and practicing teachers to articulate science disciplines with students' linguistic and cultural practices, particularly when the discontinuities between the two domains are large. Research may also examine how teachers' knowledge, beliefs, and practices evolve as they reflect on ways to integrate these two domains. In addition, research may examine challenges in bringing about change with teachers who deride student diversity, resist multicultural views, or reproduce racism through their educational practice (Ladson-Billings, 1999).

Teacher education programs that successfully promote fundamental change in teachers' knowledge, beliefs, and practices concerning non-mainstream students tend to involve small numbers of committed teachers over an extended period of time. Effective teacher professional development requires adequate time, resources, and personal commitment on the part of both teachers and teacher educators. Future research may examine what is involved in taking effective teacher education models to scale, identifying a balance between resources required and the extent of impact on large numbers of teachers. Such research may also intersect with policies on teacher education at the state or local level, and this intersection deserves further investigation.

## High-Stakes Testing and Accountability

The most dominant U.S. educational policy currently, which is particularly consequential for non-mainstream students, involves high-stakes testing and accountability (Abedi, 2004). After almost a decade of high-stakes testing in reading, language arts, and mathematics, more U.S. states are now moving to incorporate science and social studies as well. This trend coincides with the planned U.S. policy on science assessment within the No Child Left Behind Act, according to which science will be required to be included in accountability measures starting from 2007.

This policy change at the federal and state levels may bring about dramatic changes in many aspects of science education. The culture of high-stakes testing already dominates the teaching landscape in many countries. For example, an emphasis on discrete facts and basic skills in high-stakes science testing discourages teachers from promoting deeper understanding of key concepts or inquiry practices (Settlage & Meadows, 2002). Also, complex issues around assessment abound, such as which students are to be included in accountability systems, what assessment accommodations are appropriate, and how content knowledge may be assessed separately from English proficiency or general literacy (O'Sullivan et al., 2003). A basic concern is that ELL students' science achievement is underestimated when they are not allowed to demonstrate their knowledge and abilities in their home language (Solano-Flores & Trumbull, 2003). On the other hand, if science instruction is in the dominant language, simply assessing second language learners in the home language will not guarantee an accurate picture of their science knowledge and abilities.

Future research may examine the impact of policy changes on various aspects of science education. For example, research may address whether teaching for inquiry and reasoning also prepares students for high-stakes testing (and vice versa). From an equity perspective, research may examine whether recent policy changes differentially affects students from different backgrounds. More generally, research may examine the institutional, social, and political factors that so often lead educational policies to work at cross-purposes to empirically tested "best practices" in science education.

## School Science and the Home/Community Connection

Students' early cultural and linguistic experiences occur in their homes and communities. If science education is to build upon students' experiences, it requires a knowledge base about the norms, practices, and expectations existing in students' homes and communities. Unfortunately, research on the connection between school science and students' home/community environments is limited. One consequence of this is that school science tends to be presented exclusively from the perspective of Western modern science, without adequate consideration of how science-related activities are carried out in diverse cultures and speech communities. Generally speaking, the daunting task of bridging the two worlds of home and school falls on students, who may be forced to choose one at the cost of the other. Given this dilemma, it is not surprising that non-mainstream students are so often underserved, underrepresented, and disenfranchised in science.

Future research may examine the science-related "funds of knowledge" existing in diverse contexts and communities. It may focus on how parents and other

community members can serve as valuable resources for school-based science learning, or explore various educational approaches in community-based projects that can help students recognize the meaning and relevance of science for their daily lives and for their future.

## CLOSING

The literature on the intersection of school science and student diversity is currently insufficient to the task of effectively addressing persistent achievement gaps, but points in some promising directions. Deeper examination of the complex relationships among the various factors influencing student outcomes, combined with greater attention to the potential contributions of multiple theoretical perspectives and research methods, should produce significant and powerful additions to the existing knowledge base in this emerging field. Just as teachers must learn to cross cultural boundaries in order to make school science meaningful and relevant for all children, researchers must learn to cross the boundaries separating different theoretical and methodological traditions if they are to disentangle the complex connections between student diversity and science education.

## ACKNOWLEDGMENTS

Parts of this chapter appear in our book, *Science education and student diversity: Synthesis and research agenda* (Lee & Luykx, 2006). The preparation of this chapter was supported in part by grants from the Department of Education Office of Educational Research and Improvement to the National Center for Improving Student Learning and Achievement in Mathematics and Science (R305A60007) and to the Center for Research on Education, Diversity & Excellence (R306A60001). The findings and opinions expressed in this chapter do not necessarily reflect the position, policy, or endorsement of the Department of Education, OERI, or the respective national centers. The authors acknowledge the electronic search of the literature by Margarete Mahotiere.

Thanks to Julie Bianchini and Randy Yerrick, who reviewed this chapter.

# CHAPTER 8

---

## Postcolonialism, Indigenous Students, and Science Education

Elizabeth McKinley

*Auckland University*

Science education research, particularly in the English-speaking world, has become increasingly concerned with the diversity of students in the classroom, as evidenced by increasing numbers of review articles on issues of equality and equity in the last 10 years (see, for example, Hipkins et al., 2002; Krugley-Smolka, 1996; Lee, 2003). However, much of the diversity literature does not fully address the issues of indigenous learners and their communities in postcolonial societies. This literature has tended to treat minorities as requiring similar, if not the same, solutions to what is perceived as non-participation and non-achievement in school science by these groups. As a consequence of this approach, members of various cultural groups do not recognize their struggle, or their voices and visions in the literature and rightly have been perceived to have been excluded in many cases. This review examines the science education research for indigenous students as opposed to the more homogeneous groupings of diversity, minorities, or multicultural.

The chapter focuses specifically on indigenous students' interests from international contexts and recognizes the need to establish a knowledge base to promote and support academic achievement and equity in science education for these students. In my view, the knowledge base requires the consideration of students' linguistic and cultural knowledge and experiences in combination with expectations of participation and academic achievement in science education. Furthermore, these considerations need to be seen in the light of educational imperatives of the indigenous communities themselves. There is also a global imperative of maintaining indigenous worldviews, languages, and environments to which science education research can contribute. These issues, and the complex relationships among them, are reflected in the emerging international literature on indigenous students, which recognizes that many indigenous communities have often been subject to the historical and ongoing effects of colonization, including the subjugation of their

knowledge, language, and culture. Therefore, learning for indigenous communities is grounded not only on philosophical and pedagogical bases, but also on moral and political bases. As the sociologist Young (1974) and educationalist Maddock (1981) wrote over two decades ago, science education necessarily involves philosophy, sociology, history, psychology, and anthropology. Nowhere is this more so than in the circumstances of postcolonial societies where colonial rulers established formal education systems for peoples of other civilizations.

All reviews of literature are situated, partial, and perspectival, and this one is no exception, despite my use of the collective term *indigenous* to denote various peoples around the world. As Patti Lather (1999) argued, the practices of including and excluding in reviews are considered as “gatekeeping, policing, and productive rather than merely mirroring” (p. 3). First, this review surveys publications related to indigenous students and science education, mainly from the last 12 years, carrying forward from one I was involved with in 1992 (McKinley, Waiti, & Bell, 1992). Second, the review is written from the perspective of someone who identifies herself as a member of the indigenous Maori people of Aotearoa New Zealand, suggesting that I bring an “optics [that] is a politics of positioning” (Haraway, 1996, p. 257). However, I have not restricted this review to those articles written only by those who identify themselves as indigenous or separated the writers into indigenous/non-indigenous. Although I agree with the arguments and sentiments of maintaining indigenous voice at an international level, such identity classification is difficult to determine on an international basis and is connected with each country’s politics and histories. At this point in our history, such a strategy would not only exclude contributions of some countries with indigenous communities, but would also ignore some good work. Third, my own background assumes a specific context in the full range of indigenous communities. There are many characteristics regarding the nature of Aotearoa New Zealand’s location, history, and circumstance that give Maori views different from those of many other indigenous communities in other countries. My partiality will undoubtedly be evident in a number of ways to many readers, not least of all to other indigenous researchers whose situations differ markedly from my own experiences. However, I hold myself accountable to a growing community of indigenous science educators with which I identify. And last, as indigenous knowledge is seen to be local in its applications, writers can have problems in getting articles on local communities accepted for peer-reviewed international journals; this was particularly true in the past. In addition, many indigenous researchers publish in local or indigenous journals or present work orally, which means that it can be difficult to get a comprehensive picture of the research being carried out. Hence, partiality should not be considered just in terms of the writer, but also in terms of science education research itself.

Overall, the research literature in the field of indigenous students in science education is very uneven in its application. Some issues have a large literature, whereas others have little or nothing written on them. This chapter is an attempt to bring some structure to the growing research literature on indigenous students’ learning in science. Furthermore, not all issues raised are always of priority in indigenous communities themselves. First, I outline what I mean by *postcolonialism* and *indigeneity* in an attempt to clarify the terms and their use in this chapter. This is followed by a discussion of Indigenous Knowledge (IK) and Traditional Ecological Knowledge (TEK), two terms that are becoming more widespread in the literature.

Following these, the chapter is then divided into two broad sections that review the bulk of the literature in the field. The first section reviews the large and significant research about science as a body of knowledge with respect to culture. Included here is the philosophical debate between two positions constructed as a dichotomy—Western Modern Science (WMS) and indigenous knowledge bases (traditional and contemporary)—and their relationship to the science curriculum. The second broad section reviews literature related mainly to teaching and learning with respect to culture and covers issues such as stereotyping, curriculum contexts, learning, and indigenous pedagogy. I complete the review with a discussion of the small but growing debate considering the impact of the language of instruction and indigenous knowledge on classroom practice. Finally, I close with some comments about future directions for this research field in the light of indigenous communities' aspirations for themselves and their children, and how well science education research is meeting these aspirations.

### POSTCOLONIALISM AND THE PRINCIPLE OF INDIGENEITY

The term *postcolonialism* is controversial among many groups of researchers (see, for example, Ashcroft, Griffiths, & Tiffin, 1995; Mohanram, 1999). For many indigenous researchers the term signals that the European imperial project, and the appropriation of the "Other" as a form of knowledge, has been assigned to an historical past. Although this understanding is always present in postcolonialism, I continue to use it to highlight other meanings. The literary critic Homi Bhabha (1994) argued that postcolonialism can be used to mean "beyond"; instead of arguing using a lineal progression of before and after a point in history, another dimension is added with this alternative meaning. Although I do not want to dwell here on the more theoretical intricacies of this idea, it suffices to say that "beyond" suggests that boundaries or borders have become blurred. For example, the sustained contact between Maori and Pakeha in Aotearoa New Zealand, as with many other countries, has led to an intermingling of many things, including ancestry, cultural history, and language. Furthermore, it is simplistic and deterministic to think that there is ever a point in time where conditions change overnight. Colonialism is about many things, including the history and culture of countries involved in colonial rule, the policies that have been implemented before and after the independence of colonial states, and the personalities and beliefs of rulers and people of influence, both colonizers and colonized. Colonial discourse is complex and simplifying; it can lead to being overly simplistic in our analyses. Blurring boundaries takes us beyond the "them and us" (colonizer/colonized) position commonly found in colonial discourse. Hence, using postcolonialism in this chapter is not to imply that colonialism is over, but to affect a more complex picture of colonizing history and politics and its influence on science education research for indigenous students.

We need to keep in mind that beyondness is also contextually bound, as each country's pre- and post-contact experiences differ. Although those countries that have a history of being part of the British Empire often have points of similarity, their points of difference are just as startling. For example, whereas India was seen as the jewel of the British Empire (or crowns as evidenced in the display at the Tower

of London) with its mineral wealth and spices, Aotearoa New Zealand was constructed as the farm, supplying England with primary produce to feed its burgeoning population. India managed to maintain its language and culture, while Aotearoa New Zealand's Maori became numerically decimated through imported diseases, and the language and culture became threatened. Aotearoa New Zealand became a white dominion, along with Australia and Canada, while India remained part of Asia. The colonizing histories of these countries are markedly different—colonized by the same country but at different times and places. All countries, whether numerically dominated by the colonizing peoples or not, have been left a legacy of Western European culture through institutional structures and language. For many indigenous groups, the colonizing experience is ongoing in their own country. To assume that when the administrators of colonizing countries have handed over power, colonialism stops, is to view our history too simply. As Said (1994) argued, "Even as we must fully comprehend the pastness of the past, there is no just way in which the past can be quarantined from the present. Past and present inform each other, each implies the other, each co-exists with the other" (p. 2).

It is also important to understand that imperialism, especially in the time of the Enlightenment, was both a science project and an educational movement (McKinley, 2003). Explorers sought to consciously categorize, name, and label the newly "discovered" territories and peoples, and settlers sought to modernize, develop, instruct, and civilize the natives they found. Early settlers often transplanted familiar objects from their homelands to their new settlement—from books and curricula to flora and fauna—to make their new place like home. In Aotearoa New Zealand, imported flora and fauna came to infest the landscape, causing significant (and ongoing) damage to native species, such as our flightless birds—a form of ecological imperialism (Crosby, 2004). For a science curriculum this is significant. Until the early 1970s, the New Zealand Science Curriculum was based mainly on exotic plants—ones brought in by the British settlers—deliberately planted around school playgrounds in order for the children to study them. Such a movement elevated flora and fauna, and the knowledge that is inherent in such, from the old country above that of the "new" land and so undermined the basis of Maori empirical knowledge of the world. Local knowledge came to be positioned as technical knowledge for survival and/or primitive. Today, although not as obvious, the curriculum continues this legacy in other ways. For example, a common plant, deliberately developed for its pastoral qualities as a direct result of colonial settlement and the development of the land as farms, is used by Year 13 students for their plant study. The pasture plant is popular because there is a significant amount of scientific research information on it to support the students' studies, and similar research on native plants is extremely difficult to find. Ironically, Year 13 students in Maori language immersion schools continue to use it for the same reasons.

Indigeneity is a heterogeneous, complex concept that is contextually bound. For example, some groups, such as the First Nations, Inuit, Native American, Maori, and the Koorie and Torres Strait Islanders, are peoples whose colonial settlers or invaders have become numerically dominant. These indigenous groups have been termed the *cause célèbre* of postcolonial times by some writers because they have been seen as the forgotten indigenous peoples in their own countries (see Ashcroft et al., 1995). However, indigeneity also includes Third World contexts such as in Africa, South America, Southeast Asia, and India (see, for example, Semali & Kincheloe, 1999). These contexts bring with them complexities that I cannot even attempt to

comprehend or unravel here or through my own experiences. Although many of these countries had Western European settlers, the white populations never attained majority by numbers (and many did not stay), but they exerted enormous influence through institutions and language (Maddock, 1981). Another group is those who claim indigenous status but who are not necessarily legally recognized as such in their own countries, for example, the Ainu people in Japan. And then there are other indigenous groups who have no land to call home, such as the Hmong people (Chang & Rosiek, 2003). The term indigenous is not necessarily used by the groups in their own countries. In Aotearoa New Zealand, Maori are known as *tangata whenua* (people of the land), but the term *indigenous* is often used in an international context to connect with other, similar groups. Hence, the term is not used here to mean the "same," but to form a collective of people who share some similarities in their aspirations and circumstances.

For many indigenous groups, the call for recognition is related to being able to live as indigenous—having access to their language, culture, and resources (such as land, forest, fisheries, and their own institutions). Furthermore, indigenous communities believe education should be about the preparation for participation of young people as both citizens of the world and for participation in their own indigenous societies. These societies—global and local—are not separate, nor is one more backward than the other. All indigenous children live in a variety of contexts and should be able to move from one context to the other with relative ease. In addition, indigenous children should expect to live with good health and a high standard of living, along with other groups in society. A number of researchers have argued that science and indigenous community development are connected (Dyck, 2001; Dzama & Osborne, 1999). Maori researcher Mason Durie (1996) drew a connection between self-determination, improved well-being, and an improved skill base among a group. He argued that self-determination reinforces a cultural identity. Dyck argued, with respect to the Canadian situation, that development is important to indigenous people's participation in science; an indigenous-determined focus means that drawing on a long-term knowledge base and experience can help a people retain a sense of continuity in an otherwise fragmented world. Castellano (2000) argued that the challenge is "to open up space for Aboriginal initiative in schools and colleges, work sites, and organisations so that indigenous ways of knowing can flourish and intercultural sharing can be practised in a spirit of coexistence and mutual respect" (p. 23).

Science education has much to contribute to the wider goals of indigenous communities, particularly in helping indigenous students to help their communities to achieve these aspirations.

Language revitalization, development, and maintenance has become an important goal for indigenous groups to pursue, particularly through the education system, which is seen by many as having a major role in indigenous language loss in many countries (see Battiste & Henderson, 2000; L. T. Smith, 1999). In times of colonization indigenous languages were targeted as an impediment to the civilization of the natives (Barnhardt, 2001; Marker, 2004; McKinley, 2003). Policies and practices of colonial rule effectively banned indigenous languages in schools in many places. As a result, these languages were relegated to community languages or were lost altogether. Furthermore, people came to believe that the colonizer's language was better and sometimes denounced their own languages in favor of it. Any language is fundamental to maintaining worldviews, cultures, and knowledge (Aoki

& Jacknicke, 2005). Furthermore, for indigenous peoples, their homelands are the only place these languages are found, unlike most immigrant groups, whose language is secure in another place. However, the teaching of indigenous languages and cultures in the education system, and in science education, does not appear to be a priority or a foregone conclusion—in fact, their place in schools continues to be contentious in many countries. Such arguments are often constructed around and bring into focus two rights that are sometimes seen to be in conflict: the democratic rights of all citizens and the rights indigenous people assert by virtue of being first peoples of the land. In most places, the individual rights tend to take precedence; unless countries value indigenous languages and find a means of negotiating these imperatives, indigenous knowledge and worldviews will be lost, despite the current resource rush on indigenous knowledge now being seen.

Focusing this chapter on indigeneity is not intended to replace concepts of diversity or multiculturalism but to sit beside them as another form of grouping that provides further insights into the issue of equity in science education research. Science education researchers have begun to recognize their role in helping indigenous communities meet these aspirations. The following section begins to explore how the science education research community has conceptualized this role by looking at terms that denote other knowledge.

## **INDIGENOUS KNOWLEDGE AND TRADITIONAL ECOLOGICAL KNOWLEDGE**

I found few articles in science education research that attempted any explanation of the term Indigenous Knowledge (IK; also called Aboriginal or Native knowledge), though it was widely referred to in the literature. Indigenous writers Battiste and Henderson (2000) argued that there is no simple answer or any legitimate methodology to answer the question what is indigenous knowledge? (p. 35). The issues they raised center upon trying to bring together indigenous knowledge, as perceived in indigenous languages, and “Eurocentric thought” (p. 35). They highlighted three problems in defining IK. First, it is not a uniform concept across all indigenous peoples; it is diverse knowledge that is throughout many peoples and, as such, cannot be captured in the categorization of Eurocentric thought. Second, the idea of understanding IK as it is conceived in indigenous communities does not fit a Eurocentric view of culture, because no parallel word exists in some indigenous languages. And third, the act of codifying can be seen as intrusive and fragmentary as the knowledge is integral to the people and place. Kawagley (1995) expanded on this last argument by suggesting that personal context is extremely important in IK, because knowledge is created through humor, humility, tolerance, observation, experience, social interaction, and listening to conversations and interrogations of the natural and spiritual world. In fact, many indigenous writers see any attempts at definitions of IK as another way of assimilating their communities. Some definitions of IK have been published (see Battiste & Henderson, 2000) that have tended to be broad and refer to complete knowledge systems with internal validity, or they explore the epistemology involved (see Aikenhead, 1997). However, the purpose for my use of IK in this chapter is to refer collectively to the knowledges of various indigenous peoples and not to imply that these local knowledges are the same in any manner.

One of the main focuses of IK is that each group of indigenous people has constructed knowledge that reflects adaptation to a particular location or localities. Integral to such knowledge construction are people, the landscape, and the creator of all things. Furthermore, many indigenous people speak of their own specific knowledge, using their own languages, by referring to it as *matauranga Maori* (Maori), or *Qaujimaqatuqungit* (Inuit), or whatever the term may be. For example, Kawagley (1995, 1999) always writes with reference to the knowledge of the Yupiaq people, of whom he is a member, and tends to askew references to IK even as a collective. Furthermore, he writes that Yupiaq knowledge is best dealt with in the native language (Kawagley, 1999). However, other indigenous writers do use the term and speak of “strands of connectedness” throughout continents at least (see Cajete, 1986, 2000). My point here is not to bring the field into paralysis, but to draw the attention of readers in the field to the specifics in the articles when any term regarding knowledge is used. The terms IK and TEK (traditional ecological knowledge) are used mainly by writers for political purposes, such as establishing connections with other groups in order to bring indigenous work to an international stage.

Some debate has occurred in the literature, mainly confined to Canada and the United States, on establishing differences between IK and TEK. Snively and Corsiglia (2001) called descriptive ecological knowledge about nature that has been gathered over years of experience by aboriginal peoples in Canada and the United States traditional ecological knowledge (TEK). One might see TEK as the “science” of IK—that IK which is validated through scientific criteria. Indigenous writers use the term as if it is part of IK, where IK is the frame of knowledge and not science (Battiste & Henderson, 2000; Cajete, 2000). Because indigenous knowledges are deeply integrated with locality (nature) and experience, along with many other characteristics, IK is difficult to separate from TEK from an indigenous point of view. In fact, the extraction of the knowledge from the knower undermines the very basis of IK.

According to indigenous writers, TEK is highly localized and social. The web between humans, the spirits, and nature in a particular locality—such as animals, plants, natural phenomena, and landscapes—form the basis of TEK. Knowledge that has been gained by indigenous peoples is empirical, experimental, and systematic, but the models and explanations do not equate to Western scientific knowledge. Battiste and Henderson (2000) suggested that TEK is a means of understanding the “web of social relationships between a specific group of people (whether a family, clan, or tribe) and a place where they have lived since their beginning” (p. 44). Hence, the knowledge is accumulative over time and is ongoing, but is not static, as often portrayed in curricula. What is traditional about TEK, argued Battiste and Henderson, is not its antiquity but the way it is acquired and used. Furthermore, in light of previous paragraphs, it must be remembered that TEK in the literature is categorized within the frame of Eurocentric thought and language, because IK in indigenous languages makes no such distinction. Any agreement on the term by indigenous writers is most likely based on political imperatives, such as concessions to the realities of working within English-language contexts and in colonized countries.

However, IK is widespread in the literature and generally used as a universal term to denote the worldviews of indigenous peoples. In keeping with Battiste and Henderson’s (2000) concerns, most research articles refer to more specific descriptions of IK in local contexts and use local names. I do not intend to debate in this chapter whether IK and TEK should be different, or any advantages of having two names

(and hence categories) in English. For my purposes, I will use both IK and TEK for different reasons. TEK is widely used in Canadian and U.S. literature on science education research on aboriginal students of these nations; I use it in relation to the articles that objectify it. I use IK to mean the knowledge and worldviews of indigenous communities. Philosophically, and from an indigenous point of view, the two objects are the same.

## INDIGENOUS KNOWLEDGES, SCIENCE, AND CURRICULA

There is a substantial international literature that explores the relationship between indigenous and minority knowledges and Western scientific knowledge. The scientific and metaphysical nature of indigenous knowledges underlies much of the debate. A subsidiary question raised by some researchers is whether Western modern science (WMS) is a threat to indigenous knowledges (IK). This section explores debates concerning the nature of science and indigenous knowledges relevant to science education, particularly with respect to curriculum inclusion.

## UNIVERSALISM, PLURALISM, AND IMPERIALISM

One of the largest (in terms of volume of literature) debates in the field of culture and science education is about the nature of knowledge. The debate connects with a wider critique (see Kuhn, 1970) that has accompanied the emergence of post-structuralist, postmodern, and postcolonial theoretical frameworks. The relevance of this literature to schools is that a universalist understanding of science informs the assumptions implicit in school science curricula about the nature of science and how science should be taught (Stanley & Brickhouse, 2001). The debate tends to be polarized into viewing science as a universal body of knowledge—a universalist position—or understanding science knowledge as a product of its culture—a pluralist (or multiculturalist) position. Holders of the universalist position argue that WMS is the paradigmatic example of science, has a universal essence, and provides knowledge that is uniquely and epistemologically far more powerful than that of any IK or traditional sciences (Loving & de Montellano, 2003). In contrast, the pluralist position stresses that all knowledges, including WMS, exist within a cultural context (Lewis & Aikenhead, 2001; McGovern, 1999; Semali & Kincheloe, 1999; Snively & Corsiglia, 2001). Pluralists argue that portraying WMS as universal has undermined indigenous knowledges, dismissing them as inadequate and inferior and making WMS elite (Jegede, 1997; McKinley, 2003; Semali & Kincheloe, 1999; Zaslavsky, 1994).

There is a sense in which this debate has been rather one-sided, in that to take a strongly universalist position is difficult without implying approval of “a politics of exclusions” (Irzik, 2000, p. 71), that is, without being seen as implicitly supporting the current inequity between groups in society. But such a construction was inevitable as researchers found ways to articulate alternative views of knowledge and apply them to curriculum subjects. However, the universalist science approach has been widespread and influential in keeping alternative views from being articulated, particularly through international journals where quantitative methodologies were the dominating ideology for a long time. These approaches tended to con-

struct indigenous (and other minority) groups as subordinate by placing them in a position of deficit (L. T. Smith, 1999).

Semali and Kincheloe (1999) argued that the ability of WMS to present its findings as universal gives it an imperialistic power dismissive of indigenous knowledge as inadequate and inferior. Furthermore, they argued that the cultural context of WMS makes it "white" rather than "universal" science and that the conception of a universal science only arises when one fails "to appreciate the ways modernist scientific universalism excludes this 'white science' as a cultural knowledge" (Semali & Kincheloe, p. 29). This position suggests that all knowledge, including that of WMS, exists within a cultural context, and that the language (including meaning), questions, and methods used by any researcher depict a reality that reflects the cultural values, ideas, beliefs, and practices of the society with which the researcher is familiar. The pluralist position is dismissed by those who question the white science argument on the grounds that women and non-white non-Europeans have made significant contributions to scientific knowledge (Taylor & MacPherson, 1997). Furthermore, they suggested that, as a group, white men are also alienated, confused, and intimidated by science to the same extent as other groups.

Aikenhead (1997) argued that because WMS is often seen as a Western cultural icon of prestige, power, and progress, Western culture usually permeates the culture of those who engage in science. This can threaten indigenous cultures and thus cause Western science to be seen as a "hegemonic icon of cultural imperialism" (p. 15). Harding (1991, 1993, 1998), more specific in her discussion, highlighted the political utility of science to indigenous subjugation.

Scientific and technological changes are inherently political, since they redistribute the costs and benefits of nature's resources in new ways. They tend to widen any pre-existing gaps between the haves and have-nots unless issues of just distribution are directly addressed. (Harding, 1998, pp. 50-51)

M. R. Smith (1996) argued that the threat posed by WMS to Native American children is such that it may cause for them a loss of culture. According to Smith, WMS devalues Native American science and as such causes a "progressive alienation from traditional values, family and community" (p. 2). Furthermore, George (1999) argued that IK is not found in school curricula because it is not considered to be scholarly, because of the way in which it is developed and transmitted. There is compelling evidence to suggest that imperialism and colonialism have contributed significantly to WMS's domination in school curricula to the exclusion of local knowledge. The science curriculum is the site of contestation for the inclusion of a pluralist approach to knowledge.

## Contesting the Curriculum

A widespread assumption is that WMS should be part of the school curriculum for all peoples, but its place is increasingly being contested. For example, Lewis and Aikenhead (2000) asked, "How should non-Western ideas be viewed in relation to Western science? If non-Western ideas are not inferior should they be 'accepted' in science classrooms?" (p. 4). Many science education researchers argue for the inclusion of indigenous knowledges, but the debates tend to be centered around the ex-

tent to which IK/TEK should be included. In contrast, those opposing its inclusion argue that there is no place for IK unless it has been subsumed into the body of knowledge referred to as WMS, that is, unless it is made the same as WMS, in which case the status quo continues. The arguments forwarded revolve mainly around the metaphysical nature of IK. However, the arguments between IK and WMS are not as diametrically opposed as one might expect. For example, the idea that IK and WMS differ through process is agreed upon but is used to support different assertions. The following section discusses the arguments forwarded as to why IK and/or TEK should or should not be included in the curriculum. The arguments center on finding connections between the two, the proposition that IK is contemporary knowledge, that IK can enter the curriculum but not the science curriculum, and that IK has no place in the curriculum.

### **Finding Connections**

By far the most supported argument in the literature is that IK should have a place in the science curriculum. However, many researchers suggest this can be done in a variety of ways. The admission of IK in science curricula immediately poses questions about the scientific nature of traditional indigenous bodies of knowledge; it is here where researchers have taken the opportunity to form a new object of knowledge as already outlined, that is, TEK (Corsiglia & Snively, 2000). Some researchers argue that indigenous knowledge can be taught alongside Western science as distinct but not entirely dissimilar knowledge systems within a single curriculum framework (Goes in Center, 2001; Rikihana, 1996; Roberts, 1996). In New Zealand, Roberts' approach to indigenous knowledge and Western science was to compare the similarities and differences from the perspective of Pacific knowledge bases. Aikenhead (1997) undertook a similar project with respect to Canadian First Nations knowledge bases. The argument is that both WMS and IK have an empirical database with observations of the natural world having provided information that has been accumulated over time, systematized, stored, and transmitted, either orally or in written form. Roberts argued that the differences between the two forms of knowledge are in the creation of empirical databases. In many cases, IK databases have been built up over thousands of years and include qualitative as well as quantitative information, because all observations and interactions are considered relevant. In contrast, many WMS databases are comparatively short term, primarily quantitative, and frequently obtained or supplemented by experimental data gathered under controlled conditions. WMS and IK share an ability to construct theories (models) and make predictions, and are subject to verification over time. But there are differences in the framing and testing of predictions and in the treatment of results. Another view was given by Corsiglia and Snively (2000), who argued: "Indigenous science offers important science knowledge that WMS has not yet learned to produce, and that IK and TEK are being increasingly researched in Africa because they can contribute to the eradication of poverty, disease and hunger where modern techniques are deficient" (p. 235).

They argued that if IK and TEK can make valid observations, then it is not legitimate for the science classroom to present conventional science as the only way of seeing the world. It is an acknowledgment, given with reservation, that some of the insights of science can be arrived at by other epistemological pathways.

A number of researchers have made attempts at including IK into science curricula through developing resources and writing curricula in indigenous languages (see, for example, Aikenhead, 1997; McKinley, 1996, Michie & Linkson, 1999). June George (1999), in her work in Trinidad and Tobago, took a slightly different approach and identified several ways in which school knowledge and IK are both similar and different. She presented a four-fold categorization of the relationship between the two knowledge systems. The first category is where conventional science can explain indigenous practice. For example, the indigenous practice of using a mixture of lime juice and salt to remove rust stains from clothes can be explained in conventional science in terms of acid/oxide relations. In her second category, a conventional science explanation is unavailable, but likely to be developed; for example, native plants that have pharmacological properties recognized in traditional medicine, but appropriate usage has not been verified by conventional science, although conventional science does recognize its pharmacological utility. In category three, there is a conventional science link with traditional knowledge, but the principles may be different, for example, in the relationship between sugar and diabetes, where IK claims sugars cause diabetes, WMS claims the ingestion of sugars for a diabetic can worsen the condition. Finally, in a fourth category are those aspects of IK that conventional science cannot accept. George suggested that the knowledge in categories one and three could be used in classroom programs to highlight similarities between indigenous and Western conceptions of knowledge and would increase indigenous students' engagement in learning.

## IK as Contemporary Knowledge

Indigenous knowledge has been seen as knowledge that is not conversant with the modern world. Even the use of the term TEK conveys a sense of being old-fashioned. The questioning of the contemporary and continuing utility of IK is rejected by indigenous writers (see for example, Dei, 2000; Goes in Center, 2001; Kawagley, 1999; McKinley, Waiti, & Aislabie, 2004). For example, the use of Geographic Information Systems (GIS) has been taken on by indigenous communities all over the world, and many feel it has been made for us. It enables communities to analyze and organize information regarding resources, both land and people, in ways that have never been available previously, but at the same time includes "native standards, goals, and tribal wisdom" (Goes in Center, p. 121). The use of GIS to develop IK is an example of dynamism and embedding of the modern into IK.

Related to this argument is the significance of traditional knowledge to indigenous development (see, for example, Castellano, 2000; Dei, 2000; McKinley, 1997). For example, Castellano argued that the ability of indigenous Canadians to live well is inextricably linked with their traditional knowledge base, as they battle externally generated problems such as contamination of their traditional food supplies and the marginalization of rural peoples in a competitive world economy.

The knowledge that will support their survival in the future will not be an artefact from the past. It will be a living fire, rekindled from surviving embers and fueled with the materials of the twenty-first century (p. 34).

Dei (2000) made the same argument and extended it within the context of IK and African development, as did McKinley in the New Zealand context. Lujan (2001) saw science as a tool for American Indian community development, whereas James (2001) suggested that First Nations peoples need science to understand the impact of the dominating culture's schemes on individuals and communities. The link between science and indigenous peoples is acknowledged by many. The issue is not that indigenous communities wish to shun science completely, but that science needs to be integral to development of the community, not as the controlling knowledge (Durie, 1996).

## **Disciplining IK**

Many researchers suggest that science curricula need to be reconceptualized, going beyond presenting indigenous or subjugated knowledges as add-ons that provide interest or diversity to Western academic institutions, to integrating them into science curricula (see Aikenhead, 1996; Jegede, 1995; McKinley, 1996; Ogawa, 1997). Other researchers believe that IK should be part of the curriculum, but as a separate subject, just like art or literature (Cobern & Loving, 2000). The reason given for treating IK this way is a concern that IK could be co-opted into a universal paradigm by WMS's domination. Furthermore, IK could maintain a position of independence and continue to critique the practices of science from outside. The argument that IK and TEK, like other subjects, is not devalued by their exclusion from the science domain takes no account of colonial power and its ongoing nature in postcolonial societies. Subjects, such as history and art, are an integral part of Western societies and have had a tendency to claim a "real" history or art. These subjects have in the past excluded, and in many cases continue to exclude, knowledge from indigenous societies. As a result, many indigenous peoples learn the languages, histories, arts, nature, etc. of their colonizers in schools and have to find other means to learn about and appreciate their own knowledge and not feel ashamed. It is the tendency for WMS to establish itself as the only way of knowing that, Jegede (1995) argued, denigrates IK and creates difficulties for indigenous learners.

However, there has been some recognition that keepers of IK show a reluctance to discuss it, particularly with people who have a formal Western-style education, which affects curriculum inclusion (Castellano, 2000; Kawagley, 2001; L. T. Smith, 1999). As a result of assimilative education, economic dislocation, and government control often from external cultures, the intergenerational transmission of knowledge has been undermined to the extent that its survival is in danger. In addition, there has been some disruption of the application of IK to the demands of daily living within a language, where knowledge grows and moves on.

## **No Connection, No Place for IK**

Taylor and MacPherson (1997) argued that the debates regarding IK and WMS should not be taking place, because they are based on a false premise, that the modifier Western suggests that science is practiced and culturally rooted only in the West. However, many of the arguments against IK inclusion in the curriculum are of a more philosophical nature. Some researchers have argued that IK does not dis-

tinguish the physical from the metaphysical (Loving & de Montellano, 2003; Yakabu, 1994). For example, Yakabu suggested that even when people in traditional societies have been well educated in science, they find it difficult to give up the traditional solutions to problems to consider new and better ones. Others suggest such a position is overstated; in the perception of students, the two domains do not have serious interference, because the two are separated by the sorts of questions asked (Durie, 1996; Thijs & van den Berg, 1995). In the New Zealand context, Durie argued that the emphasis Maori thought places on the link between the physical and the metaphysical is not so much a point of absolute difference from conventional science, but a difference in balance. He suggested that, to some extent, the debate is about semantics. More importantly, indigenous communities emphasize a holistic approach rather than the fragmentation of knowledge.

A further argument is that WMS is culture-free or generic in its approach, if not its application. Inherent in this argument is that WMS is not at fault for excluding "others"; that has more to do with the public image of science. For example, in an African American context, Key (2003) argued that school science may even be seen as something foreign to all students, who can study science for years before reading about a scientist or inventor of their own ethnic group. Key suggested that if students do not identify with those who are doing the processing, they may internalize the idea that they cannot perform science. However, as science is culture-free, the students may perceive they cannot do science because of the cultural images, rather than any aspect of the subject matter. The issue of the image of what it is to be a scientist has been echoed by researchers of indigenous students, but not for the same reason (see Monhardt, 2003). The response to a lack of cultural representation among the community of scientists has usually been in finding indigenous scientists and writing about them in a resource that can be used by schools (see Martin, 1996).

## Concluding Comments

A suggestion has been made that non-Western cultures be asked what concerns they have, or do not have, about WMS and whether learning about WMS is a threat to the survival of their culture and about the extent to which they wish to access Western scientific knowledge (Stanley & Brickhouse, 2001). There is little doubt, according to others, that most indigenous parents want their children to acquire the best available Western scientific knowledge, provided that such knowledge does not displace their own cultural understandings (see, for example, Corsiglia & Snively, 2000; McPherson Waiti, 1990). In Aotearoa New Zealand an emphasis on an integrated approach to economic, social, and cultural development leads to the position that there is an imperative for full Maori participation in science (Durie, 1996; McKinley, 1999). Furthermore, it is emphasized that the interface between IK and WMS allows for an expanded understanding of ourselves and the world around us. Kawagley (1995) suggested that indigenous thought sees science understandings as a quest for knowledge as well as a means to live a long and prosperous life—to be used in juxtaposing it against past experience in order to see what the future holds. Although pluralists accept the effective and reliable nature of WMS, this is not the same as saying it stands outside human conceptions. In this way, not only do IK

systems have a functional significance beyond that of WMS; it is suggested that indigenous people may view science differently, which has implications for learning, in communities and classrooms, and the curriculum. The next section examines the research on learning implications of IK and/or TEK in classrooms.

## IMPROVING CLASSROOM PRACTICE

The culture and science debates in the 1980s and 1990s were linked to others. Constructivism; science for all; scientific literacy; and science, technology, and society (STS) were concerned with pedagogical change and improving the learning and achievement of a wider range of students in science education by taking into account students' prior knowledge. Unfortunately, two major research projects of the 1980s that became the basis for many research studies in science education in the years that followed, the Children's Learning in Science Project (CLISP) in Britain and the Learning in Science Project (LISP) in New Zealand, never considered culture, power, and discourse as major variables in children's understanding of school science concepts or their prior knowledge at their time. However, some science educators from African and Caribbean countries working with indigenous groups published research challenging the notion that students' prior conceptual understandings of science were culture-free (see Christie, 1991; George & Glasgow, 1988; Jegede, 1988; Jegede & Okebukola, 1991; Ogawa, 1989). One argument forwarded by these writers for taking students' cultures into account in learning science was motivation—to try to get the students to enjoy science, try harder, build their self-esteem and, hence, succeed. However, there was also an attempt to consider and find ways for science education to be more inclusive of other cultural knowledge and languages (see McKinley, Waiti, & Bell, 1992). These indigenous educators challenged the personal constructivists about conceptual change and how it occurred.

The work of the indigenous educators aligns loosely with the work of those who tried to develop a sociocultural approach to teaching and learning. A few science and mathematics education researchers began to articulate a thorough critique of the assumptions underpinning personal constructivism in the research literature at the time (see, for example, Aikenhead, 1996; Cobern, 1993; O'Loughlin, 1992; Solomon, 1987, 1994; Walkerdine, 1984). The purpose of establishing a sociocultural approach was to reintroduce a cultural perspective for science education. The issues raised in this literature, often based on anthropological studies, included that which centered on meaning-making in everyday contexts. Cobern (1993, 1996), in particular, worked on establishing a worldview theory, suggesting it as a model to determine how culturally different students will engage with science meanings. Worldview theory focuses on what will appear plausible to the students and what might not. The term *worldview* has been adopted by a number of science education researchers.

However, the criticism of the sociocultural approach is that it is still situated and focused on science and how to get students acculturated into it, "to teach students the socioculturally constituted ways of knowing that underlie science so that the process of doing science is demystified" (O'Loughlin, 1992, p. 816). The approach is still favored by a number of science education researchers who explore ways to approach science critically and work within multicultural education. How-

ever, as indigenous groups assert their first people of the land status, their aspirations extend beyond what this framework appears to deliver. Even worldview theory is a model for detecting resistance to science ideas that seem counter-intuitive to the student; it does not focus on the assimilatory tendency of WMS to indigenous views of knowledge. For example, sociocultural approaches do not articulate any differences between multicultural and indigenous studies, or enculturation and assimilation (Aikenhead, 1996).

In many ways, these early studies set the scene for classroom research on culture and science education for the next 10 years. Models of culturally based pedagogy for science education have been forwarded that include notions such as “collateral learning” of both Western and traditional concepts (Jegede, 1995); or teachers as “culture brokers” who help students to master repeated “border crossings” between their own life world and that of the science classroom (Aikenhead, 1996). There have been calls for the reorganization of science programs to reflect indigenous contexts, languages, philosophies, and thoughts (McKinley, 1996; Ogawa, 1997) and the critical scrutiny of current science education practices (Ninnes, 2003). The failure of mainstream educational movements to address indigenous people’s concerns has been noted, and alternative schooling movements are beginning to emerge (M. R. Smith, 1996), many from indigenous groups, such as the Maori language immersion *kura kaupapa* schools in Aotearoa New Zealand.

## CULTURE AND PEDAGOGY

This section examines studies that relate to improving classroom practice for indigenous students. The reality of the situation is that most indigenous students are in cross-cultural classrooms where the teacher is not from the same culture group. Furthermore, most students attend schools where indigenous peoples, language, knowledge, and aspirations are not the norm. Hence, most of the issues that arise in this section are ones that feature of all classroom research, where so much depends on the quality of the teaching and learning. The underlying assumption in many of the studies is that indigenous students are not participating or achieving in current science education classrooms. The literature argues strongly that indigenous student participation and performance in science are undermined by low teacher efficacy; low student self-expectation; cultural stereotypes; inadequate teacher subject, pedagogic, and cultural knowledge; and conflict between the culture of home and school. However, many of these factors interact with each other and are difficult to separate out, as this section indicates. I discuss the research on improving classroom pedagogy under (1) teacher expectations and efficacy, (2) using cultural knowledge in classrooms, (3) and learning for indigenous students.

### Teacher Expectations and Efficacy

Teacher expectations are seen as significant determinants of student performance. However, research has found that a deficit model often operates with respect to indigenous and minority students, that contributes to low expectations and a teacher’s sense of efficacy (see, for example, Bishop & Glynn, 1999; N. Carter, Larke, Taylor, &

Santos, 2003; Dukepoo, 2001; McKinley, 1996; Poodry, 2001). Deficit thinking can manifest itself through stereotyping, seeing other cultures as inferior, and a feeling of a lack of agency on the part of the teacher. The deficit model assumes that any fault lies within the person and/or culture, such as the person not trying hard enough, or the culture militating against scientific understandings. In other words, the lack of efficacy seems to have the effect of bringing the learning of indigenous students (and others) to a point of paralysis, because teachers believe it is the student's life circumstances that prevent learning. Teachers who lack efficacy believe that trying makes little difference to the student's success. Teachers who reject that assertion believe that they can make a difference to all students and take on the responsibility to teach everybody in their classrooms (Atwater & Crocket, 2003; Bryan & Atwater, 2002; Hill & Hawk, 2000).

A lack of efficacy is not just about the teacher's agency, but also about the student's capability. Unfortunately stereotypical views of indigenous students have led to assumptions about teaching and learning for them. For example, Ninnes's (2003) work on science textbooks in Australia and Canada identified a persistence of cultural and gender stereotypes in science education in school texts. His work showed that often there was an absence of any representation of indigenous ideas and identities. If they were represented, they were presented as traditional images that the dominating white cultures had of the indigenous culture, as indigenous peoples being homogeneous, and with science knowledge privileged over IK. Furthermore, in an accompanying survey, Ninnes (2001) found that the inclusion of this material in school textbooks was mainly there to comply with state requirements. This was supported in the project carried out by McKinley, Stewart, and Richards (2004) in Aotearoa New Zealand relating to Maori cultural contexts in the science curricula of schools. Rowland and Adkins (2003) maintained that the same problem of stereotyping exists in North American multicultural science education and Native American science education. They argued that the stereotypes are based on limited research and experience and cannot accommodate within-group variance.

The ability of the student to understand and participate in science education is inextricably linked to the closeness of the relationship between the culture of school and home. For many indigenous students, there is a significant gulf rather than a closeness of cultures. Zepeda (2001) argued that school pressures reservation children to move away from tribal traditions. The effect of such movement is to isolate children from their families, communities, and identities. Indeed, the cultural gap between home and school can be such that by the time they reach university, "some Indian students fear traditional systems because they do not understand them" (Zepeda, p. 64). For Yupiaq communities, this is a problem, as they see the encroachment of Western civilization on a world that did not seek it out (Kawagley, 1999). They seek ways in which they can maintain their culture in the face of strong opposition and set up Alaska Native camps in an attempt to find more control over the changes.

Understanding of the worlds of students is a significant contributing factor toward successful teaching in low socioeconomic, multicultural New Zealand schools (Hill & Hawk, 2000). They argued that successful teachers in these schools demonstrate a good understanding of the lives of the students, and the students know and value this highly. Furthermore, successful teachers have strong interactions with students outside the classroom and place a high value on contact with parents, more

often for positive rather than negative reasons. Understanding how large this cultural transition from the student's life world to that of school science is can help determine whether students achieve in science (Aikenhead, 1996; Jegede, 1995).

### Using Cultural Contexts in Classrooms

Resources that connect culture with science and a teacher's ability to facilitate such resources through competent teaching have been found to be problematic (Aikenhead & Huntley, 1999; Davison & Miller, 1998; Loving & de Montellano, 2003; McKinley 1996; McKinley, Stewart, & Richards, 2004; Rowland & Adkins, 2003; Sutherland & Dennick, 2002). Researchers have argued that the inclusion of culturally relevant situations in science curricula can help to raise indigenous students' achievement (Davison & Miller; McKinley, 1997). However, this objective raises a number of concerns in the literature. For example, when Aikenhead and Huntley researched teachers' views on Western science and aboriginal science in northern Saskatchewan, Canada, they found a large number of barriers preventing any meaningful engagement with aboriginal knowledge. Teachers had not recognized Western science as cultural knowledge; had little understanding that students' preconceptions could interfere with their learning and did not provide appropriate instruction; held a deficit view of their students; gave many differing responses to cultural conflict in classrooms; and possessed insufficient resources to help with supporting aboriginal knowledge in classrooms.

In their New Zealand study, McKinley, Stewart, and Richards (2004) found that teachers in English-medium or mainstream schools tried to include Maori contexts in their science lessons. The study found that all of the teachers mentioned the same topics, despite being separated by large distances; the topics were iconic (the well-known and easily identifiable aspects of Maori culture), and teachers believed these topics met state regulations. Maori topics reportedly were included to make the students feel better about themselves by seeing Maori culture valued in classrooms and to make students interested and comfortable. The students did not see it like this at all, suggesting that the connections between cultural activities and school science are not always obvious to children who live in two worlds. Other concerns raised by teachers in this study was the effect of trying to be culturally sensitive to specific populations and not causing offense, a tendency researchers found particularly among teachers not grounded in the culture of the people whom they teach. Another concern was teachers assuming that all students who identify as belonging to an indigenous group have been exposed to the same cultural knowledge.

It would appear that resource availability is variable across various countries. For example, Loving and de Montellano (2003) argued that suitable teaching materials on science, education, and culture are not available in great number because there has been a refusal of scientists and science educators to develop accurate and valid materials dealing with the issue. As a result, alternative science materials of "dubious quality" and some examples of "blatantly bad science" (Loving & de Montellano, 2003, p. 15) have been produced. However, in a recent research project carried out in Aotearoa New Zealand, McKinley, Waiti, and Aislabie (2004) found that

scientists are working with local indigenous Maori groups on science research projects and producing resources—sometimes in two languages—that can be used directly or to support resource development for teachers. This work has the potential to become an integral part of science teacher professional development. It also has the potential to help educate a wider public about Maori knowledge and its place in the curriculum.

## Culture and Learning

Another issue raised for indigenous students is that of learning styles. In a recent project in New Zealand, researchers found that significant numbers of teachers thought Maori students were tactile, visual, and oral in their style of learning (McKinley, Stewart, & Richards, 2004). At the same time, the teachers suggested other characteristics related to Maori students' learning, such as liking structure and routines. This analysis by the teachers, in turn, determined their culturally relevant pedagogy. More importantly, it determined the teachers' expectations of Maori students, suggesting that such learning styles limited the achievement of these students. However, the use of learning styles associated with particular cultural groups needs to be treated with caution (Irvine & York, 1995). It is easy for teachers to draw conclusions on the basis of simplistic assumptions regarding surface characteristics of cultures as described by ethnographers and anthropologists (Kawagley, 2001; McKinley, Stewart, & Richards, 2004). Dukepoo (2001) argued that "Indians are human . . . as such, they all have different learning styles" (p. 37). Furthermore, indigenous communities have accommodated different learning styles for thousands of years (see, for example, Dukepoo, 2001; Hemara, 2000).

Some researchers have begun to explore ways of learning in indigenous communities and suggest that these ways could provide insight into classroom learning for indigenous students. Indigenous ways of knowing include knowledge as metaphysical, interdependent and balanced, constructed through indigenous languages, and dependent on personal relationships; people have specialized knowledge and passion through intergenerational teachings and social practices. Various combinations of these have been raised by several researchers, both indigenous and non-indigenous (Aikenhead, 1996; Cajete, 1986; George, 1999; Jegede, 1995; Kawagley, 1999; McKinley, 1996; Ogawa, 1995; Pomeroy, 1992; Sutherland, 1999). For example, Allen and Crawley's (1998) study of the Traditional Kickapoo Band found a worldview that differed with respect to epistemology, preferred methods of teaching/learning, values, spatial/temporal orientation, cultural rules for behavior, and a perspective of the place of humans in a natural world. They argued that this worldview prevented the Kickapoo students from being successful in science classrooms.

Furthermore, the research literature suggests there is a means by which a person comes to know in indigenous societies. For example, Sutherland (1999) wrote that for some indigenous communities in Canada, the United States, and South America, not all knowledge is accessible to everyone, and neither is all knowledge open to public scrutiny. A person may get access to knowledge previously denied when it is deemed he or she is prepared for it. This is because with the acquisition

of knowledge comes responsibility to the community. Cree educator Ermine (1995) took coming-to-know further by arguing that, for aboriginal peoples, it is a process of self-actualization in relation to wholeness, "a being in connection with happenings" (p. 104). Battiste and Henderson (2000) add that indigenous languages are fundamental links to knowledge, and that transmission is both intimate and oral rather than distant or literate.

In the case of rural African students, Jegede (1995) proposed a model of collateral learning through identifying the sociocultural influences on non-Western students' learning. He argued that there are five predictors of sociocultural influences in the classroom, especially within non-Western environments, to which teachers must pay particular attention: authoritarianism, goal structure, traditional worldview, societal expectation, and the sacredness of science. Jegede argued that successful border crossing can occur through a process of collateral learning where "a learner in a non-Western classroom constructs, side by side and with minimal interference and interaction, Western and traditional meanings of a simple concept. Collateral knowledge, therefore, is the declarative knowledge of a concept which such a learner stores up in the long-term memory for strategic use in either a Western or a traditional environment" (p. 117).

Elsewhere Jegede (1998, pp. 80–86) gave a detailed description of collateral learning of which he suggested there were four main types: parallel, simultaneous, dependent, and secured.

Teaching in contexts of cultural familiarity to children and contrasting their life-worlds, using a critical analysis of science, and consciously moving back and forth between life-worlds and the science-world facilitate the type of border crossings that Aikenhead argued are essential to the successful acquisition of scientific knowledge by non-Western students (Aikenhead, 1996). Aikenhead suggested that border crossings can be facilitated in classrooms by studying the subcultures of students' life-worlds and contrasting them with a critical analysis of the subculture of science. The point being made in this theory of learning is that both teacher and student do this consciously. Aikenhead argued that border crossings would be further facilitated by the creation of a cross-cultural science and technology curriculum and a science-technology-society (STS) curriculum. He developed such units with six Aboriginal teachers in northern Saskatchewan.

Jegede (1995) argued that the cultural clash and difficulties associated with border crossing and collateral learning create an educational imperative that science education research must understand the cultural basis to learning within indigenous societies; otherwise the education of these communities will never be effective. The solution, Jegede maintained, involves restructuring science education and refocusing teacher education programs to ensure that their philosophical foundations are located and guided by the indigenous culture's imperatives. In practice, this requires an education that is accommodating, practical, and positively oriented. Nelson-Barber and Estrin (1995) argued that the way science is taught in classrooms has contributed to inadequate opportunities for Native American students to succeed. Furthermore, the process of presenting knowledge side by side and assuming all of the ideas are equally accessible to everyone needs to change. All this work suggests that teaching practices do little to recognize IK that indigenous students may have acquired in their everyday lives.

## Indigenous Languages and Science Education

Historically, little research has been done with respect to student learning in indigenous languages. The range of indigenous languages, their use, and their relationship to the colonizing languages (or languages) make for some very different projects. For example, Rutherford and Nkopodi (1990) argued from the results of their study in South Africa that there should be more English language use in science classrooms of North Sotho-speaking students. They argued that the use of the vernacular hindered student learning. However, Lynch (1996), in his study in Australia and the Philippines with three distinct language groups (English, Tagalog, and B'laan), found that many alternative frameworks are linguistically and/or culturally determined. He argued that science teachers need to respond to both cultural and linguistic constructs as well as to what is accurate scientifically. He also found Tagalog and B'Laan were not sufficiently intellectualized for handling conceptual correctness for Western science. Alternative frameworks and language were investigated by Kawasaki (1996, 2002) in a comparison of Western science to Japanese views of nature through each language. He raised issues of linguistic conceptual incommensurabilities and argued that Japanese science teachers need to introduce comparative science studies to Japanese students so that they can appreciate that which belongs to both cultures, and identify science education with foreign-language education.

The issue of the critical state of indigenous languages in many countries has become part of science education. The project of teaching in indigenous languages brings with it all the attendant issues of what happens not only in our science classrooms, but also in our teacher education institutes and our science degree structures. With the development of Maori language immersion schools in the 1980s, Aotearoa New Zealand has translated their national curriculum into the indigenous Maori language (McKinley, 1995, 1996), but no other reports were found where this had occurred. Unfortunately, researchers have yet to carry out research in science education on what effect, if any, this has had on Maori children's learning. Barker (1999) cited research from the United States (Alaska) and Canada, claiming that science learning in an indigenous language can reduce the "poverty of students' thinking" (p. 58). This was extrapolated from the idea that students become familiar with two worldviews and as such can go beyond either of them to formulate new ideas. According to Atwater, the research that has been done on this has provided inconclusive results (as cited in Rowland & Adkins, 2003).

Recent research in Aotearoa New Zealand suggests the Maori philosophy that drives the Maori language immersion schools dismisses stereotypes and does not treat all Maori youth as at risk. These schools are positioned instead to determine their own academic destiny by promoting being Maori as normative—teachers are Maori, learning is in the Maori language, and Maori values and philosophies take precedent. In other words, the purpose of such schooling is to empower students and communities (Bishop & Glyn, 1999). Although the goal is ideal, the pathway brings with it multiple issues. For example, Maori immersion high schools, in particular, find it difficult to employ qualified science teachers who are proficient speakers of Maori (McKinley, Stewart, & Richards, 2004). However, it stands to reason that the development and success of such programs are essential in order to act as a wellspring for cultural contexts in English classrooms. The issue of indigenous

languages and science education is an area that needs research urgently. Furthermore, such projects need to reflect the long-term effort that is required to bring back languages from the brink of extinction.

## COMMENTS AND CHALLENGES FOR FUTURE DIRECTIONS

In summary, the debate in the literature is dominated by publications in favor of culturalist approaches. However, teaching practices have changed little and remain based on traditional, universalist views of the nature of science and of science education (Aikenhead, 2001; Scantlebury, McKinley, & Jesson, 2002). The resistance of school curricula to reform efforts is well documented (Blades, 1997; Hodson, 1999). This apparent paradox may be explained by examining the key role that WMS, and associated views, has played in the emergence of Euro-American culture. Furthermore, WMS is supported by technocratic rationality and based on an economic philosophy. The current position of Euro-American culture is overwhelmingly powerful in the contemporary global situation. However, school curricula and teaching do need to change if indigenous students are to take up their rightful place in scientific endeavors and contribute to the knowledge economy and world environment. Furthermore, just as science has much to offer indigenous communities, indigenous communities have much to offer science. Science education has a responsibility to help facilitate what should be a dynamic exchange. With these goals in mind, the research currently reviewed here shows omissions that urgently need attention.

First, there is a large amount of comment on this issue of indigenous students but a general lack of empirical studies, particularly in some areas. Second, the distribution of research is uneven. For example, there is a lot of comment on philosophical debates, but little research on indigenous languages and science education. Furthermore, there is a growing amount of work on developing indigenous contexts for classroom use, but this review found no reports on assessment for indigenous students. Many of the writers suggest research in further areas. For example, Ninnes (2003) suggested that there is a need for further research "regarding the sources of knowledge pertaining to indigenous peoples, the extent of involvement of indigenous people in the production of texts that purport to represent their knowledges and that construct identities for them, and the effects of including material of this kind in science curricula of indigenous and other students' approaches to learning science" (p. 182).

Atwater and Crockett (2003) turned their attention to teacher education, suggesting that it is essential that science teacher educators and researchers examine the influence of their personal worldviews, beliefs, attitudes, and images on science learning and teaching. There is no doubt that all of these areas are important. More importantly, as researchers in the field, we need to search out and develop different frameworks for our research that match the aims of what we want to achieve.

There are a number of frameworks evident in the current research. Although a positivistic approach still exists within the field, where indigenous people are constituted as deficit, there is a definite and strong move away from this theorizing. However, we need to note that although the research may have moved, there are a significant number of teachers in front of indigenous students who have not. What

we need to take from this as researchers is how to change thinking. Are there other conceptual frameworks we can use to target deep-seated teacher beliefs with respect to indigenous students?

Dominating the field currently are approaches derived from anthropology, such as worldviews (Cobern, 1993, 1996), collateral learning (Jegede, 1995), and border crossing (Aikenhead, 1996). The anthropological approach is a seductive one because it focuses on the culture and cultural practices of different groups and treats science as a cultural activity (Hammond & Brandt, 2004). The approach has proved to be fruitful in a number of areas, such as re-orienting our focus away from deficit theorizing, and finding a place for community voice through narrative. However, the anthropological approach has limitations for studying indigenous peoples, such as having no way to deal with issues of power and economic privilege, and having a problematic history with indigenous peoples in the past. In terms of frameworks, this may be better illustrated through a question. An anthropological approach question may be, What makes teaching and learning effective for indigenous children? But the frame does not raise the question, What makes an effective indigenous language learner and teacher of science? The latter question focuses on the imperatives of the indigenous communities concerned about language loss. However, I want to raise two further frameworks that need to be considered for our science education research.

One framework that has emerged recently was developed by postcolonial studies (see, for example, L. Carter, 2004; McKinley, 2001, 2003; Ninnes, 2003). The strengths of this approach are its deconstructive methodology; its focus on language (both borrowed from poststructural analysis); its interrogation of the self/Other relationship, such as in a colonial situation; and the interrogation of epistemologies and objects of institutional knowledge. In particular, postcolonial studies explore deep-seated ideas in the psychology of the mind, recognizing that learning from the other is a psychical event. Postcolonial theory can open up persons' anxieties about encountering difference. Furthermore, postcolonial theory analyzes these anxieties through the language used in reading the unconscious or subtext of images, print, and speech. The methodology used for this analysis is deconstruction; there is not only an unpacking of ideas, but also a displacement of them. Postcolonial theory has been criticized for being too textually based, lacking agency, and using psychoanalysis (which had been developed for practice in another field).

The second framework I want to raise is that of indigenous communities themselves (see, for example, Battiste & Henderson, 2000; James, 2001; Mihesuah & Wilson, 2004; L. T. Smith, 1999). Indigenous peoples have begun to take control of their own destiny by instigating an approach that is indigenous-focused. This approach, put simply, has three prongs. First is to decolonize the methodologies that claim to produce meaningful knowledge about indigenous people. This is being done in a variety of ways by many indigenous academics. Second is to theorize, conceptualize, and represent indigenous sovereignty. This is about treating our own knowledge and ways of knowing as something to be valued, and to profile them in our work. And last, it is about producing indigenous knowledge for indigenous peoples—setting our own research agendas and carrying out what indigenous people want, and not what others think we need.

David Clark (2004) argued that the indigenous project is about “restoring well-being to our nations” (p. 230). Well-being for indigenous peoples comes from an in-

tegrated approach to social, economic, and cultural development, and from a strong sense of identity as indigenous. I wish to leave you with two broad challenges for science education with respect to indigenous students. First, there is a need to get more indigenous students participating and achieving in science. According to our own track record, this will be a major challenge in itself. The second challenge is to find a place in our curricula and classrooms for indigenous knowledge—a place that recognizes and protects indigenous information, understanding, and wisdom. This will add to our scientific knowledge and methods. This will require some major adjustments to teacher education and science courses, and, for many, will challenge our deepest beliefs. There will be much debate and conflict, but also much excitement. As we move toward the future, the world will need people with the capacity to move between perspectives and embrace both indigenous ways and science. Our work is to help create the platform for that to happen.

### ACKNOWLEDGMENTS

The author acknowledges Nga Pae o te Maramatanga/The National Institute of Research Excellence for Maori Development and Advancement for funding the project from which much of this literature is drawn, and thanks the research assistants on that project, particularly Dominic O'Sullivan and Georgina Stewart. Thanks also to William Cobern and Dawn Sutherland, who reviewed this chapter.

# CHAPTER 9

---

## Issues in Science Learning: An International Perspective

**Chorng-Jee Guo**

*National Taitung University, Taiwan*

Student science learning lies at the heart of the interplay among science education research, policy, and practice. Science education, especially as it is practiced in schools today, is strongly influenced by several important forces. In response to these driving forces, various research-informed reform efforts in science education have been undertaken in countries all around the world in recent years. It is of both practical significance and theoretical interest to look at the impact of these driving forces on a broad array of contexts, practices, and outcomes regarding science learning across different countries.

### **PURPOSE, SCOPE, AND LIMITATIONS OF THIS CHAPTER**

The main purposes of this chapter are to (a) identify some of driving forces for science education reform in the twenty-first century, (b) examine the conditions of science learning in select countries, and (c) suggest research problems for further investigation.

Student science learning is a major concern for the science education enterprise and is influenced by science curriculum, instruction, and evaluation. Research on science learning involves other topics such as inquiry, cooperative learning, learning environment, gender issues, curriculum reform, science teacher preparation, and professional development. However, the focus of this chapter will be student science learning from an international perspective. Studies on student science learning involve a range of subject areas, student characteristics, physical settings, and learning environments. A range of theoretical perspectives, including historical, cultural, societal, linguistic, and human perspectives, on science learning have been adopted, using research methods that are quantitative,

qualitative, or a combination of the two. Many of these aspects are dealt with in other chapters of this *Handbook*.

Science learning in each country occurs in a wide range of educational, social, cultural, and political contexts; significant changes have been observed over the years. Science education reforms in many countries have involved changes in the philosophy of education, instructional goals, curriculum materials, instructional practices, and teacher education. A historical account of the contexts, processes, and outcomes of student science learning in different countries is beyond the scope of this chapter. Instead, we shall focus our attention on results that have been obtained in the recent decade from large-scale cross-national studies on student science learning.

This chapter provides an overview of the current condition of science learning from an international perspective. The emphasis is not on specific and detailed accounts of the state of science learning in individual countries. What interests us here is describing the contemporary issues of student science learning worldwide and making recommendations for research studies needed to inform the problems. Because the policies and practices of science education vary significantly across country borders, the issues related to science learning differ in each country.

This chapter begins with a school-based model of science learning and a brief historical background of research on science learning internationally. The chapter proceeds to a review of some driving forces for the reform of science education worldwide. With these driving forces in mind, a broad overview of the current conditions, major problems, and reform measures related to science learning in various countries around the world is given. Following that overview, the contemporary issues of science learning worldwide are discussed in further detail. The chapter ends with some concluding remarks and recommendations for future research on science learning, as viewed from an international perspective.

## **A MODEL OF SCHOOL-BASED LEARNING IN SCIENCE**

In order to organize the information in this chapter, it is desirable to have a model of school-based learning in science from an international perspective. The model is meant to provide a representation of the relationships among important factors associated with student learning at school. The model can be used as a guide for identifying research problems and formulating research questions. A number of school-based learning models have been proposed (Huitt, 1995; Proctor, 1984; White, 1988). A modified version of Huitt's model is the organizer for this chapter.

Huitt's (1995) model includes four categories: Context, Input, Classroom Processes, and Output. Huitt emphasized the importance of context variables such as school characteristics, family, community, state and federal government, TV/movies, and the global environment, because he realized that our world is rapidly changing from an agricultural/industrial base to an information base. In his model, the input variables include two subcategories: teacher characteristics and student characteristics. Teacher characteristics include values and beliefs; knowledge of students and of the teaching/learning process; thinking, communication, and performance skills; personality; and teacher efficacy. Student characteristics include study habits, learning styles, age, gender, race, ethnicity, motivation, and moral/socio-emotional/

cognitive/character developments. The classroom processes variables include teacher behavior (planning, management, and instruction), student behavior (involvement, success on academic tasks), and other processes such as classroom climate and student leadership roles. The products or output of school learning include student achievement and other desirable skills. The structure of Huitt's model is similar to the Context, Input, Process, and Product (CIPP) model of curriculum development and evaluation (Stufflebeam, 2000), although the purposes and foci are different.

For this chapter, I developed a modified version of Huitt's (1995) model of school-based learning that includes an additional component—Driving Forces (see Fig. 9–1). This added element demonstrates explicitly that, from an international point of view, there are important forces that may influence student science learning through Contexts, Inputs, and Processes of school learning. Figure 9–1 emphasizes some of the variables relevant to student science learning as discussed in this chapter. School science learning takes place in a wide context involving family, school, community, and society. It also takes place under the influence of various backgrounds, including educational policy, historical and sociocultural development, scientific and technological development, and international conditions. Input variables important to learning processes and outcomes include the science curriculum, instructional facilities and resources, teacher characteristics, and student

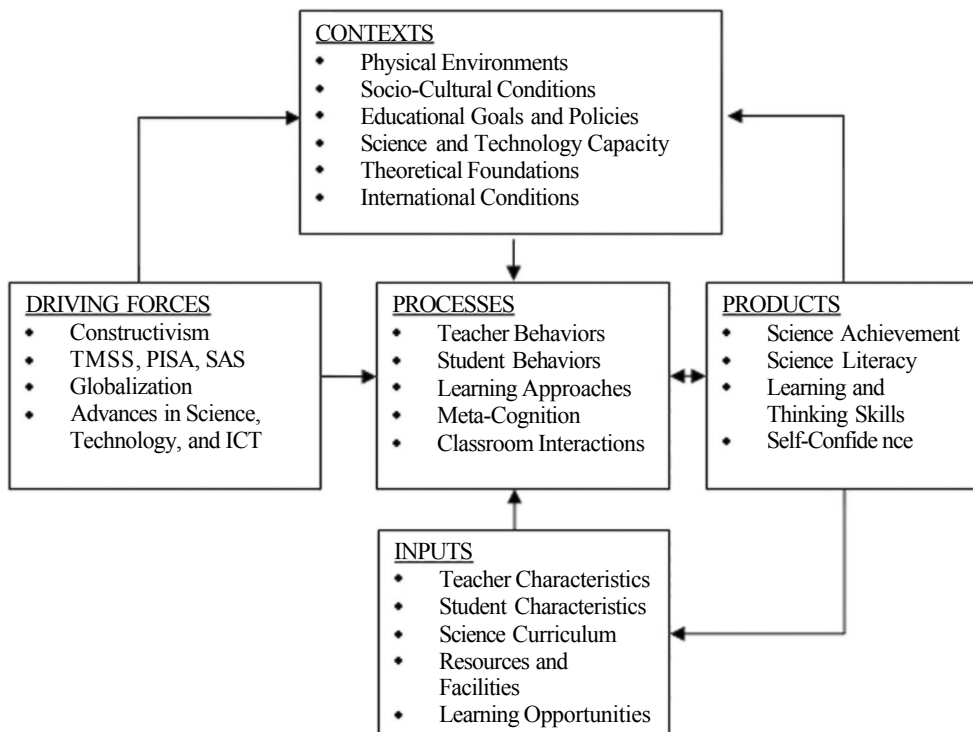

FIGURE 9–1. A school-based model of science learning.

characteristics. The importance of processes such as student learning approaches, engagement, metacognition, perception of the context, and interaction with teachers and other students has been well documented. As for student learning outcomes, a meaningful understanding of scientific facts, concepts, principles, and theories is of course essential. Other learning outcomes, such as a better understanding of the nature of science, improved inquiry skills, and international awareness and experiences, are also important for a scientifically and technologically literate person in the twenty-first century.

The arrows in Figure 9–1 indicate possible influences of the variables in one category on those in the others. Figure 9–1 suggests the direct influence of Driving Forces on the Contexts, Inputs, and Processes of learning. Driving Forces influence Products indirectly through these variables. Likewise, student learning products or outcomes are indirectly influenced by the Contexts and the Inputs of learning. Arrows pointing toward the left in the model indicate that student learning outcomes might, to a certain extent, influence the contexts, inputs, and processes of learning.

The model of school-based learning shown in Figure 9–1 emphasizes both internal and external factors that might affect student learning outcomes. It is meant to provide broad conceptual categories while indicating possible relationships. The variables in the major categories were obtained by synthesis of the research literature. More detailed diagrams could be drawn to show how student conceptions of learning might affect their approaches to learning and, consequently, their levels of understanding (Entwistle, 1998, 2000). Of course, there are limitations to the proposed model. The scheme for separating the variables into main categories is tentative; different authors may want to group the variables quite differently for different purposes. Some variables may belong to more than one category; for instance, student study skills can be taken as an aspect of student characteristics in Inputs, while at the same time it can be considered as part of Products. Although the model could be improved, for instance, by the use of more explicit conceptual and operational definitions for the variables, it will be suitable for the purposes of this chapter.

## **SITUATING RESEARCH ON SCIENCE LEARNING IN AN INTERNATIONAL PERSPECTIVE**

Significant change in research on student science learning has taken place since the middle of 1970s. The initial focus of these research studies was probing student understanding of natural phenomena and science concepts. The empirical findings, theoretical interpretations, and instructional implications were published in a great number of research reports, papers, books (Driver, Squires, Rushworth, & Wood-Robinson, 1994; Mintzes, Wandersee, & Novak, 1998; Osborne & Freyberg, 1985; White, 1988), and review articles (Duit & Treagust, 1998; Wandersee, Mintzes, & Novak, 1994). Results of these studies have led to research interest in constructivist approaches to teaching and learning in science. The impact of this research on science instruction, science curriculum reform, and teacher professional development is widely recognized.

van den Akker (1998) presented a historical overview of science curriculum development from an international perspective. He summarized recent initiatives and trends worldwide in improving the science curriculum. These initiatives include

the development of national guidelines for science education, the emphasis on teaching key conceptual issues in depth instead of covering ever-increasing amounts of information, scientific literacy for all students, alignment of curriculum and assessment, providing more encouragement and support for teacher professional development, and the rapidly growing influence of information and communication technology. In addition, there has been an increasing emphasis on lifelong learning combined with greater emphasis on skills in problem-solving, inquiry, information and communication, and a preference for active, investigatory, and independent forms of learning. The common label for the approach characterized by these inter-related aspects is "learning to learn" (van den Akker).

Keeves and Aikenhead (1995) reviewed the historical growth of science education over the previous century and discussed developments in science curricula during recent decades in an international context. They identified five scientific and societal changes with important consequences for education, including the provision of a more general education for students at the secondary level, the recognition of the need for lifelong education, the need for each individual to acquire the skills of effective independent learning and inquiry as part of learning how to learn, the emergence of science-related social issues, and the impact of technological change. In reporting these changes, Keeves and Aikenhead made several recommendations for improving the teaching and learning of science, which are very similar to those that van den Akker (1998) suggested.

The effectiveness and appropriateness of science curriculum and science instruction for science learning have long been major interests for science education researchers. However, a distinct trend worldwide regarding research on student science learning took place in the mid-1970s. Student science learning became the research focus for a great number of research studies. Initially, much of the research interest was on student understanding of natural phenomena and science concepts. Subsequently, concerns about students' conceptions of learning, of the goals of science learning, of the nature of science, and of the subjects to be studied, and concerns about student learning and problem-solving skills have received further attention. As a result of these research efforts, constructivist approaches to the teaching and learning of science have gained wider acceptance (Tobin, 1993). The impact of this body of research on science education policy, science curriculum, science instruction and assessment, and science teacher professional development is noteworthy around the world. Constructivist notions of science teaching and learning appear to be one important factor for understanding science learning from an international perspective.

## **DRIVING FORCES FOR SCIENCE EDUCATION REFORMS WORLDWIDE**

A new wave of science education reform has taken place in countries all around the world in recent decades. New goals of science education for citizens of the twenty-first century have been formulated and new science curricula developed, with the use of a number of strategies based on research findings and theoretical understandings about student science learning. In order to identify the conditions and problems of science learning from an international perspective, it is worthwhile to

examine the driving forces that have influenced the direction and development of science education reform worldwide. Some of the most important of these are constructivist views of science learning, cross-national studies of student science learning, globalization, and advances in information technology.

## **Constructivist Views of Teaching and Learning Science**

In spite of some debates and criticisms (Matthews, 1998; Osborne, 1996), Mathews (2000) stated that constructivism is undoubtedly a major theoretical influence in contemporary science and mathematics education, and few would dispute Fensham's (1992) claim that "the most conspicuous psychological influence on curriculum thinking in science since 1980 has been the constructivist view of learning" (p. 801). Numerous empirical studies on student science conceptions have led to the popularity of constructivist views of science teaching and learning. Based on these works, theoretical formulations of student science learning have been proposed, and suggestions for instructional interventions and teacher professional development aimed at facilitating student conceptual change and meaningful learning have been made (Bennett, 2003; Driver et al., 1994; Fensham, Gunstone, & White, 1994; Mintzes et al., 1998; Osborne & Freyberg, 1985; Tobin, 1993; White, 1988).

From an international perspective, constructivist notions of teaching and learning have had strong influences on science policy in recent years. For instance, the U.S. National Science Teachers Association (2003) Standards for Science Teacher Preparation, the mathematics component of the Curriculum Profiles for Australian Schools (Australian Capital Territory Department of Education and Training, n.d.), and the National Curriculum in England (Qualifications and Curriculum Authority, 2002) were influenced by constructivist thoughts. Cobern (1996) argued that science education research and curriculum development efforts in non-western countries could benefit by adopting constructivist views of science and science learning. Cobern's main point was that constructivist views led researchers to expect that students in different cultures will have somewhat different perspectives on science. He suggested that science education research should inform curriculum developers to make science instructional materials more sensitive to culture. Direct adoption of science textbooks, or their minor revisions, from one country to another may not work. For many non-western countries, it is a challenge to develop culturally sensitive science curriculum materials while trying to strike a healthy balance between the local culture and western science.

## **Cross-National Studies on Student Science Learning**

In addition to constructivist notions of science teaching and learning, the latest wave of science education reform has been influenced by the results obtained in a number of recent cross-national studies on student science learning, including Trends of International Mathematics and Science Study (TIMSS), the Programme for International Student Assessment (PISA), and Science and Scientists (SAS). The results obtained by these studies provide valuable information on the states of science learning in participating countries. The studies have generated much interest

among policymakers, science educators, science teachers, parents, and the general public in countries around the world. A brief description of these international comparative studies in science education is given below.

The National Academies Press (NAP) homepage (<http://www.nap.edu/>) provides a list of international comparative studies in education, including large-scale assessment and case studies. For science and technology (as well as for mathematics) education, a prominent example is the Third International Mathematics and Science Study (TIMSS), conducted in 1995. Subsequent iterations of the same study changed the word "Third" into "Trends." The study is now referred to by the year it was conducted. Hence the original TIMSS becomes TIMSS 1995, TIMSS-R becomes TIMSS 1999, and TIMSS 2003 remains TIMSS 2003. TIMSS is one of several studies sponsored by the International Association for the Evaluation of Educational Achievement (IEA). (Background information and downloadable reports and data files are available at <http://timss.bc.edu/>.) TIMSS provided not only assessment of student learning outcomes, but also information about the home, classroom, school, and national contexts within which science learning takes place.

The Organisation for Economic Co-operation and Development (OECD) has a large education sector that publishes various reports (available online at <http://www.oecd.org>). The OECD recently developed its own set of studies of student achievement, under the acronym of PISA. PISA works with some 40 OECD countries together with some non-OECD countries. PISA assesses in three domains: reading literacy, mathematical literacy, and scientific literacy (OECD, 1999, 2003a, 2003b, 2003c). It aims to define each domain, not merely in terms of mastery of the school curriculum, but in also terms of important knowledge and skills needed in adult life. PISA assesses students who are approaching the end of compulsory education (about the age of 15) and the extent to which they have acquired the knowledge and skills that are essential for full participation in society. The first assessment took place in 2000, with results published in 2001; PISA has continued thereafter, in 3-year cycles. Each cycle looks in depth at a major domain, to which two-thirds of testing time is devoted; the other two domains provide a summary profile of skills. Major domains by cycle are reading literacy in 2000, mathematical literacy in 2003, and scientific literacy in 2006.

The Science and Scientists (SAS) Study explored various aspects of relevance to the teaching and learning of science and technology (Sjøberg, 2000). Some 30 researchers from 21 countries collected data from about 10,000 pupils at the age of 13. The countries involved, in alphabetical order, were Australia, Chile, England, Ghana, Hungary, Iceland, India, Japan, Korea, Lesotho, Mozambique, Nigeria, Norway, Papua New Guinea, the Philippines, Russia, Spain, Sudan, Sweden, Trinidad, Uganda, and the United States. The purpose of the SAS-Study was to provide empirical input to debates over priorities in the school curriculum as well as the pedagogies that are likely to appeal to the learners.

## Globalization

Progress in transportation and the use of the Internet result in frequent economic, social, and cultural exchanges internationally. There is now an increased interdependence and interrelationship among different countries around the world. Glob-

alization is raising questions about the content, objectives, and approaches to science learning. Hallak (2001) pointed out that educational content should be designed "to meet both national demand and international concerns" (p. 3). For example, in order to get along with people from different cultural backgrounds, students should be taught to respect and understand their history and customs. In order to be well-informed citizens of the world, students should be equipped with necessary communication skills and the capability to read and speak foreign languages. Student learning experiences in science should be designed to include these important components. On the other hand, there are concerns for trying to maintain a balance between globalization and localization. For instance, Zembylas (2002) noted a number of tensions resulting from the struggle to preserve local values while incorporating global trends into the science curriculum of developing countries.

To meet the challenges of rapid globalization and the pursuit of economic and social developments in the new century, Cheng (2000a) proposed a new paradigm of school education. It is built on the concepts of contextualized multiple intelligences (referring to technological, economic, social, political, cultural, and learning intelligences), globalization, localization, and individualization in schooling, teaching, and learning. His paradigm included the formulation of a new aim for science education (Cheng, 2000b): "to support students particularly through science learning to become citizens who will be engaged in lifelong learning and will creatively contribute to the building up of a multiple intelligent society and a multiple intelligent global village" His paradigm included the formulation of a new aim for science education (Cheng, 2000b): "to support students particularly through science learning to become citizens who will be engaged in lifelong learning and will creatively contribute to the building up of a multiple intelligent society and a multiple intelligent global village" (available online at [http://www.ied.edu.hk/apfslt/issue\\_2/foreword/index.htm](http://www.ied.edu.hk/apfslt/issue_2/foreword/index.htm)).

## **Advances in Science, Technology, and Information Technology**

Rapid development of science and technologies in the previous century resulted in not only the changing face of science, but also significant changes in industrial structures and employment markets (Hurd, 1998). These advances had noticeable influences on other aspects of society, both politically and economically. Hurd noted that some changes in the nature, ethos, and practice of science have taken place. For instance, traditional science disciplines such as biology, chemistry, physics, and earth science have become fractionated into a large number of research fields; instead of physical sciences, life sciences have become the center of attention in the twenty-first century. The fields of scientific/technological research are increasingly hybridized; science is becoming more holistic, blending the natural and social sciences.

There is an increasing awareness of the importance of knowledge to the economic and technological development of our societies. Promoting creativity and reaching for excellence in science and technology are national policy goals for increasing international competitiveness. Solid and successful science education is expected to make significant contributions toward this end. For citizens of the

twenty-first century, scientific and technological knowledge and skills are crucial for actions and decisions. Meaningful and responsible participation in society assumes the ability to judge evidence and arguments associated with the socio-scientific issues that appear on the political agenda. A broad understanding of the nature, content, and methods of science and technology by the general public is important. It is imperative that students are interested in science subjects and that they have a broad understanding of basic scientific principles and ways of thinking. A comprehensive list of attributes that will enable students to adapt to the changing world of science and technology and its impacts on personal, social, and economic affairs was presented by Hurd (1998).

Advances in information and communication technologies (ICTs) have caused a revolution in living. Commercial products and services relating to ICTs, such as mobile phones, digital cameras, notebook computers, and DVDs, have found their way into all parts of our daily lives. ICT not only changes our lifestyles, but also offers tools to facilitate both teaching and learning in different settings, by incorporating a wide variety of instructional strategies, such as peer tutoring, and cooperative learning. Students and citizens of the twenty-first century need to know and be able to use ICT wisely and fruitfully. However, ICT requires considerable investment in equipment and infrastructure. Substantial costs for maintenance, training, software development, and technical support can be expected. Accessibility to ICT equipment and facilities affects the opportunities to learn at the student, school, and school district levels. Advances in ICT bring along the threat of a widening gap between developed and developing countries, with disparities in access to knowledge and information that reinforce existing disparities in resources (Lewin, 2000).

As shown in Fig. 9–1, these Driving Forces are predicted to influence the Contexts, Inputs, and Processes for student science learning. Thus, it is evident that student science learning in the 21st century will be different from the previous century in the following ways:

1. Research on science learning has led to better theoretical understandings about student learning processes. Policy-makers, curriculum developers and school teachers are becoming better informed in their efforts to improve teaching and to facilitate student science learning.
2. With results obtained from recent cross-national comparative studies such as TIMSS, PISA, and SAS, researchers in various countries can examine the conditions of student learning in science, identify goals and content areas that need to be strengthened, develop and adopt more powerful instructional strategies, and provide more supportive learning environments.
3. Demand to enhance the relevance of science learning to students' daily lives will increase as we prepare students to function competently and successfully as members of communities at local, national, and international levels.
4. The emphasis on science education to foster scientific and technological literacy for all students will increase. A wide variety of tools, resources, environments, and locations now offer new opportunities for learning science both formally and informally.

In order to provide an overview of student science learning outcomes and their influencing factors, some findings from recent cross-national studies including

TIMSS, PISA, and SAS will be described. Next, the current condition of science education in a few selected countries will be described, to illustrate the kinds of problems and issues different countries face.

## **FINDINGS FROM RECENT CROSS-NATIONAL STUDIES ON SCIENCE LEARNING**

Results obtained from recent cross-national studies including TIMSS, PISA and SAS provide valuable information on the current conditions of science learning worldwide. These results are described in the following sections.

### **TIMSS**

The Third International Mathematics and Science Study (now renamed as TIMSS 1995) was conducted in 1994–1995 at five grade levels (3, 4, 7, 8, and the final year of secondary school) in more than 40 countries. Extensive information about the teaching and learning of mathematics and science was collected from thousands of teachers and school principals, and more than half a million students. TIMSS also investigated mathematics and science curricula in participating countries through an analysis of curriculum guides, textbooks, and other curricular materials.

The TIMSS 1995 science achievement results for students at the primary, middle school, and high school levels were summarized by Martin, Mullis, Beaton, Gonzalez, Smith, and Kelly (1997); Beaton et al. (1996); and Mullis et al. (1998), respectively. Eighth-grade boys had significantly higher achievement than girls in about half of the participating countries, particularly in earth and physical science. The overwhelming majority of fourth-graders in nearly every country indicated that they liked science. Having educational resources in the home (e.g., computer, dictionary, own study desk, and 100 or more books) was strongly related to science achievement in every country. Students in most countries reported spending between half an hour and an hour studying or doing homework in science. In most countries, the challenge of catering to students of different academic abilities was the factor teachers mentioned most often as limiting how they taught their mathematics and science classes. Other limiting factors included a high student/teacher ratio, a shortage of equipment for use in instruction, and the burden of dealing with disruptive students.

Information from the 1995 TIMSS assessment on school contexts for learning mathematics and science (Martin, Mullis, Gonzales, Smith, & Kelly, 1999) included school characteristics, policies, and practices organized around five major topics: roles and responsibilities of schools and school principals, school organization and staffing, organization for learning mathematics and science, school resources, and school atmosphere. The combined results for three grade levels were discussed for a range of school factors and how they varied across countries. Another interesting report by Martin, Mullis, Gregory, Hoyle, and Shen (2000) presented analyses of the TIMSS 1995 eighth-grade data aimed at helping understand what makes some schools more effective than others. The results showed that school and classroom variables were related to average school achievement, even after adjustment for the home background of the students in the school. However, the strong relationship that persists between the average level of home background and adjusted student achievement also serves as a reminder that, in many countries, home background,

schooling, and student achievement are closely intertwined, and that teasing out the influences of the various contributing factors remains a major challenge.

TIMSS 1999 was designed as a replicate of TIMSS 1995 at the eighth-grade level (Martin et al., 2000). Of the 38 participating countries, 26 also participated in the TIMSS 1995, which enabled these countries to measure trends in mathematics and science achievement. Six content areas were covered in the TIMSS 1999 science test: earth science, life science, physics, chemistry, environmental and resource issues, and scientific inquiry and the nature of science. Chinese Taipei and Singapore had the highest average performance, closely followed by Hungary, Japan, and the Republic of Korea. Other countries that performed well included the Netherlands, Australia, the Czech Republic, and England. Lower-performing countries included the Philippines, Morocco, and South Africa.

Boys were found to have significantly higher average science achievement than girls in 16 of the 38 countries in TIMSS 1999. This was attributable mainly to significantly higher performance by boys in physics, earth science, chemistry, and environmental and resource issues. The gender gap in science achievement was especially apparent among high-performing students, with 29% of boys on average across countries in the top achievement quarter, compared with 21% of girls.

The TIMSS 1999 report also included information on students' home environment and attitudes toward science (Martin et al., 2000). The level of home educational resources varied considerably across countries. On average, students from homes with a high level of educational resources had higher science achievement than students from homes with fewer resources. The association between home educational resources and science achievement is well documented in TIMSS. Low average student achievement in some of the less wealthy countries most likely reflects the low level of educational resources in students' homes. However, there are also other influences at work. The TIMSS 1999 results indicated that, in almost every country, there was a positive association between educational expectations and science achievement. Eighth-grade students internationally had high expectations for further education. On average across countries, more than half the students reported that they expected to finish university.

To investigate what students think of their abilities in science, TIMSS created an index of student self-concepts in the sciences (Martin et al., 2000). The results indicated that eighth-grade boys generally had more positive self-concepts in science than girls. This difference was most pronounced in countries where the sciences are taught as separate subjects. Although girls in such countries had a more favorable science self-concept in biology, this was outweighed by a more favorable self-concept for boys in physics, and to a lesser extent in earth science and chemistry.

TIMSS 1999 also created an index of attitudes toward the sciences in order to gain some understanding about eighth-graders' views about the utility of science and their enjoyment of it as a school subject (Martin et al., 2000). The results showed that, although student attitudes toward science were generally positive in countries where eighth-grade science is taught as a single subject, they were less positive in separate science countries. Attitudes were most positive toward biology and earth science, and least positive toward physics and chemistry. Eighth-grade boys generally had more positive attitudes toward science than girls, particularly in physics, chemistry, and earth science. Girls had more favorable attitudes toward biology.

In comparing achievement across countries, it is important to consider differences in students' curricular experiences. Students' opportunity to learn the content,

skills, and processes tested depends to a great extent on the curricular goals and intentions inherent in each country's policies for science education. A distinction between intended, implemented, and attained curricula was made in TIMSS 1999 (Martin et al., 2000). Results indicated some discrepancies in a number of countries between the intended curriculum in science and the implemented curriculum as reported by teachers. There were many cases of topics intended to be taught to all, or almost all, students, for which teachers reported lower coverage. Interestingly, there were even more cases in which teachers reported greater topic coverage than would be expected from the intended curriculum. In all countries except Australia, Canada, and the United States, specifications for curricular goals in science existed at the national level. In 21 countries, science was taught in the eighth grade as a single general subject. In the other countries, separate courses were offered in the different science subjects.

Science teachers reported spending almost one-quarter of their class time, on average, on lecture-style presentations to the class. They reported devoting substantial percentages of their class time to student experiments (15%) and teacher-guided student practice (14%). Almost 40% of eighth-grade students in general science countries were in classes where teachers and students reported a high degree of emphasis on conducting science experiments. In contrast, emphasis on experiments was reportedly much less in separate science countries, particularly earth science and biology. Less than 10% of eighth-grade students in general science countries, and half this percentage in separate science countries, reported frequent use of computers in science class. Although there was great variation across countries, about a quarter of the students reported Internet access at school. Despite this access, only 12% on average used the Internet to obtain information for science projects on even a monthly basis (Martin et al., 2000).

Knowing basic facts and understanding science concepts received major emphasis in the official eighth-grade curricula of most participating countries, with at least moderate emphasis placed on application of science concepts. Few countries gave major emphasis to using laboratory equipment or performing science experiments, but there were some notable exceptions. Top-performing Singapore, Korea, and Japan were among the 10 countries that reported major emphasis on both. The increasing importance of technology in school curricula was reflected in the major emphasis given by 12 countries and the moderate emphasis given by 14 to "science, technology, and society." Thematic approaches were more common in science than in mathematics and received major emphasis in 13 countries. Multicultural approaches and integration of science with school subjects other than mathematics were the approaches least likely to be given major or moderate emphasis (Martin et al., 2000).

Teachers from countries in which eighth-grade science was taught as a general course were asked what subject matter they emphasized with their classes (Martin et al., 2000). In Canada, Italy, and the United States, earth science was emphasized in considerably more classrooms than in other countries. Biology was more likely than the other sciences to be emphasized in Italy and Tunisia. Countries where relatively high proportions of students had seen an emphasis on physics, chemistry, or both were Cyprus, Iran, Israel, Jordan, Korea, and South Africa.

Results from TIMSS 1999 showed that testing and assessment were widely used methods to support curriculum implementation. Belgium (Flemish) and Chinese Taipei were the only countries that reported having no public examinations in sci-

ence to certify students or select them for university or academic tracks. Approximately two-thirds of the countries conducted system-wide assessments at two or three grades, primarily to inform policymakers about achievement of the intended curriculum. Instructional time designated in official curricula for science instruction increased from 11% at grade 4 to 16% at grade 8, on average across countries (Martin et al., 2000).

Internationally, 58% of eighth-grade students were taught science by female teachers and 42% by males. In most countries, at least 80% of eighth-grade students were taught science by teachers with a major in the appropriate science subject. However, teachers reported only a moderate level of confidence in their preparation to teach science. Almost 40% of students were taught by teachers who reported a low level of confidence in their preparation. Teachers' confidence in their preparation was greatest for biology, and least for earth science, environmental and resource issues, and scientific methods and inquiry skills.

Students in schools that reported being well resourced generally had higher average science achievement than those in schools where across-the-board shortages affected instructional capacity in science some or a lot. According to their principals, nearly half the students were in schools where science instruction was negatively affected by shortages or inadequacies in instructional materials, budget for supplies, school buildings, instructional space, audio-visual resources, or library materials relevant to science instruction. Schools around the world expected help from parents to ensure that students completed their homework, to volunteer for school projects or field trips, and to help raise funds and to serve on committees. One-fifth of the students attended schools where principals reported that attendance was not a problem. However, 60% were in schools where principals reported moderate attendance problems, and 19% were in schools with some serious attendance problems. The overwhelming majority of eighth-grade students attended schools judged by principals to have few serious problems threatening an orderly or safe school environment.

## PISA

As a triennial survey, starting in 2000, the aim of PISA is to assess the knowledge, skills, and other characteristics of 15-year-olds in principal industrialized countries and other countries around the world (OECD, 2003a). PISA assesses literacy in reading, mathematics, and science, as well as asking students about their attitudes and approaches to learning. In the first assessment, about 315,000 students in 43 countries completed pencil-and-paper tests in their schools and filled out questionnaires about themselves. Schools also provided background information through questionnaires.

Performance in scientific literacy was marked on a single scale with an average score of 500 points and a standard deviation of 100 points. The scale measures students' ability to use scientific knowledge, to recognize scientific questions and identify what is involved in scientific investigations, to relate scientific data to claims and conclusions, and to communicate these aspects of science. About two-thirds of students across OECD countries scored between 400 and 600 points.

Performance in scientific literacy on PISA 2000 was summarized by way of countries' mean scores (OECD, 2003a). Japan, Korea, and Hong Kong–China dem-

onstrated the highest performance on the scientific literacy scale. Other countries that scored significantly above the OECD average were Australia, Austria, Canada, the Czech Republic, Finland, Ireland, New Zealand, Sweden, and the United Kingdom. Mean scores in Belgium, France, Hungary, Iceland, Norway, Switzerland, and the United States were not significantly different from the OECD average. Except for the Czech Republic and Hungary, all low- and middle-income countries scored below the OECD average of 500 points. The range of average scores between the highest and the lowest performing countries was large: very high performing countries scored around one-half standard deviation above the OECD average, and the lowest performing countries performed 1–1½ standard deviations below the OECD average.

Another aspect of student learning outcomes available from the results of PISA 2000 is student engagement at school. Student engagement at school is important because it can be seen as a disposition that allows one to learn, work, and function in a social institution. In the PISA study, student engagement was treated as an important school outcome in its own right. The report, *Student Engagement at School—A Sense of Belonging and Participation* (OECD, 2003b), examined PISA 2000 findings about the engagement at school of 15-year-old students. It looked at two measures: their sense of belonging in terms of whether they felt they fit in at school, and their participation in terms of classes and school attendance. PISA made it possible, for the first time in such a large international survey, to look at these characteristics alongside the performance of students in acquiring knowledge and skills.

The PISA survey found that significant proportions of students had low levels of engagement, possibly limiting their capacity to benefit from school and constraining their potential. One in four students felt that they did not belong in a school environment in at least one respect, and about one in five reported being regularly absent from school (OECD, 2003b). On the other hand, just over half of students belonged to groups that combined high engagement in school with average or high performance. Several key findings of this report are noteworthy. The prevalence of disaffected students (with a low sense of belonging or low participation) varied significantly across schools in each country. Engagement was found to link only weakly to students' social background; thus there is hope for school policy and practice to help engage more students. In addition, students in schools with strong levels of engagement tended to perform well, showing that, overall, academic performance and engagement are complementary rather than competing alternatives. However, for individual students, it was found that performance and engagement did not always go hand in hand. A quarter of students were both highly engaged and high achievers, and a similar proportion of students were highly engaged with average achievement. Students with lower levels of engagement were spread among those with high, medium, and low performance. Approximately a quarter of foreign-born students, and students from the lowest socioeconomic status or single-parent families, were more likely to be disaffected. However, those from the quarter of families with the highest socioeconomic status were not much less likely than average to show low levels of engagement. Students attending schools with a concentration of students from families with low socioeconomic status were more likely to be disaffected, suggesting probable peer effects. On the other hand, on average engagement was higher at schools with a strong disciplinary climate, good student-teacher relations, and high expectations for students. This suggests that the culture of schools plays a key role.

In addition to student engagement at school, student approaches to learning are important aspects of their learning processes. Positive student approaches to learning are necessary for success in schools and can be taken as important learning outcomes of schooling (OECD, 2003c). Students need motivation, self-confidence, and learning strategies to allow them to drive and regulate their own learning activities. The PISA 2000 analysis has shed light on the relationship between different aspects of student approaches to learning and thus on the whole process that makes students into competent autonomous learners. These findings are summarized in turn.

### **Student Learning Approaches as a Predictor of Student Performance**

One rationale behind efforts to improve student approaches to learning is that appropriate approaches to learning have positive effects on student performance. Students who can regulate their own learning set realistic goals, select learning strategies and techniques appropriate to the demands of the task at hand, shield themselves from competing intentions, and maintain motivation when learning (OECD, 2003c). The PISA findings show a high degree of correlation between positive learning approaches and strong performance. Students' attitudes—their self-confidence and level of motivation—played an important role in adopting strong learning strategies. Positive attitudes were important for performance; they made it more likely for students to adopt fruitful learning strategies. Students' approaches to learning affected performance over and above the effect of family background (OECD). In some countries, this was most obvious for motivational variables such as interest in reading and students' self-efficacy. A large amount of the variability in performance was associated with student background: students from more advantaged backgrounds tended to have stronger characteristics as learners. To reduce social disparities in performance, it will be necessary to reduce the differences in student approaches to learning. However, only a fraction of the differences in student performance (about a fifth) were related to the variations in approaches to learning. Differences also depended on a range of other factors, including prior knowledge, capacity of the working memory, and reasoning ability. All of these factors facilitate the process of comprehension during reading; they free resources for deeper-level processing, such that new knowledge can be more easily integrated into the existing framework and hence more easily understood (OECD).

### **Student Learning Approaches as an Outcome**

The PISA study established five student attributes that could be directly compared across cultures: students' use of memorization strategies, self-concept in reading, mathematical self-concept, self-efficacy, and preference for cooperative learning. The OECD (2003c) report presented student profiles in terms of the average strength of these learning characteristics in each country, the degree to which students clustered into groups with strengths or weaknesses across characteristics, and the learning attributes of different subgroups of the population. Comparison of the mean values of learner characteristics indicates that country differences in this respect were relatively small. Also, the differences across schools were small when compared with differences within schools: relatively few schools succeeded in promot-

ing particularly strong approaches to learning among their students. Attention thus needs to be focused on teaching practices within schools and on system-wide change to improve classroom practices. Cluster analysis identified a group of students with particularly strong motivation, self-confidence, and learning strategies in combination as compared with a group particularly weak on these attributes. Clearly, the latter group needs targeted support, not just to help them succeed at school, but also to equip them with learning attitudes and habits that will be important in their later lives. That this clustering effect is of similar strength in all of the countries surveyed demonstrates that no country can ignore the existence of students at risk for learning.

### **Relationships Between Different Learner Characteristics**

Effective, self-regulating learners cannot be created by the fostering of cognitive strategies alone. Learners also need to have the motivation to deploy these strategies (OECD, 2003c). In all countries, students who controlled their own learning processes and adapted them to the task at hand were characterized by a high level of confidence in their own abilities. Students were more likely to use control strategies if they were motivated to learn by concrete incentives (e.g., occupational aspirations) or specific interests. Overall, about two-thirds of the differences in the degree to which students used self-regulating strategies could be explained by differences in motivation and self-concept. Because the attitudes and learning behaviors of students were closely intertwined, an integrated approach is needed to improve these characteristics as a whole.

### **SAS Study**

Compared with TIMSS and PISA, the SAS Study operated on a less comprehensive and ambitious scale. The project Science and Scientist was an investigation of the interests, experiences, and perceptions relevant to the learning of science by children in many countries (Sjøberg, 2000). The SAS Study was an attempt to open up for a critical discussion how to approach science teaching and learning in ways that take into consideration the cultural diversity within a country as well as differences across countries and cultures. Gender-related performance was of particular importance in the SAS Study.

The project involved 30 researchers from 21 countries. Some 9,300 children at the age of 13 answered the questionnaire. The quality of the sample varied from country to country; thus, the results should be interpreted with care. The SAS questionnaire consisted of seven questions aimed at probing student attitudes and perceptions on matters such as scientists as persons, out-of-school experiences, things to learn about, what is important for a future job, science in action, scientists at work, and me as a scientist.

Children in developing countries articulated a more positive view toward science and technology than children in industrialized countries. Some children in industrialized countries (mainly boys) portrayed the scientist as a cruel and crazy person, whereas most children in developing countries saw scientists as idols,

helpers, and heroes. The low interest for learning science and technology expressed by Japanese children was remarkable. Gender differences in learning different topics of science varied among countries, but were higher in the Nordic countries (and in Japan) than in other regions. The study also provided examples to illustrate how different contexts and applications appealed differently to girls and boys.

## CURRENT CONDITIONS OF SCIENCE LEARNING IN SELECTED COUNTRIES

Results obtained from TIMSS, PISA, and SAS indicate that students' learning outcomes and processes and the conditions of science learning at schools vary significantly both across countries and within a given country. Wide variations in science education practices, policies, and research in different countries are expected. Countries have different problems to be solved, and the ways in which they solve their problems may involve different purposes, approaches, and strategies. Thus it is helpful to know the current condition of science learning in different countries.

### Science Education in Developing Countries

In 1990/1991, the International Institute for Educational Planning conducted a survey on the state of science education in 12 developing countries (Caillods, Gottelmann-Duret, & Lewin, 1997). The countries selected included four African countries, three Latin American countries, two Arabic countries, and three countries from the Asia and Pacific region. Focusing on science at the secondary school level, the information collected included participation in science education, curriculum organization, the conditions of teaching and learning, teaching methods, cost of science education, student achievement in science, and the destination of school leavers. Detailed discussion on the state of science education in the selected countries can be found in work by Caillods et al. (1997).

In terms of educational inputs, most African countries face a lack of financial and human resources. Even in countries where essential resources appear to be available, much remains to be done to improve the quality of education and student achievement in science. The organization of curricula and the forms and degrees of specialization in science subjects differ among countries. Factors affecting science achievement include curriculum content, the amount of time devoted to science, availability and quality of textbooks, and subject knowledge and subject-related pedagogical skills of teachers. Certain conditions of science education, such as the qualification level of science teachers, have improved almost everywhere. Most countries have made tremendous efforts to increase the participation of students in science education (Caillods et al., 1997).

Based on the findings of this survey, Lewin (2000) noted four factors that shape the policy context for science education. The first identifies questions related to participation, the second notes the importance of financial constraints, the third explores the dimensions of supply and demand for science education, and the fourth draws attention to different needs for different groups. In this context, Lewin discussed the current status and main problems of science education in developing countries.

1. There are large disparities among developing countries in gross enrollment rates at the secondary school level. Middle-income developing countries have a majority of children enrolled in the secondary grades. In contrast, some of the poorest countries have gross enrollment rates of between 5% and 10%. In many of the higher income developing countries and some of the low-income countries, female enrollment is greater than that for males. Participation rates at upper secondary are typically 30–50% of those at lower secondary, as a result of attrition, policies on mainstreaming, and availability of other options.
2. The amount spent per secondary student in different countries varies significantly. The richest countries allocate more than \$5000 per child per year; the poorest less than \$50. Money allocated to science education per year in the poorest countries can be as low as \$1 per child. Sustainable levels of resources are low in poor developing countries. These countries may have to select students to specialize in science who will have access to facilities similar to those in richer countries.
3. Regarding the supply and demand in education and the labor market, the basic questions revolve around whether participation in science education is supply or demand constrained at different levels, and whether there is a case to increase supply or demand related to national development strategies on human resource development.
4. Lewin also discussed the different needs of five groups of stakeholders: those who will become qualified scientists and engineers, those destined to work in sub-professional roles that require or benefit from a grounding in science, the remaining general school population, members of marginalized groups with special needs of one kind or another, and those in the informal sector.

## Science Education in European Countries

Sjøberg (2002) described and analyzed some of the challenges facing science and technology education in European countries by relating these challenges to their wider social setting. Keeping in mind that problems and issues may be perceived differently from different perspectives, Sjøberg pointed out the following:

1. Falling enrollment of students studying science. In many European countries, there is a noticeable decrease in the numbers of students choosing to take physics and mathematics. In many countries, there is also a growing gender gap in the choice of scientific and technological subjects at both the secondary and tertiary levels. Many countries have had a long period of steady growth in female participation in traditionally male fields of study, but this positive trend seems to have been broken in some countries.
2. Critique of large-scale international comparative studies. Comparative research in education, such as TIMSS, is important. However, the test items tend to become decontextualized and rather abstract. Sjøberg (2002) suggested complementing the data from TIMSS-like studies with open-ended and culturally sensitive information and perspectives.

3. Public understanding and attitude toward science. There is a political concern about how the general public relates to science, including the nature and level of public scientific and technological knowledge, attitudes and interests, and the degree of public support for scientific and technological research.

Sjøberg (2002) mentioned the widely the accepted notion that science curricula play important roles in developing and sustaining pupils' interest in science, and in preparing citizens for the twenty-first century. Yet, there is broad agreement about the shortcomings of traditional curricula that prevail in most countries: that science is conveyed mainly as a massive body of authoritative and unquestionable knowledge; that there is a lack of relevance and deeper meaning for the learners and their daily lives; and that students do not make the commitments necessary to learn science.

### Cases of Science Education Reform Worldwide

An international workshop on reform in the teaching of science and technology, held in Beijing in 2000, presented current trends and main concerns regarding science curriculum development and implementation in selected countries in Asia and Europe (Poisson, 2001). A total of 15 countries were involved, including China, France, Hungary, India, Indonesia, Israel, Japan, Malaysia, the Netherlands, New Zealand, the Philippines, the Republic of Korea, Sri Lanka, Thailand, and the United Kingdom. Reports from each country focused on the following three aspects: (a) the status of teaching science and technology in the country under discussion, (b) the main problems that country confronts in teaching science and technology, and (c) the most recent science education reform implemented in the country. In order to illustrate the range of variation in the reports from different countries, I have decided to describe the results for China, France, Israel, Japan, New Zealand, and the United Kingdom. The selection is somewhat arbitrary; it is meant to be illustrative of the range of conditions and reforms in science education worldwide.

*China.* Rapid development of science and technology coupled with substantial socioeconomic growth now poses unprecedented challenges to China. Efforts are under way to enhance the content and the delivery system to reform curriculum and instruction. The main problems in the Chinese science curriculum were reported by Poisson (2001). In terms of the instructional goals, the emphasis is on science, rather than technology, and there is undue stress on acquiring knowledge; the development of student ability to apply scientific skills and knowledge to problem-solving remains neglected. The curriculum is subject-centered and knowledge-centered. For classroom practices, recitation of science prevails over science as inquiry, and teachers fail to inculcate scientific attitudes, values, processing skills, and higher-order thinking skills in their students. The separation of science into major disciplines impedes the comprehension of the interconnectedness among physics, biology, chemistry, and earth science.

Relative to science curriculum reform currently under way in China, Poisson (2001) recommended changing curriculum objectives that overemphasize knowledge transmission. The stress should be on the education of physically and emotionally healthy citizens with good characters. Desire, attitude, and ability for life-

long learning among students need to be cultivated. The tendency to structure curricula crammed with many subjects having little or no integration should be changed. Efforts must be made to ensure qualities of comprehensiveness, balance, and selectivity during the structuring of curricula. Curriculum content should be relevant to modern society and promote the development of science and technology. There should be an emphasis on integrating formal education with informal education in form and content, and on avoiding overemphasizing receptive learning, rote memorization, and passive imitation in the teaching process. Learning activities such as active participation, cooperation, exploration, and discovery should be advocated to enable students to become independent learners. Textbook content should be related to students' daily lives and be able to meet specific needs of students and schools in different areas. The variety and number of different versions of textbooks should be increased, and schools should be allowed to select their own textbooks. As for assessment, less emphasis should be placed on factual knowledge and rote memory. A new assessment system characterized by multiple methods that take into account both outcomes and processes is being established. In addition, there is an effort to replace the originally highly centralized system of curriculum management by establishing national, local, and school-level curriculum management policies. This will ensure the overall quality of basic education in China and improve its adaptability.

*France.* In France, science and technology teaching takes place at all levels of schooling, but to widely differing degrees (Malleus, 2001). It is intended that everyone should have science education up to the age of 16. Science teaching takes account of the need to educate future citizens. There is constant emphasis on scientific questioning and increasing progression from the concrete to the abstract. Practical work is an expensive requirement, but one the system strives to satisfy at all levels. Information technologies have become essential in modern science teaching. Changes in the curriculum are evidence that the education system is constantly adapting to societal changes, based on continuous assessment (Malleus).

A strong tradition in France in the teaching and learning of science was to value mainly abstract studies and mathematics. Until the 1960s, the teaching and learning of physics and chemistry in France had not changed for 30 years. Pupils tended to believe that science was final, perfect, removed from reality, and not to be questioned. The introduction of practical work into the school curriculum was a difficult task. It took nearly a quarter-century to change. Change occurred as a result of giving teachers examples of new and interesting experiments, convincing teachers that pupils should not be taught science the way they themselves were taught, leading schools to build laboratories and buy equipment, and lobbying national and regional decision-makers to invest in practical work. Nowadays, assessment of new types of abilities such as problem-solving is emphasized, and links to everyday life and the environment are developed in science curricula. *Hands-on Science* for 5–12-year-olds was developed in 1995 and gradually grew and gained prestige. One important innovation was the introduction of supervised personal projects, which provided direction to pupils to understand the ultimate purpose of what they were learning. A new curriculum is under way, with the main idea of “less is more,” emphasizing skills over knowledge (Malleus, 2001).

*Israel.* In order to prepare the next-generation citizens for life in the twenty-first century, the goals of science and technology teaching in Israel emphasize knowledge and understanding of facts, concepts, laws, and principles that every citizen will need. Science and technology courses are expected to achieve the following objectives (Ilan, 2001): to develop creative and critical thinking, as well as understanding of research methods and enhanced problem-solving skills; to improve comprehension of the importance of science and technology knowledge that will help pupils make decisions regarding national and international issues; to help students recognize the possibilities and limitations of science and technology when applying them to problem-solving; to develop smart consumer thinking and behaviors by using a decision-making process when selecting a product or a system; to prepare individuals to take care of the environment; and to encourage the development of both individual and team learning skills and good work habits.

The characteristics and rationale of the Israeli science and technology curriculum (Ilan, 2001) are as follows. Science and technology should be integrated, while emphasizing the uniqueness of each subject; the integration of science and technology can be done in various ways; and different models should be evaluated in order to show the range of possibilities. Science and technology teachers choose their curriculum from the subjects given in the national syllabus and decide how to integrate them; they are encouraged to engage in team teaching. Students are expected to acquire the relevant knowledge, skills, and attitudes in key technology and science areas in order to be able to tackle human needs and problems. Ultimately, students should be able to follow a full process of problem-solving within a technological and scientific environment.

*Japan.* In Japan, the science and technology syllabus includes scientific phenomena commonly encountered by students in day-to-day life. The aim is to train students in the practical aspects of scientific learning through laboratory and other experiments, develop their powers of observation, and hone their ability to interpret and apply their knowledge. Although the overall academic achievement of Japanese children is considered to be satisfactory, there are still problems that need to be addressed (Goto, 2001). These problems include a substantial number of children who do not fully understand the syllabus content; limited opportunities for children to develop their abilities to study, to think for themselves, to express their opinions, and to view things from different perspectives; children's inability to solve comprehensive science problems related to the environment; and children's lack of interest in science and its study.

The new curriculum and the reform of science education in Japan are aimed at the following goals (Goto, 2001): to help a child develop humanitarian values, social ability, and self-identity as a Japanese person living in the international community; to help a child develop the ability to learn and to think independently; to help a child develop his/her individuality by providing ample scope for learning opportunities; and to encourage each school to show ingenuity in developing distinctive educational activities. In addition, more specific objectives and reform measures were formulated for students at different levels. The suggested reforms at the elementary school, for instance, emphasized fostering problem-solving abilities and student understanding of the relationship between science and daily life. Lifelong learning is also emphasized.

*New Zealand.* In New Zealand, the major aim of science education is to help students develop knowledge and coherent understanding of living, physical material, and technology components of their environment; skills for investigating the above in scientific ways; and attitudes on which scientific investigation depends. The main problems in teaching science and technology in New Zealand are as follows (Kelly, 2001): lack of teacher confidence, knowledge of subject matter, and knowledge of subject pedagogy; lack of science facilities in primary schools; lack of an established base of teaching, learning, and assessment experience in technology; lack of familiarity with “real world” technological practice, the legacy of craft-based curricula in years 7 and 8; and the difficulties of attracting and retaining teachers, especially at the secondary level, in the physical sciences.

In New Zealand, the science curriculum was updated in 1992–1993. A curriculum assessment was planned for 2000–2002. The Ministry of Education produced resource materials and contracted providers to support the introduction of curriculum change to inservice teachers, assess learning, and monitor student progress in science (Kelly, 2001).

*United Kingdom.* In the United Kingdom, the aim of the science curriculum is to stimulate pupils’ curiosity about phenomena and events taking place in the world around them. Both scientific knowledge and scientific methods are emphasized. Pupils are expected to understand, to question, and to discuss how major scientific ideas contribute to technological change; affect industry, business and medicine; and improve the quality of life for all (Osborne, 2001).

The report edited by Millar and Osborne (1998) described the current state of science education in the United Kingdom. On the bright side, science is a universal curriculum for all pupils from age 5 to 16, and 80% of pupils undertake a program at age 16 that covers all of the major sciences. Science is also a core subject of the 11–16 curricula, along with English and mathematics. The current significance of science is reflected in the fact that it now occupies the curriculum high table, with literacy and numeracy, as an essential core of the primary curriculum. Moreover, there has been a general acceptance that learning science involves both knowing about the natural world and having opportunities for personal inquiry.

Although the results of TIMSS for the United Kingdom appeared to be satisfactory, Millar and Osborne (1998) noted that most students lack familiarity with the scientific ideas that they are likely to meet outside school—they lack the ability to deal effectively and confidently with scientific information in everyday contexts. School science, particularly at the secondary level, fails to sustain and develop the sense of wonder and curiosity of many young people. The apparent lack of relevance of the school science curriculum contributes to too few young people choosing to pursue courses in science and mathematics after the age of 16. Millar and Osborne suggested several reasons for these problems. There is an overemphasis on content in science curriculum, which can appear as a catalogue of ideas, lacking coherence and relevance. The science curriculum lacks a well-articulated set of aims or an agreed model of the development of pupils’ scientific capability for the ages of 5–16 years and beyond. Assessment is based on exercises and tasks that rely heavily on memorization and recall, quite unlike those contexts in which learners might wish to use the science knowledge or skills in later life. The National Curriculum separates science and technology. There is relatively little emphasis within the science curriculum on discussion or analysis of the scientific issues that perme-

ate contemporary life. Thus, science appears detached from and irrelevant to young persons' concerns and interests. There is a lack of variety of teaching and learning experiences, leading to too many dull and uninspiring lessons. The science curriculum fails to take adequate account of the range of interests and aptitudes of young people of this age.

Reform measures in the United Kingdom include the following (Osborne, 2001): the introduction of societal issues into the science curriculum; the use of more student-centered approaches; changing the assessment system to reflect the aims of the science curriculum; and increasing out-of-school and informal sources of science teaching, including the Internet and science-related television programs.

## **MAJOR PROBLEMS AND CONTEMPORARY ISSUES OF SCIENCE LEARNING WORLDWIDE**

In view of the discussions presented in the previous sections, I now present a summary of the major problems and contemporary issues of student science learning, using Fig. 9.1 as an organizer.

### **Student Learning Outcomes in Science**

Low student achievement in science for a portion of students, as shown in the TIMSS and PISA studies, is a major concern in many countries. Gender differences exist, with boys having significantly higher average science achievement than girls, particularly in physics, earth science, chemistry, and environmental and resource issues. Inasmuch as different students (with different needs, purposes, beliefs, social-cultural background, prior knowledge, learning experiences, learning approaches, and so on) learn science differently, a problem of both theoretical and practical interest is how to motivate, teach, and assess their learning in science so that optimal results can be obtained for students' individual development and for the benefit of society as a whole. There are gaps between the intended, the implemented, and the attained curriculum, although there is wide consensus that the goals of the science curriculum are meaning making, understanding, and conceptual change (Mintzes & Wandersee, 1998). It is also recognized that, besides achievement in the cognitive domain, student learning outcomes should include aspects such as motivation, self-concept, social-cultural and linguistic aspects, study skills, engagement, learning how to learn, global awareness, and the effective use of ICT. The desired learning outcomes are aligned with science curriculum reforms that are taking place in many countries. To improve learning outcomes, many problems must be solved, including the formulation of science education goals, the development and implementation of new curricula, the preparation and professional development of science teachers, the evaluation of science education programs, and securing financial and material resources and parent and societal support.

### **Learning Processes**

As shown in Fig. 9-1, learning processes in classroom and school settings include many factors expected to link to learning outcomes. In order for a significant proportion of students to achieve the desired learning outcomes, the current state of

science learning processes in many countries appears to be inadequate. For instance, in TIMSS 1995, students in most countries reported spending between half an hour and an hour studying or doing homework in science. In most countries, the challenge of catering to students of different academic abilities was the factor teachers mentioned most often as limiting how they taught their mathematics and science classes. Other limiting factors were a high student/teacher ratio, a shortage of equipment for use in instruction, and the burden of dealing with disruptive students. In the PISA study, significant proportions of students had low levels of engagement, which limited their capacity to benefit from school and constrained their potential in the future. The PISA findings showed a high degree of consistency within each country in the association between positive learning approaches and strong performance. But within each country, there were many students whose learning approaches were less effective.

More favorable conditions for developing student learning processes in science are required. For instance, greater attention should be paid to shaping positive learning behaviors and helping students develop effective learning approaches and metacognitive skills. To be conducive to science instruction aimed at the desired learning outcomes, more favorable teacher behaviors and classroom practices are needed. These will require, in turn, significant efforts in the preparation and professional development of science teachers.

## **Inputs to Learning**

Student characteristics such as their prior knowledge, ability, motivation, goals, IQ, conceptions of learning, conceptions of teacher, and conceptions of the nature of science are important inputs to learning. The TIMSS 1999 results indicated that, in almost every country, there was a positive association between students' educational expectations and their science achievement. The results also indicated that eighth-grade boys generally had more positive self-concepts and attitudes in science than girls. PISA 2000 showed that students' attitudes—their self-confidence and level of motivation—played an important role in adopting strong learning strategies. Overall, about two-thirds of the differences in the degree to which students used appropriate learning strategies could be explained by differences in motivation and self-concept.

Another important input is teacher characteristics such as educational training and experience, beliefs, content knowledge, pedagogical knowledge, pedagogical content knowledge, self-confidence, instructional skills and teaching styles, and conceptions of teaching and learning. The TIMSS 1999 results indicated that eighth-grade students were taught science by teachers with a major in the appropriate science subject. However, eighth-grade science teachers reported only a moderate level of confidence in their preparation to teach science. Teachers' confidence in their preparation was greatest for biology, and least for earth science, environmental and resource issues, and scientific methods and inquiry skills.

Science curriculum and opportunity to learn are also important inputs to learning. Student opportunity to learn the content, skills, and processes in science depends to a great extent on the curricular goals and intentions inherent in a country's policies for science education. Discrepancies exist between intended and implemented curricula in science. Knowing basic facts and understanding science con-

cepts received major emphasis in most countries. Shortcomings of traditional curricula in many countries include the fact that science is conveyed mainly as a massive body of authoritative and unquestionable knowledge, and that the curriculum lacks relevance and deeper meaning for the learners and their daily lives.

Financial, material, and human resources are also important inputs to learning. In the TIMSS studies, having educational resources in the home was strongly related to science achievement in every country. Students in schools that reported being well resourced generally had higher average science achievement than those in schools where across-the-board shortages affected instructional capacity in science. Likewise, public understanding, support, and attitude toward science are important inputs to learning.

## Contexts of Learning

Important context inputs include the physical environment and social-cultural conditions at the home, classroom, and school levels. TIMSS 1995 showed that classroom variables were related to average school achievement even after adjustment for the home background of the students. The strong relationship that persists between the average level of home background and student achievement serves as a reminder that, in many countries, home background, schooling, and student achievement are closely intertwined. Teasing out the influences of the various contributing factors remains a major challenge.

The contexts of learning at classroom and school levels also involve factors such as educational goals and policies, prevailing theories of learning and teaching, educational philosophies, the scientific and technological capacities of the nation, supply and demand in education and the labor market, and other international conditions. These factors are influenced by the driving forces of science education reform shown in Figure 9.1. Important problems and issues can be raised while considering the constraints imposed on and the opportunities provided to the learning process.

## CONCLUSIONS AND RECOMMENDATIONS

A global look at science learning is helpful for examining problems faced within a country, working out possible solutions, and taking necessary actions. Through an overview of the conditions of science learning worldwide, it is evident that many old problems persist, new challenges occur, and research-based reforms and policies are needed. To conclude this discussion, I present a global view of science learning in the twenty-first century. Finally, I offer some suggestion for international research studies on science learning.

### A Global View of Science Learning in the Twenty-first Century

*Old problems.* Across national boundaries, problems of student science learning persist. Regarding the inputs for school science, there are problems due to falling enrollment of students studying science, student lack of interest in science,

lack of adequate supply and professional development of science teachers, and limited resources for science instruction. Science education policies are not well informed by research, and there is a lack of public understanding and support of science. Regarding the processes of learning science, there are problems that have to do with goals for curriculum/instruction/assessment, effective practices in science instruction and learning, and attending to student individual differences and special needs. In terms of problems related to the products of science learning, in addition to concerns about student achievement in science, other desired student learning outcomes need to be considered, including student abilities to apply scientific concepts in daily life, understanding the nature of science, attitudes toward science, and knowledge and skills for professional careers and for dealing with science-related social issues. Student learning outcomes in these areas are generally not as good as expected. It is easier to identify problems related to student learning processes and outcomes in science than to find effective methods to improve student learning, to inform teachers of research findings and teaching strategies, or to institutionalize change.

*New challenges.* The purpose of learning science has changed in recent years. Students and citizens need to be well prepared for a science- and technology-oriented twenty-first century. Rather than preparing selected elites for science careers, schools now are expected to promote scientific literacy for all students. Science teaching, learning, and assessment are expected to stress meaningful learning of basic science concepts, a better understanding of the nature of science, and communication skills, critical thinking, cooperative learning, and problem-solving. Science curriculum and instruction are expected to have relevance to students' daily lives and deal with social issues. The international trends toward globalization and a knowledge economy create opportunities for international cooperation and competitiveness in science and technology. Improved science curriculum, instruction, and learning are expected to play important roles in national development and economic growth in many countries. New waves of science education reforms are sweeping the world. However, based on the lessons of previous science education reforms, it is clear that piecemeal reform attempts will not meet the new demands or solve the existing problems. What is needed is systemic reform, which involves research-informed policy-making and practice.

*New opportunities.* On the research side, there is now a better theoretical understanding of student science learning from philosophical, sociological, psychological, and physiological points of view. A wide range of research methods in the qualitative and quantitative paradigms has been developed, enabling more valid, reliable, and fruitful studies of science learning. A number of international studies have been conducted, providing useful information, examples of best practices, and databases useful for secondary analysis. On the practical side, new instructional strategies, learning materials, delivery systems, learning environments, and assessment methods have been developed in recent years, often using ICT. There is a proliferation of technological tools that provide opportunities, locations, environments, and aids to science learning. Of course, the ways to make the best use of these new tools and opportunities need to be more thoroughly investigated.

## Recommendations for International Research Studies on Science Learning

Sound theoretical and empirical bases are important to the improvement of student science learning and science education as a whole. In light of results obtained from international studies such as TIMSS and PISA, many important research questions may be answered meaningfully from an international perspective. Exchanging and sharing research findings among countries and international cooperation in doing research studies are important steps that the science education research community should take in the future.

Research studies with participants from more than one country can serve a number of purposes. For instance, Chabbott and Elliot (2003) pointed out three types of international comparative studies: (1) type I studies, which focus on comparing students' outcomes internationally; (2) type II studies, which are designed to inform education policy by examining specific policies and their implementation in other countries; and (3) type III studies, which are designed to increase general understanding about educational systems and processes. With the help of ICT, these studies can be more easily planned, carried out, and disseminated. Thus, a larger international community may be able to use the research results to inform science education practices and policy-making. Such studies can provide opportunities for educators and researchers from a given country to reflect on the educational goals, beliefs, and practices that they take for granted. Considering the wide range of educational, social, cultural, and historical contexts in different countries may help reduce the effects of intervening variables that plague most quantitative studies carried out in individual countries. These contexts also can provide a wider spectrum of situations to be considered in qualitative studies. Research results obtained from well-executed international studies can enhance the knowledge of what works best in different contexts, yield more reliable relationship between relevant variables, and deepen understanding of the phenomena involved.

Because of the trends in globalization and ICT, many countries face similar problems and challenges related to student science learning. Because research funds for doing science education studies are limited in most countries, international cooperation involving activities such as the exchange of research scholars and joint research studies should be encouraged. Strong commitment and support from public and private funding agencies, universities, research centers, and professional organizations are desirable.

Studies on student science learning are important in informing educational policy decisions and improving teaching/learning/assessment practices. The interest and scope of such studies may vary from individual students to groups of students, classes, schools, and countries. It is important to recognize that science education exists within historical, cultural, and institutional contexts that differ among countries. The educational goals, instructional conditions, teaching and learning practices, and students' learning outcomes in different countries also vary. From an international perspective, it is therefore important to take a systems approach in selecting research topics, priority, strategies, and methods in the planning of such international studies.

By examining important issues in science learning from an international perspective, I have tried in this chapter to provide useful information, discussion, and

recommendations for the planning and execution of research studies on science learning from an international perspective. I hope that the model of school-based learning in science, the implications of the driving forces for science education reforms in the twenty-first century, and the current conditions of science learning worldwide as reviewed in this chapter will provide background information and guidance for conducting international research on science learning in the future.

## ACKNOWLEDGMENTS

# CHAPTER 10

---

## Gender Issues in Science Education Research: Remembering Where the Difference Lies

**Kathryn Scantlebury**

*University of Delaware*

**Dale Baker**

*Arizona State University*

Take the fact of education. Your class has been educated at public schools and universities for five or six hundred years, ours for sixty . . . though we see the same world we see it through different senses. Any help we can give you must be different from that you can give yourselves, and perhaps the value of that help may lie in the fact of the difference. Therefore before we agree to sign your manifesto or join your society, it might be well to discover where the difference lies, because then we may discover where the help lies also. (Woolf, 1938, p. 17)

If there is any misleading concept, it is that of coeducation: that because women and men are sitting in the same classrooms, hearing the same lecture, reading the same books, performing the same laboratory experiments, they are receiving an equal education. They are not, first because the content of education itself validates men even as it invalidates women. Its very message is that men have been the shapers and thinkers of the world, and that this is only natural. (Rich, 1979, p. 241)

In the early twentieth century, Virginia Woolf (1938) noted that men had centuries of experience with and in public education. Access to public education had only recently become available to women, and she suggested that women saw the world “through different senses.” Woolf suggested that exploring those differences has provided an opportunity to improve education. For the past 40 years, gender research in science education has explored those differences. Often, curriculum choices, assessment techniques, and pedagogical practices that improve women and girls’ knowl-

edge, understanding, attitudes, and participation in science are also beneficial to the majority of their male peers. Since gaining access to science education, women and girls have overcome many obstacles, and although females perform well on various measures of science achievement, comprise at least 50% of the graduates from many undergraduate and graduate science programs, and have used their senses to conduct scientific research differently from their male colleagues, inequities in science education between females and male still exist at all levels and across different societies.

Twenty years ago, Rich (1979) challenged the equitable nature of coeducation, and educators continue to assume the stance that females and males receive equal and thus equitable education. However, in the United States, 20 years after the landmark Title IX of the Elementary and Secondary Education Act legislation that banned sex discrimination in education programs and activities, the American Association of University Women (AAUW) published a series of studies that focused on gender differences in K–12, noting that girls were “shortchanged” in the education they received and describing the environment in public schools as hostile toward females (AAUW, 1993, 1998a, 1998b; Wellesley Center for Research on Women, 1992). Other researchers observed that the U.S. educational system “failed at fairness” (Sadker & Sadker, 1994), and 30 years of gender research found similar patterns in other Western countries (Arnot, David, & Weiner, 1999; Kelly, 1998; Kenway, Willis, Blackmore, & Rennie, 1998).

Science education researchers often fail to acknowledge “where the difference lies” and to take steps to redress those gender differences. This chapter foregrounds gender issues in science education by defining the term, reviewing the influence of gender on the historical and sociocultural aspects of science education, discussing access and participation rates for females in science from an international perspective, considering the impact of educational policies that introduced standards-based teaching and high-stakes testing, and finally proposing directions for future research in the field. Our chapter focuses on research studies, and because of page limitations many examples are Eurocentric. When possible, we have used other literature reviews to support our arguments.

## DEFINING GENDER

*Gender* and *sex differences* are terms that are used interchangeably and incorrectly (Rennie, 1998). For many, *gender* is “a polite way to talk about the sexes” (Haslanger, 2000, p. 31). However, the current trend is to use the term *sex differences* to refer to the biological dichotomy of male and female bodies, whereas *gender* is a social construction, usually based upon the biology of one’s body. Studies in gender research and science education have tended to ignore the interplay of sex, the body, and biology in the social construction of gender (Gilbert, 2001).<sup>1</sup> This limited focus has influenced science education researchers by establishing an oppositional stance between feminine and masculine, causing a nonexistent dichotomy<sup>1</sup> that limits theoretical, em-

---

1. Where relevant, throughout the chapter we highlight studies that have focused on males, however there are few studies in science. Much masculinity literature focuses on reading or males in high-risk groups, e.g., in the US. African American or low socio-economic Eurocentric males, in Australia, Aboriginals, in New Zealand, boys from Maori or Samoan groups.

pirical, and qualitative studies to exploration of gender as a “closed box” (Gilbert; Henwood & Miller, 2001). In this chapter we consider gender a social construction and have expanded the discussion to include aspects of sex differences in science education.

Recently, gender research in education has been broadened to include issues related to gay, lesbian, bisexual, and transgender (GLBT) people and masculinity. To date, there are few published studies in these areas focusing on aspects of science education. Research in this area has implications for science teacher education, teacher and student identity, the nature of the curriculum, and the safety of students as it affects their ability to learn science (Snyder & Broadway, 2004; Fifield & Swain, 2002; Kosciw, 2004; Letts, 2001).

Sex, the body, biology, and the social construction of gender have all influenced students’ access to general education and, more specifically, science education, as well as the kinds of research questions scholars have asked. This chapter synthesizes the gender research, especially with regard to science education, and identifies several major issues. The first section of this chapter focuses on the historical aspects of gender research in science education. The next section discusses the current international situation for girls in science education. In the third section, we discuss sociocultural aspects, which include student attitudes; interplay of gender with race, ethnicity, sexuality, socioeconomic status, language, and religion; and science teacher education. We conclude with a discussion of the impact of policy on gender research and future research directions.

## HISTORICAL PERSPECTIVE

In this section we focus on the history of science education for girls, a history that until very recently was confined to the West, and a synopsis of research into factors influencing the rates of females’ participation in science. Because of space limitations, we illustrate our points with a selection of representative studies, position papers, and examples.

### **The History of Science Education for Girls**

Many scholars have taken a historical perspective that places equity in science education in the context of the nineteenth and twentieth centuries’ socially approved gender roles for middle- and upper-class women (Baker, 2001; Blair, 1998; Fry, 1988; Gaskell, 1998; Theobald, 1996; Tolley, 2003; Yates, 1998). Thus, at the beginning of the nineteenth century middle-class girls’ education in the United States, the United Kingdom, New Zealand, and Australia was limited to private instruction at home or in academies where the curriculum included drawing, painting, and needlework. Society perceived studying science as a threat to a girl’s health and her virtue. However, by the mid-nineteenth century, girls were attending public primary and secondary schools, but there was continued debate about whether they should be studying science and curricula focused on music, painting, modern languages, and mathematics. Charles Perry, an Australian bishop, stated that women should know only enough science for drawing-room conversation but should not study profes-

sional science. His views were reflective of the Western world, especially Cambridge intellectuals. In New Zealand, primary education for girls often took second place to their contribution to the family's economic well-being (Mathews, 1988).

By the end of the nineteenth century, more girls than boys were studying science in high school in the United States and Canada, and girls were receiving better grades than boys. However, only urban, white girls living in the northeastern United States had access to science education. All students in rural areas of the United States and Australia were less likely to attend school, as were First Peoples in Canada (Baker, 2001; Gaskell, 1998; Theobald, 1996). In the United Kingdom, lower-class girls trained to be domestics instead of attending secondary school. Middle-class girls could enroll in endowed private schools located primarily in London, Cambridge, and Oxford. These schools stressed educational achievement in subjects that included science (Blair, 1998). In New Zealand, secondary education for girls was still considered a luxury, and the curriculum reinforced traditional gender roles (Fry, 1988). European girls also had limited access to science education. For example, girls in Germany could not attend the *Gymnasium*, where the rigorous curriculum (including science) prepared students for university (Sime, 1997). In Poland, Marie Skłodowska (Curie) was educated at home so that she could study mathematics and science (Quinn, 1995).

Sadly, the positive trend for girls' education in science declined in the early decades of the twentieth century in the United States, the United Kingdom, and Canada (Baker, 1998, 2001; Gaskell, 1998). The vocational education movement and the post-World War I "back-to-the-home" movement created a mechanical or university track for boys and a business or home economics track for girls. This resulted in a decrease in the number of girls taking science. There was an 80% drop in enrollment in physics in the United States between 1900 and 1928, and girls' chemistry classes focused on the home, cooking, and food adulteration (Rury, 1991, as cited in Baker, 2001). In the United Kingdom in 1902, the National Board of Education made training in housewifery mandatory and allowed girls to substitute domestic science for natural and physical science.

The Great Depression further exacerbated girls' limited access to science in the United States and the United Kingdom and reinforced traditional gender roles (Baker, 2001; Blair, 1998). Girls in the United States, but not boys, were actively discouraged from taking science to reduce the amount of materials consumed and thus the cost of education. In the United Kingdom, the National Board of Education justified a female curriculum by stating that girls' futures would be as homemakers. In the early part of the twentieth century, state governments in Australia also tried to promote a curriculum for girls that emphasized domestic skills, but there was active resistance from women teachers, parents, and girls (Yates, 1998).

The decline in girls' participation in science caused little or no concern in the United States until the mid-twentieth century, when Truman's science advisors argued for a foundation to fund science research and improve science teaching in schools (DeBoer, 1991). The result was the National Science Foundation, which funded the development of new science curricula. These curricular reform projects came under sharp criticism for a variety of reasons. They were directed by men, were based on the theories of male psychologists, and did not result in large num-

bers of girls choosing science or doing well in science (DeBoer). Scholars interested in gender concluded that the new curricula in the United States ignored the needs of girls. They continued their efforts to bring girls into science.

Until the 1970s, Australia offered a sex-differentiated vocational curriculum in addition to the academic secondary curriculum, and girls took fewer science courses than humanities, commercial, or domestic courses. Reports, generated in the 1970s, prompted in part by the women's movement, recommended curricula to help girls. Changes in Australia included campaigns to encourage girls to choose nontraditional careers, school-based projects, and inclusive curriculum (Yates, 1998). Canada and the United Kingdom were also involved in curriculum reform in the 1970s and 1980s that was sensitive to girls' needs. This led to guidelines for nonsexist curriculum materials, the elimination of sexist guidance materials, and an effort to increase girls' interest in science (Blair, 1998; Gaskell, 1998). Feminists in New Zealand also challenged the sexist nature of the curriculum at this time (Watson, 1988). In addition, the international organization known as GASAT (Gender and Science and Technology) was founded in 1981 to engage in research and grassroots activities to promote gender equity in science and technology worldwide. GASAT has created a global network of women and provided a forum (international conferences held every 2–3 years) for sharing ideas for promoting gender equity in science and technology.

Efforts to increase the participation of women in scientific careers have had an impact, although participation in engineering is still lagging. According to New Zealand's 1996 census, statistics engineering was the field with the largest number of male university graduates (New Zealand Bureau of Statistics, 2004). Males numbered 133,950, in contrast to females, who numbered 3,633. The gap between men and women choosing science as a field of study was much smaller. Approximately 15,742 men graduated from university in all fields of science, as compared with approximately 13,000 women. Other western countries have similar enrollment and graduation patterns in science, mathematics, engineering, and technology (SMET), and although engineering remains a highly gendered occupation, there has been a steady increase of women interested in the field (Clair, 1995).

A gender gap between the enrollment of women and men in SMET also exists in Australia. In 2003, 11% of female students were studying engineering, but 42% were studying all areas of science. Furthermore, only 55.5% of women in the natural and physical sciences and 43.1% of women in engineering were employed full-time, as compared with 73.3% of males in the natural and physical sciences and 81.4% of males in engineering. The number of doctorates awarded to men and women in the natural and physical sciences in 2003 revealed a smaller gender gap (male = 863, female = 752) than in engineering, where men received 752 doctorates and compared with 97 females (Australian Bureau of Statistics, 2004).

Canadian statistics indicate that 15% of engineering students, 36% of mathematics and physical science students, and 58% of agriculture and bioscience students were female (Statistics Canada, 2004). In the United States, the number of women in engineering is low, but women now earn more bachelor's degrees in science than men (Mervis, 2003). In the next section, we discuss the research on factors influencing females' participation rates in science, the question of a gender gap, and how research has changed over time.

## Research into Factors Influencing Rates of Participation in Science

One of the earliest studies of gender differences was conducted by Field and Copley (1969) and focused on cognitive style and achievement differences between males and females in Australia and the United Kingdom. They concluded that there were "basic and important psychological differences between the sexes in the processing of information" (p. 10) and that the "slower development of formal operations by these girls" (p. 8) was responsible for boys' higher science achievement scores. Kelly (1978), reviewing the research of the 1960s and 1970s, also acknowledged that males performed better than females on science assessments worldwide; but she concluded that researchers did not know the causes of girls' underachievement in science and that most explanations have not been empirically tested. She then proceeded to test three hypotheses (cultural, school, attitude) to explain sex differences in International Association for the Evaluation of Educational Achievement (IEA) data. She concluded that societal/cultural expectations contributed to the magnitude of sex differences, that school experiences could limit achievement differences, provided girls studied as much science as boys, and that the relationship between liking science and achievement was stronger for boys than girls.

Kahle and Meece (1994) synthesized the gender-related research from the 1970s to early 1990s, noting the "recent concern" about the low participation of women and girls in science, and placed this research in the context of "factors underlying the differential participation of boys and girls in school science" (p. 542). While Kahle and Meece acknowledged the impact of family, cultural, and social factors on gender issues in science, they focused on school-related factors, because teachers and administrators could influence those factors. They also reviewed the research on interventions designed to increase girls' participation in science and identified areas for further research. Kahle and Meece noted that the gender gap in mathematics achievement was closing in 1988, but not in science. The most recent Third International Mathematics and Science Study (TIMSS) data (IEA, 2000) continue to support this conclusion, indicating that from 1988 to 2000 the U.S. gender gap did not decrease, except at the middle-school level. Here, the performance of girls and boys is the same, as it was found to be for six other countries (Beaton et al., 1996). In the United Kingdom, the gender gap has reversed and now favors girls (Arnot et al., 1999).

Kahle and Meece (1994) also reviewed the now controversial work of Benbow, Stanley, and colleagues; of Maccoby and Jacklin; and of other researchers looking for what were then called sex differences in cognitive abilities. They concluded that there was more evidence for attributing performance differences in mathematics and spatial ability to differential experiences (e.g., course taking, out-of-school activities) than to innate differences attributable to biological sex. Furthermore, they concluded that the differences that did exist in mathematics and spatial ability were not large enough to explain the differences in science achievement. Kahle and Meece noted that part of the gender gap could be attributed to test bias in standardized test format, and that girls had better grades awarded by high school science and mathematics teachers. These two factors often have been ignored in the discussion of differences in male and female achievement.

The cumulative effect of teacher expectations, classroom interactions, and the type of instruction, all of which favored boys, was identified as the main educational factor that influenced girls' participation in science. Intervention programs designed to increase girls' participation in science had limited impact, because they focused on single rather than multiple causes and were not grounded in theoretical models that integrated psychological and sociocultural variables (Kahle, Parker, Rennie, & Riley, 1993).

Baker (2002a), in an editorial, asked, "Where is the gender and equity in science education?" (p. 659). To answer that question, she examined articles and editorials in the *Journal of Research in Science Teaching* by decade, beginning with the 1970s. She included "articles that addressed planning for the future, setting priorities, establishing a research agenda, and describing our theoretical orientation as well as articles that took gender and equity as their main theme" (p. 659). During the 1970s and early 1980s, there was little research that addressed gender or equity. The few studies that were identified ( $n = 12$ ) addressed sex differences in cognitive ability and implicitly or explicitly used a deficit model with male performance as the norm. In the late 1980s, Baker found approximately 20 articles that were primarily concerned with gender. These articles were less focused on sex differences and more on gender equity. This change in perspective brought about a questioning of the meaning of differences and attempts to get more girls interested in science. However, this research did not as yet question the locus of the problem. Girls, not science, had to be changed.

## Race, Ethnicity and Socioeconomic Status

Kahle and Meece (1994) criticized a large portion of gender research because it was based on a deficit model that implied that girls lack the cognitive, personal, and experiential characteristics that promoted achievement in science. They called for research that focused on school and workplace barriers, paid more attention to individual differences, and examined the role of ethnicity and socioeconomic status as moderators of success. Several years later, Kenway and Gough (1998) identified the key areas of the gender and science education discourse as documenting differences in participation, attitudes, achievement, and learning strategies. They critiqued the dominant focus on differences and suggested that the research should move away from the male-female dichotomy and encompass race, ethnicity, and class. In a 2000 editorial in the *Journal of Research in Science Teaching*, Gallagher and Anderson (2000) also criticized the research in science education for excluding gender, race, class, or ethnicity.

One of the exceptions to the dominant focus critiqued by Kenway and Gough (1998) was the book *Gender, Science and Mathematics* (Parker, Rennie, & Fraser, 1996). Parker et al. included the work of many scholars, albeit from Western countries (Australia, Canada, Germany, Norway, the United Kingdom, the United States), working within a gender-inclusive perspective. Baker (1998) also synthesized the research that addressed the role of ethnicity and socioeconomic status in participation in science worldwide. She noted that until recently science was the province of white upper-class European and North American males and found that continuing inequities in the educational systems of countries serving large minority and

indigenous populations (e.g., the United States, Canada, Australia, New Zealand) made it particularly difficult for girls of color to be successful in science.

Research that has focused on socioeconomic status and ethnicity has provided a more nuanced picture of girls' participation in science. The second IEA study found that the higher the educational level of parents, the more books in the home, and the smaller the family size, the higher the science achievement for all students (Baker, 1998). Also, studies have found that for some minority students, participation in science requires a large cultural shift. In the United States, this shift has been easier for African American females, who are less constrained by traditional gender roles and community than some other minority groups, such as Latinas, who are more constrained by traditional gender roles and community (AAUW, 1998a).

Concurrently with gender, race, ethnicity, and social class, culture and language were making a breakthrough in the science education literature (Baker, 2002a). These two lines of research had, for the most part, moved along on parallel tracks with few links that would bring them together. For example, Baker criticized the work of Michael Apple (1992), who wrote about economic oppression and curricular reform, but failed to mention the special effect of economic oppression on women. She also criticized the work of Michael O'Loughlin (1992), who focused on issues of culture, power, and discourse in the classroom only in relation to students of color without acknowledging the research on gender in these areas or considering the double impact of color and gender. Other authors were more sensitive to the complexities of gender in race, class, ethnic, and sociocultural contexts and struggled to avoid oversimplification. Krockover and Shepardson (1995) made a strong argument for including these "missing links" in gender research. On the other hand, many of the writers in the 1990s were concerned that issues of gender would be subsumed by issues of culture or race.

Nevertheless, the 1990s also brought official recognition that gender was an important issue in science education, and journal editors supported special issues that focused on recommendations for gender reform. The 1990s saw approximately 30 articles published in the *Journal of Research in Science Teaching* on the topic of gender. These articles went beyond describing well-known phenomena and moved toward explaining what the phenomena meant. The deficit model was discarded, and new feminist and emancipatory theories and methodologies were employed. Gender research in science education had turned a corner (Baker, 2002a).

## **Masculine Nature of Science**

Kelly (1985) identified the masculine stereotyping of science in Western culture as a major barrier to participation not found in non-Western countries. In addition, Kahle and Meece (1994) identified gender role expectations (reinforced by parents and culture) and conflicts about balancing family, children, and a scientific career. These stereotypes and gender role conflicts continue to exist to varying degrees, depending upon context and remain a concern for women worldwide. Kenway and Gough (1998), in their critique of science education research, found that most explanations for differences blamed girls, the curriculum, or the learning environment; the explanation did not take into consideration educational politics and showed a reluctance to attribute differences to science as a masculine discourse. For example, women

were largely missing from the academy until the middle of the twentieth century, and currently, issues of child care, especially release time for bearing and raising children, impede women's progress in academe. The structure of the academy within science still favors men, who often have no or minimal child-care, home, or other family responsibilities (Baker, 1998).

Despite barriers that the masculine nature of science erects for girls and women, there are some encouraging data. Baker (1998) found that girls often rejected the masculine aspects of science (de-contextualized activities, competition, mechanistic views of nature) and the tedium of school science, but not science itself. Moreover, the outcome of girls' attitudes toward science seems to depend on which attitude measures are used (Kahle & Rennie, 1993).

## INTERNATIONAL PERSPECTIVES

Women and girls' participation in science in many countries is restricted by their limited access to education. In 2002, the World Bank estimated that of the 150 million children in primary school, 100 million were girls who were expected to leave before completing their education. United Nations Educational, Scientific and Cultural Organization (UNESCO) (2003) estimated that 104 million children, aged 6–11, worldwide are not in school each year and that 60 million of these children are girls. Nearly 40% of out-of-school children live in sub-Saharan Africa. For example, 90% of girls aged 15–19 in Chad have not finished primary school, and 80% in Burkino Faso have not completed primary school (Hertz & Sperling, 2004). Another 35% of the out-of-school children live in South Asia. In Laos, fewer than one in four girls attend school beyond primary years, and only 12% of girls in Cambodia are enrolled in secondary school (UNESCO).

Urban-rural disparities are striking, especially for girls. In Niger, 83% of the girls living in the capital attend primary school, compared with only 12% of rural girls. In Pakistan, three times as many boys as girls living in rural areas complete primary school, and in urban areas of Pakistan, twice as many boys as girls complete primary school (Hertz & Sperling, 2004). One-third of girls in Africa and South Asia who have completed primary school are still functionally illiterate and cannot read, write, or do simple arithmetic (Hertz & Sperling).

Data for secondary and tertiary enrollment comparisons are limited because of changes in international statistics (United Nations Development Fund for Women [UNIFEM], 2004). However, when comparing the number of females with males enrolled in secondary education, there are 82 females per 200 males attending school; the exception is Latin American/Caribbean countries, where there is one female per 100 males. For tertiary education, there are 63 females per 100 males in sub-Saharan Africa and 58 females per 100 males in South Central Asia. Overall, there are 75 females per 100 males in university in developing countries. The exceptions, where females outnumber males, are Latin American/Caribbean, Southeast Asian, and Western Asian countries. These numbers are ratios and do not represent the actual number of students enrolled, which are very small for both males and females.

Girls in developing countries who attend school face instruction that fosters gender stereotypes and discourages girls from achieving. Curriculum materials portray women as passive (i.e., in Togo, Ethiopia, Kenya). For example, curricula in

Kenya describe men as leaders, fighters, or soldiers, and women are described as breast feeders, fertile, or pregnant (Hertz & Sperling, 2004). In Nigeria, classroom interactions favor boys, who are given more time to ask and answer questions, use materials, and take leadership roles. They are also provided more time and opportunities to engage in science tasks compared with girls (United Nations Children's Fund, 2003).

Science and technology courses at all levels of education are limited in developing countries, and where they exist, enrollment is dominated by men. Among the major barriers to female participation in science are the lack of the basic prerequisite education, and the perceptions of teachers, counselors, family, and peers that science and technology are for males. Thus, half of the world's workers are in sex-stereotyped occupations (UNIFEM, 2004). In addition, cultural norms prevent even scientifically educated women in developing countries from entering the upper echelons of science (UNIFEM, 1995). Almost all of the 479 members listed as members of the Third World Academy of Science (2002) are male.

### **Latin America**

Women in Latin America have not experienced the educational disadvantages of their sisters from other developing countries. This is attributed in part to the egalitarian attitudes of indigenous populations and a push toward industrialization. However, women at university still tend to choose professions that reflect traditional gender roles (Bustillo, 1993). Latinas' access to education steadily increased during the twentieth century until the 1980s. Primary-school enrollment for boys and girls was equal, female illiteracy rates dropped, and the number of women entering university increased. However, the economic downturn of the 1980s and the slow recovery of many countries in Latin American has placed the education of women, especially of rural women, at risk and increased the dropout rates for girls who feel that an education no longer ensures economic and social mobility (Conway & Borque, 1993).

### **Middle East**

Throughout the Middle East (Iran, Iraq, Israel, Jordan, Oman, Qatar, and Yemen) illiteracy rates are at least twice as high for women than men, ranging from 5% to 45% for males and 16% to 77% for females. Jordan has the lowest rates (5% male, 15.7% female) and Iraq the highest rates (45% male, 77% female). Only in Israel are the illiteracy rates less than 10% for the population (3% male, 7.2% female) (United Nations [UN], 2004a). Science is taught in Muslim countries as an integrated compulsory subject from the beginning school grades. It is also part of the curriculum in the last two or three years in secondary school. However, fewer girls than boys enroll in these courses because girls are encouraged to enroll in arts and humanities classes; there is stereotyping of science and technology as suitable only for boys, and the curriculum does not relate science to the everyday life of women (Hassan, 2000).

Change is taking place in Iran, among those women who graduate from secondary school and go on to tertiary education (Koenig, 2000). In Koenig's report, almost 60% of incoming university students were female and, unlike in the past

patterns, they were choosing science. Two-thirds of the students in chemistry at the University of Isfahan were female and 56% of all students in the sciences were female. This included one in five Ph.D. students. Some observers attribute women's dedication to the gains in their science participation. However, others believe that women in Iran have fewer career options than men and so devote more time to their studies. Despite increasing female enrollments, the number of women in faculty positions in universities is still low. In 1999, women were 6% of full professors, 8% of associate professors, and 12% of assistant professors in all academic fields.

Iran was the only Muslim country to participate in TIMSS. In Iran, gender differences that occurred in science at fourth grade favored boys in earth science, but there were no gender differences in life or physical sciences, or environmental issues and the nature of science. At the eighth grade, gender differences favoring boys appeared in earth science and physics, but not in life science, chemistry, or environmental issues and the nature of science. Data for the final year of secondary education were not reported (IEA, 2000).

To avoid getting a false picture of female participation in science, it is important to look at the actual numbers rather than percentage of enrollment. Of the 18,000 students enrolled at the University of Kuwait in 1996–1997, 623 graduated with a science or science-related degree. One hundred and eighty-one of the students in the sciences were female, 142 females were in engineering and petroleum, 52 women were in medicine, and 38 women were in allied medicine fields (e.g., nursing) (Kuwait Information Office, 2002). In 1997, Jordan had 39% of female university students studying natural and applied science nationwide for a total of 12,227 women, and 19% of graduate students in these areas were women ( $n = 1,719$ ) (Jordan Higher Council for Science and Technology, 1997). Other Middle East countries have similarly high percentages of women in science (17–75%), but absolute numbers are low (e.g., 28% represents 7,344 women in Egypt) (Hassan, 2000).

The number of female faculty in universities varies from country to country, with countries such as Syria with 7% of women in science and engineering-related fields ( $n = 410$  nationwide) and Lebanon with 24% female science and engineering faculty ( $n = 111$  nationwide). Overall, statistics for female faculty in Muslim countries are similar to those found in the United States, where representation in the health sciences is highest, followed by biological science; the fewest women are found on the faculties of engineering. However, the more prestigious the academic institution, the less likely it is that women will be on the faculty in senior positions, even at the level of department head, and even fewer women scientists are in policy-making positions (Hassan, 2000). This participation pattern also exists in Western academic institutions.

Turkey, although not in the Middle East, is an Islamic country, but because of its secular government, there are more women in science and there is less gender discrimination than elsewhere (Cohen, 2000). The number of years of schooling completed is 10.4 for males and 8.5 for females (UN, 2004b). Consequently, far more students are enrolled in university and more in science compared with other Muslim countries. However, a disturbing trend was noted in 1994, in the form of a shift in secondary enrollment for girls from technical and general education schools, where the curriculum focused on preparation for further education or the workplace, to schools focused on religious education that emphasized traditional women's roles

(Turkish Republic State Ministry for Women's Affairs and Social Services Directorate General on the Status and Problem of Women, 1994).

The secular nature of Turkey's government means that women have attended university and studied science and engineering since 1927. In 2002, more females ( $n = 6,327$ ) than males (6,054) graduated from Turkish universities with degrees in mathematics and natural sciences, more females (6,263) than males (4,801) graduated with degrees in health sciences, and more than three times as many males (14,614) than females (4,850) graduated with degrees in the technical sciences such as engineering (Women Information Network in Turkey, 2004).

Seven percent of the female Turkish workforce in 2000 was employed in scientific or technical fields, as compared with 7.5% of the male workforce. However, in absolute numbers, the levels of participation of men and women were far apart. There were 653,035 women or slightly more than half the number of men ( $n = 1,248,704$ ) employed in scientific or technical fields in 2000 (Women Information Network in Turkey, 2004).

## Europe

TIMSS data for European countries indicate that gender differences in favor of males appear at the fourth grade and continue through to the final year of secondary school, with the gender gap widening at each level (IEA, 2000). Differences appear in the earth and physical sciences at fourth grade, and the Netherlands has the largest gender gap overall at this grade. Gender differences in earth science continue, and physics and chemistry are added at eighth grade. At the final year of secondary school, gender differences favoring males in science literacy emerge. Males also had significantly higher scores in physics in all countries except Latvia.

By the eighth grade, students' attitudes toward science and mathematics begin to show gender differences. More males than females believe it is important to do well in science and mathematics to get their desired job. These differences may account, in part, for the low participation rates of women in higher levels of science in Europe.

The European Union (EU) has been concerned about the low participation of women in science but does not collect gender-related data and cannot describe the extent of the problem. According to Rees (2001), what is known is that "irrespective of discipline, the proportion of female undergraduates in the discipline, and country, women leave scientific careers in disproportionate numbers at every stage, but particularly after the post-doctoral level" (p. 260). We also know that less than 10% of full professors in science in European countries are women (e.g., 6% of Germany's full professors are women) as compared with 15% in the United States. Furthermore, statistics for women scientists in industry are completely lacking (Williams, 1998). Underrepresentation is less severe in Southern European countries and Finland than in the rest of the EU (Dewandre, 2002). For example, in Portugal, women make up 48% of the researchers at all professorial ranks in the natural sciences and 29% in engineering and technology in institutions of higher education. In contrast, the Netherlands has only 8% women researchers at all professorial ranks in the natural sciences and 6% in engineering and technology in institutions of higher education (Holden, 2002).

However, the higher rates of participation in some parts of the EU do not mean that women in these countries are immune to gender discrimination. In Italy, only 13% of women as compared with 26% of men reach the most senior positions. Nor is the number of female science majors in university reflected in the number of female professors. For example, in the United Kingdom women have comprised 50% of biology majors for the past 30 years, yet women are only 9% of the full professors in biology (Dewandre, 2002). This problem will likely continue, because the rate of increase in the number of women full professors in science in EU countries is approximately .05% to 1.0% per year (Bulmahn, 1999).

Some of the barriers that EU women in science face are reflected by the consistently smaller grant awards they receive compared with men (e.g., in Denmark), demands for 2.6 times higher publication rates than for men, fewer postdoctoral fellowships (e.g., in Sweden), and the use of gender as a criterion for grant awards (e.g., in Netherlands) (Dewandre, 2002; Williams, 1998).

## Asia

According to the Korean National Statistics Office (2004), 41% ( $n = 250,917$ ) of females 15 and older were studying natural sciences compared with 13% studying engineering ( $n = 247,064$ ). These numbers mirror the participation of women in science versus engineering in most countries. Employment numbers indicate that scientifically and technically trained women are participating in the workforce at similar rates in Korea compared with Western countries. TIMSS data for Korea indicated gender differences at the fourth grade in earth and physical science favoring males, and differences favoring males in earth science, physics, and environmental issues and the nature of science at the eighth grade. Data for the final year of secondary education were not reported (IEA, 2000).

TIMSS data for Hong Kong indicated that gender differences favoring males appeared in the physical sciences at the fourth grade (earth science, physical science) and eighth grade (earth science, physics, chemistry). Japanese data followed the same pattern. Singapore had no gender differences in any area of science at either the fourth or eighth grade. No data were available for the last year of secondary school for Hong Kong, Japan, or Singapore (IEA, 2000).

The number of women in science in Japan is quite low, reflecting traditional values and a secondary education system that reinforces women's participation in home economics while boys study technology (Kuwahara, 2001). At the tertiary level, women typically enroll in humanities or education and study topics that interest them (Ogawa, 2001). Attitudes toward science are generally positive for both males and females at the primary level, but decline in junior high school and throughout high school. Physical science, physics, and chemistry are disliked even by Japanese women studying science at university, and even more strongly disliked by men studying non-science subjects. Biology is viewed as a female subject and is only liked and taken in high school by women planning a science major at university or by males planning a non-science major at university (Scantlebury, Baker, Sugi, Yoshida, & Uysal, 2003).

Gender issues are something that Japanese culture is just beginning to address. A survey conducted in 2002 by the Japan Society of Applied Physics found that

women scientists reported a glass ceiling, slower advancement than their male counterparts, and difficulties reentering the scientific workforce after having children (Normile, 2001). Another survey of university science and non-science majors (Scantlebury et al., 2003) found that women in both science and non-science majors were well aware of gender issues, but that males, especially in non-science majors, avoided answering questions concerning gender issues by responding that they did not understand the question. Initiating such surveys was a big step forward in Japan, which has little baseline data about gender issues.

In China, participation rates in physics during the 1970s were among the world's highest, with one in three women students in top Chinese universities studying physics. The number of women has dropped below participation rates in the West to less than one in ten. The high levels of the 1970s are explained by women asserting their equality and inflated numbers. The downturn in the number of women in physics has been attributed to the same gender barriers as found elsewhere, stereotypes encountered by women in physics, and current media messages that emphasize marrying a good husband and raising children (Jianxiang, 2002).

Nearly 30 years ago, the United Nations officially called for women's equal rights and access to education as a "fundamental right" (UNESCO, 2004). UNESCO's policies state that female education is a key strategy to eliminating poverty and improving development. Although females' access to science education has improved, regardless of culture or country, masculine hegemony promoting stereotypical gender roles remains a strong barrier to female's participation in science. Females in many countries are expected to place family and child-rearing responsibilities (private sphere) ahead of education or working outside the home (public sphere). Although government policies have removed the structures that promoted different science education for females and males, few countries have implemented policies to address the imbalance in domestic and family responsibilities between females and males. In the following section, we use a U.S. example of women in academic science to illustrate the dilemma women face in moving between private and public spheres.

### **MOVING BEYOND SCHOOL: WOMEN IN COLLEGE SCIENCE MAJORS AND CAREERS**

The number of women moving into science majors and careers has increased steadily during the past few decades. In the United States, women account for 27% of doctoral degrees in the physical sciences, 31% in the geosciences, and nearly 50% in the life sciences (National Science Foundation [NSF], 2002), and they are reaching parity in several undergraduate and master's degree programs. However, women of color are especially underrepresented in academe. For example, the largest group, African American women, represent only 2% of full-time science faculty (Gregory, 2002).

There is a dearth of women faculty in the sciences at colleges and universities, and women are underrepresented at the senior ranks (NSF, 2003). Promotion and tenure rates for women science faculty are lower, compared with their male peers (Rosser & Lane, 2002). Researchers have begun to explore the reasons for the failure of universities to attract, promote, and retain women scientists and have identified a number of barriers (NSF, 2003; Rosser, 2004; Scantlebury, Fassinger, & Richmond, 2004). Although major barriers, such as access to science education, have been re-

moved, micro-inequities between women and men scientists build to a cumulative disadvantage throughout an academic career (Valian, 1998). For example, after interviewing 50 female tenured professors in the chemical sciences, Scantlebury et al. found a pattern of "sabbatical babies." Women planned their pregnancies to coincide with a post-tenure sabbatical leave. This strategy meant that women could avoid requesting maternity leave and dealing with unsupportive administrators. The micro-inequity occurs because male scientists are more likely to use their post-tenure sabbatical to focus on their research (duties in the public sphere), rather than child-rearing responsibilities (private sphere). Although not unique to scientists, the balance of career and family is difficult for women in academe (Rosser, 2004; Scantlebury et al., 2004; Valian, 1998). For example, the structure of academe is counter to women's biological clocks, and although many institutions stop the tenure clock during maternity leave, there is an expectation that faculty will maintain their research programs at a productivity level similar to that of their peers.

Overwhelmingly, the climate for women in research science remains hostile, isolating, and un-collegial. Recent studies suggest that female graduate students and post-doctoral research associates are choosing not to enter academics because of the treatment they received and observed during their graduate school experiences (Rosser, 2004). However, several structural mechanisms are in place to counteract the negative academic environment for women. Recently, the NSF established ADVANCE (NSF, 2004) awards for institutional transformation to change the climate for faculty. Institutions receiving grants through the program have identified and are beginning to remove the institutional barriers that exist for the recruitment, retention, and promotion of women in STEM fields. For example, the Georgia Institute of Technology (2004) established a mentoring program, developed tenure and promotion training workshops that address issues of bias, and instituted more family-friendly policies that recognize that the tenure clock often is in competition with a woman's biological clock. In the United States, funding agencies are recognizing that structures exist that limit women's advancement and participation in science. ADVANCE (NSF, 2004) encourages academic institutions to identify where the difference lies and supports their efforts to change those structures that support research science and recognize the demands that the private sphere places on public lives for women and men.

## SOCIOCULTURAL ASPECTS

A decade ago, Kahle and Meece's (1994) handbook chapter on gender issues in science education focused on the impact of sociocultural aspects such as home, family and teachers and teaching, the implementation of intervention programs to promote girls' participation and retention in science, and learners' individual characteristics, such as attitudes and cognitive abilities. They also proposed a need for a theoretical model that would address multiple variables and not use a deficit view of gender.

Several major changes in the sociocultural context for science education have occurred since the previous handbook chapter. First, in Western cultures, there has been a shift from allowing teachers independence with respect to how and what they teach, to a climate where teachers and students are held accountable for what

is taught and learned. Second, in response to policymakers' stance on student and teacher accountability, content standards in science have been written in many countries, and countries such as the United States have introduced high-stakes tests at the state level.<sup>2</sup> In this section, we discuss gender issues related to student attitudes, sociocultural classroom environment, assessment and testing practices, and teacher education, with reference to research studies. Because of page limitations, we draw mainly on studies conducted in the United States.

### **Attitudes Toward Science**

Since Kahle and Meece's (1994) chapter, two studies reviewed students' science attitudes. Weinburgh (1995) conducted a meta-analysis, and Osborne, Simon, and Collins (2003) published a literature review. Both studies reported that gender is still the major factor differentiating students' attitudes toward science and that females' participation in science has similar patterns in most Western countries. For example, girls in Britain chose not to enter undergraduate programs in the physical and computer sciences and engineering (Osborne et al.).

Recent research found that gifted girls attribute their academic success and/or failure in science to effort and strategy (Li & Adamson, 1995). These research results are consistent with an ongoing pattern identified by gender researchers in the 1980s (Kahle, 1985). Recently Jones, Howe, and Rua (2000) reported that the U.S. intervention programs of the 1980s and 1990s had little impact on the recruitment and retention of girls and women into science. This may be due to the deficit model approach that many of these programs used—that is, a “fix the girls” approach—rather than projects challenging science structures. However, we cannot ignore the social structures that affect students' science identity.

Barton (1997, 1998, 2001) has challenged science educators to rethink the concept of gender so that the field is more inclusive of all students. Brickhouse (1994) challenged the field to rethink the curriculum in order to “bring in the outsiders” and their perspectives. Gilbert (2001) called for a redefinition of the terms *science* and *gender* so that students who typically have not viewed science as part of their identity would choose to do so. Two U.S. studies that addressed science identity were contradictory. In their study of four African American middle-school girls, Brickhouse, Lowery, and Schultz (2000) found that the girls, whose teachers encouraged them to develop their science identities, also aligned themselves with the feminine stereotype of quiet, studious schoolgirl. However, Scantlebury (2005) found that teachers who had encouraged girls who challenged the feminine stereotype and engaged those girls in science, alienated quiet girls.

### **Sociocultural Classroom Environment**

Several studies suggest that changing teachers' practice will improve students' attitudes, especially the attitudes of girls, toward science (Parker & Rennie, 2002; Weinburgh, 1995). Kahle, Meece, and Scantlebury (2000) found that middle science teach-

---

2. Prior to this time the only state that with a state-wide high stakes testing program was New York, with the Regents' exam.

ers using standards-based teaching practices positively influenced urban, African American students' science achievement and attitudes, especially those of boys. Current reforms in science education place an emphasis on standards-based teaching that provides students with opportunities to learn, which in turn should improve students' achievement. The concept of opportunity to learn (OTL) incorporates instructional strategies, curriculum materials, and the psychosocial environment to promote student achievement and attitudes (Stevens, 1993). Yet, ongoing studies of the classroom suggest that girls still have limited opportunities to learn science compared with boys.

Harwell's (2000) study of middle-school girls researched five areas: (a) girls as learners, (b) perception of the nature of science, (c) perceptions of classroom environments conducive to learning science, (d) perceptions of teachers' actions to enhance science learning, and (e) girls' suggestions for improving science learning. Sixty-four percent of the girls in the study reported that they would prefer to learn science in an active way, that is, doing science, experimentation, hands-on experiences, observations, or a combination of these approaches. However, the girls' reported preferences were in stark contrast to their classroom experiences. The results of this study reflect strong and enduring cultural patterns—nearly 80% of the girls reported that they were passive learners. Only 47% of the girls reported that their teachers used some “new” teaching approaches such as demonstrations, hands-on activities, or fieldwork.

Other studies found similar patterns. Jovanovic and King (1998) examined gender differences in performance-based assessment science classrooms; they found that boys appropriated equipment and dominated the use of resources. Girls often had passive roles, such as reading instructions and writing down results. Freedman's (2002) study showed the positive impact that laboratory experiences had on ninth-grade students' attitudes and achievement in physical science. Jones et al. (2000) focused on elementary student dyads using tools to develop their science understanding. Girls' and boys' engagement with the equipment reflected patterns first identified by Kelly (1985). Girls carefully followed teachers' directions and the “rules,” whereas boys dominated resources, tinkered with the equipment, and were competitive. Girls developed social relationships while working in their dyads. Jones et al. offered the same suggestion that Kahle (1985), Kelly (1981), and others made 20 years ago—that teachers create an environment where girls have permission to tinker, take apart the equipment, and “color outside the lines” (p. 781).

During the past decade, gender research in science education has sought to tell the stories of people from groups underrepresented in science (e.g., people of color, rural, urban, economically disadvantaged). Using feminist methodologies and theoretical frames, researchers have diversified the knowledge base. For example, in K–12 settings, Parrott, Spatig, Kusimo Carter, and Keyes (2000) reported on an intervention project that targeted the intersection of poverty, race, and place of non-privileged, middle-school Appalachian girls. They selected eight girls for in-depth study and found that the science teaching they received was often not standards-based. Teachers felt driven to a didactic approach because of the changes in educational policy that held them and their students accountable to a defined set of learning goals, which were usually established through high-stakes tests.

In urban school settings, African American girls tend to outperform their male peers on measures of science achievement (Coley, 2001; Pollard, 1993). The differ-

ences in science achievement of these students may be attributed to a number of school contextual factors that limit learning opportunities for all African American students, but especially for male students (Davis & Jordon, 1994; Selier, 2001). African American males, when compared with their female peers, have a disproportionate number of school suspensions, expulsions, and absences. In one study, home environment and peer support had a positive effect on African American girls, suggesting that high-achieving African American girls are more likely to seek support from their peers, but high-achieving African American males do not (Kahle et al., 2000). Scantlebury (2005) noted girls' roles as *othermothers* (surrogate mothers) prevented urban, African American girls from regularly attending school. In Brickhouse and Potter's (2001) study of two African American girls enrolled in a computer science program at a vocational high school, the picture was more complicated because of the interplay of gender with race and socioeconomic status.

Although some reforms have had positive outcomes, such as pushing teachers in urban schools to expect more from their students, the move toward accountability potentially has negative outcomes, because teachers teach to high-stakes tests (Henig, Hula, Orr, & Pedescleaux, 1999; Olsen, 2001). When "teaching to the test" means drilling students on repetitive examples, we run the risk of further alienating students from learning science, and the gains seen in girls' involvement with school science may be lost.

### High-Stakes Test-Taking Patterns

Penner (2003) examined the gender by item difficulty for high-school students on TIMMS results from 10 countries (United States, Canada, Australia, New Zealand, Lithuania, Czech Republic, Sweden, Austria, South Africa, and Cyprus.) The effect size difference for science literacy ranged from .30 to .51 in favor of boys. A pattern emerged indicating that girls had more difficulty with harder items than boys. Although this difference is clear, the source of the difference is not. Understanding the source of differences on high-stakes testing is a major challenge in gender research and has implications for determining the success of reforms.

In the past decade, standards-based reform efforts in science education in the United States have produced national standards, a plethora of state-wide high-stakes tests, and demands by politicians, parents, and other community members for student and teacher accountability, especially related to student outcomes (National Research Council, 1996). As educational systems begin to adopt standards-based reforms and request the funds needed to implement changes, policymakers and politicians call upon educators to provide evidence and reform efforts are directly attributable for improvements in students' achievement.

Student outcome data, such as achievement scores on a state test, have become high-stakes. That is, many states require students to attain minimally passing levels on state tests for high-school graduation. Boone's (1998) research highlights a gender issue researchers should take into account when considering the impact of high-stakes testing. Boone conducted an analysis of test-taking patterns as a function of race and gender with the use of a 28-item multiple-choice science test for middle-school students. A significantly larger number of females, compared with males,

and African Americans compared with white Americans, did not answer a number of items at the end of the test. As a consequence, the researchers shortened the test, removing overlapping items that tested similar content because the purpose was to document students' science achievement, not their test-taking skills.

In contrast, Lawrenz, Huffman, and Welch's (2001) study of 3,550 U.S. ninth-graders reported no gender-differentiated patterns across question types of multiple choice, open-ended format, hands-on, and full investigation. The study did not report gender by race results. And at the college level, Weaver and Raptis's (2001) study of the responses of female and male undergraduate students on multiple-choice and open-ended questions on exams associated with introductory atmospheric and oceanic sciences found no gender differences.

Often data from the high-stakes tests are disaggregated by gender or by race, but never by both gender and race/ethnicity. For example, the Council of Chief State School Officers (2004) report, *State Indicators of Science and Mathematics Education 2003*, provided data on gender or race/ethnicity distribution for students taking science and math courses, but did not disaggregate the data by gender and race. This omission makes it difficult to measure our success in supporting science achievement for all groups of students.

### Single-Sex versus Mixed-Sex Science Classes

Since the late 1970s, researchers have identified the masculine hegemony of the sociocultural environment experienced in science classrooms as one reason for the lack of women and girls in science courses and careers (Ginorio, 1995; Kelly, 1985; Seymour & Hewitt, 1997). Coeducation assumes that all students receive an equal education, but Rich (1979) noted that this assumption was clearly erroneous. Based upon historical studies of the characteristics of women scientists, Rossiter (1982) found that many of these women had a single-sex schooling experience. Parents, teachers, and researchers have viewed single-sex science classes as one strategy that would provide girls the experiences they needed to succeed in science.

Several reviews of the research have challenged the idea that single-sex environments are good for girls (AAUW, 1998b; Mael, 1998; United States Department of Education, 1993). All of these reviews concluded that single-sex classrooms in the United States do not necessarily translate into higher achievement or reduced stereotyping of women's roles. Much depends upon what goes on inside the classroom. For example, Baker (2002b) found that the curriculum topics and the pedagogy employed by teachers were more important than the fact that Latino/a middle-school boys and girls were in single-sex mathematics and science classrooms. There was no clear evidence that the single-sex classroom resulted in higher achievement, but it did provide girls with a strong sense of empowerment. This finding replicated the work of Wood and Brown (1997), who found that single-sex mathematics classes had no effect on achievement. Nor did Wood and Brown or Forgasz and Leder (1996) find an effect on future course-taking. A reanalysis of data from single-sex Catholic schools (LePore & Warren, 1997; Lewin, 1999) indicated that the higher academic achievement attributed to secondary Catholic schools was the result of pre-enrollment academic differences between students in single-sex

and coeducational schools rather than the single-sex environment, curriculum, or instruction.

On the other hand, the evidence is strong that single-sex environments do provide girls with a sense of empowerment, confidence to ask questions in class, an intimidation-free classroom climate, and a positive attitude toward science (Baker, 2002b; Forgasz & Leder, 1996; Parker & Rennie, 1995; Rennie & Parker, 1997; Streitmatter, 1999; Wollman, 1990; Wood & Brown, 1997). Conversely, Shapka and Keating (2003) found greater positive effects on mathematics and science achievement for girls in single-sex Canadian classrooms than on boys or girls in coeducational classrooms. Furthermore, they did not find positive effects for affect. The single-sex environments did not have an effect on students' attitudes toward mathematics, math anxiety, or perceived math competence. Parker and Rennie found positive science achievement effects for girls in single-sex classrooms in Australia.

Lee, Marks, and Byrd (1994) found that gender stereotyping was as likely to occur in single-sex boys' or girls' schools as in coeducational schools. Girls' schools reinforced academic dependence and had the least academically rigorous instruction (Lee et al.). The data for single-sex schools or classrooms in developing countries are contradictory. Mael (1998) concluded that in the United States, single-sex education had more benefits for males than females, primarily because single-sex male schools received more resources than female schools. Lee and Lockheed (1998) came to the opposite conclusion, based on studies in Africa (Beoku-Betts, 1998; Kiluvandunda, 2001), where cultural values, patriarchal religion, and male hegemony have led to a curriculum that reinforces gender stereotypes (Baker, 1998).

The instructional strategies employed may determine the success or failure of single-sex education. Parker and Rennie (2002) found that it was easier for teachers to implement gender-inclusive strategies in single-sex science classrooms than in coeducational classrooms. The single-sex classroom reduced management problems (a finding noted by Kenway et al., 1998) and allowed more time for girls to develop their hands-on inquiry skills. Teachers in all-male classrooms found that they spent more time on management problems than teaching.

## **Heteronormative Science Education**

In the broader educational context, Kosciw (2004) found that institutions of education promote heterosexuality as the norm, which produces a caustic climate for GLBT youth and adults. GLBT youth reported high levels of verbal and physical harassment, which occurred 84% of the time within hearing of school faculty and staff. Students reported that 42% of the time adults failed to intervene. Gay boys were more likely to experience physical violence than lesbian or transgendered youth. However, all students reported missing school because of isolation and ostracism (Kosciw). Opportunities to learn for GLBT students are thus diminished because of hostile school environment and absenteeism.

The issues of GLBT in science are closely related to the preparation of teachers, the curriculum, and scientific knowledge. Letts (2001) discussed science's heteronormative masculinity and proposed introducing a critical science literacy into elementary science teacher education to counteract these dominant discourses. Fifield and Swain (2002) used queer theory to problematize science teacher education and,

in particular, biology education's heteronormative stance on issues of identity and knowledge. Using personal stories, they illustrated the need for science teacher educators to reconstruct the concepts of gender and diversity for ourselves and for our students. Snyder and Broadway (2004) queered text of eight high-school biology textbooks to focus on the silence with regard to sexuality that is not heterosexuality. In reviewing high-school biology textbooks, Snyder and Broadway noted that the texts portrayed homosexuals as a high-risk group for contracting acquired immunodeficiency disease (AIDS). There was no discussion of scientists' sexual orientation, and they found that the dominant heteronormative perspective did not allow students to develop knowledge in topics such as genetics, behavior, nature of science, sexuality, or AIDS.

## FUTURE RESEARCH DIRECTIONS

Consciousness raising is not any guarantee that a person will not succumb to a hidden curriculum. But still, one is in a better position to resist if one knows what is going on. Resistance to what one does not know is difficult, if not impossible. (Martin, 1994, p. 167)

Gender research in science education initially focused on "where the differences lie," and from that data, educators developed intervention programs to increase girls' skills and influence their attitudes toward science. The field has moved from this deficit model, but fewer researchers are focused on gender issues in science education. There is a possibility that girls and women will become invisible in science education research.

A literature search using the ERIC database to identify journal articles published from 1990 to 2004 with the terms *gender* and *science* generated 817 articles. Adding *race* into the keyword search decreased the number of articles to 61. An examination of these articles indicated that 15 articles were not research in science education but in areas such as library science, economics, or political science. Thus during that 14-year period, less than 6% of the research articles on gender and science included a focus on race.

The failure to consider gender and race or ethnicity is not unique to researchers. In the United States, the No Child Left Behind Act has tied state funding to student performance. Yet, Kahle (2004) reported that this critical piece of legislative policy does not require data disaggregated by gender. Requiring such data will help researchers as well as U.S. state and national legislators to critically examine the impact of this legislation and potentially prevent girls from becoming invisible once more. It will allow us to determine the interactions of gender with race and socioeconomic status to identify what works and for whom. As Baker (2002b) found in her study of single-sex classrooms, what works for Latina girls may not work for Latino boys, and the issues affecting African American girls differ from those affecting their male peers (Kahle et al., 2000; Scantlebury, 2005; Seiler, 2001).

In 1994, Kahle and Meece recommended that research on gender issues in science education also explore the impact and interaction of socioeconomic status, race, and ethnicity. Krockover and Shepardson (1995) repeated that recommendation, characterizing research on gender and sociocultural aspects, ethnicity/race, and identity as "missing links." Baker (2002a) also noted the limited research on

gender, race, and socioeconomic status in an increasingly complicated field. Why have calls to examine gender and race gone largely unheeded? Perhaps the answer lies in the challenges to conducting gender research. Research that focuses on the intersection of gender with other variables must avoid oversimplification of complex settings. Ignoring the nuances and dilemmas within the field limits the development of theoretical models and frameworks that can assist researchers (Kenway & Gough, 1998; Rennie, 1998).

In an effort to keep gender in the forefront of science education, the Henry Booth Foundation in New York conducted a seminar, *Nurturing the Next Generation—Research on Women in the Sciences and Engineering* (Daniels, 2004). Disaggregating data (by race, SES, rural/urban) from gender research in science education remains a critical issue, especially in the determination of how gender, social class, race, and sexuality affect students' science trajectories, career decisions, and participation. Gender researchers also need to develop sophisticated survey instruments and analysis to identify micro-inequities in schooling, students' science trajectories, and career paths. Furthermore, research is needed on fostering institutional transformations to change the climate of academic science departments and understanding the transitions from community college to bachelor's, master's, and doctoral degrees.

Science teacher educators also face challenges in preparing teachers who understand the subtleties and nuances of gender affects on students' science learning and their teaching. Many schools promote cultural reproduction of stereotypical gender roles that are more inflexible and more polarized than those held by the wider society (Ruble & Martin, 1998). Those stereotypical gender roles and behaviors noted by Kahle (1985) and Kelly (1981) are still observed by researchers today. Although the percentage of girls participating in K–12 science and achievement increased in the past three decades, recent studies suggest that their involvement, engagement, and attitudes toward the subject have not (Altermatt, Jovanovic, & Perry, 1998).

Science teacher educators need to engage current and future teachers in an exploration of gender roles and their attitudes toward those roles. The subtle inequities in classrooms are barely noticed by the participants in classroom life (Kahle, 1990; McLaren & Gaskell, 1995; Spender, 1982). The acceptance and consistency of traditional gender roles in schools are often invisible to students and teachers (McLaren & Gaskell, 1995; Spender, 1982). Gender inequity is the "norm" and anything else is "not normal." Most people only consider gender inequities a problem when the inequity challenges the norm (e.g., homosexuality) or is blatant (e.g., sexual harassment).

However, we science teacher educators need to practice what we preach and examine from a gender perspective the issues that exist in our planned and enacted curriculum, pedagogical practices, enrollment patterns of students in teacher education programs, hiring policy, tenure and promotion of faculty, and policy documents that influence our field (Scantlebury, 1994).

For nearly three decades, researchers in science education have examined the hidden curriculum influencing women and girls' participation in science. More recently, we have also begun to address the exclusive impact of science's heteronormative view. Although there has been some progress in increasing the participation of girls and women in science, much remains to be done. Gender differences in par-

ticipation, achievement, and attitude still exist. The social construction of gender in terms of the legitimacy of women's access to education and the heteronormative view of science in the classroom has not been challenged.

Many people remain at the margins of science, in both the developed and developing world. Science continues to promote a Western, masculine worldview that many girls and women reject. And research still faces the challenge of considering gender, race, and socioeconomic status within accountability systems that want simpler answers than we can provide.

# CHAPTER 11

---

## Special Needs and Talents in Science Learning

**J. Randy McGinnis**

*University of Maryland, College Park*

**Gregory P. Stefanich**

*University of Northern Iowa*

Every learner in science is unique, with diverse abilities. Teachers as well as educational researchers have long recognized and used that understanding to varying degrees in their teaching and research. Learners in science who differ substantially in their performances from typical learner performances (physical, cognitive, or behavioral dimensions) and who need additional services and supports are the focus of this chapter. Those learners who exceed typical performances are described as possessing special talents; those learners who do not achieve at the typical level are identified as having special needs. Both of these groups of learners require additional educational, social, or medical services to support them in learning and performing science. Professionals in the field of special education use the comprehensive term “exceptional learners” to refer to learners with learning and/or behavioral problems, learners with physical or sensory impairments, and learners who are intellectually gifted or have a special talent (Hardman, Drew, & Egan, 2002; Heward, 2000). We continue use of that nomenclature to refer collectively to learners in science with special needs and talents.

Science education researchers, interested in developing a knowledge base that would guide policymakers and teachers in achieving their goal of “science for all” (Fensham, 1985), have been attracted to studying these two groups of learners. The purpose of this chapter is to outline what is known about how exceptional learners learn science, including consideration of how the totality of science education (context, personnel, curriculum, and assessment) supports or hinders this process, and to use that understanding to make recommendations for future research directions. Included is a discussion of how certain schools of thought on learning influence the research in this area. Structurally, this chapter reviews in two parts the literature on

science learning by exceptional learners. Part I focuses on the science learning population with special needs. Part II focuses on the science learning population with special talents.

## **THEORETICAL PERSPECTIVES GUIDING RESEARCH ON EXCEPTIONAL LEARNERS**

There is no one accepted theoretical model of learning that provides a grand explanation for why learners engage science in differing ways and at varying levels of achievement. Three prevailing schools of thought on learning that have guided research on exceptional learners in science are the behavioral, developmental, and cognitive perspectives (Stefanich & Hadzegeorgiou, 2001). Although the behaviorist perspective historically has dominated research by special educators in this area, a growing number of researchers dissatisfied with that perspective, including those in science education, have been drawn to more contemporary applications of cognitive science that include an appreciation of social context (Rogoff, 1990). In addition, a fourth school of thought, a sociocultural perspective, also has its proponents.

Behavioral psychologists believe that learning consists of making connections between events (stimuli) and behaviors (responses). External forces, such as rewards and punishments, and drives, such as hunger, provide the learner motivation to make stronger connections between stimuli and behaviors, that is, to learn. Although the primary form of data valued in this theoretical perspective is observable behavior, theorists applying behaviorism to educational research have expanded on the theory to include hypotheses on mental states, including thinking, understanding, and reasoning (Bransford, Brown, Cocking, Donovan, & Pellegrino, 2000). Behaviorists assert that instruction should be based on the identification of clear outcomes and be directed toward those outcomes. Developmental psychologists believe that the thinking of children is distinctly different from that of adults. They assert that as individuals progress through life, their thinking patterns change dramatically over short periods of time and then remain somewhat stable for an extended period. A key assumption is that rates of learning vary per individual. Developmental psychologists examine the external factors (such as science instruction) that might influence an individual's rate of intellectual maturity. A cognitive science perspective examines mental functioning, in the individual and the social contexts, frequently by using technology to collect biological data on the brain. It uses a multidisciplinary approach that incorporates developmental psychology, computer science, and neuroscience, as well as other fields of study. The testing of theories of teaching and learning characterizes studies in this perspective. The sociocultural perspective is distinguished by its attention to the interaction between learners' mental functioning and their cultural, historical, and institutional settings (Wertsch & Kanner, 1992). A key assumption is that learners' mental development the result of a complex interaction among multiple factors and is not determined solely by their biological structures.

Recently, some researchers, influenced by emerging findings from brain research, have proposed that there are disrupted brain functions in some learners that can be identified and hypothetically "rewired," producing additional compensatory activation in other brain regions (Shaywitz, 2003; Shaywitz et al., 2002; Simos et al.,

2002; Temple et al., 2003). However, other researchers have challenged these tenets. Donald (2001) rejected the explanation that certain brain regions perform specialized operations. Instead, he stated that the mechanisms and connectivity for language are set by experience with countless interconnection points, or synapses, which connect neurons in various patterns. He concluded that learning and experience create and shape the brain's circuits, and, therefore, these circuits are not predetermined. Lieberman (1998) proposed that human language is a system of neuro-anatomical connections that are distributed throughout the brain. Coles (2004) argued that brain researchers have misconstrued data and have drawn conclusions to justify unwarranted beliefs. Coles stated, "Dyslexia remains no more of a proven malady among a substantial percentage of beginning readers than when Glasow ophthalmologist James Hinshelwood first discussed it as 'congenital word-blindness' at the end of the 19th century" (p. 351).

Awareness of these four schools of thought may assist researchers in making sense of the reported studies on exceptional learners in science. Although it is the nature of this scholarship area to be advocacy oriented, individual articles may include reported data (either in empirical studies or summary articles) that can be inferred to reflect one of these theoretical perspectives. For example, many researchers holding a cognitive or sociocultural perspective discuss inquiry as an important and effective/efficient feature of learning in science, whereas those taking a behaviorist perspective place an emphasis on the mastery of skills and information. Likewise, the literature on inclusion can be viewed as being founded primarily on a learning perspective that places highest value on social context and developmentalism.

## PART I: SPECIAL NEEDS IN SCIENCE LEARNING

### Definitions

If education is devoted to offering opportunities for all students to gain sufficient schooling to help them make life choices and become productive members of society, it is essential that all teachers have the knowledge to make appropriate adaptations so that every student with special needs or disabilities can become an active participant in the learning process. This basic statement brings to the forefront the complex nature of the issues of teaching science to students with special needs or disabilities. Because of that complexity, there has been much effort devoted recently to educating science teachers worldwide to learn how to make needed accommodations and adaptations and, therefore, to differentiate effectively the science curriculum for students with special needs (Smith & Sherburne, 2001).

To understand the scope of the problem, data from the U.S. school population provides one example: the United States Department of Education (2002) *Digest of Educational Statistics* indicated that in 2000–2001, 12.7% of the U.S. school population (6- to 21-year age group) was identified as eligible for special education services, up from 12.4% in 1995–96. The numbers, percentage of the total population and percentage of the population of students with special needs, are reported in Table 11.1.

Students with special needs are typically divided into two large categories that can overlap, those with physical impairments and those with cognitive, social-personal,

**TABLE 11.1**  
**Students with Special Needs (Ages 6–21) in the US, 2000–2001**

<i>Population</i>	<i>Number</i>	<i>Percentage of total</i>	<i>Percentage of special needs population</i>
Ages 6 to 21	45,264,278	100.0	
Individuals with disabilities	5,775,722	12.8	100.0
Learning disabilities			
Specific learning disability	2,887,217	6.3	50.0
Speech-language impairments	1,093,808	2.4	18.9
Mental retardation	612,978	1.4	10.6
Emotional disturbance	473,663	1.0	8.3
Hearing impairments	70,767	0.15	1.2
Orthopedic impairments	73,057	0.16	1.3
Other health impairments	291,850	0.64	5.1
Visual impairments	25,975	0.05	0.4
Multiple disabilities	122,559	0.27	2.1
Traumatic brain injury	14,844	0.03	0.2
Developmental delay	28,935	0.06	0.5

From US Department of Education (2002).

or intellectual disabilities. The first category consists of individuals with physical impairments, many of whom are considered to have the cognitive, social, and intellectual capabilities to potentially become career scientists, mathematicians, or engineers. Approximately 24% (1,386,173) of U.S. students with disabilities would fall into this group. Approximately 19% (1,093,808) of these students have speech and language impairments that require minimal accommodation in a science classroom or laboratory. This group is still significantly underrepresented in the disciplines of science. Historically, members of this group who succeeded in science were persons of special talents and exceptional persistence.

The second category of students, 76% of the total U.S. school-age population with disabilities, consisting of 4,389,549 students with cognitive or social-personal disabilities, often experience difficulty with science in secondary and post-secondary education. Some do have potential for the highest levels of science achievement, but they need assistance to have a career in science. For the others, a reasonable goal is general science literacy as opposed to a professional career in a science field.

## Exceptional Students and Issues of Race

The *National Research Council Report on Minority Students in Special Education and Gifted Education* (Donovan & Cross, 2003) indicated that minority students are overrepresented in U.S. special education programs. In the report, Donovan and Cross described the percentage of minority students in special education categories as compared with the majority population. The percentages of minority students identified with a learning disability (the largest classification of all disabilities) were reported as follows: Native American and Alaska Native students 7.45%, Black stu-

dents 6.49%, and Hispanic students 6.44%. In comparison, the percentage was 6.02% for White students. Percentages for developmental disabilities were 2.64% for Black students and 1.28% for Native American and Alaska Native students. Emotional disability ratios were 1.45% for Black students and 1.03% for Native American and Alaska Native students. States vary widely in how they determine students with disabilities. For example, at the extreme, the ratio for Black students being identified as developmentally delayed was 10 times higher in Alabama than in New Jersey.

The figures themselves explain nothing and hold the danger of reinforcing the notion that some groups are superior to others. A number of potential factors that can be generated to explain the performance of certain groups include poverty, family dysfunction, transience, and devaluing of academic achievement. These factors can be treated relative to the individuals involved rather than being ethnicity- or race-based. More importantly, these are mutable circumstances; appropriate interventions can serve to lessen their damaging effects.

The educational research community at times questions the labeling of students as holding special needs in science (or otherwise) by school personnel. In challenge to the research on special needs, Gray and Denicolo (1998) contested research that purported to be objective within an empirical-analytic paradigm. Instead, they advocated an alternative paradigm that attempts to challenge the normalization approach to teaching learners designated as having special needs. In science education, in a study that examined the science participation in an environmental education activity by two students who were labeled by their school as learning disabled, Roth (2002) supported Mehan's (1993) argument that the placement of learners into a special needs category resulted from how they were assessed in specific learning situations, and did not convey valid information as to their attributes across situations.

## Science for All

Within the field of science education, contemporary key science education reform documents have supported science education's goal of science literacy for all, regardless of any categorization of learners' abilities (McGinnis, 2000). The primary purpose of such documents is to provide a vision of the teaching and learning of science and to provide criteria for measuring progress toward that vision. In the U.S. *National Science Education Standards* (National Research Council [NRC], 1996), students with special needs are viewed explicitly as participating (as fits their ability and interest) in inquiry-based science classrooms.

The key principle guiding the development of the U.S. *Standards* (NRC, 1996) is "Science is for all students" (p. 19). This is defined as a principle of "equity and excellence" (or "fairness") (p. 20) that strongly advocates science in schools for students with special needs. In addition, all students are to be included in "challenging science learning opportunities" (p. 20). This equity principle is reflected in Teaching Standard B: "Teachers of science guide and facilitate learning" (p. 32). In order to accomplish this, it is imperative that teachers "Recognize and respond to student diversity and encourage all students to participate fully in science learning." "Students with physical disabilities might require modified equipment; students with learning disabilities might need more time to complete science activities" (p. 37).

The equity principle is also reflected in Program Standard E (NRC, 1996): "All students in the K–12 science program must have equitable access to opportunities to achieve the Standards" (p. 221). Actions to promote this include "inclusion of those who traditionally have not received encouragement and opportunity to pursue science" by "adaptations to meet the needs of special students" (p. 221). This equity principle is further reflected in Assessment Standard D (NRC): "Assessment practices must be fair. . . . Assessment tasks must be appropriately modified to accommodate the needs of students with physical disabilities [and] learning disabilities" (p. 85). This is not only an ethical requirement, but also a measurement requirement.

### **Legislation Affecting the Rights of Persons with Special Needs**

In addition to considering learning theory and science education policy documents, it is also necessary for researchers in this area to be knowledgeable about how legislation affects the educational rights of persons with special needs. It is informative with regard to the science education documents to note that Collins (1998) stated that policy documents such as the U.S. *Standards* were designed in a political context and were therefore "political in context, political in process, and political in intent" (p. 711). Special education in the United States found its present profile and substance through federal law, the Civil Rights movement, and resulting court cases, as well as the evolutionary influences of politics and society (Friend & Bursuck, 1999; Smith, Polloway, Patton, & Dowdy, 1998). The legislation having the greatest impact on educational practice in U.S. schools was passed in 1975. The Education for All Handicapped Children Act (1975) was passed by the U.S. Congress as PL94-142. The law required that children with special needs be provided a free and appropriate public education (FAPE) in the least restrictive environment (LRE).

The passage of this law mandated integration of students with special needs into general education classes with typical peers. The name of the law reflected the language of the day and required states to educate all students, regardless of disability (Lipsky & Gartner, 1997). The major components of this landmark legislation included FAPE for students ages 6 through 17; mandates for the creation, review, and revision of an Individual Education Program (IEP) for each student receiving special education services; a guarantee of placement in the LRE; and detailed parental rights (Sherwood, 1990; Tiegerman-Farber & Radziewicz, 1998). Public Law 94-142, a turning point for those with disabilities, addressed the issue of where students with disabilities would be educated, not simply whether they would be educated.

As a result of the passage of PL 94-142, many students with mild disabilities in the United States began a new era in the general education classroom and saw success. Students were placed in the LRE (Smith et al., 1998; Takes, 1993), or school districts created accommodations in the form of separate classes and separate schools for those with more severe disabilities. At the time, this was considered by most advocates as an equitable move forward because students with greater needs had previously been denied public education in any form.

The Regular Educator Initiative (REI) associated with PL 94-142 was viewed as a major first step in the movement to include students with special needs in typical

education settings (Fuchs & Fuchs, 1994; Schumm & Vaughn, 1991; Will, 1986), even though the term *inclusion* does not appear in the law itself. Although the students who benefited most from inclusion were those with mild disabilities (Lipsky & Gartner, 1997), a major milestone was achieved in making science (and other subjects) more accessible to students with disabilities.

The U.S. Congress has passed many laws designed to deal with the rights of people with disabilities, but it has taken a long time to enact and enforce them. Legislation from PL 94-142, Senate Bill 504, the Individuals with Disabilities Education [IDEA], and the 1990 Americans with Disabilities Act [ADA] were all initiatives intended to provide equal opportunities for persons with disabilities to experience the same full and independent life available to the general population. The legislation essentially extended equal opportunity to those with disabilities so they could experience the services and opportunities that were available to the general population. IDEA mandates that those identified as eligible for special services be given a free and appropriate public education, an education in the least restrictive environment, and an individualized education program (IEP) (Turnbull & Cilley, 1999).

Other significant U.S. legislative actions related to the education of learners with special needs include:

1. *Sections 501, 503, and 504 of the Rehabilitation Act of 1973.* The major impact of this legislation was to prohibit federal agencies, federal contractors, and recipients of federal financial assistance from discriminating against otherwise qualified persons with disabilities solely on the basis of disability (Tucker & Goldstein, 1992).
2. *Section 02 Amendments, 1978 & 1979.* These amendments authorized federal agencies to provide grants to state units overseeing work with people with disabilities; establish and operate comprehensive rehabilitation centers; and make the remedies, procedures, and rights of Title VI (Civil Rights Act, 1964) available to section 504 discrimination victims.
3. *Section 504 Amendment, Civil Rights Restoration Act of 1987 [CRRA].* This amendment clarified "program or activity" to mean all of the operations of a college, university, or other post-secondary institution, and that if federal financial assistance was extended to any part of an institution, all of the operations were covered.
4. *Education for All Handicapped Children Act [EAHCA] 1975.* This act required states to provide all children with disabilities with FAPE.
5. *Americans with Disabilities Act [ADA] 1990.* This legislation required that students with special needs would be served as much as possible in the general education classroom (Smith et al., 1998); that "handicapped children" was changed to "children with disabilities"; and that two new categories of disability, traumatic brain injury and autism, were eligible categories for special education services.
6. *Individuals with Disabilities Education Act [IDEA] 1990, 1997, 2004.* This act contained provisions concerning the rights of individuals with disabilities to receive an equivalent education and the opportunity to learn with other students of all abilities. It required the participation of the regular classroom teacher in the IEP process and in the delivery of an equivalent education.

## Review of the Literature

For heuristic purposes the review of the literature on special learners in science is presented in two subsections: Curriculum and Instruction, and Assessment.

### Curriculum and Instruction

The literature concerning curriculum and instruction in science of learners with special needs is associated with collaboration (the sharing of the teaching responsibility among educators of different professional expertise, content and pedagogy) and with the advocacy and study of inclusion (the placement of learners with disabilities in the general classroom, including science).

#### *Collaboration*

Collaboration is a supportive system in which teachers utilize the expertise of other educators to solve problems (Pugach & Johnson, 1990). Science teachers often find themselves isolated in their efforts to serve students with special needs who are placed in their classrooms (McGinnis & Nolet, 1995). Isolation makes teachers more resistant to the changes involved with including students with special needs. Perceptions that may interfere with effective collaboration can become ingrained in professional practice. Unless they are brought to the surface, they serve as persistent bottlenecks to collegiality between professionals.

Since the Education for All Handicapped Children Act (EAHCA) was enacted in the United States in 1975, learners receiving special education services have increasingly been served in the general education setting. The traditional dual system of general education and special education fostered definitive boundaries between these two areas, with little sharing of expertise and support. The concept of inclusion represented a radical departure from the typical school setting and involved, among other things, cooperative and collaborative efforts. There is no one standard model of collaborative service; however, Bauwens (1991) described three common models: teacher assistance teams, collaborative consultation, and cooperative teaching. Of the three basic models, cooperative teaching is the more frequently implemented practice in most school districts (Reeve & Hallahan, 1994). Cooperative teaching, also generically referred to as "collaboration," involves general and special educators coordinating efforts to jointly teach heterogeneous groups of students in integrated settings to meet the needs of all students (Bauwens & Hourcade, 1997).

McGinnis and Nolet (1995) reported one possible model for science teacher preparation and science instruction when the goal was for general and special educators to work collaboratively as way of meeting the science context needs (curricular, instructional, and evaluative) of learners with disabilities. They presented a model based on earlier reported work by Nolet and Tindal (1993). It was designed to bridge the gap between the fields of special education and science education by focusing on the development of what McGinnis and Nolet termed "a new professional relationship between the practitioners" (p. 32). The model was built on the premise that if the needs of the student with disabilities were to be met in authentic school settings, then the focus of the collaboration between the general and the special educator should be on science content and the effective teaching of such knowledge. Dif-

fering aspects of expertise were identified for the general science educator (key science knowledge forms: facts, concepts, principles, and procedures). They also identified for special educators the pedagogy of students with special needs (designing instruction, implementing classroom management, and motivational strategies).

Research in instituting collaboration has found that the underlying belief system within a school building must be examined thoroughly before embarking on a mission of collaborative change. The building administration must embrace the theory and concept behind collaboration, support the teachers initiating such a change, and provide structural supports that will allow the collaboration to occur. Walter-Thomas, Bryant, and Land (1996) suggested that administrators provide administrative support and leadership, select capable and willing participants, provide ongoing staff development, establish balanced classroom rosters, provide weekly scheduled co-planning time, facilitate the development of appropriate IEPs, and pilot test classroom and school collaborative efforts.

A belief system within a school that promotes open sharing among colleagues would be most beneficial to a collaborative model. Traditionally, educators have not always been prepared to share and work in a collaborative fashion with other teachers. They have been taught to be autonomous and self-sufficient, for the most part, within their classrooms (Leithwood & Jantzi, 1990). Because of the physical separation of individuals within a building, teachers historically have learned to accept this isolation as the norm or the existing condition of work in the education field. Many teachers, however, see this condition as isolation from the peers who can provide badly needed professional support within schools filled with high-need students. A collaborative environment may help provide the support teachers feel is needed under these conditions. Many schools are thus turning toward the establishment of collegial norms.

Special and general educators can work collaboratively on making adaptations, using the student's IEP as a framework and reference (Golomb & Hammeken, 1996). Myles and Simpson (1989) found that adaptations are most successful when general education teachers are involved in making decisions about designing and implementing the adaptations for students with disabilities.

### *Inclusion*

Mainstreaming, integration, and inclusion have all been used to describe the movement to meet the needs of learners with special needs in the general school setting. Inclusive schools are those in which students with and without special needs are educated together within one educational system (Stainback & Stainback, 1990). Research in this area is extensive. As result, this section is presented in subsections identified by their headings.

*Science as an inclusive setting.* As reported by McGinnis (2000), historically teachers inclined toward inclusion (a minority of all teachers) have identified science classes as especially suited for students with disabilities (Atwood & Oldham, 1985). These teachers identify the perceived relevance of the content, the possibility for practical experiences, and the opportunity for group learning with typical peers as the strengths of science classes for inclusion purposes (Mastropieri et al., 1998). However, this perspective does not mean that most contemporary teachers in science

(or otherwise) are comfortable including students with disabilities in their classrooms (McCann, 1998; Scruggs & Mastropieri, 1994; Welch, 1989). Instead, as reported by Norman, Caseau, and Stefanich (1998), both elementary and secondary science teachers identify teaching students with special needs as one of their primary concerns.

Contrary to the teachers' misgivings, findings reported in the special education educational research literature appear to support inclusion (including in science learning contexts) as a more desirable alternative than segregated instruction for students with disabilities. Ferguson and Asch (1989) found that the more time children with disabilities spent in general classes, the more they achieved as adults in employment and continuing education. This held true regardless of gender, race, socioeconomic status (SES), type of disability, or the age at which the child gained access to general education. Research reviews and meta-analyses known as the special education "efficacy studies" (Lipsky & Gartner, 1989, p. 19) showed that placement outside of general education had little or no positive effect for students regardless of the intensity or type of disability. In a review of three meta-analyses that looked at the most effective setting for educating students with special needs, Baker, Wang, and Walbert (1994) concluded that "students [with disabilities] educated in general classes do better academically and socially than comparable students in noninclusive settings" (p. 34). Their review yielded the same results regardless of the type of disability or grade level.

Regarding students with severe disabilities, Hollowood, Salisbury, Rainforth, and Palombaro (1995) found that including these students in the general education classroom was not detrimental to classmates. Other researchers (Costello, 1991; Kaskinen-Chapman, 1992) found such inclusion enhanced classmates' as well as their own learning (Cole & Meyer, 1991; Strain, 1983; Straub & Peck, 1994) and yielded social and emotional benefits for all students, with self-esteem and attendance improving for some students considered "at risk" (Costello). This research, coupled with strong public press to change current models of delivery in schools, provided a strong impetus for major educational reform.

Some researchers have generated questions about serving mildly developmentally delayed students via pull-out programs because of their limited growth abilities (Epps & Tindall, 1987; Idol-Maestas, 1983; Polloway, 1984). Other researchers have indicated that providing adaptations within the general education classroom instead of pull-out programs may prove to be more effective (Baker & Zigmond, 1990). Current research on effective schools and effective classroom practices supports the integration of students with special needs into general education classes (National Council on Disability Report, 1989).

Supporters of the early inclusion movement (1980s) cited such claims as basic rights of all individuals to have equal opportunity to life in a typical manner and attend school with typical peers, to participate as fully as possible (Ferguson, 1995; McNulty, Connolly, Wilson, & Brewer, 1996). Many researchers claimed that all students would benefit from having students with special needs in the general classroom (Fuchs & Fuchs, 1995; Lipsky & Gartner, 1998; McLeskey & Waldron, 1996; Ryndak, Downing, Morrison, & Williams, 1996; Stainback, Stainback, & Stefanich, 1996; Vaughn & Schumm, 1995). Mercer, Lane, Jordan, Allsopp, and Eisele (1996) found that teaching methods and strategies utilized in special education classrooms did not differ so drastically from those used in general classes. Service models that

required the students to leave the classroom for prescriptive services denied the students much valuable instructional time and socialization in the general classroom (Sapon-Shevin, 1996). Wang and Reynolds (1996) reported that when students with disabilities left their class to attend resource or pullout programs, they incurred a risk of being negatively labeled and stigmatized.

These researchers and others have documented that adaptations are often needed if students with special needs are to receive instruction in the content areas. In meta-analyses that examined the best setting for students with special needs, Baker et al. (1994) and Stainback et al. (1996) reported that learning core subjects such as social studies, science, and mathematics is beneficial for the long term for students with disabilities, including those with severe disabilities. These researchers and others have documented that adaptations are often needed if students with special needs are to receive instruction in the content areas.

*Approaches of professional organizations and the attitudes of teachers to inclusion in science.* Some professional organizations have voiced concerns over the inclusion issue. The spectrum of support for inclusive education ranges from total and unrestricted support from the Association of Persons with Severe Handicaps (1991) to cautious regard for a continuum of services while supporting inclusion (Council for Exceptional Children, 1993), concern for the provision of needed services (Learning Disabilities Association of America, 1993), and guarded caution by the American Federation of Teachers [AFT] (1994) and the National Education Association (1994) in supporting appropriate inclusion (Lipsky & Gartner, 1997; Vaughn, Schumm, Jallad, Slusher, & Saumell, 1996).

The AFT (1994) called for a moratorium on inclusion in response to expressed concerns about lack of teacher preparation addressing the need of students with disabilities in a regular classroom. Practitioners consistently cite the need for inservice opportunities to promote successful inclusion for both students with special needs (Sapon-Shevin, 1996). Research has indicated that the need for teacher inservice and skill development in serving students with disabilities through collaborative efforts is one of the most important aspects of the general educator's role in serving all students (Stainback et al., 1996; Sapon-Shevin, 1996).

Cawley (1994) reported that science teachers generally have little experience or preparation for teaching students with disabilities, and, in general, special educators have little or no exposure to science education. In a survey of special education teachers, Patton, Polloway, and Cronin (1990) found that 42% of special education teachers received no training in science; 38% of children in self-contained special education classes did not receive any instruction in science; among special educators who did teach science, nearly half devoted less than 60 minutes a week to science; and nearly 90% of the teachers surveyed depended upon a textbook for science instruction. Ysseldyke, Thurlow, Christenson, and Weiss (1987) reported that for students with mild disabilities, approximately 200 minutes of reading instruction was received for each minute of science instruction. Often when students with disabilities do receive science instruction, it is from special educators who have little, if any, training in science instruction (Gurganus, Janas, & Schmitt, 1995).

Lang (1994) found that the majority of instruction deaf students receive in science is from teachers with inadequate content preparation in the discipline. Less than 5% of teachers of deaf children reported a major in the physical sciences. Lang

concluded, "Although 86% of deaf students report liking science, their academic preparation is inadequate for post-secondary education" (p. 148).

In a study focused on undergraduate science teacher preparation, McGinnis (2003) reported that teacher interns (general education and special education populations collaboratively learning pedagogy) expressed differing beliefs concerning the inclusion of students with special needs in science classrooms. A significant finding was that the general education majors were more likely to support the inclusion of students with developmental delays, whereas those majoring in special education expressed reservations. An examination of the teacher interns' epistemological perspectives of learning (cognitive-based or behavioral-based), as well as their perspectives on group participation in inclusion classroom settings, offered explanatory insight into their inclusion/exclusion decision making. In addition, McGinnis reported an analysis of the ways in which teacher interns modified their science lesson plans to include a hypothetical learner with a developmental delay. In the majority of instances where interns supported the inclusion of the learner with special needs in general science lessons, the pedagogical action taken was to have others (the students' peers or a teacher's aide), rather than the science teacher, provide the learner support in the classroom, typically addressing only social needs. It was rare for any intern to use the ideas recommended by the literature to meet the student's intellectual needs. McGinnis concluded, "As a field, science educators are in moral jeopardy without a moral perspective in making decisions on the inclusion/exclusion of students with disabilities, particularly those with developmental disabilities, in the science classroom" (p. 212).

Stefanich (1994) reported on typical learners' attitudes toward the inclusion of learners with special needs in their science classrooms. He detected a concern for fairness. Too often both teachers and students perceive that equal treatment of all students is fair. This often becomes a barrier to the acceptance of inclusion with its necessary curricular accommodations for some students.

*Adaptations to facilitate inclusion and instruction of students with special needs in science.* The inclusion initiative has resulted in efforts to adapt science curriculum and instruction to provide students with special needs with rich experiences that they may not receive in traditional settings. However, because of the limited science background of many general educators, adapting science curriculum can present special challenges. According to a review of the relevant research by Scruggs and Mastropieri (1994), classroom teachers can successfully include students with disabilities in science when the following are present: administrative support; support from special educators; an accepting classroom atmosphere; effective teaching skills; student-to-student peer assistance; and disability-specific teaching skills.

When students with special needs are included for science instruction, the most commonly used approach is the content approach (Scruggs & Mastropieri, 1993). In this approach, textbooks are the primary source of curriculum and instruction. A contrasting approach is the activity-oriented approach. In this approach, the teacher may still employ direct instruction, but students are also actively engaged in the exploration of science concepts (Scruggs & Mastropieri). In the activity-oriented approach, the use of the textbook and the need for acquisition of new vocabulary is significantly decreased, and students can apply the processes of science—observa-

tion, classification, measurement, comparison, predictions, and making inferences. Activity-oriented approaches to science that address fewer topics in greater depth can be especially beneficial for students with special needs (Patton, 1995). Both content- and activity-oriented approaches can be adapted and modified to meet the diverse learning needs of students.

General education teachers do implement a wide variety of adaptations to meet student needs, but they do not always find that all types of adaptations are as readily implemented as others. The most feasible adaptations centered on using positive methods and multisensory techniques that were readily integrated into daily classroom routines (Johnson & Pugach, 1990). Adaptations less favorably rated involved dealing with students individually. Yesseldyke, Thurlow, Wotruba, and Nania (1990) found that teachers rated the following methods desirable classroom adaptations: identifying alternative ways to manage student behavior, implementing alternative instructional methodologies, using a variety of instructional materials, and using alternative grouping practices.

In many instances, it is appropriate and necessary for teachers to make curricular and instructional adaptations for students. Teachers use typical adaptations more frequently than substantial adaptations. Typical adaptations include altering the format of directions, assignments, or testing procedures. Substantial adaptations include changing the difficulty level for students, such as implementing altered objectives, assigning less complex work, and providing texts with lower reading levels (Munson, 1986). This research suggested that even though there are a wide variety of adaptation types, teachers will implement the types they are most comfortable with and understand. Teachers in effective schools feel that they have the instructional freedom to alter instruction and assignments to meet the individual needs of their students (Jackson, Logsdon, & Taylor, 1983). When teachers understand typical and substantial adaptations and believe that they have the freedom to make such adaptations, students in inclusive settings benefit.

Mauer (1996) supported the application of effective schools research in making curricular and instructional adaptations for all students, particularly those with special needs. Some characteristics of effective schools are directly related to the classroom teacher. Stefanich (1983) identified the attributes of teachers in effective schools that support the instruction of students with special needs: maintain a clear focus on academic goals; select instructional goals; perceive the students as able learners; implement an evaluation system based on individual student learning, rather than on a comparison with other students' achievements; accurately diagnose student learning needs to foster high student achievement; prepare lessons (including adaptations) in advance; meet students' needs in both academic achievement and socialization; be readily available to consult with students about issues and problems; attend staff development courses to continue your professional development; and keep parents informed and involved.

Multimodality instruction is especially critical in helping students with disabilities gain a familiarity with the content material. Scruggs, Mastropieri, Bakken, and Brigham (1993), in presenting suggestions for teaching science lessons to students with disabilities, stated that students with disabilities are likely to encounter far fewer problems when participating in activity-oriented approaches to science education. The use of multimodality approaches both in teaching and in assessment has shown positive effects (Cheney, 1989). Wood (1990) noted that strategies that

lend multiple exposures to new terms and concepts enhance opportunities for all students to understand that content more fully. As a result, actual examples or models are considered to be especially helpful to students with disabilities.

Curricular adaptations are often varied according to content and grade level expectations. They can be designed for groups of students and for individual students. Booth and Ainscow (1998) suggested that one type of curricular adaptation is allowing students to participate in setting their own learning and social objectives, combined with the teachers' objectives in the same areas. The students can then evaluate their progress on their goals as well as the teacher's goals. However, Stainback et al. (1996) warned that writing separate or varying learning outcomes for one student or small groups of students can foster a sense of isolation and separateness in the general education setting.

*The process by which teachers implement adaptations.* In inclusive settings, instruction can be adapted to ensure the academic success of all students (Smith et al., 1998). But to do this in content areas, such as science, a match needs to exist between the student's abilities and learning preferences and the curriculum and instructional methodologies. Stainback et al. (1996) stated: "Some students exhibit learned helplessness when there is not a good match between learning objectives and student attributes" (p. 14). Making adaptations for students is one way to create that match (Salisbury et al., 1994).

If teachers are given structures and supports for implementing adaptations, they will use them effectively in the general education classroom (Fuchs, Fuchs, Hamlett, Phillips, & Karns, 1995). Scott, Vitale, and Masten (1998) reported that when these support systems are in place, teachers make the necessary adaptations for students. Udvari-Solner (1996) found that when teachers decide what adaptations need to be implemented, they engage in a personal, reflective dialog with self-questioning. This leads to these same questions being posed when they meet in a group setting with other educators and parents. Parents often desire the opportunity to work collaboratively with teachers when determining appropriate adaptations for their children (National Council on Disability, 1989). This collaboration can foster positive relations between home and school, one of the effective school correlates (Salivone & Rauhauser, 1988).

When teachers determine whether adaptations should be made, the next question to consider is, what are the goals of such adaptations? Researchers such as Salisbury and associates (1994) argued that curriculum adaptations should achieve two main goals: promote positive student outcomes and optimize the physical, social, and instructional inclusion of the student in ongoing classroom lessons and activities. Creating an inclusive science classroom is thought to be a balance of designing an accepting environment, implementing effective instructional techniques, and adapting curriculum, materials, and instruction. Inclusive science classrooms are important for students (Patton, 1995).

Designing and implementing curricular and instructional adaptations in the science classroom is similar to those in other content areas. However, science adaptations can sometimes pose special challenges due to the nature of experiments and the materials used (Stefenich, 1994). Teachers must plan lesson adaptations in advance and anticipate difficulties that students may encounter with the materials needed or the science activity.

When teachers believe that the types of adaptations are feasible and desirable, they will use them (Johnson & Pugach, 1990; Ysseldyke et al., 1990). In inclusive settings where adaptations are made, all children can learn, feel a sense of belonging, and achieve their educational and social goals (Winter, 1997). Many teachers believe that they are skilled, accommodating, and willing to serve on IEP Teams in all aspects of planning and implementation of appropriate education for students with special needs (Friend & Bursuck, 1999). However, many also now believe that mechanisms are lacking to capitalize on their skills and respect their professional talents and limitations.

The role of the general educator in the development, implementation, and evaluation of IEPs has become a critical issue in response to compliance efforts of schools to IDEA 1997 (Fuchs & Fuchs, 1994; Sapon-Shevin, 1996). Studies at the secondary level indicate that although the majority of general education teachers who had learners with special needs included in their classes felt successful, over one-third of them received no prior or ongoing preparation or professional development for inclusion, and less than one-half had been involved in development of the IEP (Rojewski & Pollard, 1993). Other findings indicated that teachers did willingly make specialized adaptations when the IEP teams advised them to do so and supported them (Fuchs, Fuchs, & Bishop, 1992; Sapon-Shevin). Research studies indicate that many teachers do not attempt to meet IEP guidelines or modify or adapt any classroom procedures or expectations for any students with disabilities (Ysseldyke et al., 1990). Other studies indicated that adapted techniques may be highly desirable, yet practice does not follow the belief in some classrooms with mainstreamed students (Lipsky & Gartner, 1989, 1997; Reynolds, Wang, & Walberg, 1987; Turnbull & Turnbull, 1998).

## Assessment

Assessment is a major and necessary component of education. But the assessment of students with special needs in science and elsewhere typically leads to controversy. Some believe assessment can serve as a stimulus for education reform, whereas others think it is a deterrent to educational programs sensitive to individual differences.

Much of the controversy swirling around educational assessment exists because groups involved have different agendas, views on the validity and reliability of standardized assessments, concerns about how the results of assessment will affect the students being tested, concerns about how the results of assessment will be used to evaluate those giving instruction or delivering programs, concerns about how legislative bodies will use the information from assessments in funding and evaluating schools, concerns about the use of assessment in labeling and categorizing students, and concerns about whether the test(s) accurately assess the knowledge of the individuals and their ability to perform in tasks relating to qualifications.

Kohn (2001) asserted that school testing is driven by a top-down, heavy-handed, corporate-style version of school reform that threatens the basic premises of school improvement, and that the current high-stakes assessment system suits the political appetite for rapid, quantifiable results (Thompson, 2001). Innovations supported by best-practice research are overlooked particularly in communities where the need

for developmentally appropriate practice is most needed. Eisner (2001) expressed concern that when there is a limited array of areas in which assessment occurs, students whose aptitude and interests lie in other areas become marginalized. Science is particularly vulnerable. One of the easiest ways to raise test scores may be to teach in ways not recommended by the U.S. *Standards* (National Research Council, 1996), that is, to use direct instruction to present a huge amount of declarative knowledge in a superficial fashion (Kohn, 2001).

U.S. citizens have the right to (a) equal protection under the law and (b) due process when state action may adversely affect an individual. In education, constitutional rights translate into a guarantee of equal educational opportunity (not equal outcomes). Section 504 of the U.S. Rehabilitation Act of 1973 mandated that admissions tests for persons with disabilities must be validated and reflect the applicants' aptitude and achievement rather than any disabilities extraneous to what is being measured. The Education for All Handicapped Children Act (1975) PL 94-142 mandated that all children with disabilities receive a free, appropriate public education. It also mandated due process rights, responsibilities of the federal government in providing some financial assistance, and the requirement that special education services be monitored. According to Suran and Rizzo (1983): "The tests used to evaluate a child's special needs must be racially and culturally nondiscriminatory in the way they are selected and the way they are administered, must be in the primary language or mode of communication of the child, and no one test procedure can be used as the sole determinant of a child's educational program" (p. 175).

The passage of the Americans with Disabilities Act in 1990 (PL 101-336), although intended mainly for industry, has many implications for education, specifically for the licensing/certification/credentialing process. This act requires that the test application process and the test itself be accessible to individuals with disabilities. Although a person may not be able to meet other requirements of the credentialing process, he or she may not be barred from attempting to pass the credentialing exam. The agency or entity administering the test must provide auxiliary aids and/or modification and may not charge the individual with a disability for the accommodations made. Accommodations that may be provided include an architecturally accessible testing site, a distraction-free space, an alternative location, test schedule variation, extended time, the use of a scribe, sign language interpreter, readers, adaptive equipment, adaptive communication devices, and modifications of the test presentation and/or response format (Thurlow, Yesseldyke, & Silverstein, 1993).

Concerning performance examinations in science, the facilities must be accessible and usable by individuals. Acquisition or modification of equipment or devices, appropriate adjustment or modifications of examinations, qualified readers or interpreters, appropriate modification in training materials and/or policies, and other similar modifications must be made for individuals with disabilities (42 USC 12/11, Section 101(9)), who must provide documentation of the disability.

Research has indicated a continuing lack of responsiveness by science teachers to adjust the learning environment so that students with disabilities feel a sense of success and accomplishment. In an examination of science grades for over 400 students with mild disabilities in grades 9–12, Cawley, Kahn, and Tedesco (1989) reported that 50–60% of the grades were Ds or Fs. Donahoe and Zigmond (1990) reported 69%

of the science grades for ninth-grade students with learning disabilities were D or below.

Research has indicated that teachers should be cautious in their actions as a result of interpretations of student performance on standardized assessment instruments (Darling-Hammond, 1999). The use and interpretation of evaluation instruments is a fundamental concern in student identification for special services. Indeed, the validity and reliability of tests used for classification and placement has been repeatedly challenged (Gartner & Lipsky, 1987; Stainback, Stainback, & Bunch, 1989; Wang & Wahlberg, 1988). Gartner and Lipsky described these tests as "barely more accurate than a flip of the coin" (p. 372). Addressing the relative permanence of classifications based on these tests, Gartner and Lipsky reported that less than 5% of the students are declassified and returned to the general education classroom.

Many students with special needs are unable to demonstrate their true level of understanding under traditional testing conditions. Winter (1997) advocated the use of alternative assessment strategies for learners with special needs. Jones (1992) indicated that students with learning disabilities "often fail to develop efficient and effective strategies for learning. They do not know how to control and direct their thinking to learn, to gain more knowledge, or how to remember what they learn" (p. 136). Women and/or minorities with disabilities face even more obstacles to obtaining quality education because of the compounding effect of the disability with other actions of discrimination and/or low expectations.

## Conclusions

A key principle in the U.S. *National Science Education Standards* (NRC, 1996) is to provide all students in science with challenging learning opportunities appropriate to their abilities and talents. Many students who are capable of high performance in science are labeled as students with disabilities because of low performance or limitations in other areas not related to reasoning in science. Science teachers must be prepared to recognize these differences and respond to the unique learning needs of each student. Evidence indicates that both practicing and prospective science teachers note the inadequacy of their preparation to make instructional adjustments for students with disabilities.

Other limitations are evidenced when students receive instruction in science primarily from special educators, including time allocated to science, delivery of science through textbook teaching as the primary mode of instruction, and limited teacher knowledge of the science content. Science teachers themselves are generally open to typical adaptations (i.e., format of directions, assignments, and testing) but seldom make substantive accommodations (i.e., altered objectives, less complex work, alternative texts) for students.

Accommodations consistently found to improve the learning of all students are teaching through multimodality instructional approaches, allowing students opportunities to resubmit and improve assignments, and willingness to collaborate with other educators about ways to better serve the needs of all students. Modifications that allow students with disabilities opportunities to share what they have learned in both formative and summative assessments (that are required in

U.S. legislation) result in improved student participation in and commitment to the learning process.

There is no substantive empirical evidence that students with special needs process information differently than other students. Coles (2004) surmised that, after a skill is attained, brain activation changes toward that commonly found in individuals with good use of the skills. When a student has difficulty learning a skill or concept, causes can be difficult to diagnose. Effective teaching of students with special needs must be grounded in interaction between the learner and the learning environment, making efforts to understand the cognitive processing that occurs. Currently, much controversy exists as to whether exceptional learners require approaches to instruction not contained in the repertoire of general classroom teachers, or whether adaptations of well-known instructional practices are sufficient for the vast majority of students. Findings from research on student performance indicate that teachers who use greater variety in their teaching and take time to get to know their students are more effective with all students, regardless of ability.

### **Future Research Directions**

In general, a question certain to be addressed in the U.S. courts (as the newest legislation covering the educational rights of persons with disabilities is enforced) is the extent and degree of responsibility educators have in accommodating the educational needs of students with disabilities. Research that documents the extent and efficacy of science curriculum, instruction, science teacher education context, and assessment of students with special needs is urgently needed.

Other, more specific research questions to investigate include: How have teachers (with data disaggregated by school level and by science discipline) included students with special needs (with data disaggregated by type of disability and personal characteristics) in the general science classroom? What has been the outcome of such efforts across multiple dimensions (e.g., class ecology, curriculum and instruction, and assessment)? What types of teacher professional development throughout the teacher professional continuum have been designed to prepare teachers to teach students with special needs, and what outcomes have those experiences had on the teachers' practices? What outcomes are associated with the differing approaches to teaching science to learners with special needs, and to what extent do these outcomes align with local and high-stakes assessment requirements? What sense do teachers make of adaptations for learners with special needs in science, and how does their perception of their school culture influence such understandings and actions? What strategies help teachers to make adaptations for learners with special needs in the science classroom? From the general classroom teacher's perspective, what mechanisms and strategies would support them in contributing productively at meetings for learners with special needs in their science classrooms? How are the various collaboration models between the general science teacher and the special educator enacted in school environments? To what extent and with what limitations do the various models help learners with special needs to learn for understanding as well as to perform on assessment tasks (traditional as well as alternative)? From the perspective of learners with special needs, how do they access the general curriculum in science? We wonder what new insights in research in special needs

might emerge if researchers posed such questions and used alternative paradigms outside of the objectivist paradigm.

## PART II: SPECIAL TALENTS IN SCIENCE

George DeBoer, in *A History of Ideas in Science Education* (1991), pointed out that in the field of science education, particularly with regard to the U.S. context, a long-standing barrier to meeting the unique needs of learners with special talents was sensitivity by educators to avoid charges of favoritism. Spurred on by concerns for national security in the post-World II period, the American Association for the Advancement of Science (AAAS) Cooperative Committee argued that, by not recognizing the special abilities in talented learners, science education was committing a double error: (a) not addressing the unique educational needs of such individuals and (b) not developing a national resource that was in high need (DeBoer). Although the record since that period has not been an unqualified success for learners with special talents in science, progress has occurred.

Learners with special talents in science previously have been referred to as "gifted." Contemporary labels seek to describe this group of learners by placing a greater focus on "creativity," "extraordinary abilities," or "talents" (i.e., observable performances in situated events, context, and domain-specific activities) rather than relying solely on superior test-taking performances (academic or IQ examinations) (Ericsonn & Charness, 1994). Maker (1993) described such a learner as a problem solver who "enjoys the challenge of complexity and persists until the problem is solved . . . [and who is capable of] a) creating a new or more clear definition of an existing problem, b) devising new and more efficient or effective methods, and c) reaching solutions that may be different from the usual, but are recognized as being effective, perhaps more effective, than previous solutions" (p. 71).

Tannenbaum (1997) proposed two types of talented individuals: performers and producers. Performers are those who excel at "staged artistry" or "human services" (p. 27); producers excel at contributing "thoughts" and "tangibles" (p. 27). Other theoreticians, such as Piirto (1999), placed attention, especially in precollegiate education, on precocity (the ability to easily do those things typically seen in older learners) as a hallmark of the talented.

As result of the multiple views of researchers, policymakers, and education professionals interested in education for the talented, between 3% and 15% of the student population can be identified as fitting into this category of learners (Hardman et al., 1999). Whitmore and Maker (1985) and Willard-Holt (1998) investigated talented learners in the population with special needs (visual, hearing, physical, and learning disabilities population) and suggested that a similar percentage would apply to the identification of the talented in that group of learners as well.

### Legislation Affecting the Rights of Talented Learners in Science

In contrast to U.S. legislation that mandates educational services for learners with special needs, learners with talents in science (or any areas) have no such legal entitlement. Instead, the U.S. federal Gifted and Talented Children's Act of 1978 and the

1993 Javits Gifted and Talented Education Act provided definitions of talented learners as well as some funding to support a national research center, demonstration programs, and activities for leadership personnel throughout the United States (Gallagher, 1997). Accordingly, funding for talented learners in science is a state and local issue. The U.S. Department of Education's (1993) definition of the talented is:

1. Children and youth with outstanding talent perform or show the potential for performing at remarkably high levels of accomplishment when compared with others of their age, experience, or environment.
2. These children and youth exhibit high performance capability in intellectual, creative, and/or artistic areas, possess an unusual leadership capacity, or excel in specific academic fields. They require services or activities not ordinarily provided by the schools.
3. Children and youth with outstanding talents are present in all cultural groups, across all economic strata, and in all areas of human endeavor. (p. 3)

## **Review of the Literature**

For heuristic purposes the review of the literature on talented learners in science is presented in two subsections: Curriculum and Instruction, and Identification of Talented Science Learners.

### *Curriculum and Instruction*

The basic principles of education for the talented have been identified as acceleration of content delivery, selective grouping of the learners, and enrichment of the curriculum (VanTassel-Baska, 2000). Research on the study of curriculum and instruction for talented learners in science has examined two intervention models: a specialized administrative model (enrolling only talented learners) and a general education model (differentiation of instruction for all ability groups). Other studies have sought to document and understand the perspectives of all stakeholders (administrators, teachers, learners, and parents) concerned with science education for the talented.

*Intervention models.* Researchers have sought to understand the impact of special programs in science, such as accelerated summer experiences or specialized school science courses, designed to meet the needs of talented learners. This intervention model is the specialized administrative model. Wolfe (1985) reported an in-depth study of 23 talented learners in science who participated in the McGill Summer School for Gifted and Talented Children in Montreal. The researcher's focus was determining from the learners' perspectives what messages about science were conveyed when an instructional intervention was used. The pedagogical intervention approach focused on developing six talent areas (creativity, decision making, planning, forecasting, communication, and thinking ability) to enhance the inquiry skills of the learners. From analyses of the classroom interactions in five science lessons, Wolfe determined that only two inquiry skills were being developed in the lessons, and in such a manner as to promote an unacceptable sensationalist view of science.

Lynch (1992) examined the effectiveness of an accelerated summer program in science (biology, chemistry, and physics) at Johns Hopkins University that taught talented learners (ages 12–16) a year of content in three weeks. The study extended over six years and included 905 learners. Lynch found that the summer program effectively prepared learners to accelerate in science content, and that the learners also benefited by beginning high school sciences earlier than regularly allowed. In a similar line of investigation, Enersen (1994) surveyed a sample of talented secondary students ( $N = 161$ ) who had attended high school summer science residencies and found that their attitude toward science increased by participation. In a follow-up survey, most students reported that they were studying or working in scientific fields (no difference between genders). Bass and Ries (1995) investigated the scientific reasoning abilities of talented students in a high school's gifted education program. The researchers designed a data collection strategy that used analogous problems and questions to measure understanding of basic scientific concepts and skills. They determined that the talented learners did not uniformly benefit from the experience; their performances varied on measures that documented their ability to solve different kinds of scientific problems.

Jones (1997) reported on a six-year pre-collegiate intervention program designed to prepare academically talented, lower socioeconomic minority learners for college. The Young Scholars Program at Ohio State University transformed the way agriculture was presented to the learners. Success was measured in achievement and in career interest. In a series of evaluation studies that measured the curricular impact on elementary-level talented learners in science, Boyce, VanTassel-Baska, Burruss, Sher, and Johnson (1997) and VanTassel-Baska, Bass, Ries, Poland, and Avery (1998) reported that problem-based learning and integration of disciplines in science benefited talented learners, as measured by increased motivation, enhanced process skills, and greater ability to make intra- and interdisciplinary connections. In an exploratory study that sought to understand how a sample of talented secondary learners displayed domain-relevant skills possessed by experts in disciplinary content knowledge, Fehn (1997) found that the talented learners in science among his sample varied most widely in critical abilities (interpretation, evaluation for bias, and synthesis). The talented science learners who had previous experience with primary sources in history performed better than those with no experience. Fehn speculated that this finding had strong implications not only for teaching the history curriculum to talented science learners, but for all instructional contexts that required such skills.

Renzulli, Baum, Hebert, and McCluskey (1999) reported on the problems of underachievement by high-ability learners. The researchers presented a new perspective and advocated a strategy to increase success for such learners. *Type III Enrichment*, an educational experience for the talented, encouraged learners to take on the role of actual investigators by studying problems of their choice. The learners were responsible for carrying out their investigations with appropriate methods of inquiry and presenting their findings to an audience. Over 80% of the learners showed gain in the areas of achievement, effort, attitude, self-regulated behavior, and positive classroom behavior. This evidence supported the work of Fort (1990), who had earlier argued for talented learners in science to be allowed to conduct independent research projects.

Another intervention model that researchers have examined is the general education model, in which talented learners in science share the experience with other

learners. In a study that examined the impact of mixed-ability classes for science learning in secondary schools, Hacker and Rowe (1993) reported negative results. They found that the mixed-ability class resulted in deterioration in the quality of classroom interactions of both high- and low-ability learners. However, in a study that investigated the differentiation practices of a sample of Scottish secondary science teachers, in which differentiation was defined as teaching individual students in a class at different paces and in different ways, Simpson and Ure (1994) reported evidence of success. Success resulted when teachers shared with their learners (of varying abilities, including the talented) the management of their learning, promoted the belief that achievement can improve, used a wide range of information and support, identified a range of needs, and gave and received continuous feedback.

*Perspectives of talented learners, parents, and school personnel.* In addition to researchers' interest in examining the impact of intervention models, they have investigated the perspectives of talented learners, their parents, and school personnel along a range of topics. Johnson and Vitale (1988) conducted a survey study of a large sample of South Dakota sixth- through tenth-grade talented learners to measure their perceptions of science. The learners enjoyed science as a discipline and believed it should be a national priority. They thought that science made the world a better place to live, improved the standard of living and the development of the country, and helped to solve everyday problems. However, students reported that, in general, school science was not challenging.

Lynch (1990) investigated credit and placement issues for talented learners in science following accelerated summer studies in science and mathematics. She reported that although the learners and their parents appreciated the acceleration, their schools were less receptive. Schools had practical concerns about how to incorporate the summer credits into existing academic programs and appropriate course placements for the learners.

Cross and Coleman (1992) documented by survey methodology the perspectives of a high school sample ( $N = 100$ ) of talented learners in science. The key finding was that the learners felt restrained by the pace of instruction and the science content of their science courses. They expressed frustration with the lecture-memorization instructional strategy and desired to be more challenged academically.

### *Identification of Talented Science Learners*

The identification and description of learners who would be considered talented in science has been of interest to the research community. Brandwein (1955) wrote a widely read and influential book, *The Gifted Student as Future Scientist*, which along with presenting ideas for increasing the number of talented students in science, began the contemporary conversation on the identification of talented learners in science.

School districts' reliance on aptitude tests to select for talented science learners has drawn the interest of investigators. Piburn and Enyeart (1985) compared the reasoning ability of a large sample of elementary students (grades 4 to 8) designated as gifted ( $n = 217$ ) and mainstreamed ( $n = 91$ ) who were enrolled in the same science-oriented advanced curriculum. The researchers used a battery of Piagetian measures designed to assess combinatorial reasoning, probabilistic reasoning, and

the ability to isolate and control variables. They found that their study sample of talented science learners was accelerated over the mainstreamed comparison group by more than two grade levels. Piburn and Enveart concluded that results had implications for how to select talented students for local enrichment programs in science. Instead of complete reliance on standardized aptitude tests, they argued for additional use of a full battery of reasoning ability tests.

Jarwan and Feldhusen (1993) studied the procedures used in selecting talented learners for state-supported residential high schools for mathematics and science. The researchers used both quantitative and qualitative research designs. They determined that the learners' home school adjusted grade-point average was the best predictor of first- and second-year grade-point averages. Their performance on the Scholastic Aptitude Test was the second best predictor. Most significantly, they determined that statistical prediction was superior to professional prediction by interview or ratings of learner portfolio files. In addition, they determined by examination of enrollment data that African American and Latino learners were underrepresented.

## Conclusions

Researchers' attention has been drawn to understanding how talented learners in science can be assisted to perform to the best of their abilities in science. A limited number of studies have investigated what talented learners have gained academically from participation in specific science programs and what perceptions talented learners express about science and their schooling. Limited findings suggest that talented science learners do benefit from learning situations that decrease the focus on memorization of information and increase opportunities for problem solving and inquiry.

Although the current research in science education has not determined which type of intervention model is most effective for talented learners (acceleration or enhancement), available evidence suggests that both types of models offer benefits and challenges that call for further exploration. Summer science acceleration programs for the talented have resulted in measurable academic and attitudinal gains.

There is a paucity of research concerning the instructional and learning process for learners with special needs who also have special talents. One limitation is a lack of legal entitlement for students with special needs who meet or exceed academic proficiency requirements. Additional services to address their talents are often ascertained as a general classroom issue without the same type of IEP reporting requirements of those identified with academic learning deficiencies.

Researchers have examined possible ways to identify talented science learners. The limited research in this area suggests that complete reliance on aptitude tests is not warranted and that other measures should be considered (including interviews and reasoning ability instruments).

## Future Research Directions

Because of the limited nature of research in science education for talented learners, research is urgently needed in key areas. Recommended specific research questions

include: What happens to the talented female learners in science as they proceed through their educational programs (mixed-ability and high-ability groupings)? What happens to the talented learners in science with special needs as they proceed through their educational programs (mixed-ability and high-ability groupings)? What happens to the talented learners in science from different cultural backgrounds or living in poverty as they proceed through their educational programs (mixed-ability and high-ability groupings)? And, what relationship, if any, exists between the identification of talented learners in science and the types of outcomes that the talented programs in science are designed to achieve?

## CONCLUDING THOUGHTS

There is continuing tension in the research of exceptional learners in science. A major reason for this tension is special education and science education researchers' use of different theoretical views on learning and teaching. Special education researchers' widespread use of behaviorism as a theoretical lens in research is often in conflict with science education researchers' more common use of cognitive and sociocultural views of learning and teaching. Science educators' strong commitment to inquiry for all in science learning and instruction, as opposed to a focus on skill and information acquisition, contributes to a discernible schism between these two fields of educational research. As a result, researchers in this area who seek cohesion will find that need unmet at this time.

Compounding the epistemological disagreement among researchers interested in understanding the learning in science by exceptional learners is the unique role of legislation in regulating the education of exceptional learners. A clear consequence of the legislative involvement is that a preponderance of researchers have focused their attention on pressing issues of curriculum and instruction within the legal and administrative contexts of schools. The hope is that future research on exceptional learners in science will be expanded to address more fundamental questions of learning theory.

## ACKNOWLEDGMENTS

Thanks to Janice Koch and Sharon Lynch, who reviewed this chapter.

# CHAPTER 12

---

## Science Learning in Urban Settings

**Angela Calabrese Barton**

*Michigan State University*

Last year I was interviewing a group of sixth-grade students from a high-poverty urban school in New York City. I had spent a great deal of time with them in an after-school program and thought I had a good sense of what they cared about. I had also spent time in their science class. The science class was interesting, primarily because most students held strong opinions about the teacher, Mr. Logan. Nearly all of the students I talked to believed that Mr. Logan was a good science teacher. Yet, nearly all of the students also said that they did not like science class!

As I began to probe this contradiction with the students, I said to them, “Tell me about one thing you learned in science class today.” I was immediately struck by their overwhelming response: “We didn’t learn anything!” On the one hand, I knew that Mr. Logan had spent time that week talking about the parts of cells and was getting the students ready to make their own cell models. I had the urge to say to this group of students, “Come on, of course you learned something! What about the cell?” On the other hand, I wanted to explore why they thought they really had not learned anything at all. What did the students really mean by their statement about *not learning*?

As I reflect on this experience, my gut reaction to the students’ response is that students are learning all of the time whether they realize it or not. However, *what* students learn and *how* they learn it are open for debate. In other words, learning is oriented toward an outcome (what are students learning?) and a process (who is learning, and when, where, and why?).

When learning is referred to as a *product* it is often conflated with achievement. Indeed, the past 20 years have given rise to a number of carefully documented studies focused on student achievement as an outcome measure of student learning. It is well established that these studies have helped to quantify and clarify the very specific challenges faced in urban science education. Achievement studies have highlighted who is (and is not) achieving, demonstrating that gaps in achievement still exist between ethnic, racial, and socioeconomic groups as well as between

high-poverty and non-high-poverty urban students (see also Chapter 8, this volume). Achievement studies have also spurred more focused investigations that examine reasons for differential achievement in urban centers, including access to resources, teacher qualifications, and other classroom-related barriers.

When learning is referred to as a *process*, it is often discussed relative to a given context (*What* are students learning? *Where* are students learning?) and characterization (*What* actually constitutes learning in these settings?). Situated cognition theories tell us learning ought to be considered as a form of participation, with individuals and contexts intertwined. This lens for understanding the process of learning underscores the importance of both culture and community. In her study of urban high school students participating in a summer gardening program, Rahm (2002) pointed out that what accumulates through participation in science is not only deepening understandings of scientific facts, but also a way of talking, acting, and becoming a member of a community. Understanding learning as a process is also important in urban science education because it influences how we understand what students are learning and the means by which they do so.

Thus, I find myself contemplating the questions: What learning matters in high-poverty urban science classrooms and who should decide when learning takes place? What does learning in these urban classrooms feel like and sound like from different stakeholders' perspectives? The students I interviewed attend a school that is labeled as failing, and they exist in a system marked by high-stakes exams, strict rules regarding behavior, and certain ways of knowing that are deemed acceptable. In addition, their teachers are not always encouraged to be attentive to their students' home languages and cultures. Their educational futures are not always determined by whether they believe they have learned something—or anything—in their science class.

## FRAMING QUESTIONS

In this review, I begin by examining those studies that document the outcomes of student learning through achievement, attempting to show how these studies have laid a foundation for the characterization of who is learning (and who is not learning) science in urban centers. As part of this review, I include a discussion of those studies that draw upon achievement patterns to examine the barriers or obstacles that frame opportunities to achieve in science. Thus, the questions I take up in the first section include the following:

1. Who is learning science in urban schools?
2. What are the conditions that mediate student achievement and learning?

Second, I move on to those studies that examine the process of learning in urban science settings and examine how science learning is mediated by context, including those contextual factors that influence not only how students learn (i.e., discourse, culture, etc.) but also what students learn in the name of science instruction. As part of this review I closely examine the tools researchers use to document the “differences” in the language, culture, and practice of science that mediate learn-

ing in science classrooms. Thus, the questions I take up in this second section include these:

1. What are the primary tools that urban science education researchers employ to understand and bridge differences in what and how urban students learn science?
2. What else are students learning in science class besides science?

As these questions suggest, learning as a process cannot be divorced from the process of teaching. Therefore in my discussion of these questions, I will also take up issues of teaching relative to when and how students learn.

Before I delve into either set of questions, however, I want to backtrack for a moment to address two additional questions: First, why is it important to understand learning within a uniquely urban context? Second, what kinds of articles are included in a review on learning and urban science education and why is this so?

## URBAN SCIENCE EDUCATION THROUGH RESEARCH

There has been a growing interest in urban science education studies over the past 10 years. As a result, a growing number of published articles in journals like *Science Education*, *Journal of Research in Science Teaching*, *Research in Science Education*, and the *International Journal of Science Education* have titles that include words like *urban* or *city*. As I have reported elsewhere (Calabrese Barton, 2002), urban science education research, in a broad sense, studies the intersections among students, their families and their teachers, science, schooling, and the historical, physical, environmental, social, economic, and political aspects of urban life. This perspective suggests that urban science education research is especially attentive to the forces that frame the urban context through both the research questions and methods, and that the analysis and subsequent knowledge claims made reflect a propensity for generating a specialized knowledge based around urban science education.

Therefore, I developed a list of 39 articles<sup>1</sup> that I believe fit into urban science education studies and that address issues of student learning. To develop this list of articles, I examined the contents of the major science education journals over the past decade for relevant studies. I then examined the reference lists in these studies, which led to additional articles. I also used the search engines ERIC, First Search, and Ingenta to conduct a refereed journal-wide search for urban science education articles. I analyzed each article for questions, research frameworks, guiding assumptions, and findings.

The selection of these articles, by the nature of what they report, places further boundaries on what is reported in this chapter. First, the majority of the articles

---

<sup>1</sup>For the purposes of this review, I relied only on articles published in research-oriented refereed journals, and primarily upon those articles published in the major research-oriented science education journals (*International Journal of Science Education*, *Science Education*, *Research in Science Education*, and *Journal of Research in Science Teaching*).

focus on those aspects of urban life that contribute to the great divide between those urban communities that have and those that do not. In some cases, published reports reviewed here use the word *urban* synonymously with *urban poverty* or *urban minority*. I want to avoid this assumption in this chapter. However, because of the nature of the studies published in the science education literature, urban studies have taken a decidedly focused perspective on poverty, race, and language issues. Additionally, urban schools in the United States, for example, are “more likely than ever to serve a population of low-income, minority students, given increased residential segregation and recent court decisions releasing schools across the country from desegregation orders” (Oakes, Muir, & Joseph, 2000, p. 5). Second, the vast majority of the studies I reviewed were situated in the United States. I recognize that this limitation is partly my responsibility, as I only reviewed articles available in English. To compensate for this limitation, I have tried to point out the differences in the urban issues of concern in the United States and how this may or may not differ from other geographic and national locations.

## ACHIEVEMENT IN SCIENCE IN URBAN CENTERS

In contemporary educational discourse, achievement and learning are often conflated. In a detailed study commissioned by the Council of Great City Schools, Snipes, Doolittle, and Herlihy (2003) found that urban districts effective in promoting student achievement across racial and socioeconomic gaps “focused on student achievement” and encouraged teachers “to use achievement data as a tool to help them improve instructional practice, diagnose students’ specific instructional needs, and increase student learning/achievement” (p. xx). As these authors suggest, conflating achievement and learning is generally the result of targeting the outcomes of the learning process, as high-stakes assessments generally do. Outcome measures of learning, however, must be part of the science learning conversation because of their profound implications for urban students. For example, recent legislation in some states in the United States has linked high-stakes outcome measures with state-endorsed diplomas, school funding, and teacher pay.

The studies reported below reveal three key findings: (a) that a significant gap exists between urban and suburban learners, and that this gap is punctuated by differential achievement between White students and students from minority backgrounds; (b) that the achievement gap is a function of the sociocultural status of learners; and (c) that the achievement gap is also a function of students’ and teachers’ access to resources to support the teaching and learning of science. Thus, in what follows I review studies that examine (a) urban science achievement patterns across sociocultural status and access to resources and (b) the function and form of resources in urban science student achievement and learning.

### **The Urban Science Achievement Gap Is a Function of Sociocultural Status**

Norman and his colleagues (Norman, Ault, Bentz, & Meskimen, 2001) offered an in-depth analysis of the achievement gap between White students and Black students in urban America. This study demonstrates that there exist “multiple achievement

gaps" among urban science learners and that these gaps are a complex phenomenon, sustained by a complex organization of factors that frame urban communities, such as race, ethnicity, immigration patterns, and socioeconomic status.

Using a historical macro-analysis, Norman et al. (2001) suggested that a significant gap exists between Black and White students, and that this gap has a distinctly urban-suburban undertone, given the demographic patterns that mark urban and suburban settings in the United States. However, in comparing his finding for urban Black Americans with other ethnic and racial groups over the last 100 years, Norman et al. argued that the achievement gap in urban science classrooms more likely reflects the *sociocultural* position of groups in society rather than racial differences. To make a case for achievement as a sociocultural phenomenon, Norman et al. presented an analysis of the different achievement gaps in the United States during the twentieth century. Their analysis reveals that at different times achievement gaps existed and then disappeared for a number of immigrant groups, that these groups had a low scholastic profile at the same time that they occupied a low-status position, and that as the immigrant groups became mainstreamed and assimilated, their achievement gaps diminished and they generally moved away from urban centers into more suburban locations.

Norman et al.'s study (2001) suggests that achievement gaps are complex phenomena that shift over time with changing populations and changing contexts. This study sheds light on the complex phenomenon of the achievement gap, and it raises many questions worth pursuing. First, within the urban Black population, do these same trends hold for the multiple ethnic populations? Are similar trends found for Latino populations for whom similar sociocultural barriers also exist within U.S. society? How might a micro-analysis of urban Black Americans who defy the achievement trends in the United States provide insight into how sociocultural status and school success overlap? One major implication of this study is that actual achievement gaps may be a reflection of a combination of other gaps, including a group's social and political power, knowledge of U.S. systems such as schooling, and access to resources.

## **The Urban Science Achievement Gap Is a Function of Resources**

Most researchers are generally familiar with the chilling statistics that describe high-poverty and minority urban students' differential access to resources in U.S. schools. Students attending poor, urban schools in the United States by and large have limited access to updated scientific books and equipment and science-related extracurricular activities (Oakes, 1990). They also have limited access to certified science teachers or to administrators who could support high-quality science teaching, such that students are either denied high-level science courses (because they are not offered) or they take courses with uncertified or unqualified teachers (Darling-Hammond, 1999; Ingersoll, 1999). High-poverty urban students are disproportionately tracked into low-level classes where educational achievement typically focuses on behavior skills and static conceptions of knowledge (Oakes, 1990). In fact, some studies have shown a complete absence of science in low-track urban science classes (Page, 1990).

The impact of differential access to resources has been particularly detrimental to urban students. Oakes' studies (1990; Oakes et al., 2000), which analyzed student scores on national exams and course-taking patterns in California, reveal that although both achievement and course-taking have increased for all groups of urban students, serious gaps remain between White and non-White students and between high-poverty and non-poverty students, and that these gaps correlate with inequalities in opportunities to learn between schools and within them (Oakes et al., 2000).

Similar studies have been conducted in Australia. Two studies in particular compare student achievement in urban versus rural settings and demonstrate the complexity of the relationship between location, resource availability, and achievement. It is worth examining these studies in detail. Using data from the Third International Mathematics and Science Study, Webster and Fisher (2000) conducted a multilevel analysis, which took into account school-, classroom- and student-level variance, to determine levels of achievement in Australian urban and rural communities and their association with location and access to resources. Although larger variances in achievement were noted at the student level when issues of socioeconomic class and sex were considered, when researchers controlled for these differences at both the classroom and school level, rural schools demonstrated statistically significant positive differences in achievement. In making sense of these differences, researchers noted that "contrary to what has been written previously, the information provided by the schools in this study shows that rural schools are more adequately resourced than urban schools." However, researchers noted that access to resources was a factor in student achievement significantly only at the student level rather than also at the school level. This study is important, and its findings suggest the need for further investigation into how achievement trends may vary when the analysis more rigorously accounts for location, such as the differences in kinds of urban and rural locations investigated.

This concern has been taken up in part by Young (1998), who, by using multilevel modeling techniques in an effort to question the generalizability of the comparison of rural with urban schools, found that the location of the school had significant effects on achievement. Her study revealed that differences in achievement were more pronounced among students from remote locations. In particular, she determined that when achievement levels were examined only in Western Australia, students attending rural and remote schools did not perform as well as those students in urban schools, nor did they have access to as many resources as students from urban schools. This study indicates the importance of general access to resources in student achievement; but it should also be noted that when these data were analyzed relative to student socioeconomic status, sex, aboriginal status, English-speaking background, and academic self-concept, the size effect of these findings is relatively small.

These two Australian studies, therefore, indicate the importance of the relationship between access to resources and student achievement in science in urban versus rural settings. However, they also show how complex student achievement relative to location is, and how models developed to explain differences need to consider the nuances of specific locations and student ability differences. Like Norman et al.'s study (2001), which demonstrates the complexities in how achievement gaps ought to be understood as both individual and group phenomena, this study also suggests that careful consideration must be given to how individual factors inter-

relate with broader-scale factors (i.e., classroom, school, regional, social) to confound larger effect size. In urban science education studies this is of particular importance, given that higher-level policy discussions around educational practices in urban settings, like New York, have been based on generalized large-scale learning outcomes.

Thus, this collection of studies highlights the conditions under which many high-poverty and minority urban youth attend school and the impact the conditions have on their growth and development as science learners. They also set a baseline measure of differential access and opportunity and challenge basic assumptions around how access to resources in urban contexts changes across countries and even within countries.

### **The Form and Function of Resources and Science Achievement**

The next series of articles examines what actually counts as resources and how resources are activated in the support of opportunities to learn science.

The most comprehensive set of studies that has examined access to resources has been conducted at the school, system, and state levels. In her research on the *Equity Metric*, Kahle (1998) demonstrated a relationship between differential achievement and access to resources. The *Equity Metric* advances our understanding of how achievement suffers in under-resourced schools, such as those in high-poverty urban centers, because it quantifies a set of human, social, and material resources to make sense of how well a school is moving toward equity goals. Furthermore, rather than focusing on equity in terms of individuals or groups of individuals, the *Metric* addresses the conditions within a system (a classroom, school, or district) that define equity in science education.

The *Equity Metric* and related research provide a flexible reconceptualization of what ought to be counted as resources, including clearly understood and accepted goals for reform; responsible and accessible leadership; teachers who feel efficacious, autonomous, and respected; and a community that is supportive and involved (Hewson, Kahle, Scantlebury, & Davies, 2001). For example, application of the *Metric* reveals that even in U.S. urban schools where academic achievement plans with strong equity components were in place, students were still exposed to a science education that was inequitable along three resource fronts: lack of home resources and the cultural knowledge to succeed in schools, a lack high expectations and culturally relevant practices, and a lack of engagement in science education reform practices (Hewson et al., 2001; see also Kahle, Meece, & Scantlebury, 2000; Roychoudhury & Kahle, 1999).

These studies focused on the *Equity Metric* reveal that a combination of resource-oriented factors, which the authors believe to be unique in urban schools, consumed the attention of science teachers such that they had little time or energy to teach science.

In successful schools, teachers assume they will have the conditions needed to support quality teaching. Try as they might, [the urban] science teachers could not focus on science teaching. Webster's [suburban] science teachers, in contrast, worked in a coopera-

tive, stable environment that provided the time and space to focus their energies on teaching science. (Hewson et al., 2001, p. 1142)

This last point is crucial to understanding the connection between student achievement and resources in urban settings, for it suggests that there are resource concerns unique to urban centers, at least in the United States. Such a conjecture is worth further study.

Spillane, Diamond, Walker, Halverson, and Jita (2001), like Kahle (1998), examined the form and function of resources as both the building and district levels. In their study, they focused more on how the activation of resources—in addition to their actual presence—is fundamental to opportunities to learn science in urban settings. Whereas Kahle and her colleagues (1998, 2000) worked to quantify resources, Spillane and his colleagues drew upon a fluid conceptualization of resources and focused on the importance of the activation processes used by school leaders to utilize available resources. Their study, which examined 13 high-poverty Chicago elementary schools' efforts to lead instructional change in science education, demonstrates the importance of framing resources in terms of how material, human, and social capital is identified, accessed, and activated. Using an in-depth case study of one of their schools, where resources for leading instruction were extremely limited and unequally distributed across subject areas—more for literacy and math, fewer to none for science—Spillane et al. showed that successful changes in school-wide science achievement were brought about by school leaders who placed value on how leaders activated resources for science instruction, developed teachers' human capital, recognized and used social capital inside and outside of school, and juggled all with an eye toward achievement and accountability measures.

Each of the authors above argues for a broader conceptualization of resources in school science settings. However, it is interesting to note that their reasons for doing so are different. Spillane et al. (2001) were interested in how teachers and leaders might use what is around them to build more equitable learning opportunities in an under-resourced subject. Kahle (1998) was interested in setting standards for adequate resources in urban schools and making a case for how some of the overlooked but extremely important resources affect student achievement. Each of these articles also makes a case for how resources inform the process of how students go about learning in urban settings. These studies reveal challenging questions about the role that resources play in student learning. Spillane et al.'s study suggests that it is possible for a broad and nontraditional repertoire of resources to positively affect school science, but it only provides us with a glimpse of the resources drawn upon by school leaders in promoting reform-based science instruction, and does not show how students may also activate a fluid resource bank. What could we also learn if more systematic attention were paid to the strategies for activation that matter to students, teachers or leaders, and to whether the employment of differing strategies matters in learning outcomes?

Thus, studies on resources in urban science education provide a baseline understanding of how urban student achievement and attitudes in the sciences are directly linked to the access and activation of resources. They urge us to consider how various conditions within schools, communities, and nations are centrally part of how resources ought to be understood and activated. Although the debate is rich

and at times contentious with regard to how the identification and enactment of resources ought to be framed—as measurable quantities or fluid contexts dependent upon arrangements—such richness opens up powerful lines of questioning and research. At this point, one could also argue for including those studies that examine the use of local resources or student funds of knowledge as starting points for a curriculum (see Bouillion & Gomez, 2001; Fusco & Calabrese Barton, 2001; Seiler, 2001). However, I have decided to include studies that approximate this concern in a later section dealing more directly with the role of cultural toolkits and funds of knowledge in the *process* of student learning.

### **THE PROCESS OF LEARNING: ARTICULATING THE RELATIONSHIP BETWEEN THE URBAN LEARNER, SCIENCE, AND THE LEARNING ENVIRONMENT**

Studies of achievement and resources in science only crack the door for understanding student learning in urban settings. Although they provide us with a framework for understanding who is succeeding in educational environments and who is not, they are unable to provide us with insight into why some high-poverty groups succeed in urban schools and others do not. They demonstrate a compelling relationship between access to resources and academic achievement, but most leave open questions around how nontraditional resources facilitate learning or the motivation to learn. In this next section, I move on to those studies that take up these questions more directly by focusing on the process of learning.

With the introduction of the ideal of scientific literacy into international science education discourse, achievement studies of urban student populations have been complemented by studies that focus on how *context* frames urban student learning in science. Situated within the broad framework of social cognition, these studies, taken as a whole, have attempted to step away from singular outcome measures in order to characterize what learning is in urban science education settings and how learning is mediated by the local context. Just as achievement studies have revealed differences in learning outcomes among differing populations within urban centers and between urban and non-urban centers, social cognition studies have revealed that successful science learning is an artifact of the learning environment created for or by students.

Even though understanding context is central to understanding the process of learning in urban science education, the investigation of context is a difficult one. It is a dynamic construction, grounded in a set of geographic and structural features as well as in the histories, cultures, experiences, and identities of those individuals who make up that context. Each of the studies described below offers either an analytic lens for making sense of student learning in science or a depiction of the link between student learning and context. Thus, the questions I take up in this section include:

1. What are the primary tools that urban science education researchers employ to understand and to bridge differences in what and how urban students learn science?
2. What else are students learning in science class?

## Understanding and Bridging Differences

In this section, I examine a set of articles that present tools for making sense of student learning in urban environments. By “tools” I refer to theoretical constructs that researchers have developed or adopted to help describe and explain the process of student learning. Across the studies reviewed for this section, three categories of tools are covered: (a) appropriation frameworks, (b) congruence, and (c) legitimate participation.

### Appropriation Frameworks

The studies presented in this section describe tools that provide insight into how urban students learn to appropriate or assimilate science content and culture. Each of the studies shares two ideas. First, each is grounded in the belief that science is a cultural practice, with its own ways of talking, acting, and becoming a member of a community. Second, each draws upon the idea that the process of learning to become part of the scientific culture ought to be transformative for the students, for the classroom-based scientific culture they join, and for the teachers who help to form that culture. The tools described in this section include genres, everyday sense-making, and cultural toolkits.

*Genres.* Varelas, Becker, Luster, and Wenzel (2002), in their study of the oral and written work of students in a sixth-grade African American urban science class, used the framework of genres to analyze student learning. Genres, according to Varelas et al., are “staged, goal-oriented social processes” that suggest a “purposeful way of doing things in a culture” and that help students to organize ideas, experiences, and practices in ways that make sense to them (p. 581). In a typical science classroom, there are two categories of genres that frame science learning. There are student genres, which include youth genres, classroom genres, and student science genres. There are also teacher genres, which include their favored classroom genre and their own science genre. According to Varelas et al., genres can be a useful tool because they “may shed light on the fullness, complexity and richness of learning science in urban classrooms” (p. 583).

Genres may be a particularly interesting analytic framework for understanding student learning in urban contexts if we apply them to making sense of pedagogical conflict in the classroom. I see three powerful points emerging from this study. First, genres provide an explanation for why and how students often *resist* learning science. Learning science requires students to incorporate a new way of talking, knowing, and doing into their assimilatory frameworks that they use to make sense of the world. Part of learning is using one’s assimilatory framework to make sense of an experience; but an equally important part of learning is allowing the assimilatory framework to be changed by that experience. Second, genres bring into focus the ways in which science learning can be facilitated or constrained by how well values and expectations overlap in the classroom. If student genres do not map onto teacher genres, then conflict may emerge and learning is hindered. Conflicts between genres can result from differences in what is valued by the teacher or the science education community, but also from the student’s enculturation into a view

of schooling or science that may not reflect reform-based practices. Third, the conflict generated over the meeting of genres can be instructive for both teachers and students. Situating the source of conflict within the realm of how ideas, values, and so forth are assimilated, rather than within an individual and her capabilities, opens up more empowering challenges to teachers and students.

*Everyday sense-making.* The next appropriation or assimilatory framework tool is everyday sense-making. Whereas genres focus on “ways of doing things within cultures,” everyday sense-making examines how what students, teachers, and science contribute to the learning environment frames the nature of that environment and the interactions that occur there.

The idea of everyday sense-making suggests that there are different cultures that frame what and how students learn science. Students’ cultured understandings of science can be used as a tool for enhancing the learning process (Warren, Ballenger, Ogonowski, Rosebery, & Hudicourt-Barnes, 2001). Warren et al. argued that everyday experience and ways of talking/knowing are seen not only as discontinuous with those of science, but also as barriers to robust learning in science learning settings, negatively affecting urban students and students from minority backgrounds in their opportunities to learn science. Drawing upon sense-making, this research group attempted to reverse this trend. Using descriptive case-study analysis, they provided rich examples of students making sense of science by employing accounts of everyday experience as both a context for understanding scientific phenomena and a perspective through which to engage with new dimensions of a given phenomenon, making such accounts analytically generative. For example, Ballenger reported on how some urban learners, as a way of making sense of science, engage in “embodied imagining,” where they imagine themselves in the scientific phenomenon they are trying to understand (Ballenger, 1997). Viewing student learning as a process of everyday sense-making, grounded in the cognitive, physical, and cultural dimensions of being, opens up new channels for how learning in classrooms is encouraged and understood.

*Cultural toolkits.* Cultural toolkits also fit under appropriation because they offer an analytic lens for understanding how youth draw upon and activate those aspects of their capital in order to appropriate science in ways transformative to them. As Elmesky (2003) wrote, “By understanding the structure of different cultural environments in which students interact and the associated strategies of action within their cultural toolkits, teachers can become better equipped with the skills for helping their students learn science in a manner that will encourage social transformation” (pp. 32–33).

Cultural toolkits offer a unique tool for understanding how youth learn to appropriate science along three different lines of thought: identity, power, and practice. In terms of identity, Seiler (2001), in her critical ethnographic account of student learning in a lunchtime program, demonstrated how students draw upon funds of knowledge that are not necessarily part of the traditional school day to craft a new place in the discourse and community of science. Looking closely at eight African American male high school students, Seiler poignantly showed how cultural and language differences are important markers of personal and group identity and can serve as a valuable form of capital to be drawn upon in learning in

the science classroom. Furthermore, what Seiler's article also brings to light is that often students do not realize that the capital to which they have access can serve them well in school and does have connections to science learning. She argued that one important outcome of her study linking resources to science learning is the importance of making sound curricular and pedagogical decisions that help students to recognize the science in their everyday activities.

In terms of power, my own research group has examined how the *activation* of resources from one's toolkit is influenced by how the activation process is understood and taken up by others within the learning setting. For example, in one publication we drew upon case studies of five urban homeless children to make two points relative to power and activation of resources (Calabrese Barton, 1998). First, more important than understanding that differential access to material, human, and social/organizational resources exists in high-poverty learning communities is understanding how "a margin-center" continuum set up by differential access is often construed as a natural rather than a created phenomenon. This continuum often leaves students with access to traditional resources on the margins of school practice. Second, students without traditional resources are institutionally set up to fail, while not having the ways in which they activate their nontraditional resources recognized in their attempts to learn science.

Finally, in terms of practices, Elmesky (2003) looked at how using a cultural toolkits framework can help teachers to re-envision the role of confrontation in science learning, and in particular the practices of what are traditionally referred to as disrespect, acting out, and violence. The author made a persuasive case that confrontational strategies of action, both verbal and physical, exist as part of a toolkit shaped within a structure that demands excellence, respect, and sometimes survival of the fittest, and utilization of such strategies in turn reinforces the structure that exists. She argued that when youth spend the majority of their time within fields structured by ideology, it is not surprising that they unconsciously engage these strategies within the classroom. However, I wonder about the overt focus on what are construed as stereotypical qualities of inner-city youth. On the one hand, this could be an attempt to shatter stereotyping by transforming our understanding of those strategies of action. On the other hand, I wonder why other more socially positive examples were not selected, or if it is necessary that teachers take into account all possible strategies of action available to students.

*Implications of and questions for appropriation frameworks.* Everyday sense-making strategies, like genres and cultural toolkits, are well-equipped theoretical constructs to offer new ways of understanding science learning in urban classrooms. They reveal to us the diversity of resources that youth draw upon to learn science—especially those resources not traditionally viewed as scientific. They also show us how even the most experienced teachers can struggle with the challenge of knowing what to do with students' ways of sense-making, even when they recognize them and see connections. All of these tools also clue us into some of the less spoken of challenges that teachers face when attempting to implement reform-based science education: conflicts in science class can and do emerge when the ideals of science (i.e., collaboration, shared responsibility) conflict with the ideals of schooling (i.e., individualism) or the ideals of students (individual ownership).

These appropriation or assimilation framework tools raise many questions worthy of further study. For example, to date, none of these research lenses for understanding learning take up the question of how school science and high-stakes testing require students to express certain ways of knowing and of articulating that knowing. In what ways might genres, sense-making, or cultural toolkits foster real integration of student ways of knowing with scientific ways of knowing that still enable the kind of scientific literacy valued in schools to be possible? Finally, these studies all appear to be initial studies. Although rigorous, each study is small in scale. Clearly, more broad-scale studies need to be conducted across different ethnic groups, different urban centers, different kinds of schools, and different ages of students. After all, the science demands of high school students are quite different from those of elementary school students. School science goals in science magnet schools may look different from goals in general comprehensive schools or schools with other foci. Such studies will deepen the complexity of our understanding of the import of genres, sense-making, and cultural toolkits.

## Congruence

Congruence, as congruent third space (Moje, Tehani, Carillo, & Marx, 2001), instructional congruence (Lee & Fradd, 1998), and composite culture, is a framework used to describe those pedagogical practices that bridge the worlds of students with the worlds of science and school in ways meant to be empowering and relevant to students. Studies focused on congruence pay close attention to the funds of knowledge that students bring to the classroom and those required to do science well in a school setting. How those funds of knowledge are validated and applied meaningfully in the learning of science is the crux of studies that examine congruence.

*Congruent third space.* In describing congruent third space, Moje et al. (2001) examined how, in urban middle school science classrooms, science learning is framed by differences in culture and discursive practices. However, they also showed that more often than not, the discourse of science is privileged over social, everyday discourse even when both are used and valued in the classroom. Moje et al.'s work challenges urban science educators to consider how the process of bridging the worlds of students and science is more complex than simply bringing both into the classroom. Rather, they argued that bridging differences is insufficient to facilitate learning among urban students, and that science learning is facilitated (or constrained) by how well discourses are *integrated*. These dynamic moments of authentic integration, otherwise known as the congruent third space, provide the mediational context and tools necessary for students' social and cognitive development.

*Instructional congruence.* Similar to congruent third space is the construct of instructional congruence. Instructional congruence, according to Lee and Fradd (1998), is the process by which teachers build epistemological, cultural, and linguistic bridges between science and students. These authors asserted that instructional congruence is an important way to make science learning fair and just to second-language learners in urban settings, because it expands school science from being

about not only knowledge (knowing, doing, and talking) and the habits of mind (values, attitudes), but also the languages (academic discourse, social discourse, and cultural understandings) of the students. Lee and Fradd used several examples from years of mixed-methods research in Miami-area public schools to make this point.

**Composite culture.** Composite culture, developed by Hogan and Corey (2001), describes the classroom culture of science that students actually experience. These researchers argued that science learning is a process of enculturation, or of learning to take on the culture and practices of the professional science community as reconstructed by classroom life. They argued that science learning, when viewed as enculturation, can be understood as mediated by the intersections of the experiences that students bring to the classroom, the pedagogical ideals of the teacher, and the teacher's explicit understanding of how to bring together the dimensions of professional science practice and pedagogical ideals.

The researchers made the case that composite culture is a useful construct in urban classrooms, because it sheds light on how teachers and students work to negotiate common understandings of science across what are sometimes vast cultural differences. For example, in their investigation of how low-income, urban fifth-graders engage in the study of ecology, Hogan and Corey (2001) used composite culture to show that students have opportunities to experience the culture of professional science. They also used composite culture to raise questions around the role a teacher's understanding of composite culture can play in her ability to prepare her students to be successful within that culture.

**Implications of and questions for congruence.** Congruence suggests that there are different cultures that frame what and how students of science learn. It provides us with a way to understand how and why tensions might arise in the learning of science, such as when there is conflict between the culture of the students and the composite culture of the science classroom.

Although the outcomes of instructional congruence and congruent third space are similar—to facilitate learning among students for whom science poses different discursive and cultural practices—the form and purpose of congruence differ. Whereas *congruent third space* refers to the learning community established when students' discourses are fully integrated into scientific discourses, *instructional congruence* refers to the pedagogical process that serves to bridge the epistemological, cultural, and linguistic practices of students and science. Moje et al.'s (2001) construct of third space creates a new shared space that exists in both the world of the home and the world of the school, where urban educators should strive to be with their students. Lee and Fradd (1998), although they did not argue that their ultimate goal was to bring youth over to the culture of science, also did not make a case for the worlds in between. Furthermore, Moje et al. paid more attention to the role that conflict in discourses might play in mediating the creation of a congruent third space and student learning, whereas Lee and Fradd did not directly address conflict.

Despite these differences, both Moje et al.'s (2001) and Lee and Fradd's (1998) research, along with Hogan and Corey's (2001) research into composite culture, carry political overtones; both articles also suggest that learning in urban class-

rooms is embedded with power relations that frame who is labeled scientific or capable of learning science. The findings from these studies suggest that it would be important to advance this research, to study what happens when instructional models of congruence are applied in urban schools, and to learn more about how they affect youths' achievements in science as well as their visions of what it means to do science and be a part of the scientific community.

## Legitimate Participation

Those studies that I group under *legitimate participation* all make a case for how learning science in urban settings is also about being legitimate participants or valid members of or contributors to a science community. The studies that fit in this category are all grounded in the pedagogical belief that urban learners ought to be afforded formal learning opportunities to participate in authentic science or science-like experiences.

**Connected science/project-based learning.** Connected science, a form of project-based learning (PBL), is both an approach to student learning and an analytical construct for understanding the design of leaning environments. As an analytical construct, connected science foregrounds the importance of the funds of knowledge that students bring to class and situates science learning within a community context. As an approach to science teaching, connected science draws upon mutually beneficial partnerships and real-world problems as contextual scaffolds for bridging students' community-based knowledge and school-based knowledge.

Connected science, as a form of project-based learning, is centered around authentic driving questions and activities that matter to students. Teachers who practice connected science, or PBL more generally, create learning environments where students socially construct knowledge based upon readily available resources. Because PBL environments shift the focus of science learning away from such indisputable, "correct" answers to debatable and refinable solutions, they create a dynamic space where power, authority, control, learning, and teaching are shifted between teacher and student (Moje et al., 2001). Although connected science has not been used to show achievement gains, PBL, in general, has been used in urban classrooms (Schnieder, Krajcik, Marx, & Soloway, 2002).

Bouillion and Gomez (2001) qualitatively reported that a connected science approach among fifth-grade urban learners and their study of ecosystems led students to a deeper understanding of ecosystems *and* a more situated understanding of the nature of science (i.e., in reporting on their understandings of ecology, students also reported on how they viewed their relationships with and in science in a connected fashion). Drawing upon connected science as an approach to student learning and an analytical construct for the design of leaning environments presents the science education community with a set of tensions with which to grapple. Finding real-world problems that meet science standards and the cultural context of the school and community raises questions of what can count as connected science. Moreover, how should the science education community constructively confront how power differences between students learning science and businesses frame how experiences and the science learning agenda are prioritized? These questions are worth further investigation.

*Multiscience.* Hammond (2001) used the construct of “multiscience” to capture a kind of learning community and a vision of science similar to connected science. In an ethnographic account of a collaboration involving a team of bilingual/multicultural teacher educators, teachers, students, and community members in an urban California elementary school and their efforts to build a Mien-American garden house, Hammond described how students, teachers, and student teachers learn a new kind of science—a multiscience—by garnering a community “fund of knowledge” about the science to be studied in the classroom. Multiscience refers to the incorporation of indigenous science and personal science into Western modern science, which is a foreign culture that must be learned by all students, whether they are indigenous or mainstream. Hammond argued: “All students bring to the science classroom the indigenous science of their own culture’s folklore and their own personal world view, derived from their age, gender, sociohistory, and many other factors. In order for Western science to be learned, meaningful reflection upon and dialogue with these cultures of science must occur” (p. 987).

What is particularly interesting about Hammond’s (2001) construct of multiscience is its focus on collateral learning. Collateral learning suggests that when learners are confronted with conflict due to the discrepancies between formal scientific knowledge and their own indigenous knowledge, instead of holding the two contradictory systems of knowledge in parallel, conflicts are explored until they are gradually resolved, allowing both systems of knowledge to be transformed. However, although Hammond advanced the claim that students learn “to see science as accessible and relevant to their lives” and to learn to view participation in science as “centered in praxis rather than in learning for its own sake” (p. 988), she did not report on what students actually learned through their participation in the Mien-American garden house experience. Further questions for investigation include how a multiscience approach might allow for collateral learning in the nature of science as well as in a student’s understanding of the concepts and processes of science.

*Emergent learning experiences.* Rahm (2002) took up the question of learning as participation through her qualitative case-study exploration of emergent learning opportunities in an inner-city youth gardening program. She writes of how work, science, and community can be integrated in a community of practice around gardening in out-of-school science programs. What is important in this study from a learning science perspective is that it demonstrates not only what science youth learn as a result of their participation in the program, but also how learning science was tied to learning about doing science in authentic and applied contexts. She reported that this kind of learning moves beyond motivating students to learn science. It also captures a way of being or participating in a community that has consequences for the individual and for the community. This is a different take on learning science than is seen in other articles, because it focuses on the interrelationship between the individual and the community and the mediating role that science (or doing science) plays. It also focuses on unplanned emergent learning moments that were created by the interaction of the participants with the context. For example, Rahm reported how the participants in her study first and foremost became members of their community of practice (i.e., gardeners for City Farmers). Rahm provided a multitude of other examples that show how student talk around gardening led to several scientific investigations that were not necessarily a formal part of the

program. These emergent learning opportunities were one primary reason the students described City Farmers a place where “you get to do the whole package.”

Similarly, my colleagues and I (Calabrese Barton, 2001, 2003; Calabrese Barton & Darkside, 2000; Fusco, 2001; Fusco & Calabrese Barton, 2001) have drawn upon critical ethnographic accounts of urban middle and high school students learning science in a community-based science setting—a practicing culture of science learning. In our research youth transformed an abandoned lot into a community garden. Through emergent learning opportunities, we have focused on three kinds of learning. Students develop deep conceptual understandings about content knowledge, such as what plants grow and how they grow, urban pollution, and skills such as mapping, computation, measurement, observation, analysis, and the communication of results. Students also learn about the value-laden and context-embedded nature of science. Third, students learn how to be legitimate participants. In our studies, we reported on how youth underwent cultural shifts in such areas as identity (from shelter youth to caring squad) and in the production of science (from “fake” school projects to real social action).

Both sets of studies reported here, however, took place in out-of-school contexts, providing a kind of freedom in the learning environment not afforded by schools—with differing time constraints, access to materials, and adult-to-student ratios, and the obligatory-voluntary nature of the experiences.

*Implications for legitimate participation.* Each of the studies presented here makes a distinction between “doing” science and “talking” science that frames learner’s engagement with science. Just as Rahm’s (2002) students reported that City Farmers gave them the “whole package,” students in the Fusco and Calabrese Barton study (2001) remarked on how doing science made it real. Second, science learning emerged from having purpose and real-world obligation. For example, Bouillion and Gomez (2001) reported that science and science ideas emerged from doing science in the service of community, supported by a context where young people were givers and creators of a plan to improve the community. Third, each of the studies emphasized how emergent opportunities were socially oriented rather than task oriented. For example, in my own research around student’s community gardening (Fusco & Calabrese Barton, 2001), students learned about qualities of soil because they wanted to transform a lot into a garden.

The implications for legitimate participation approaches to framing urban science learning are that learning as participation centralizes the embeddedness of the individual in the sociocultural world and the ways in which new knowledge is negotiated and remains situated in context. “Through participation what accumulates is not scientific facts but a way of acting, talking, and becoming a member of a scientific community” (Rahm, 2002, p. 165). Furthermore, although what authentic and meaningful science looks like differs across the articles discussed in this section—from out-of-school gardening programs to in-school project-based science—cutting across each article is an attentiveness to doing as both an epistemological and cultural bridge between the worlds of professional science and student lives. In other words, in each of these studies students learned about the culture of science and learned to appropriate it and transform it into a new culture that was inclusive of other things.

These studies guide us toward fruitful avenues of research. Hammond (2001) acknowledged that the roles of teachers and students will have to change to em-

brace learning environments supportive of legitimate participation. One important next step might be to explore the implications this has for classroom science. Furthermore, each of the articles presented in this section addressed the fact that the process of embracing legitimate participation changes what students may learn about or in science. One direction for further study would be to explore how such an approach might be made compatible with the instructional goals, time constraints, and logistical concerns of schooling, especially in high-poverty communities. Finally, fundamental to each of the arguments presented in this section is a shift in goals for science education—that doing science is learning science. Further investigation into the ways in which students may have opportunities to metacognitively reflect on this process is important. Also important are investigations into what kinds of authority students or community members ought to have in deciding upon the focus of a project, or in what is worthwhile and related to *their* real world.

### **Emergent Questions in Understanding and Bridging Difference**

Many researchers make the claim that if science were to be represented differently—that if it were built upon the experiences of students—then urban students would connect to it and learn better. The studies in this section, focused on understanding and bridging differences, examine this claim from different angles and compositely suggest that this is a much more complex process than such a statement lets on. Considerations must be taken into account, not only of the funds of knowledge that students or teachers bring to the classroom, but also of how these experiences are integrated with the world of science. Furthermore, although science learning may be about the content of exploration, it is also a process of participating—of learning to do science in a community.

However, embedded in each of these studies are tensions around culture, community, and science learning. The researchers whose work is presented here are clearly cognizant of the contradictions that emerge when the worlds of home and community are brought together with the worlds of science. What would happen if researchers also used that powerful space of contradiction to push forward our understandings of culture, power, and a just education? Finding these spaces of contradiction and using them in deeply contextual ways may help to deepen our understandings, not only of what teachers know (and need to know) and the spaces they occupy (and need to occupy), but also of what youth know (and need to know) and the spaces they occupy (and need to occupy). Furthermore, understanding the tools for bridging difference would be served by an in-depth set of policy studies that provide analyses, both content-wise and conceptually, of the major reform documents in various national contexts, that drive science for all in urban settings.

### **What Else Do Students Learn? Success and Participation**

The previous section detailed the tools for understanding the differences between urban learners and school science and the role that understanding these differences might play in designing effective learning environments. Yet, embedded in the sub-

text of many of the research studies reported above is the conclusion that much goes on in a science learning community besides the learning of content. In this section of the chapter, I report on those studies that address urban learners and science from the angle of what other things the students learn as part of their science experience. As the studies outlined below indicate, studies around urban science learning shed insight into *learning to* (a) succeed and resist and (b) participate.

## Learning to Succeed: The Normative Practices of Schooling and Resistance

Haberman (1991), in defining the pedagogy of poverty, argued that urban teachers work within tremendous constraints, including large class sizes, inadequate prep time, lower levels of training, inadequate classroom space, and outdated materials. These constraints result in a directive, controlling pedagogy that runs counter to reform-based practices.

A pedagogy of poverty and similar teaching models have been observed in urban classrooms and have contributed to success in science class as based upon rule following and cognitive passivity rather than conceptual learning (Griffard & Wandersee, 1999; Seiler, 2001; Seiler, Tobin, & Sokolic, 2001; Songer, Lee, & Kam, 2002; Tobin, Seiler, & Walls, 1999).

For example, Griffard and Wandersee (1999) shared qualitative case studies of two African American female biology students to make a case for a cycle of “cognitive disengagement.” In this study, based primarily on observations and clinical interviews in a math and science public school, attention to behavior over learning and to academic habits over cognitive engagement appeared to be the norm that defined the academic learning environment for students. These practices taught students that success in science was based upon rule following and that academic engagement was not necessary.

Just as students in Griffard and Wandersee’s (1999) article learned to be cognitively passive, students in other urban settings act upon these institutional expectations to play a role in reproducing a culture of low expectations. In a series of articles, Tobin and his colleagues (Seiler, Tobin, & Sokolic, 2001, 2003; Tobin et al., 1999) made the case that framing science success through following norms and expectations leads students to resist, which at its heart is an opposition to being controlled. Across a set of three studies, these researchers outline how the “normal practices of schooling” such as tracking, teaching to the test, and curricula geared toward minimal attainment led to a “culture of low expectations” in science for high-poverty urban students. Yet, the same students who were exposed to these low expectations helped to reproduce the culture of low expectations by engaging in multiple forms of resistance, including resistance to high expectations, learning, the teacher, and attendance, even when science instruction was being led by a competent, caring teacher. What we can read from these studies is powerful: that resistance is an active process that students use to make claim to their own space in schools and by which students and teachers negotiate control in schools—control over identity, over what schooling is about, and over relationships and respect.

At issue here is the very notion of control. School agents either knowingly or unknowingly control students by framing their participation, effort, and achieve-

ment in narrow cognitive terms. Little attention is paid to how cognitive goals may be deeply rooted socioculturally. In other words, the teachers in Tobin et al.'s (1999) studies embedded learning in a culture of respect, where respect ranges from valuing the interests that students bring to the classroom to utilizing the primary discursive practices of the students. Such differences in the currency of schooling leads students to act differently from what teachers wish from and for them, even when those wishes are well intentioned. These different actions, which often conflict with "desired" actions, are labeled resistant.

My colleagues and I (Calabrese Barton, 1998; Calabrese Barton & Yang, 2000) have drawn upon resistance and its connection to the culture of power in school science. In a case study of one young father, Miguel, we showed how, during his teenage years, he resisted the culture of school science while at the same time, as a self-taught herpetologist and businessman, he sought to create his own subculture of science in his close-knit neighborhood. For Miguel, resisting school science turned out to be both an act of self-preservation and an act of defiance. Both Miguel's peer culture and the culture of school science were restrictive, demanding conformity to a narrow set of norms that failed to connect his interests and talents to the wide range of possibilities offered by our society and economy. Miguel was placed in a position of having to choose one over the other. Yet, unlike his peer culture, schooling did *not* provide a safety net of support if he chose to conform to schooling over peer culture. What is particularly interesting to us in this case study is how science itself could have mediated this difference. As a self-taught herpetologist, an occupation highly respected among his peers, Miguel possessed the interest and capacity for a practice of science that could have bridged these two worlds.

One important issue raised by these studies that ought to be studied further is that resistance has been framed as an individual activity rather than a community action. All of these studies focus on individual students. If we begin to understand resistance as a social phenomenon, then we are offered new options for interpreting what students may be resisting and why. As Moscovici (2002) suggested in a critique of Seiler et al. (2001), what if we viewed student actions through the larger lens of becoming immersed in science rather than as resistance? Individual actions that may come across as behavior challenges or resistance to teacher direction may be a result of students actually aligning with the overarching desires of the teacher—to engage in science meaningfully. A second issue raised specifically by Seiler et al. (2003) is that labeling actions as "resistant" is culturally constrained. In other words, student actions labeled as appropriate are actions that fit neatly into what a teacher or researcher expects to see. Those student actions labeled as resistant are actions that do not fit neatly. Further investigation of how student resistance could facilitate learning could be conducted, as Seiler et al. suggested, by examining what science educators view as resistant through the lens of cultural exchange, rather than as a negative action that detracts.

## Learning to Participate

Who can do science and what it means to be a legitimate participant in science is another question that has garnered attention in the focus on student learning in urban science education. In urban science education, those studies that examine what

students learn about who can do science concentrate on developing two kinds of claims. First there is the claim that students come to believe in whether they can participate in science based upon their perceptions of what science is and who science is for. Part of this claim is rooted in identity studies, which suggest that learning ought to be thought of as a process of identity formation. Part of this claim is also rooted in broader sociocultural studies, which suggest that one's vision of what science is or who it is for is also grounded in community-supported expectations and practices. Second, there is the claim that science is a social, cultural, and political practice and that if urban youth are to feel they are part of science, then all of these dimensions of science must be integrated into the learning environment. Although few studies in urban science education take up the question of participation, those that do pack powerful and provocative claims.

Brickhouse and Potter's (2001) ethnographic case studies of urban girls revealed that, through the experience of marginalization in the science classroom and even in peer groups, urban girls learn that membership in a school science community is often impossible or undesirable. Using the construct of identity, Brickhouse and Potter showed us how complex the relationship between identity and success in school and in peer groups can be for urban girls. Having a science- or technology-related identity does not mean that one will necessarily succeed in school, if that science-related identity does not also reflect the values of school-mediated engagement, or if students do not have access to the resources they need to do science well. However, successful participation in school science or technology, despite a lack of resources in the home environment, can be better facilitated when students have a science-related identity they can fall back on. Indeed, one of the primary claims made in this study is that students who aspire to scientific competence, yet do not desire to take on aspects of the identities associated with membership in school science communities, face difficulties and even school failure. Brickhouse and Potter's study is important because it raises questions about how to help students retain an identity that is desirable to them in their home communities, yet also allows them to cross the boundaries of race, class, and gender in order to get access to a science culture that too often resides only in more privileged communities.

In our case study of Miguel discussed earlier in the section on resistance (Calabrese Barton & Yang, 2000), we showed how Miguel learned through experiences at home and at school that science was only for "special people" or that scientists were discovered rather than self-made. Miguel expressed a keen interest in science through the Boy Scouts and through his herpetology business, yet Miguel still believed he was not capable of becoming a scientist. He had no science role models in his low-income urban neighborhood who he reported remembering, and his teachers and counselors did not encourage his interest seriously.

Only one study to date makes an explicit examination of how school-based interventions can foster students' learning to develop positive science identities. In her study of standards-based learning among high school African American studies in Philadelphia, Seiler (2001) reported on the impact that a lunchtime science group had on the students' scientific identities. In this study, she revealed how learning science intersects with learning to participate in science. However, she also suggested that learning to participate in science is hampered because the emphasis on the acquisition of certain school-based ways of speaking and interacting in science has devalued African American students' ways of being and has inflicted symbolic

violence on them. Seiler's primary finding was that when science learning opportunities reflect the funds of knowledge and the strategies of action that students bring to science, then students will be more willing to appropriate scientific discourse. As a result, she reported that students learn to begin to see themselves as scientific—as individuals who can contribute to and participate in science.

What is interesting about these participation studies is how neatly they overlap each other in terms of their findings. Yet, what could we learn if this question of participation were to be taken up more systemically? Miguel, like the students in Seiler's study, believed that science was not for him. Yet, other studies included in this review that did not focus on participation presented stories of successful participation in science among high-poverty and minority urban youth. What did the students in Rahm's (2002) study of urban gardening or Bouillion and Gomez's (2001) students of urban ecosystems learn about participation in science? Was a scientific identity as important in those learning environments as these studies suggest it to be?

### **Implications for "What Else" Students Learn**

The studies presented in this section show that learning in science class ought to be broadly conceived to cover things other than just content and process skills. Although learning how to identify with science or about what success means are most likely much more subjective components of science education than learning content might be, the studies reviewed here suggest that how or why students achieve in science depends upon these measures. This review also shows us that few studies have been conducted within the subfield of urban science education studies that use this kind of analytic lens. What does it mean to craft a science learning community that favors the positive development of scientific identities among urban youth? What resources are necessary in this environment? How does identity formation relate to learning and to success in school-based science? What role does the teacher, the curriculum, or the school culture play in how or why students as individuals or as members of a community try on new identities or new ways of interacting in the classroom? Does understanding the forms of resistance help to guide us toward new pedagogical approaches to classroom practice? Does rethinking the production of resistant communities actually help to promote student learning in science? The studies presented here open up what has really been uncharted territory in science education worthy of exploration.

## **CONCLUSIONS**

How do urban studies change the landscape of what learning is in urban science education in both its form and its function? Today's educational climate is marked by a propensity for high-stakes exams and outcomes-based learning. The process of learning has become obscured by its product, and little attention has been paid to just how much either context or the multiple purposes of learning matter. In the United States, policies are being written and implemented that exchange a focus on learning standards for a standard process of learning. Although science education has yet to go the way of mathematics or literacy in cities like New York or Los Angeles, where teachers are prescribed page-a-day teaching requiring teachers and students in all classroom to be on the same page of the curriculum on the same day, one could easily

imagine science education moving along the same trajectory. These policies have hit urban centers hard, especially those communities within urban centers where poverty rates are high and where schools serve majority minority populations.

Two considerations are crucial. First, despite what we know about learning science in urban settings at the policy level, learning continues to be addressed primarily as a unidirectional process and product with the goal of promoting learning of science content or process. However, as this review suggests, we ought to also be considering how the science education community might reshape learning so that it is viewed as a multidirectional process/product, framed not only by content goals but also by identities, purposes and goals, and context, and why this is particularly important in urban settings. Although the studies presented in this review mark only the beginning of a potentially powerful research trajectory, as a community, science education must be diligent with regard to how these kinds of studies find their way to the policy arena.

Second, although in this review I focused on student learning, it is also important to focus on the learning of others involved in science education—parents, teachers, administrators, and policy makers—and to do so through the same multidirectional lenses utilized by the studies on student learning. Our own research into parental engagement in science education in high-poverty urban schools reveals that parents often activate innovative combinations of traditional and nontraditional resources in their efforts to learn how to engage powerfully in their children's schooling. Like the students in studies presented here, their learning also covers the content of school subjects along with the processes of schooling and how home/community does or should connect with what happens in schools (Calabrese Barton, Drake, Perez, St. Louis, & George, 2004).

Current science reform efforts are largely built upon visions of scientists, science, and the scientific community that may or may not reflect what urban youth and their teachers bring or have access to in the urban classroom. Although the ideas embedded within such policies and their ascribed practices are crucial components to any balanced approach to facilitating scientific literacy among urban students, the articles covered in this review suggest that these ideas alone may not be sufficient in supporting and sustaining meaningful learning in urban science education. Although the purpose of this review is not to answer the question of who should decide the learning agenda, the research findings presented in this review suggest that a vision for science learning must include the day-to-day practice, struggles, and meaning-making of students and their teachers as part of the portrait of learning.

# CHAPTER 13

---

## Rural Science Education

**J. Steve Oliver**

*University of Georgia*

A variety of challenges are inherent in bringing together the research literature on rural science education. Perhaps the most significant challenge arises from the recognition that rural science education is not easily defined, and that it is not always easy to discern what is and what is not research on rural science education. In the same way, it has not been possible to create a useful and generalizable characterization of what is a rural school or even a rural place. Characterizations abound; finding agreement among these characterizations presents a problem. This enigmatic quality of ruralness is reflected in the way that popular writers and scholars describe not only schools, but also rural people and the places they inhabit.

Sher (1983) has written that rural schools have recognizable tendencies, such as less specialization, less equipment, and less bureaucracy than schools in non-rural sites. He has found that rural schools tend to exhibit a tendency toward teaching the basics and more reliance on the unique qualities of individual teachers, and are “more familial and relaxed in their operating style” (p. 257). These characteristics suggest that this chapter should begin with a personal story.

My earliest memories are of events on a farm in the southern Appalachian Mountains of the United States that had not seen the arrival of petroleum-powered farm equipment. That equipment had not arrived because the land was too steep, and perhaps because high-cost investment did not fit with a subsistence farming mindset. The type of farming I observed as a child has been labeled Upland Southern Mixed farming (Jordan-Bychkov, 2003) or, more simply, hill farming: “Hill farming evolved into a post-pioneer stability, becoming somewhat more market-oriented in the process. In time, it degenerated into rural poverty . . . allowing mining, logging, welfare, and tourism to play larger and destructive roles. Eventually the farming system disappeared from the countryside, perhaps about 1950 or 1960, but many vestiges remain” (p. 45).

The idyllic vision of this rural hill-farming culture persists, but the public school reality is the one of extensive poverty that Jordan-Bychkov suggested. In 1975, only 20% of America’s rural population either lived or worked on farms (Sher, 1977).

Thirty years later, the percentage is smaller still. Like a few people born in the 1950s, I witnessed the end of the era when the fields were worked with only the power from the muscles of horses and people. But I knew that I was in a rural area (though people preferred to call it “the country”) because things like milk cans, horse-drawn mowing machines, and wood-fired cook stoves were still used to accomplish the tasks of daily life, not as items to hold flower arrangements or umbrellas. For many, the distinction between rural and urban has been based in the availability and impact of science and technology.

The main character in Terry Kay’s 1976 novel, *The Year the Light Came On*, growing up outside of Royston, Georgia, in the years just before World War II, also came to understand the distinction between rural and not. He reasoned that the world was divided between the haves and have-nots, based on access to electricity in the home. The Rural Electrification Act would be the vehicle to bring prosperity to all. Again the distinction between rural and non-rural was a correlate of the absence or presence of science and technology.

This distinction persists in some ways for rural schools today. Accounts like the one by Celis (2002), which documented a community’s struggle with the conduct of a one-roomed school in Colorado, depict a variety of ways in which ruralness equates to an absence of technology. They depict rural places as pastoral, happy, and pretty, although life there is composed mostly of hard work. Celis’s description of a walk from the school grounds into the mountains mirrors the myth of rural schooling from long ago where students living in isolated places walked long distances through difficult weather to arrive at school. Today that myth has many points of identification. On the negative side, it is imagined that the rural school offers the students a deficit education due to issues such as lack of science activities (Stine, 1997) and lack of a consistent curriculum (Amaral & Garrison, 2001). For the teacher, this deficit model of ruralness includes geographic isolation (Amaral & Garrison) and high teacher turnover (Barrow & Burchett, 2000).

Thus the rural school can to some degree be recognized when we are there, but the ability to provide a generalized demographic description of a rural school has grown increasingly problematic with each passing year. Many demographic definitions have been presented over the past 25 years (University of the State of New York, 1992). The U.S. Census Bureau defined rural as “a residential category of places outside urbanized areas in open country, or in communities with less than 2,500 inhabitants, or where the population density is less than 1,000 inhabitants per square mile” (Stern, 1994, cited in Horn, 1995).

One key factor that is often missing from the definitions of *rural* is the idea of isolation (Sampson-Cordle, 2001). For the schooling and living of a place to be reflective of its ruralness, it must be isolated to some degree from those areas of the world that are not rural. In the United States this rarely occurs today. Mass media, the World Wide Web, and other inlets pour in culture to essentially all sites. The availability of technology is rarely a reflection of geography. Isolation must be largely self-imposed for it to have this impact. Crockett’s (1999) study of science education in an Amish Mennonite community in South Carolina illustrated the point. This fellowship-based community lives without television, radio, or computers in the home and school in order to maintain its religious beliefs. Yet at the same time, its members use technologies, including computers, that aid their business endeavors.

On the farms, there was widespread use of artificial insemination of cattle. Somehow, using technology in business is not seen as a cultural spigot.

Another factor that may characterize rural children is using education to find a new life beyond the community and home in which they were reared. This contrasts with the description by Tobin and Carumbo (2002) of an inner-city student. They discussed how the obstacles of the inner city frequently present too great a barrier for a child to “crash through”:

If Amirah were to follow this trend and crash she would add to the great divides of US schooling, urban/suburban, Black/White, and female/male. Urban, Black, female, the triple threats, must crash through the oppressive structures that characterize urban high schools to reap the promise of social transformation through science education. (p. 22)

If these are the great divides of US schooling, where does the rural school fit? Schools, whether found in the most crowded inner city or the most sparsely settled rural area, have made promises of social transformation. Whereas social transformation can be enacted within short distances of the inner city neighborhood (e.g., a new home in another neighborhood), they typically lie at great distance from the isolated rural home. Thus, the oppressive structures through which the rural child must crash are largely characterized by the fact that accomplishment equates to leaving that physical site a great distance behind. The rural child may also be a member of a minority racial group or be from a family living in poverty, but since he is not seen as one of many who have to overcome the problems of the urban setting, the problems the rural child faces seem more vague, though perhaps more manageable.

In a developing country, however, this may not be true at all. Developing countries have unique issues with regard to the problem of discerning a role for science education in their populations and in their schools. The degree to which those issues mirror the U.S. rural science education is likely a function of the similarities between industrialization and transportation. To see parallels, a look back in history of U.S. schools might be instructive.

Ghose (1982) examined out-of-school science and technology education as a means of achieving rural development in Southeast Asia. His study originated from the finding that the education provided to school children was found lacking. Ghose described the situation in this way: “Formal education was found inadequate to meet the challenge of national development in general and rural development in particular” (p. 19). These inadequacies were summed up in four points: (a) the curriculum is unsuited to agriculture, though agriculture is the primary means of making a living; (b) the curriculum tends to be “bookish in nature” and thus tends to alienate young students; (c) formal schooling tends to be inefficient in areas with high drop-out rates among students; and (d) limited economic resources do not allow formal education to be spread to everyone.

Informal science education has filled the gap in some places. Science clubs and science camps served a rural development role in some areas of Malaysia, according to Ghose (1982). They were a very important complement to formal education throughout Asia but challenging to start in rural areas. In the Philippines, science clubs played an additional community service function. Through these clubs, students conducted “analysis and resolution of community problems through out-of-school science education laboratories” (p. 22). Such clubs were also active in India.

Ghose also reported that science fairs played a community service role with the examination of realistic and relevant problems. Agriculture extension was also a force for science education and thus for "modernization" and rural development.

I hope that that this chapter illustrates how the rural science education issues in developing nations identified by Ghose (1982) in the 1980s mirror the story of rural education in the United States. This mirroring happens in two ways. First, there is the idea that science education in rural areas can have a much stronger connection to the community in which the schooling takes place. Nachtigal (1995) suggested that science projects based in the community context of the rural United States can make a significant impact on environmental and business issues of rural locations. Ghose found this to also be the case in the Philippines. Second, the history of rural science education in the United States has shown that, in the early part of the twentieth century, when electricity, good roads, and modern modes of transportation were not widely available in rural locations, students seemed primarily interested in science related to local vocations and phenomena, just as suggested by Ghose for Southeast Asia.

In many ways, this chapter is an update to the volume edited by Otto (1995), *Science Education in the Rural United States*. That volume covered a wide range of issues facing rural science education, including "[the] status of rural education, research implications, the integration of science within the science disciplines, integration with mathematics and technology, STS, distance learning, sequence which led from the definition and philosophy of rural science education, to the political implications, Native Americans, and other cultures in rural science education" (Otto, p. ix).

This volume also posed intriguing questions about the future of rural science education. The question of greatest significance seemed to be: Does the rural school offer the student a deficit education with regard to science learning? The authors of the Otto (1995) volume seemed to be in agreement that it did not. Individual papers within the volume identified areas of need such as accessing distance learning technologies, integrating curriculum across the school subjects, recognizing the role of place and context of schooling, and attending to the needs of rural science students who are members of minority ethnic and racial groups. The research compiled by Otto began to shed light on these issues, but the need remains for more attention to be focused on rural science education.

## OVERVIEW OF THE CHAPTER

This description of science education research in rural schools begins with an examination of historical studies of rural science education. As a guide to the selection of these studies, I have drawn from the digests prepared by Francis Curtis and others (Boenig, 1969; Curtis, 1926/1971a, 1931/1971b, 1939/1971c; Lawlor, 1970; Swift, 1969), as well as other historical sources.

After the historical studies, the chapter moves on to an examination of studies that were conducted around the United States in the 1980s and 1990s to determine and to describe the condition of rural science teaching. In some cases, these studies contrasted rural teachers with other teachers and in other cases they did not. I emphasize in particular one study that examined the conditions of rural classrooms in eight states.

From there, I turn to the issue of what is and what is not rural research in the present-day science education literature. There have been a great many studies that use *rural* as a title word or descriptor and then simply describe the physical appearance of the school's setting. Representative examples are used to distinguish these studies from those that can more validly be described as studies of rural science education.

Following this, the chapter examines the studies that to date have been documented in the examination of the National Science Foundation (NSF)-funded Rural Systemic Initiative projects around the United States. Although these reports are not by and large published in refereed journals, they do offer insight into the present-day rural school. This is true in part because of the restrictive nature of the definition used for qualifying for inclusion in the Rural Systemic Initiative program.

The next section examines current published research that contrasts the distinctions between rural and other schools with regard to the science taught. Though few in number, these studies do make a provocative statement for understanding what a rural school is and is not in terms of student characteristics.

Science teacher education for rural schools is the theme of the next section. Though limited in scope because of a lack of published examples, this section examines both preservice and inservice science teacher education.

Finally, a summary and suggestions for future research conclude this chapter. In each section described above, I have attempted to include the research from international sources on rural science education, as well as research done in the United States. The future of rural science education research is not as obvious as it might have been in the last decades of the twentieth century. I end by considering the factors that may shape this indefinite future.

## HISTORICAL STUDIES

Francis Curtis, and those who continued his work (Boenig, 1969; Curtis, 1926/1971a, 1931/1971b, 1939/1971c; Lawlor, 1970; Swift, 1969), published a series of digests to examine research in science education during the first 57 years of the twentieth century. The studies they chose for inclusion were printed as abridged versions of the original research articles in order to maximize the number included. These abridged reports emphasized findings over motivations and rationale.

Curtis (1926/1971a) described the groups to whom the digests would be of value. His description of the first group, when transferred to the science education researchers of today, was an apt description for those who will read this current handbook: "All workers in educational research, particularly in the field of the teaching of science, who need to have readily available a list of important problems in educational research together with a description of the techniques used in their solution" (p. xiii).

The relative infrequency of manuscripts in the Curtis *Digests* that dealt with rural science education was a result of a variety of factors. First, Curtis (1926/1971a) asked the National Association for Research in Science Teaching (NARST) membership to supply recommendations of articles for inclusion in the digests. He then asked that same membership to evaluate each article's value for inclusion in those

volumes. Research design was an important factor in the evaluation by the NARST membership. My own experience as editor of a historical column in the journal, *School Science and Mathematics*, suggests that rigorously designed research on rural science education was quite rare. Second, there was probably not a great deal of research of any kind done on rural schools in the pre-World War II era simply because of problems with access, sample size, and efficiency.

An examination of the first digest compiled by Curtis (1926/1971a) revealed essentially no mention of rural schools. The word *rural* was contained in the title of only one article, and that article dealt with students' knowledge of agriculture. Many of the researchers stated that their data was purposely collected from high schools in cities. Curtis himself did not elaborate further.

Although not specifically identified as a study of rural schools, one study (Davis, 1923/1926) that was included by Curtis (1926/1971a) dealt with the effect of class size and its relationship to "teaching efficiency." Teaching efficiency was defined in terms of the proportion of the different grades (A, B, C, etc.) given in courses across classes of different size. This study (Davis) was conducted in schools from "very small to very large" during the 1921-22 academic year. The results were somewhat ambiguous, because although more students in small classes scored A's and B's, the author concluded that, "considering only the percentages of low marks, the best size class for science is large" (Davis, p. 94). About all we can conclude from this study is that class size and school size were on the minds of some researchers. The representation of rural science studies in the first digest indicated it was not on the minds of many.

In the second digest of science education research assembled by Curtis in 1931/1971b, an abridged version of an extensive study by Palmer (1926/1931) was included. In this work, Palmer asked teachers, beginning in 1921, to "send in the nature-study questions which had been asked by their pupils" (p. 36). In the five years that followed, the rural New York teachers who participated in the Cornell Nature Study program sent in over 7,000 questions. The most numerous categories of questions, representing over 30% of the total, related to the "habits of plants and animals." When broken down over grade level, this category of question was always the most prevalent. It seemed clear that the rural school students of that day were interested in things they encountered in their daily life.

It was often the case that research from earlier times served as a mirror for later works. For instance, the needs assessments of the 1980s and 1990s are very much in keeping with an early study reported in the *Journal of Chemical Education*, and included in the second digest, that dealt with the teaching of chemistry and other sciences in South Dakota. Written by Jensen and Glenn (1929/1931), the study reported the results of research that had used both quantitative and qualitative research methods. In the words of the authors, these were called, respectively, "statistical studies" and "visitatorial studies." They (1929/1931) reported:

... some of the outstanding needs of small high schools are (a) a reasonable science program with a definite science sequence adapted to the needs of a given community, [and] (b) an alternation of the science subjects offered in the first and second years of high school and those offered in the third and fourth years in order to reduce the teaching load of the instructors and thus provide more time to prepare daily lessons adequately for the subjects taught. (pp. 330-331)

Also high on this list of needs was “a state law making it impossible for a Board of Education to employ a teacher to give instruction in a subject in which he is not adequately prepared” (p. 331). As with many issues in the history of science education, this has again come full circle with the creation of the U.S. presidential mandate encapsulated in the No Child Left Behind Act (U.S. Department of Education, 2002).

Curtis (1927/1931) conducted a survey of the “scientific interests of pupils enrolled in the ninth grade in small high schools and of adults living in small towns and in the country” (p. 341). Returns were received from 32 Michigan high schools in towns with a median population of 309. A sample of the responses contained an interesting expression of rural and small-town science interests. Physical science, rather than biological science, was found to “predominate,” even though all of the students in the study were studying biology. Small-town and rural girls were found to have “somewhat greater” scientific interests than boys, just as “the range of the scientific interests of these country women is slightly greater than that of these country men” (p. 344). Perhaps the greatest distinction between rural and not was summed up in the finding that the issues of greatest interest to the rural dwellers were those of a “technical” nature. For instance, Curtis found that “a comparison of questions submitted in both studies, shows, moreover, that the rural dwellers ask many technical questions bearing upon horticulture or agriculture—i.e. related to their vocational life—while the city dwellers ask technical questions relatively unrelated to their vocational life” (p. 344).

Research in this vein continued into the 1930s as well. Wolford (1935/1939) conducted a study of persons living in the southern Appalachian Mountains of the United States to determine the appropriate curriculum for an eighth-grade science course. He found that, whereas city schools typically provided teachers with a description of the course of study, “teachers in small town and rural high schools must either make their own . . . or lean heavily on the adopted textbooks. They usually do the latter” (p. 49). Wolford presented findings related to parental occupations, the students’ planned occupation, and reading interests. The great majority of occupational interests expressed by parents and children related to activities such as “farming, homemaking, and health, industrial, and mechanical problems peculiar to the region” (p. 50). The readings mirrored this interest in local issues.

In a study of “the teaching of biology in the secondary schools of the United States” originally published in the 1940s, Riddle, Fitzpatrick, Glass, Gruenberg, Miller, and Sinnott (1942/1969) attempted to examine all aspects of the teaching of biology. They mailed 16,000 copies of a “rather elaborate questionnaire” to teachers across the United States. However, they cautioned that rural schools and schools of the South were not adequately represented. Apparently the means to find addresses for rural science teachers was simply not adequate, even though 34.7% of replies to the survey were returned from rural science teachers. Given these deficiencies, two results stand out. First, rural teachers reported having “good school buildings” in only 62% of cases, whereas cities reported “good school buildings” in 79% of cases. Second, rural schools reported an average of 36 books on biology available to their students, whereas city schools “reported an average of 150 books of a biological nature” (p. 184).

Johnson (1950/1969) conducted a national study of science teaching in U.S. public high schools in 1947–48. He drew a stratified random sample of the 23,947 high schools with 10 or more students. He found that chemistry was typically not

offered in very small schools, but that in high schools with enrollments of fewer than 100 students that did offer chemistry, approximately 25% of the 11th-graders were enrolled. In contrast, physics was much more commonly offered and enrolled about one-third of 12th-graders.

In the late 1960s, a study was conducted to examine the “differences among urban, suburban, and rural children’s particular interests in science” (Clarke, 1972) as part of a larger study to examine a variety of factors that influenced elementary school science learning across Massachusetts. Clarke offered a single vague finding regarding the rural and non-rural distinction: “a significant commonality of interests exists regardless of whether the children live in urban, suburban, or rural communities” (p. 135).

Studies of science in rural schools during the first two-thirds of the twentieth century were aimed at creating understanding of a few main issues. Curricular relevance and the nature of science were frequently topics of interest. But the physical isolation of many rural schools, coupled with their small size, tended to remove them from consideration as potential research sites.

The vision of rural as pastoral and happy, yet full of hard work, was alive and well during the first half of the twentieth century. Perhaps this was the time when the daily reality of rural schooling was in the process of becoming the myth. Clearly the negative aspects of the myth—the deficit model of rural education, including the need to alternatively teach portions of the curriculum to reduce teacher work loads, the belief that rural children were interested primarily in the objects of their daily life, and the comparatively poorer quality of buildings—were to varying degrees supported by research. Although there was little research on science education in rural schools during the 1960s and 1970s, in time interest would grow.

### **RENEWED INTEREST IN RESEARCH ON RURAL SCIENCE EDUCATION: THE 1980S AND 1990S**

Horn (1995) noted that rural education in general “enjoyed a new and more positive recognition” beginning in the mid-1970s. Before this time “literally no one in the federal government would claim responsibility for rural education” (Horn, p. 13). Recognition of the need to examine the teaching and learning in rural schools came from a variety of sources beginning in the 1980s. In 1983, U.S. Secretary of Education Bell announced the first policy on rural education (Horn). The policy was labeled the Rural Education and Rural Family Education Policy for the 1980’s and was intended to ensure equal access to funds and services provided by the U.S. Department of Education (USDOE). Horn reported that this policy was announced at the annual meeting of the National Rural Education Association and simultaneously focused attention on both the organization and the problems of rural communities as seen through the eyes of educators.

Although it is not clear whether it occurred as a result of the announcement of the national policy from the USDOE, there was a complementary surge of interest and published studies on rural schools among science educators. The research that produced these reports began in the mid to late 1980s and persisted into the mid-1990s, though perhaps not much beyond. This resurgence led to the formation of a group known as the National Committee for the Study of Options for Rural Sci-

ence Education (Prather & Oliver, 1991). Much of the research conducted during this resurgence came from needs assessments to determine the status of rural science education.

The largest needs assessment study was conducted by Baird, Prather, Finson, and Oliver (1994), who used a 100-item instrument developed by Zurub and Rubba (1983) and administered to 1,258 teachers in eight states. Nearly half of these teachers indicated their school as being "rural." Thus Baird et al. were able to conduct a comparison between rural and non-rural teachers. Additional needs assessments were conducted by Enochs, Oliver, and Wright (1990) in Kansas; by Carlsen and Monk (1992) in New York; and by Barrow and Burchett (2000) in Missouri. Although Carlsen and Monk (1992) found that rural teachers have less experience than urban or suburban peers, have fewer undergraduate science courses, have fewer teaching methods courses, are less likely to have a graduate degree, and are more like to teach non-science courses, the teachers in the Baird et al. study (and to a lesser degree in the Enochs et al. study) indicated remarkably similar needs across their school size and location. The top four needs identified by rural and non-rural teachers were the same and were ranked in the same order. These needs were (a) motivating students to want to learn science; (b) identifying sources of free and inexpensive materials; (c) using computers to deliver science instruction; and (d) using hands-on science teaching methods. Within the four highest ranked items, the only dissimilarity came from the higher absolute value of the need for using "computers to deliver science instruction." Science teachers in rural areas rated this need several percentage points above non-rural counterparts. As might be expected from the historical research on rural schools reported within this chapter, updating "knowledge/skills in environmental sciences" was the first item to break the parallel order between rural and non-rural teachers, taking a higher position for the rural teachers.

On the low end of the need scales were items related to issues of planning and implementing instruction. Both rural and non-rural science teachers gave low ratings to these issues. A few items across the spectrum of topics surveyed did show wide disparities between rural and non-rural science teachers. "Learning more about multicultural science education" had the greatest disparity, with 57.4% of non-rural teachers rating this as a moderate to great need, versus 46.1% of rural teachers. This was closely followed by percentages found for "maintaining student discipline." In this item, 37.7% of rural teachers rated this as a moderate to great need as compared with 47.7% of non-rural teachers.

In like manner, when identifying the frequent or serious problems in the teaching of science, rural and non-rural teachers agreed on several issues. These included insufficient student problem-solving skills, insufficient funds for equipment and supplies, inadequate laboratory facilities, and poor reading ability. Each of these was rated as a frequent or serious problem by 50–70% of each group of teachers. But several problems produced distinct response rates. Lack of science career role models and too many class preparations per day were seen as much more serious problems by rural science teachers. In contrast, large class size and lack of student interest in science were seen as more serious problems for the non-rural teachers.

Baird et al. (1994), by allowing science teachers to classify themselves as rural or not, gave wide latitude to the constitution of rural schools. This wide latitude mirrors the difficulty of creating a definition of rural schools. The variety of schools

included furthers the consequential difficulty of focusing the study of rural science education. Many schools look like rural schools because they are situated in rural places or in proximity to agricultural lands and woodland expanses. But as shown in a variety of studies (e.g., Gilbert & Yerrick, 2001), these rural schools sometimes have student populations bussed from city locations who live in communities much more appropriately characterized as urban. At the same time, some validity to this system of classification is offered by the ways in which teachers rate their problems in the self-identified rural versus non-rural schools. Correspondence was found when teachers who reported their schools to be rural also identified less need for professional development related to classroom management. Likewise, validation of this self-identification of ruralness was established when those teachers also reported a greater need for professional development dealing with computers in the classroom.

### WHAT IS RURAL IN A CONTEMPORARY SENSE?

One of the major problems for science educators attempting to review the research on rural education is the definition of what is and what is not rural. In many respects, this is largely an intractable problem. Rural schools frequently have physical characteristics that will be recognized when seen, but do not easily lend themselves to description. Horn (1995) saw it in this way: "The simple fact is that rural people, rural communities, and rural conditions are so diverse that one can find evidence to support nearly any characterization" (p. 3). Thus distance from a city, population density, apparent isolation, availability of resources, homogeneity of population, and similar characteristics are all considered important in some places but not in others. To complicate this factor even further, consider the following examples of research that dealt with self-described rural situations.

In the first example, Bradford and Dana (1996) titled their article "Exploring Science Teacher Metaphorical Thinking: A Case Study of a High School Science Teacher." *Rural* was not mentioned in the title but was a school descriptor applied by the authors. In the section of the manuscript regarding the participant, the school was described as being in a "rural school district in an economically disadvantaged part of a mid-Atlantic state" (p. 199). The reader learned no more about the school or the district than that single statement. It is difficult to classify this as rural research, although I do not intend this to be a negative reflection on the quality of the research.

Consider a second example. Gilbert and Yerrick (2001) titled their article "Same School, Separate Worlds: A Sociocultural Study of Identify, Resistance, and Negotiation in a Rural, Lower Track Science Classroom." This was an excellent study of how learners manipulate the classroom environment in order to "lessen the teacher's demands" for accomplishment and achievement and maneuver the teacher to accept work that was only marginal with regard to the original teacher-stated goals. Yet was this research rural? The researchers posed research questions that have the idea of "rural" at their core. For instance, their first question was: "What are key components of lower track science classroom discourse specific to rural contexts?" But the characterization of the school's ruralness seemed to disappear in the ultimate discussion of findings. Identified by the pseudonym Ridgemont High School,

this school was defined as rural by its location, 10 miles from a city of 50,000. This was the only criterion for its ruralness. The article stated that the black students come from within the city limits to the rural site to “rebalance” the racial mixture of the district’s schools. A central issue from the findings of the research was encapsulated in a single statement: “Instead of sharing a common discourse, lower track students and their teachers maintain separate discourses that are carved in response to and in opposition to the world view of the other” (p. 594). Did these discourse issues arise from the physically rural location of the school and its contrasts to the “in town” and “in the neighborhood” experience of the students? Quite likely the reader will be forced answer both yes and no. But the discourse issue was not really a rural school issue per se as much as an indication of a difficult mixing of socioeconomic class and racial and ethnic groups.

An older article raised a slightly different issue with regard to identifying rural science education research. Brown, Fournier, and Moyer (1977) titled their article “A Cross-Cultural Study of Piagetian Concrete Reasoning and Science Concepts among Rural Fifth-Grade Mexican- and Anglo-American Students.” The authors’ primary motivation came from the lack of research done with Mexican-American children at that time. They chose the rural school for this study out of convenience, as this school was willing to allow the needed testing. The children of Mexican-American heritage scored lower on both tests given, but the authors did not relate this to their ruralness. We were left to assume that rural schools of the U.S. West were simply where Mexican-American children were found.

Finally, a fourth study, which presented a picture of a rural community and ethnography of science education within this community, made an important point about rural science education research. In an article titled “Classroom and Community Influences on Youth’s Perceptions of Science in a Rural County School System,” Charron (1991) set the stage by writing, “Rural communities, like their urban counterparts, are composed of individuals with diverse backgrounds and points of view” (p. 671). These characteristics of individuals over long periods of time created “local universal understandings.” These understandings in turn created community perspectives on schooling and the value of learning; Charron attempted to capture how these understandings “influence children’s ideas about science.” Within the study of this rural community, it is impossible to discern how the findings might contrast to a non-rural setting; nor was this the author’s goal. We are not able to say in fact that the findings were uniquely rural, but rather were an ethnographic characterization of this particular community.

When two local parents were interviewed about the value of science, neither mother could name a single instance where she had made use of science knowledge in her daily life. Likewise, when the learners within this district’s schools reported their perceptions of science, characteristics emerged that are common among students from a wide range of locations and school settings. The students perceived that a description of science equated to a “laundry” list of topics, that science was a body of facts rather than a process of discovery, and that the activity of science led to the resolution of one correct answer that all scientists can agree upon. But in one statement there was a recognizable link to historical and contemporary findings from rural schools. Charron (1991) reported that “many students seem to focus almost exclusively on natural history content when discussing science out of class” (p. 684).

Charron (1991) reported that the community, although close to a university community, "maintained a large measure of commercial and cultural separateness" (p. 673). This statement suggested agreement with the condition suggested by Shroyer and Enochs (1987) that the rural schools lie outside the "sphere of influence" of the city. Charron's conclusion that "educators need to first identify community influences, and then build upon them" marks another point of convergence with this story of research in rural schools.

In the examples above, research was conducted and defined as rural, though it is not clear that each study would meet a test of ruralness based on demographic characteristics or governmental definitions. In each case, to the degree it was knowable from the publication, the school and community did not completely meet a set of criteria, including physical isolation, and size needed for identification as rural. In most of these examples, important contributions to the research literature of science education have been accomplished. But are they rural? To answer this question we are left in the position of the teachers in the Baird et al. (1994) study, mentioned earlier, where classification as to ruralness was allowed entirely by self-report. In that case, the researchers found reasons to believe their approach to classification as rural was valid; perhaps we must allow other researchers the same freedom even when we cannot match their classification scheme to any rational typology that used quantifiable statistics or data.

Perhaps statistics and data are the real issue. As has been shown in a great deal of research across the discipline of science education over the past 20 years, qualitative assessments of science education can sometimes supersede quantitative methods for their value of description and communication of understanding. And thus qualitative methods and especially ethnographic explication may signal an end to the long search for a definition of rural education that may no longer exist.

## **THE RURAL SYSTEMIC INITIATIVE REFORM IN RURAL SCIENCE EDUCATION**

The Rural Systemic Initiatives in Science, Mathematics, and Technology Education Program (RSI) were the third in a set of systemic reform initiatives to be created by the U.S. NSF (Russon, Paule, & Horn, 2001). Offered on a competitive basis to governmental, educational, and foundation-based groups, these grants were funded to "enhance mathematics, science, and technology education in economically disadvantaged rural areas through community development activities and instructional and policy reform" (p. 1). Thus the RSI reform was aimed at schools that were the educational institutions for concentrations of rural poor (i.e., counties with at least 30% of the school-age population living in poverty as designated by the U.S. Bureau of the Census; Horn, 2001). As such, the RSI program provided directives to its grant recipients that pointed their efforts toward "policy, leadership, and work force issues by involving communities in creating a comprehensive and sustainable system of mathematics, science and technology education that reflects current advancements in the area" (p. 1).

"Systemic reform" was a descriptive term developed by the NSF to describe an innovation in funded projects from that agency. Bruckerhoff (1998) reported that "systemic reform is the 'third wave' in contemporary educational reform" (p. 4) in the United States. Launched as a way to accomplish the government's Goals 2000

objectives, systemic reform was a product of the first Bush presidency and was created to “emphasize the federal government’s leadership role in systemic educational reform” (Bruckerhoff, p. 4). The idea of systemic reform was centered on the concept of reforming education comprehensively across a system. And though “system” was defined across a range (e.g., the schools of a district, city, state, or rural region might be considered a system), changing the system was believed to be key to profound and fundamental reform. In practice, the RSI program was one component of a much larger systemic effort that included local systemic initiatives, urban systemic initiatives, and statewide systemic initiatives.

At the heart of the systemic educational reform movement was a set of essential educational elements formulated to describe the range of goals around which the participating educational systems would attempt to change. Operationalized as the “drivers” of systemic reform, and tailored to the rural educational systems involved, these six principles became the force behind the implementation and evaluation of the RSI projects. And yet, these drivers did not always represent what rural educators as well as rural residents thought of as ideal educational goals. In the words of Russon et al. (2001), “the values and beliefs of some rural residents run contrary to the tenets and assumptions of systemic reform” (p. 8). Part of this rift was based in the assumptions of the degree to which the federal government should have any impact whatsoever in rural schools. As Fenstermacher (2002) has pointed out, the federal government must, if we are to have a liberal democratic government, maintain a minimal interest in education. In the United States, the state’s role in education is “deeply embodied in American history and heritage” (p. 22).

The six drivers of rural systemic reform cross the spectrum of educational provenance. These drivers were intended to be guideposts or standards about which the progress of systemic reform could be measured. Driver 1 was created to focus efforts on the implementation of standards-based curricula. Included was a companion notion that the assessment of student learning would occur across every classroom, laboratory, or other learning venue. Driver 2 focused reform efforts on the development of consistent sets of policies aimed at accomplishing high-quality science education. These policies included the need for excellent science teacher education, professional development, and administrative support toward the goal of improving achievement of all students. Driver 3 complemented Driver 2 by providing direction to the convergence of all resources, regardless of their source, and the ongoing monitoring of progress in the implementation of reform ideas. The fourth driver sought to provide a directive through which all stakeholders were brought into a single effort. Parents, policy makers, businesses, foundations, and others directed their efforts in consistent support of the systemic reform. Driver 5 was a statement regarding the need to accumulate a body of evidence, both broad and deep, so as to ensure that the program enhanced student achievement. Finally, Driver 6 spoke to the improvement of achievement of all students, including those historically underserved.

In order to create a tool for measuring how the various rural systemic projects were accomplishing the drivers, Horn and his colleagues (Russon & Horn, 1999) at Western Michigan’s Evaluation Center created a list of 123 indicators. These indicators were drawn from the research literature of three areas: systemic reform, evaluation of systemic reform, and rural education literature. The indicators were then subjected to a matching process through which they were aligned with one of the six drivers. Using a two-round Delphi technique, for which the Research Advisory

Team for the RSI Evaluation project served as judges, there was ultimately an 80% agreement regarding 75 indicators from the original list with regard to their driver match.

This list of indicators was then used as the basis for both the quantitative and qualitative evaluations of the RSI projects. When used quantitatively, the indicators presented a picture of the factors that school stakeholders found most important in the accomplishment of rural systemic reform. Indicators related to Driver 1 (implementation of a standards-based curricula) tended to be rated highly by all respondents (mean = 4.06 on a 5-point scale). Interestingly, the lowest ratings for the importance of this driver came from the stakeholders of the schools of a Native American community. Those respondents in Gila River, Arizona, rated this item with a mean of only 3.68 out of 5. The highest rating was for Driver 4 (administrative support for all persons . . . to improve student achievement). With an overall mean of 4.13, 5 of 6 site visit locations rated Driver 4 the most important (Horn, 2001).

Within the evaluation data for the RSI projects, there were also indicators of the status of rural schools and the science teaching in these schools. Across the six data-reporting categories, teaching experience showed a progression toward more experienced teachers. The data reported were as follows: less than 1 year, 7.7%; 1 to 5 years, 17.1%; 6 to 10 years, 16.9%; 11 to 20 years, 25.2%; and more than 20 years, 33.1%. These figures did not stray in significant ways from the national averages, though it has been commonly reported that more experienced teachers migrate to urban/suburban districts. Demographics related to race pointed to the distinctive nature of the schools within the RSIs. Overall, just over 26% of the teachers and other school personnel were African American, and almost 70% were reported to be Caucasian/white. At the level of individual sites, wide disparities come to the fore. An eastern Kentucky site in the Appalachian RSI reported 98.6% of its personnel as white. A Mississippi delta site reported that 75.2% of its personnel were African American. Llamas (2000) reported that the Utah, Colorado, Arizona, New Mexico (UCAN) RSI included 46 Tribal Nations as well as historic communities. Within these communities, 53% of students were Native American and 25% Hispanic. A commonality among these communities also was that the sites were home to large numbers of people living in poverty. Although populations within RSI sites were often homogeneous with regard to race or ethnicity, across sites almost all major cultural and racial groups of the U.S. population were represented.

The evaluation of the RSI projects used quantitative measures to assess the impacts of the resources provided. Across the three RSIs that were first evaluated, professional development activities were rated as having had the highest impact. Specifically, the most valuable professional development resulted from those activities that were aimed at changing the way teachers perform. Close behind, however, the districts' stakeholders rated the impact of new resources and curriculum changes brought to the district (Russon, Stark, & Horn, 2000).

Findings throughout the sites validated the important role of school administrators in encouraging reform. When asked about the factors that facilitated reform, stakeholders reported that district administration and school principals were far and away the most important. Approximately 88% of respondents identified these two groups as the most important facilitators of reform. The existence of state curriculum standards ranked third, followed by the school board, computer availability, and other educational materials. In contrast, the primary barriers to systemic re-

form in school districts were money, lab equipment, and science materials, followed by teacher turnover, community support, and expectations for students. The other less-mentioned factors included such things as teacher preparation, teacher subject knowledge, educational materials, and other district projects. The three factors with the lowest ratings with regard to putting up barriers were state standards, school boards, and school consolidations (Russon, Stark, & Horn, 2000).

### **Driver 1: Standards-Based Curricula**

In small rural schools, a variety of factors converged to make the accomplishment of the RSI Drivers a reality. In the area of Driver 1 (curriculum-related), small school size and the availability of human resources presented considerable challenges (Russon et al., 2001). The small school, for instance, might have been unable to offer higher level courses in mathematics or science. As Russon and his colleagues stated, these were precisely the courses favored by the advocates of systemic reform. In answer to these concerns, RSI school districts responded by using those tools and techniques available to them. Course "audits" were conducted by the RSI staff to examine the match between curricular/instructional activities of a particular teacher in a specific course and the state-level assessments for that course. At the Appalachian RSI, a web site of standards-based curriculum materials was maintained and supplemented professional development and course audits. A school district on a western Native American reservation created curricula that were not only standards-based, but also culturally relevant. In accordance with the historic farming tradition that has characterized the Gila River Indian Community, members of the community aided the school in creating a garden that was the centerpiece of the school's curriculum. The Appalachian example was clearly a product of NSF resources funneling to the district through the RSI, but the Gila River project probably happened independently of those particular resources.

Analysis of other sites within the RSI projects showed that long-term planning based on standards-based curricula was not possible in any realistic sense. One southern Mississippi county had such a high turnover rate among science teachers that it was impossible to consistently deliver a standards-based curriculum. Other rural districts in states with high-stakes testing programs reported that the curriculum was as much a mirror for the testing program as it could be made to be (Russon et al., 2001).

### **Driver 2: Consistent Policy**

The rural school districts sampled as part of the RSI evaluation ranged across the social and political spectrum with regard to the population from which they were drawn and the governance from which their policies were built. Thus a district's ability to respond to Driver 2 (development of a coherent and consistent set of policies) was somewhat at odds with its strictures. One school district on a Native American reservation consisted of a set of schools that were overseen variously by community, district, tribal, county, state, national, and/or religious governance. Different schools within this single district were overseen by different combinations of these seven, including one school that was governed by a combination of religious and tribal boards (Russon, Horn, & Oliver, 2000).

### **Driver 3: Convergence of Resources**

The third Driver was probably the most successful across the spectrum of RSI districts. The financial resources of the RSIs were used to bring together all resources to support science and mathematical education. The evaluators felt that “RSIs mostly worked to promote the convergence of human resources. This was primarily accomplished through professional development and directed assistance in utilizing state and federal grant funds to support a common effort to improve science and/or mathematics education” (Russon et al., 2001, p. 37).

### **Driver 4: Broad Support from Stakeholders**

Traditionally the belief is that schools in rural areas receive the support of their communities, and clearly some do. But the full accomplishment of Driver 4 (broad-based support from parents, policy makers, institutions of higher education, business and industry, foundations, and other segments of the community) among RSI projects was rarely seen. “Some schools received an abundance of support from parents. Math and science nights were common across the RSIs, and in some cases they were well attended. In other cases, the parents were far more likely to support the football or basketball team” (Russon et al., 2001, p. 38). Likewise, some districts and RSIs were successful in bringing institutions of higher education into their sphere of financial and resource supporters. The Appalachian RSI was notable in its success in creating collaboratives with five partner institutions of higher education (Horn, Oliver, & Stufflebeam, 2000). Other RSIs had more limited success.

The UCAN RSI designed its primary approach for working within the community: “From the outset, UCAN RSI believed and acted on the premise that the ‘community’ as locally defined would best represent the constituents that we wanted to serve. Operationally this meant correctly identifying and working with the unit of change at the local level” (Llamas, 2000, p. 16).

Llamas went on to describe at length the means by which community partnerships and collaborations were formed in the UCAN states:

In a similar vein, RSIs had only scattered success with business and industry partnerships. A few sites within the projects found ways to create meaningful partnerships that resulted in new resources or grants. Ultimately, the evidence related to this Driver demonstrated most effectively that school districts considered the RSIs to be a valuable addition to their pool of resources, but not a universal remedy. Discussions with school personnel showed that it was not always possible to separate the effect of RSI resources from the input of other funded and gifted projects. In some districts, there were many of these “other” projects. (Horn et al., 2000)

### **Driver 5: Evidence of Student Achievement**

The current tenor in the United States and elsewhere requires increased student achievement as the most important justification of funding. But in the rural districts of the RSIs, many problems were encountered in the accomplishment of Driver 5. Although the body of research that had accumulated regarding rural school curric-

ula over the past 100 years suggested the need for local relevance and applicability in science and mathematics study, there is no evidence arising from the RSIs that standardized assessments can measure this. In fact, as Russon et al. (2001) wrote in their summary to the case studies of the six RSIs under study,

There is no clear evidence that standardized tests prepared for mass administration across all school districts in all states are related to the missions and goals of the schools, the focus of the schools' curricula, or the classroom instruction students receive. Failure to meet the standard for any one of these three conditions would invalidate the results as being a fair assessment of student achievement or even instructional/school effectiveness. (p. 39)

### **Driver 6: Improvement of Achievement for All Students**

In the site visits of the RSI evaluation team, the results regarding Driver 6 were difficult to discern. (This is probably an example of needing to wait a bit longer before reaching a conclusion.) Because the requirements for inclusion in an RSI were that the site be an isolated rural place as well as one with a high number of students qualifying for free and reduced lunch, the ethnic and cultural variability among the students tended to be greatly reduced. In other words, these schools were typically completely or almost completely homogeneous with regard to race and ethnicity. In two study sites, the white students attended private academies, leaving the public schools almost entirely attended by African Americans (Horn, 2000). A study site on a Native American reservation was attended by an entirely Native American student body. Thus within these study sites, almost all students could be described as historically underserved.

So what can be said about the RSI evaluation data at this point in time? First and foremost, the evaluation process is ongoing, and a final report may shed light in places that the formative reports did not. But the idea that a single large-scale project can have a substantial impact on the rural poor school districts of a region that included six states and hundreds of qualifying schools may simply be too much to ask. Regardless of this, the evaluation of the rural sites for the RSI projects is providing an important source of information about the status of schools that hold the responsibility for educating rural students living in poverty.

## **CONTRASTING RURAL AND NON-RURAL SCHOOLS**

Studies that contrast characteristics of teachers or students in rural schools with their non-rural counterparts are relatively rare. A few were mentioned in the previous "Needs Assessment" section. Three other recent studies that examined science education in rural and non-rural schools are considered here.

In 2000, Deidra Young examined the impact of ruralness on student achievement in Australia and the impact of student perceptions of their own academic ability. This longitudinal research was part of the *Western Australia School Effectiveness Study*. Involving a total of over 1000 students, data were collected during 1996 and

1997 from students in 21 schools representing 106 classrooms. Instruments included a version of the TIMSS achievement test and an instrument to measure classroom climate and academic self-concept of students (Young, 2000).

This study challenged the belief that there was a value-added component of expected student achievement that resulted from the school's special characteristics. Rather, Young (2000) found that most of the variability in the construct of student achievement occurred at the student and classroom levels.

In keeping with typical beliefs about rural schooling, Young (2000) found that "students in country schools [described as both rural and remote] appeared to be more satisfied with their schools. They felt that their teachers were more supportive, friends were more supportive and generally felt safer" (p. 212). However, with regard to achievement, the author concluded:

. . . while rural differences were apparent to student outcomes such as science and mathematics achievement and academic self-concept, these differences were of no consequence when investigated using sophisticated multilevel modeling techniques. That is, rural students were not disadvantaged by their location. Rather, rural students were disadvantaged by their self-concept. Students in rural schools did tend to have a weaker belief in their own academic ability to perform, irrespective of their actual ability. (p. 221)

In the United States, Simpson and Marek (1988) found a somewhat different result. Building from an assumption that rural students have fewer opportunities for intellectual development, the authors conducted a study to test the hypothesis that "students attending large schools [would] show more instances of understanding . . . of the concepts of diffusion, homeostasis, classification, . . . and food production" (p. 363). They found that students attending large high schools developed greater understandings of the concepts of diffusion and homeostasis. However, with regard to the concepts of classification and food production in plants, there was no relationship of understanding to school size.

Simpson and Marek (1988) hypothesized that the difference in the learning accomplishment observed could be due to a variety of factors. One factor that figured prominently in their thinking was that the differences "could be due to a higher percent of students in large schools capable of formal operations; sound understandings of diffusion and homeostasis required students to use formal operations" (p. 372). But they also pointed to occurrences in the daily lives of the students. In the rural schools within the study, Simpson and Marek indicated that many students were children of cotton and wheat farmers. Their experiences on these farms "allowed them [the students] to develop some understandings of food production in plants and prevented instances of misunderstanding from being developed" (p. 372). The idea of the importance of teaching and learning within the local context again was thus a recurring theme.

Two researchers from Utah State University conducted a large-scale study (Fan & Chen, 1999) of the data generated by the U.S. National Education Longitudinal Study of 1988. Overall their results suggested that "rural students performed as well as, if not better than, their peers in metropolitan schools" (p. 31). Their work covered the entire curriculum and included an excellent review of the relevant literature.

Fan and Chen (1999) subdivided their analysis across racial/ethnic subcategories (e.g., Asian/Pacific, Hispanic, Caucasian, and African American), locational subcategories (e.g., rural, suburban, and urban), grade-level subcategories (e.g., 8th grade, 10th grade, and 12th grade), geographical subcategories (e.g. Northeast, Midwest, South, and West), and subject matter areas (e.g., reading, mathematics, science, and social science). The analysis used multivariate statistics to test hypotheses across these many subcategories instead of more commonly applied univariate tests. They showed that univariate tests lacked the power to discern statistical significance between the categories of variable in their data. Ultimately, they concluded: "Students from rural schools perform as well as their peers in metropolitan areas in the four areas of school learning: reading, math, science, and social studies. These results did not support the conjecture that students in rural schools nationwide are at a general disadvantage in terms of the quality of their education, at least, as reflected in their performance on a standardized achievement test" (p. 42).

This study did not allow for the inclusion of "extreme rural communities" because the data was classified according to U.S. Census categories that do not provide that degree of specificity.

## RURAL SCIENCE TEACHER EDUCATION

The preparation and continued professional development of rural science teacher education have been the subjects of a variety of research efforts over recent history. These efforts have tended to focus on inservice rather than preservice science teacher education, though there has been representation across the levels. Much of what has been written regarding rural science teacher education and development is not research in the rigorous sense of the word, but rather what might be characterized as documentation and comment. The overall depiction of research on rural science teacher education is and has been one of neglect (Finson & Beaver, 1990; Shroyer & Enochs, 1987).

However, consistent throughout the literature of rural education teacher education is the idea that rural education and the context in which it occurs combine to form a core construct that must always be considered. Science teacher education designed to produce teachers for the rural areas must be cognizant of this issue. Nachtigal (1995) was speaking at least partially about teacher education when he wrote, "Science education in the rural schools, rural student and rural communities [has] not been well served by the mass production, one-best-system of schooling" (p. 116).

Yerrick and Hoving (2003) pointed to the writings of Nachtigal when they suggested that science teacher education for rural students must be cautious not to promulgate ideological positions that promote "injustices against . . . underserved students" (p. 414). These authors found that effective preservice teacher education that prepares prospective teachers to teach rural African American students in early high school physical science courses could be accomplished through a combination of strategies. These strategies include formal opportunities to make recordings of teaching sessions and conduct examinations of them; collaborative reflection; focus groups with students; "access to exemplary teaching curriculum" (p. 414); modeling alternative teaching strategies; and course readings that are helpful in creating dialogues about common problems (Yerrick & Hoving).

Inservice professional development for rural science teachers was the subject of a study by Shroyer and Enochs (1987). They worked with a group of teachers drawn from a pool of 141 U.S. school districts “outside the sphere of influence of cities with populations over 100,000 and [having] less than 600 students K–12” (p. 39). Their work began with a “needs analysis” recognizing that small schools must identify their unique needs as a first step. The program of professional development continued through “strength assessment” and then to “action planning.” In the action planning phase, the teachers created a plan for implementation as a means to ensure that the reform initiatives were in keeping with the nature of this rural school.

In research on rural schools, it is often true that the rare study that takes a comprehensive look at the entire rural school is particularly enlightening. A study by Scribner (2003) accomplished this by examining teacher professional development in three rural high schools. These schools were identified based on two criteria—small dispersed school populations and seasonally based community economies. Although not specifically about science teaching, the article was highly relevant to science teacher professional development in the rural school. Scribner found that the small rural high schools did not have a departmental context as is found in larger schools. In the absence of these departments, Scribner reported that the most important context for the teachers was the classroom “or at times, their professional community external to the school” (Discussion section, paragraph 2). Interestingly, he also found that in these schools, teachers of “well-defined knowledge bases such as math and science” (Discussion section, paragraph 3) tended to focus their efforts on the transfer of conceptual knowledge. Teachers of other disciplines, specifically identified by Scribner as language and social studies, “used the content of their subject area to broadly address student needs” (Discussion section, paragraph 3). Furthermore, teachers in these schools found professional development that was locally sponsored by the school or district to be of little value, in contrast to the value they seemed to place on state “legislated” support. Overall, Scribner found that teachers were tightly wound into the student-teacher interaction of the classroom and tended to value only the “most practical and immediately applicable knowledge/skill” (Discussion section, paragraph 4) as a means to inform their practice.

These few studies of preservice and inservice teacher education represent much of the research available on science teacher education for the rural school. This paucity of research is a reflection of the field of rural science teacher education. Although there are many college and university science teacher education programs that serve areas that are largely rural, they only rarely serve areas that are exclusively rural. Thus one does not find teacher education programs aimed at producing science teachers exclusively for the rural school, but rather science teachers for the bigger markets.

Consistent themes run throughout these studies of teacher education and development. These themes center on the need for rural teachers to teach science within a frame of reference that consciously builds a curriculum with a cooperative inclusion of community, the unique student and school needs found in that community, and the inimitable capabilities of the teachers found in those schools. The aspects of these themes hark back to the characteristics of rural schools suggested by Sher (1983). Thus science education in the rural school must be constructed from the building blocks that exist in rural schools.

## SUMMARY AND IMPLICATIONS

A major chapter in the life of rural U.S. schools has ended with the closing of the ERIC Clearinghouse for Rural Education and Small Schools (ERIC Clearinghouse on Rural Education and Small Schools, 2003). And yet, almost simultaneously, U.S. Secretary of Education Rod Paige announced a new recognition for the needs of rural schools: "too many rural students have not received the high-quality education they deserve. . . . Although our nation's rural schools may be physically removed from urban areas, they are no longer isolated from policy-makers" (USDOE, 2003, paragraph 5).

Perhaps it is a good moment to ask, what has really happened in rural science education? The 1970s and 1980s renaissance noted by Horn and others (Horn, 1995; Prather & Oliver, 1991), after such time when "literally no one in the federal government would claim responsibility for rural education" (Horn, 1995, p. 13), seems to have run its course. The excitement among a group of science educators, which resulted in the formation of the Committee for the Study of Options for Rural Science Education and the completion of several significant projects (for instance, Baird et al., 1994), has faded. In educational research, such conditions often signal that a rebirth is just around the corner. It is for a new group of educators to take up this torch, if it is to be taken up at all.

Rural science education research has quite often lacked the theoretical sophistication of other work, though the research of Charron (1991) and Gilbert and Yerrick (2001) provides excellent counterpoints to this assertion. Rural science education research has tended to reflect the myth of rural America with its emphasis on pragmatism and resourcefulness. The RSI program made an impact by focusing attention on the areas that are home to the rural poor. It is perhaps here, where a concentration of individuals exists and shares a set of "local-universal understandings" consisting of socioeconomic, political, cultural, and ethnic characteristics, that we find the definable rural place. But so often this definable rural place also faces a harsh reality that is mired in poverty. Thus, there is great need for the people of this place to bring forth any available pragmatism and resourcefulness to address the issues of schooling and especially science education. This is what Prather (1995) meant when he wrote, "The necessities of rural school teaching have made thoughtful and determined risk-takers of many teachers and school officials" (p. 40).

In 1935, Wolford found that rural high schools usually had to either create their own curricula or follow the textbook. He concluded that most did the latter. This was not a surprising finding in the 1930s, or in any later decade. Horn (1995) described the rural school curricula as minimal, including only what is required by the state. In those districts, the observer would expect to see science teachers following a textbook. But what else could that rural district do? Hope has persisted across the past 100 years that locally relevant curricula could be enacted in rural and small schools in the United States and throughout the world. These locally created and locally relevant curricula have been seen at various times and locations as the means to motivate learners and to address needs of the community. But the realities of standardized tests, frequent turnover of teachers, lack of material support, and lack of administrative support conspire to suppress curricula creation and enactment. And yet the hope remains alive. Perhaps best stated by Blunck et al. (1995), "Science education in rural settings may be able to provide the most conclusive and

useful examples of successful reforms due to the ability of personal experiences to drive knowledge exploration in real life contexts" (p. 90).

Studies of the teachers of science in rural areas and the students in their schools have suggested a lack of difference between them and their non-rural peers. From the needs assessments, distinctions can be drawn between teachers of rural and non-rural places, but these fade into the scenery created by the similarities. Likewise with students, there are differences to be noted, but the bigger picture is one of similarity. If we look at the individual trees of this forest, we might miss the bigger picture. Clearly and quite importantly, the RSI evaluation has shown that there are unique forests, or at least groves (to fully expend the metaphor) within that sphere that stand apart from the norm where students with great educational needs are well educated. The response to these needs will quite likely come from researchers and educators who have a particular interest in a specific aspect of the rural schooling story.

And finally, where do we leave the question of technology and its potential to bring universal access to knowledge to all persons regardless of location? Finson and Dickson (1995) found that geographic isolation of rural schools became less of a barrier to student learning when distance learning technologies were employed. The World Wide Web offers a distance learning technology a quantum leap above the technologies to which Finson and Dickson referred. The day is quickly coming when the number of books in the library simply will not matter, because all of the important books will be accessed through electronic media. The day is also quickly coming when the substance of the textbook will not be the most important source of the structure of science-based curricula. Computer-based technologies that re-create the curricula with the use of animations, simulations, digital video, and hypermedia, combined with the powerful search capabilities within the World Wide Web, will offer learning opportunities that are truly new and widely available. Whether these learning opportunities are able to capture the relevance of a local community's science issues, measure outcomes with assessment tools complementary to these approaches, and not merely rely on the learner's knowledge of science facts remains to be seen.

## ACKNOWLEDGMENTS

Thanks to William Baird and Jerry Horn, who reviewed this chapter. The author would also like to thank Dr. Jim Spellman, who as a graduate student assisted in the search for the research literature reviewed in this chapter.

## Science Teaching

# CHAPTER 14

---

## General Instructional Methods and Strategies

**David F. Treagust**

*Curtin University, Australia*

There is a multiplicity of instructional methods and strategies used in science classes that vary from those that are primarily didactic or teacher-centered to those that are primarily student-centered or learner-centered. A major consideration in writing this chapter was to organize these methods and strategies within some coherent framework such that readers can also locate instructional methods and strategies not described and discussed in this review.

Instructional methods and strategies can be organized in terms of the amount of direct control that teachers and instructors have over their implementation. Consequently, the organizing theme for this review is the degree of teacher-centeredness compared with student-centeredness of the methods. Six general instructional methods and strategies in teaching science in schools and universities are discussed, namely, demonstrations, classroom explanations, questioning, forms of representations, group and cooperative learning, and deductive-inductive approaches such as the learning cycle. Each of these general methods has elements of both teacher-centeredness and student-centeredness, but the order of presentation in this chapter ranges from more to less teacher-centeredness in the instruction. Strategies and teaching approaches have been omitted from this review, and it is intended that the reader can determine where omitted teaching approaches fit in the framework. Gabel (2003) has reported a similar range of effective strategies for learning science.

Four considerations over the past two decades have had a major influence on the type of instructional methods and strategies used in science classes, and these underpin the methods reviewed. The first consideration is the acknowledgment that learners construct their own individual understanding and that this can be promoted by specially designed instruction (Anderson & Helms, 2001; Duit & Treagust, 1998). Within this consideration, learners intentionally construct their own knowledge, using their existing knowledge, and thereby are able to view the world in ways that are coherent and useful to them (Sinatra & Pintrich, 2003). The second consideration is that the content of the science to be learned is acknowledged as a

problematic issue. Few researchers who investigate students' learning of science comment on the problematic character of the science content itself. Rather, the accepted focus of several decades of cognitive pedagogical research has been to provide suggestions for improving the teaching and learning of particular science topics (see, for example, Fensham, 2001; Fensham, Gunstone, & White, 1994).

The third consideration that pervades the instructional methods discussed is the promise that teaching strategies and approaches aimed at enhancing student metacognition might lead to corresponding improvements in conceptual understanding of curricula (Gunstone, 1994; Hennessey, 2003). According to Baird & White (1996, p. 194), "metacognitive strategies are employed by a person in a process of purposeful enquiry and . . . comprise reflection (to determine purpose) and action (to generate information)." Consequently, there is much "promise that interventions aimed at enhancing student metacognition might lead to corresponding improvements in conceptual understanding of curricula content." Strategies such as the use of concept maps (Novak, 1996), predict-observe-explain tasks (White & Gunstone, 1992), personal logs, reflections, portfolios, and discussion have been shown to be of value in the development of metacognitive capabilities. The fourth consideration is the realization that many teachers have utilized many of the methods described here in a form of action research as they examine, implement, and evaluate these methods (see, for example, Hodson & Bencze, 1998).

Each section starts with the key theoretical and empirical issues of learning identified in the literature that underpin each type of instructional approach. This is then followed by some examples of research to illustrate the effectiveness or otherwise of each instructional approach. This short review of general instructional methods and the usefulness of these strategies discusses existing research and is intended to help readers to re-evaluate the status of these methods and strategies in science education, to ask new questions, and to spark further improvement in some new directions in research and practice related to general instructional methods and practices.

## DEMONSTRATIONS

For over a century, laboratory work has been used in teaching and learning school science. With the popularity of the constructivist-informed teaching approaches since the 1980s, teachers have emphasized the role of hands-on experiences in learning science (Hofstein & Lunetta, 2004). In this chapter, the focus is on demonstrations in teaching science, which are a less expensive or a safer way of providing students with experiences of laboratory experiments. Drawing on an extensive literature review of laboratory work, White (1996) argued that this ubiquitous practice of teaching school science for more than a century did not appear to directly improve understanding of science because "imaginative practices are rare and mindless routine common in school laboratories" (p. 771). Details about the laboratory in science teaching are found in Chapter 16 and are not repeated here. Although the use of demonstrations in teaching science does not serve all of the main goals of laboratory work highlighted by Lazarowitz and Tamir (1994), such as skills, concepts, cognitive abilities, understanding the nature of science, and attitudes, it does serve to motivate students in the science classroom (White, 1996).

## Demonstrations for Motivation

Laboratory demonstrations in the teaching of science can provide colorful, surprising, or dramatic effects—such as burning a piece of magnesium ribbon before a junior class of science—which motivate students but do not necessarily help them develop an understanding of the particular concept being demonstrated. Roth, McRobbie, Lucas, and Boutonne (1997) have shown that there are good reasons why students may fail to learn from demonstrations about motion, namely because students who come to the practical classes with their own ideas about motion do not observe the phenomena they studied as expected by their teacher. Similarly, the teacher expected the instructions to be self-evident but did not realize that their students did not share his theoretical perspective. Consequently, for demonstrations to be effective, research has shown the central importance of the instructor as a mediator of student learning and an interpreter of the content of science (Watson, 2000).

Demonstrations that create interest have the potential to engender learning by combining demonstrations with teachers' classroom explanations (Ogborn, Kress, Martin, & McGillicuddy, 1996). Ogborn et al. produced an interesting and thought-provoking analysis of how science teachers can utilize demonstrations in the classroom to explain science and thereby improve the level of understanding of the science concept introduced by the demonstration. Their work is discussed more fully in the section on Explanations.

## Demonstrations to Increase Student Cognitive Involvement

To make demonstrations more student-centered, teachers may consider using Predict-Observe-Explain (POE) activities described by Champagne, Gunstone, and Klopfer (1985); White and Gunstone (1992); and Gunstone (1995). POE activities can be a very useful way to juxtapose demonstrations with explanations. In a POE activity, students are first asked to predict what would happen next in a demonstration. Subsequently, they have to observe the demonstrations carefully and finally to explain what they have observed. The teacher can have a follow-up group or whole-class discussion with the students to discuss their observations and explanations. One example of effective use of POEs in teaching science is Palmer's (1995) study in primary schools in which the POE technique was used by teachers to identify students' knowledge and to understand their science conceptions and their process skills development. As another example, Liew and Treagust's (1995) studied the use of POEs for the topic of heat and expansion of liquids with grade 11 physics students. Students' learning was evident in their observations and interpretations; frequently their prior beliefs, knowledge, and expectations influenced their observations, which both positively and negatively affected their new learning.

## Demonstrations Enhanced by Computer Software

The use of technology in science education has been extensively discussed by Linn (2003), although her review did not directly mention demonstrations. However,

three of Linn's discussion points were science visualization, science simulations, and modeling, each of which can be relevant to demonstrations. Indeed, computer technologies allow more interactive POE activities to be used in instruction to engender student understanding. As an example of these activities, Kearney, Treagust, Yeo, and Zaknik (2002) incorporated POE tasks into a multimedia computer program that used real-life digital video clips of difficult, expensive, time-consuming, or dangerous scenarios as stimuli for these tasks. Projectile motion phenomena in physics were used in designing the POE tasks in the study. The findings indicated that multimedia-supported POE tasks had a noticeable impact on the 10th- and 11th-grade classroom environment in allowing students to control the pace of their learning, to confidently discuss their learning while manipulating and observing the demonstrations.

In another study, science teachers used POE activities from an interactive computer program BioLogica (Concord Consortium, 2001) in 10th-grade classrooms to foster a deeper understanding of genetics reasoning (Tsui & Treagust, 2003). In the computer activities, students were given tasks that involved the prediction of the observable changes when they manipulated the objects in the multimedia. The findings suggested that the multiple representations of genetics in BioLogica with embedded POE tasks might have contributed to students' development of genetics reasoning by way of engendering motivation and interest. Furthermore, such POE tasks embedded in computer multimedia are likely to foster classroom social interactions conducive to co-construction of knowledge. This latter concern was evident in Kozma's (2000) study on students learning chemistry with computer multimedia; the findings suggested that the new symbol systems per se were not sufficient to aid learning and that "these new symbolic systems and their symbolic expressions may best be used within rich social contexts that prompt students to interact with each other and with multiple symbol systems to create meaning for scientific phenomena" (p. 45).

The general findings from these studies indicated that demonstrations in the form of POE tasks delivered through interactive computer multimedia can provide new learning opportunities for students in science education and have implications for authentic technology-mediated learning in science classrooms. When students became more motivated and more engaged, they were more likely to develop a better understanding of the content of science because they can play an active or intentional role in the process of learning (Bereiter & Scardamalia, 1989).

## CLASSROOM EXPLANATIONS

In order to contribute to students' ability to make sense of the world, science teachers' descriptions and explanations of scientific phenomena are critically important activities in classroom teaching (Horwood, 1988). Accordingly, description is intended to provide pieces of information, not necessarily related, but explanation is intended to connect between and among pieces of information. Treagust and Harrison (1999) highlighted the importance of teachers' effective explanations in the classroom and how the expert teachers "draw creative word pictures that both appeal to and inform a diverse group like a class of students" (p. 28). As such, how to verbally explain science concepts to students and teach them how to verbalize their

understanding is important. As Johnson-Laird (1983) put it, "if you do not understand something, you cannot explain it" (p. 2).

In science teachers' classroom explanations, it is very common to employ deductive and inductive strategies in an interactive way. Usually verbal or written language is used together with gestures, and sometimes the explanations may also use some actional-operational strategies, such as physical models or demonstrations (Gilbert, Boulter, & Elmer, 2000). Researchers have identified the use of language in classroom explanations as having paramount centrality for understanding science (see, for example, Yore, Bisanz, & Hand, 2003; Sutton, 1992). Furthermore, the work of Ogborn et al. represents a marriage of frameworks from the more traditional science education and those from language and communication, particularly semiotics. Ogborn et al. considered classroom explanations of science as analogous to stories and summarized four roles of language used in meaning-making during explanation of science in the classroom: (1) creating differences—the teacher explains science by making use of the differences between herself and her students (e.g., knowledge, interest, power, familiarity of the content, etc.); (2) constructing entities—the teacher explains by using some created entities or "new chunks of meanings" (e.g., *energy*, *heat*, or *gene*) (p. 14) about which students are to think when the teacher "talk[s] [them] into existence" (p. 14); (3) transforming knowledge—the teacher explains the constructed entities by using narratives, particularly analogies and metaphors (e.g., an eye as a camera or the pituitary gland as the conductor of the hormonal system) (see Sutton, 1992); and (4) putting meaning into matter—the teacher explains by demonstration and persuades students that things are as they are shown or by imposing meaning into the things (e.g., tissue is to be seen as cells).

The first two roles are mainly deductive strategies in which the teachers communicate to the students the concepts of science and provides some necessary contexts as motivators or advance organizers. The third and fourth roles engage the students in the use of inductive and deductive reasoning in an interactive way while the teacher emphasizes the explanation to engender student understanding of the particular concept.

Ogborn et al.'s work on classroom explanations is in line with recent interests of science educators in the use of language (e.g., Halliday & Martin, 1993; Lemke, 1990; Yore et al., 2004) and more discursive practices (e.g., Bell, 2000) in classroom instruction. Their work is also in keeping with another recent interest in Vygotskian perspectives among science educators such as Hodson and Hodson (1998) and Howe (1996), who argued for using a Vygotskian sociocultural perspective in the teaching and learning of science.

## QUESTIONING

Discursive and sociocultural practices in the science classroom are relevant to instructional practices such as wait time (Rowe, 1974), dialogue patterns (Lemke, 1990), and checking student understanding in classroom discourse (Mortimer & Scott, 2000).

First, research has indicated that questioning during classroom teaching is often unproductive without wait time for students to think before answering. On the basis of an extensive review of the literature, Tobin, Tippins, and Gallard (1994) con-

cluded that wait time (Rowe, 1974) appears to be an important factor in instruction when teachers pursue higher-cognitive-level learning in their students. Appropriate wait time during questioning affects higher-cognitive-level achievement directly by providing additional time for student cognitive processing and indirectly affecting the quality of discursive teacher-student interactions.

Second, teacher and student discourse in the classroom is affected by the way that teachers use questioning. For better meaning-making, more useful questioning has to go beyond the triadic dialogue in which the teacher asks questions, calls on students to answer them, and then evaluates their answers. In analyzing such discourse, Lemke (1990) suggested dialogues other than the triadic dialogue, such as student-questioning dialogue—a pattern in which students initiate questions on the content of the lesson and the teacher answers them; the teacher-student duologue—a prolonged series of exchanges between the teacher and one student in triadic dialogue or student-questioning dialogue; teacher-student debate—a prolonged series of exchanges in which students challenge or disagree with the teacher on the content of the lesson; true dialogue—a pattern in which the teacher and the student(s) ask and answer one another's questions and respond to one another's amendments as in normal conversation; and cross-discussion—a pattern in which students speak directly to one another about the subject matter and the teacher acts as a moderator or an equal participant without special speaking rights.

Third, to ask questions on higher-level thinking has been shown to be significant in improving the quality of classroom discourse. For example, Mortimer and Scott (2000) used the flow of discourse framework to analyze classroom talk. The framework is based on Vygotskian and neo-Vygotskian perspectives (Vygotsky, 1978; Wertsch, 1991) that classroom talk can mediate the development of meaning and understandings between teachers and students and student learning of science concepts. The importance of such analysis is that a teacher's ability to manage classroom discourse can support students' development of knowledge and meaning-making. Mortimer and Scott expanded upon the triadic dialogic pattern to a form of teacher intervention as he or she regulates and guides the classroom discourse. One form of a teacher's intervention is to support student meaning-making by asking questions to check student understanding in three ways: to ask for clarification of student ideas, to check individual understanding, and to check consensus in the class about certain ideas. As the authors argued, teacher intervention in the classroom discourse is one aspect of teacher knowledge that is often overlooked in the analysis of teaching practice.

Overall, as a general instructional strategy, questioning in classroom teaching and learning plays a very important role in determining the quality of discourse and the ways in which students learn and understand science. However, the type of questions being asked is what is important to engendering improved student learning outcomes in science (Koufetta-Menicou & Scaife, 2000).

## FORMS OF REPRESENTATIONS

Many scientific phenomena, such as those studied in cosmology, geology, chemistry, or biology, are beyond the learner's temporal, perceptual, and experiential limits

(Kozma, 2000). Consequently, our understanding of these phenomena depends on “our ability to access and interact with them indirectly” (p. 12). This is an important issue in effective instruction and is dependent on the teacher’s expertise in representing his or her scientific knowledge in ways appropriate to the content and the way that content should be presented to a particular or group of learners. Essentially this is the notion of pedagogical content knowledge (PCK) that Shulman (1987) has argued “represents the blending of content and pedagogy into an understanding of how particular topics, problems, or issues are organized, represented, and adapted to the diverse interests and abilities of learners and presented for instruction” (p. 8). A teacher’s pedagogical content knowledge includes models, analogies, equations, graphs, diagrams, pictures, and simulations that can help the learner understand an idea. These representations may be exhibited in a variety of forms/modes such as verbal, mathematical, visual, and actional-operational. Different types of representations are used to enhance conceptual understanding, and a considerable amount of research has been conducted to investigate the effect of a single representation on learning.

Gilbert, Boulter, and Elmer (2000) considered a model in science as “a representation of a phenomenon initially produced for a specific purpose” (p. 11). From the perspectives of modeling and models in science education, Gilbert et al. delineated nine different models used in science education: a mental model, an expressed model, a consensus model, a scientific model, a historical model, a curricular model, a teaching model, a hybrid model, and a model of pedagogy. Through interactions, an expressed model is placed in the public domain by individuals or groups. According to Gilbert et al., one or more of the following six modes of representations are significant in expressed models: (1) concrete mode consisting of the use of materials (e.g., a wooden model of a car); (2) verbal mode consisting of the use of metaphors and analogies in speech (e.g., a textbook descriptions); (3) mathematical mode consisting of mathematical expressions (e.g., universal gas equation); (4) visual mode consisting of graphs, pictures, and diagrams; (5) symbolic mode consisting of visual, verbal and mathematical modes; and (6) gestural mode consisting of actions (e.g., hand movements). Each of these modes has direct application to teaching strategies, and several are discussed in more detail in this section.

## ANALOGIES AND METAPHORS

Representations include analogies and their allies, particularly metaphors. According to Glynn (1991), an analogy is a process for identifying similarities between different concepts; the familiar concept is called the analog and the unfamiliar one the target. The famous seventeenth-century astronomer Johannes Kepler (cited in Polya, 1954) once wrote: “And I cherish more than anything else the Analogies, my most trustworthy masters. They know all the secrets of Nature, and they ought to be least neglected in Geometry” (p. 12). Given the historical importance of analogical reasoning in scientific discovery, insights, and explanations, analogies have been used by textbook authors and classroom teachers to explain science concepts to students. Furthermore, learning science is the reconstruction of the products of modeling (Justi & Gilbert, 2002), and analogies are at the heart of modeling.

Teachers' use of analogies, in one or several forms of representation, has been an important line of research into teaching and learning of abstract science concepts, and reasoning and problem solving, and for conceptual change (Dagher, 1995). Analogies and metaphors have been used in science education as instructional strategies to engender interest, motivation, and understanding (Harrison & Treagust, 1994; Martins & Ogborn, 1997; Venville & Treagust, 1996). Since the time before computers were used in the classroom, science teachers have been using a range of different representational techniques to present information to students, such as verbal and written language, graphics and pictures, practical demonstrations, abstract mathematical models, and semi-abstract simulations (van Someren, Boshuizen, de Jong, & Reimann, 1998).

Research has shown that analogical teaching approaches can enhance student learning. For example, the findings of the study by Treagust, Harrison, Venville, and Dagher's (1996) indicated that a teacher's use of a cart with wheels moving obliquely over different surfaces as an analogy for refraction of light in a 10th-grade physics class successfully engendered conceptual change in student learning about the refraction of light. Martins and Ogborn explored how primary school teachers used metaphors to think about scientific ideas of DNA and genetics. The results of the study indicated that these primary school teachers creatively and imaginatively assimilated and constructed metaphorical models, drawings, and analogies to understand the scientific ideas of DNA and genetics. Metaphors and analogies thus connected their everyday knowledge to scientific ideas. In another example, a cross-age study involved secondary school, undergraduate, and postgraduate students' use of analogy and anthropomorphism along with their alternative conceptions of mental models of chemical bonding (Coll & Treagust, 2002). Findings indicated that learners made use of analogy and anthropomorphism to aid their explanations of chemical bonding. Coll and Treagust suggested that teachers need not only to encourage learners to use analogy but also to carefully examine curriculum and to postpone instruction of complex models to a later stage in the students' program of study. However, when analogies were used for chemistry problem-solving in a college preparatory chemistry course, Friedel, Gabel, and Samuel (1990) showed that the use of analogies was not an appropriate teaching strategy when the teachers did not determine whether the analog was meaningful to the students or when the instructional time was too short.

In brief, despite the fact that analogies appear to be useful as strategies in teaching and learning of abstract concepts, they are "double-edged swords" (Glynn, 1991, p. 227) which, when not used cautiously, may lead to miscomprehension and misdirection. Two further problems with analogies presented in textbooks and used by classroom teachers are when teachers use analogies as mechanical clichés, that is, when they are used without thought about their meanings, and when inconsistencies between the analog and the target result in students being unable to map the shared attributes and delineate the limitations of analogies. To address these problems, Treagust, Harrison, and Venville (1998) developed a teaching model called FAR—referring to Focus, Action, and Reflection—whereby teachers overtly direct students' attention to the similarities and dissimilarities of the analog and target concept. This teaching model was developed in cooperation with science teachers based on an earlier analysis of exemplary analogies in textbooks (Glynn, 1991).

## FROM MULTIPLE ANALOGIES TO MULTIPLE REPRESENTATIONS

In view of the problems in using analogies as part of instruction, Glynn (1991) suggested using several analogies (for a single concept), which can allow students to examine the concept from more than one perspective. Each perspective (analogy) brings particular features of the concept into a clearer focus; thus students will have a more comprehensive understanding of that concept and its relationship to other concepts.

Along this line of thinking, Harrison and Treagust (2000) reported a year-long study of the role of multiple models in student learning about atoms, molecules, and chemical bonds in an 11th-grade chemistry class. The outcomes suggested that students who socially negotiated the shared and unshared attributes of common analogical models for atoms, molecules, and chemical bonds used these models more consistently in their explanation. As well, students who were encouraged to use multiple particle models displayed more scientific understandings of particles and more interactions than did students who concentrated on a single model. Harrison and Treagust proposed, among other pedagogical recommendations, that multiple models should be introduced at an early stage and consistently developed and invoked during learning discussions. In view of the weakness in the ways models were represented in this study, the authors suggested that further research be done to find out what influence the representational form of analogical models has on the effectiveness of model-based learning.

Recently, new perspectives on computer-based multiple representations used in instruction (Ainsworth, 1999) have provided a more robust framework for interpreting analogical models and their relatives such as metaphors, which have been in use for centuries as vehicles for reasoning. According to Ainsworth's (1999) conceptual analysis of existing computer-based multirepresentational learning environments (Ainsworth, Bibby, & Wood, 1997; Hennessy et al., 1995), there are three major functions that multiple external representations (MERs) serve in learning situations—to complement, to constrain, and to construct. The first function of MERs in Ainsworth's (1999) functional taxonomy is to use representations that provide complementary information or support complementary cognitive processes so that learners can reap the benefits of the combined advantages, such as using both diagrams and verbal-textual representations. The second function is to use a familiar representation to constrain the interpretation (or misinterpretation) of a less familiar representation so as to help learners develop a better understanding of the domain. The third function of MERs is to encourage learners to construct a deeper understanding of a phenomenon through abstraction of, extension from, and relations between the representations. Ainsworth's functional taxonomy of MERs has been based largely on research in mathematics (see, for example, Ainsworth et al., 1997; Larkin & Simon, 1987) and physics (see, for example, Hennessy et al., 1995). The notion of multiple representations has also been used to improve learning in other domains such as chemistry (see, for example, Kozma, 2000) and medicine (see, for example, Boshuizen & van de Wiel, 1998).

In school learning, multiple representations provide new opportunities to engender student motivation, interest, and understanding. In a recent study on the

motivational aspects of learning genetics (Tsui & Treagust, 2004), a science teacher used an interactive computer program called BioLogica alongside other teaching strategies and resources to teach genetics in a 10th-grade biology class. Findings showed that MERs in the computer program intrinsically motivated the 10th-grade students in their learning of genetics, which is a linguistically and conceptually difficult topic in biology. The salient features of the MERs of the computer program identified in this study included instant feedback, flexibility, and visualization. Students' motivation was interpreted as curiosity, control, fantasy, and challenge, which were similar to Malone and Lepper's (1987) taxonomy of intrinsic motivations. The finding of this study also indicated that most students improved their genetics reasoning after instruction, indicating that computer-based MERs hold promise in providing new opportunities for learning abstract concepts in science.

### LEVELS OF REPRESENTATION

One major difficulty for learning science at school is that scientific knowledge can be represented at a number of levels, some of which are not observable to the learners. Scientists must be able to represent knowledge in order to conduct research, and teachers must do so in order to teach students. Perhaps this is most important in the field of chemistry, which is difficult to learn because many concepts are abstract and are unfamiliar to students, whose personally constructed representations are often in conflict with scientifically accepted explanations (Treagust & Chittleborough, 2001). Learning of chemistry is a matter of learning about its representation at different levels, which can describe (descriptive and functional), represent (representational), and explain (molecular) chemical phenomena (Johnstone 1993).

Teachers do need to be cognizant of the three levels of representation and their meaning as follows: symbolic—comprising a large variety of pictorial representations, algebraic and computational forms; submicroscopic—comprising the particulate level, which can be used to describe the movement of electrons, molecules, particles, or atoms; and macroscopic—comprising references to students' everyday experiences. According to Johnstone (1991), most teachers used the triangle of multilevel thought in their teaching without being aware of the demands being made on the students. In Johnstone's triangle of multilevel thought, knowledge of chemistry can generally be organized as three ideas of structure, bonding, and energy. Johnstone argued against teachers using all three levels in their teaching. To make learning easier, teachers should teach chemistry only at the macro level or at most at two levels. Johnstone also extended this triangle of multilevel thought to the teaching of physics and biology. In physics there are also three similar levels of representations: the macro (visible moving bodies), the invisible (e.g., forces, reactions, electrons), and the symbolic (mathematics, formulas). The pedagogical implications of Johnstone's notion of multilevel thought are that teachers cannot simultaneously present the three levels of representations in teaching difficult science concepts. Otherwise, students would become overloaded with information and be unable to see the connections between the levels.

In biology, too, there are three levels: the macro (plants or animals), the micro (cells), and the biochemical (DNA, etc.). Marbach-Ad and Stavy (2000) articulated Johnstone's triangle of multilevel thought to explain why genetics in biology is so

difficult to teach and learn because it is difficult to understand meiosis (micro level) and the connection between meiosis and Mendelian genetics (macro level).

## GROUP LEARNING AND COOPERATIVE LEARNING

As reviewed by Lazarowitz and Hertz-Lazarowitz (1998), the use of group learning in science education has been rather recent, but the learning outcomes are very promising. For science teachers, Stahl's (1996) handbook provides a comprehensive selection of highly effective and widely used cooperative learning strategies that science teachers can use in the primary and secondary science classrooms.

To encourage students to construct meaningful knowledge networks, science teachers need to provide opportunities to engage the students in motivating and interactive activities and cooperative learning activities (Treagust & Chittleborough, 2001). A review of the literature on cooperative learning indicates that most of the studies are on biology learning, and the major learning outcomes focused generally on the cognitive domain rather than on the affective domain (Lazarowitz & Hertz-Lazarowitz, 1998). Accordingly, five cooperative methods of instructions have been used in science education:

1. Learning Together and Alone (Johnson & Johnson, 1975) involves students in heterogeneous groups of four or five working together to achieve some common goal in such a way as to develop both personal and group skill.
2. The Jigsaw Classroom (Aronson, Stephan, Blaney, & Snapp, 1978). In this method, the class is divided into jigsaw groups of five (students a to e), with each student assigned a special part of a group task, and an expert group with members from those with the same part. The expert group members, after mastering their skills, return to the jigsaw group to tutor their teammates to achieve the goal.
3. Student Teams and Achievement Division (STAD) (Slavin, 1978) and Teams Games Tournaments (TGT) (De Vries & Slavin, 1978). These are the same in involving five common components: class presentation by the teacher followed by discussion, teams working on teacher-prepared worksheets, quizzes (STAD), or game/tournament (TGT);
4. Group Investigation (described in Lazarowitz & Hertz-Lazarowitz, 1998) integrates the four basic features of investigation, interaction, interpretation and intrinsic motivation. In the group investigation classroom, groups work on different but related topics using a variety of resources to generate questions, gather information and actively construct their own knowledge.
5. Peer Tutoring in Small Investigative Group (PTSIG) (Lazarowitz & Karsenty, 1990). PTSIG involves four basic features of investigation, interaction, interpretation, and intrinsic motivations combined into six stages of the model.

According to Lazarowitz and Hertz-Lazarowitz's (1998) review, previous research has shown positive results of cooperative learning in different subject areas across different academic levels in the cognitive, affective, and social domains of learning. At the primary school level, the positive learning outcomes included increased stu-

dents' academic achievement, helping behavior, and peer support. At the high school level, both junior and senior students improved their learning, as demonstrated by higher cognitive achievement, more positive attitudes, greater self-esteem, more engagement on tasks, and increased motivation and enjoyment. Fraser (1998) also reported that cooperative learning promoted a positive learning environment. Similar positive learning outcomes were reported at the college level when the studies included cognitive preferences, concept learning, and gender differences.

Although cooperative learning appears to be a promising strategy for the cognitive, social, and affective development of student learning at school, teachers and researchers have to develop relevant, rich, and challenging curricula. There are several challenges of using group and cooperative strategies in supporting student learning. First, such strategies should be able to address student learning along multiple dimensions of the cognitive, affective, and social domains of learning. Second, science teachers using group and cooperative methods to address classroom learning issues have to be cognizant of any sociocultural peer effects due to ability, gender, and cultural differences (see, for example, Forman & Cazden, 1985). Third, cooperative learning involves interaction with peers in communities of learners and with computer data bases in a distributed fashion (see, for example, Brown et al., 1993; Windschitl, 1998). These challenges should be incorporated into the teacher education programs to allow pre-service teachers and in-service teachers to develop their knowledge of group and cooperative learning strategies used in their teaching.

### INDUCTIVE AND DEDUCTIVE REASONING— THE LEARNING CYCLE APPROACH

The traditional textbook approach to science learning provides information and challenges students to think deductively by reasoning from cause to effect. However, this reasoning contrasts with the way that many scientists, such as geneticists, inductively reason and learn in their research work from effect to cause. Indeed, this approach is consistent with most science teaching approaches using laboratory experiments that implicitly assume that students learn by inductive reasoning. However, as previously stated, whether laboratory work will necessarily improve student learning is a contentious issue (White, 1996), and the challenge of inductive reasoning could be what makes laboratory tasks difficult for students.

The learning cycle approach has survived into the present time as an important instructional strategy (see, for example, the review by Abraham, 1998). According to Lawson, Abraham, and Renner (1989), the learning cycle originated from the work of Robert Karplus in the Science Curriculum Improvement Study (SCIS) program for U.S. elementary and junior high schools in the late 1950s and 1960s, and in Chester Lawson's work in biology education in U.S. high schools and universities during the same period. It was from Lawson's project that the famous Biological Science Curriculum Study (BSCS) project had developed during the post-Sputnik reforms in science education.

Originally known as *exploration-invention-discovery* (Karplus & Thier, 1967), the inquiry-based learning cycle approach consists of three phases. First, the *exploration* phase provides students with the experience of the concept to be developed, such as the use of laboratory experiments, which involves deductive thought. Then, in

the *conceptual invention* phase, the students and/or teacher develop the concept from the data through classroom discussion, which involves inductive thinking. Finally, in the conceptual expansion phase, the student is given the opportunity to explore the usefulness and application of the concept.

The three phases in its latest version, according to Abraham (1998), are simply “inform-verify-practice” or  $I \rightarrow V \rightarrow P$ . The three phases in sequence are *identification* of a concept, *demonstration* of the concept, and *application* of the concept. The common justification of using the learning-cycle approach is based on the Piagetian notions of learning new concepts through assimilation and disequilibrium in the first phase, accommodation in the second phase, and conceptual expansion in the third phase. “The three distinct phases with a definite sequence and structure are necessary for the development of conceptual understanding” (Tobin et al., 1994). Through this three-phase sequencing of hands-on laboratory experiences to engender knowledge construction, the learning-cycle approach can address the concern that laboratory work is unable to improve conceptual understanding.

Two well-documented case studies using the learning-cycle approach are the studies of Renner, Abraham, and Birnie (1985) and Abraham and Renner (1986). Renner et al.’s study—conducted in three 12th-grade physics classes in a U.S. secondary school using all or some of the phases of the learning-cycle approach—highlighted the necessity of all the three phases and the importance of their sequence in concept development of physics. The content of the student investigation in Renner et al.’s study included linear motion, heat measurement in solids, static electricity, and current and magnetism. In the second case-study example, Abraham and Renner (1986) investigated different learning cycles in six classes in senior secondary school chemistry and indicated that the normal learning cycle sequence, gathering data  $\rightarrow$  Invention  $\rightarrow$  expansion, is the optimum sequence for achievement of content knowledge of chemical concepts associated with heat laws. Since the 1980s, many studies on the learning-cycle approach have been conducted in different domains and at different school and university levels (e.g., Jackman, 1990; Lavoie, 1999; Lawson, 2001; Libby, 1995; Marek, 2000; Odum & Kelly, 2001). Research on the learning-cycle approach has confirmed that this is an effective instructional strategy with many advantages over more traditional approaches in terms of student attitudes, motivation, process learning, and concept learning. Science teachers should make use of instructional materials with key characteristics of the learning-cycle approach (Abraham, 1998).

There are two trends in instructional strategies using the learning-cycle approach that are worth a more detailed discussion here. First, there has been an increase in the use of ICT in teaching with the learning-cycle approach (e.g., Dwyer & Lopez, 2001; Gibson, 2001; Marek, 2000). Dwyer and Lopez’s study involved Australian students using the simulation software Exploring the Nardoo in all phases of the learning cycle. In this study upper elementary and middle school science students were observed, along with their teacher, using simulations as they engaged in learning-cycle lessons revolving around river ecosystems. Students were asked to address complex water management issues affecting the fictional Nardoo River and improve the environment. The simulation is intended to develop students’ investigation and problem-solving skills. Findings indicated that with specific guidance in simulations, students performed better and that simulations could be used again to apply newly learned concepts in different contexts in the expansion phase of

the learning cycle. Second, the learning cycle continues to be used in instructional practices at the university level (Ana G. Mendez Educational Foundation, 1987; Farrell, Moog, & Spencer, 1999; Jackman, 1990).

The most important conclusion based on research is that the inquiry-based, laboratory-based learning-cycle approach has provided students with not only hands-on experiences to learn the concepts but also the opportunity for knowledge construction from their personal experience and for application to new situations (Abraham, 1998). Nevertheless, the learning-cycle approach has its limitations, particularly when it is applied to the ICT-rich learning environment. Based largely on Piagetian psychology, the learning-cycle approach focuses on individual learning more than group learning and more on personal construction than social construction of knowledge. Although discursive practices are expected in the second phase or exploration phase, the focus is more on personal construction of knowledge developed from the data or observations in the experiments.

### SUMMARY

As is apparent from this brief review, there is a wide variety of instructional methods and strategies used in the teaching and learning of science that range from those that are more teacher-centered to those that are more student-centered. Each of the six methods and strategies has a growing body of theory to support each instructional approach, and enough research has been conducted with each of these different methods and strategies to have some confidence in their effectiveness in enhancing the learning, and opportunities for learning, of students from elementary school to university. None of the approaches by themselves should be seen as a panacea that will improve science learning but each method or strategy can be part of a successful science teacher's instructional repertoire.

### ACKNOWLEDGMENTS

I wish to thank Dr. Chi-Yan Tsui for his valuable contributions to the conceptualizations that initially framed this review and for helping with the first draft of this chapter. Thanks also to Michael Abraham and Richard Gunstone, who reviewed this chapter. I hope that I have done justice to their critiques.

## Learning and Teaching in the School Science Laboratory: An Analysis of Research, Theory, and Practice

**Vincent N. Lunetta**

*Pennsylvania State University*

**Avi Hofstein**

*The Weizmann Institute of Science, Israel*

**Michael P. Clough**

*Iowa State University*

Knowledge of the natural sciences is constructed to explain objects, phenomena, and their interactions in the natural world. With time, scientific ideas or concepts become connected by wider-ranging theories, and especially since the Renaissance, new knowledge and understanding has developed through continual, dynamic interaction between scientific theories, research, and experimental data. This complex interaction sometimes results in the rejection or modification of prior ideas and the development of newer ideas that link concepts together, in turn suggesting new methods, new interpretations of data, and new questions. Often, but not always, the data have come from carefully controlled studies conducted in scientists' laboratories. This kind of interrogation of nature often brings forth information that would not have been evident simply through direct observation of the natural world.

There are interesting similarities and differences between the ways that scientific communities develop new knowledge of the natural world and the ways that learners come to understand their world. Novice learners also construct ideas about

the natural world based, in part, on observations of objects, phenomena, and their interactions. With time, these ideas also become linked and tested through the learner's experiences and his or her interactions with the ideas of others. In the process, learners come to retain and develop some concepts and explanations, to reject others, and in turn to wonder about connections to new ideas and implications. Teachers have unique opportunities in science to help students wonder about the exciting natural world, experience and observe interesting objects and phenomena, explore meaningful theoretical ideas, and grow in scientific understanding. The school science laboratory is a unique resource that can enhance students' interest, knowledge of science concepts and procedures, and knowledge of important tools and skills that can develop new understanding. Experiences in the school laboratory can also help students glimpse ideas about the nature of science that are crucial for their understanding of scientific knowledge. These are among the reasons that *laboratory activities* (*practical activities* in British Commonwealth parlance) have had a prominent place in the science curriculum since early in the nineteenth century. A classical definition of school science laboratory activities that would have been acceptable in the nineteenth century and most of the twentieth is: *learning experiences in which students interact with materials or with secondary sources of data to observe and understand the natural world* (for example: aerial photographs to examine lunar and earth geographic features; spectra to examine the nature of stars and atmospheres; sonar images to examine living systems). The development and increasingly widespread use of digital computing technologies in school science near the turn of the twenty-first century provide new tools for gathering, visualizing, and reporting data and findings as well as important new tools that can support learning. New tools also offer simulation resources for teaching and learning science. Some of these new tools and resources blur the interface between learning in the laboratory and learning with simulations that are representations of nature. In fact, work with simulations has caused some to perceive that school laboratory activities are themselves simulations of some of the things that scientists do (Lunetta, 1998). The new electronic tools and resources for teaching and learning associated with the school science laboratory also offer important new opportunities to study learning in science, and they warrant careful scholarly study by researchers in science education in the twenty-first century.

## A HISTORICAL OVERVIEW

For almost 200 years, science educators have reported that laboratory activities can assist students in making sense of the natural world (Edgeworth & Edgeworth, 1811; Rosen, 1954). Over the years, many have argued that science cannot be meaningful to students without worthwhile practical experiences in the school laboratory. Unfortunately, the terms *school laboratory* or *lab* and *practical* have been used, too often without precise definition, to embrace a wide array of activities. Typically, the terms have meant experiences in school settings where students interact with materials to observe and understand the natural world. Some laboratory activities have been designed and conducted to engage students individually, and others have sought to engage students in small groups and in large-group demonstration settings. Teacher guidance and instructions have ranged from highly structured

and teacher-centered to open inquiry. The terms have sometimes been used to include investigations or projects that are pursued for several weeks, sometimes outside the school, and on other occasions they have referred to experiences lasting 20 minutes or less. Sometimes laboratory activities have incorporated a high level of instrumentation, and at other times the use of any instrumentation has been meticulously avoided.

Historically, school *labs* have ranged from activities where data are gathered to illustrate a previously stated relationship to activities where students seek patterns or relationships in data they gather. In the early part of the twentieth century John Dewey and others in the progressive education movement energetically advocated an investigative and more utilitarian approach in learning. Through the 1950s, however, laboratory activities were used almost exclusively for illustrating information presented by the teacher and the textbook, and scholarly research on the educational effectiveness of the school laboratory was relatively limited.

Subsequently, in the science education reform era of the 1960s in both the United States and the United Kingdom, major science curriculum projects developed “new” curricula intended to engage students in investigation and inquiry as a central part of their science education. In that period, major curriculum projects used the learning theories of Jerome Bruner, Robert Gagne, and Jean Piaget to justify curricula emphasizing student inquiry and hands-on activities. Projects, including those of the Physical Science Study Committee and the Biological Sciences Curriculum Study in the United States and Nuffield in the United Kingdom, developed inductive laboratory activities as a fundamental part of the science curriculum. In these projects the laboratory was intended to be a place for inquiring, for developing and testing theories and assertions, and for practicing “the way of the scientist.” George Pimentel (see Merrill & Ridgeway, 1969) noted that in the CHEMStudy project, the laboratory was designed to help students gain a better idea of the nature of science and scientific investigation.

For more than a century, laboratory experiences have been purported to promote central science education goals, including: the enhancement of students’ understanding of concepts in science and its applications; scientific practical skills and problem-solving abilities; scientific “habits of mind”; understanding of how science and scientists work; and interest and motivation. Periodically, and particularly in the late 1970s and the early 1980s, serious questions were raised about the effectiveness of the school laboratory in promoting science learning (Bates, 1978; Hofstein & Lunetta, 1982). Questions emanated from multiple sources both within the science education community and beyond. Research on learning brought forth knowledge of learners’ development and new insights about the learning of science concepts. Scholarly efforts identified serious mismatches between stated goals for science education and the learning outcomes visible in school graduates. Particularly noteworthy for laboratory learning, researchers reported that students regularly performed school science experiments with purposes in mind that were very different from those articulated by science educators for such experiences. In addition, comprehensive analyses of laboratory handbooks also provided evidence that major mismatches existed between goals espoused for science teaching and the behaviors implicit in science laboratory activities associated with major curriculum projects (Tamir & Lunetta, 1981). Lunetta and Tamir (1979) were among those who recommended greater consistency between goals, theories, and practices in the learning

and teaching of science. In addition, important perspectives about the nature of science began to be applied to science education more broadly and to science laboratory activities in particular. These too fueled many concerns about the ways introductory sciences should be taught to promote learning with scientific understanding.

Nevertheless, in spite of a long series of reform efforts incorporating important elements from the history and nature of science, the predominant pattern of science teaching visible in schools through the turn of the twenty-first century has omitted the story of science. Instead, the science visible in schools has focused on "covering" knowledge of science topics and limited problem-solving skills. Within that framework laboratory activities have engaged students principally in following ritualistic procedures to verify conclusions previously presented by textbooks and teachers. In general, students have had limited freedom and time to explore and to make sense of phenomena. Objectives articulated for teaching and for student behaviors have often focused on specific tasks to be accomplished, such as "doing the density lab," rather than on the student learning that is to be accomplished, such as "learning about the relationships between mass and volume for different materials." Duschl and Gitomer (1997, p. 65) noted that teachers tend to see teaching as "dominated by tasks and activities rather than conceptual structures and scientific reasoning." Kesidou and Roseman (2002) reported that contemporary curricula did not engage students in laboratory activities consistent with goals for learning. Weiss et al. (2003, p. 1) reported that 59% of the science and mathematics lessons they observed were low in quality, often reflecting "passive learning" and "activity for activity's sake." This emphasis on dozens of tasks and activities rather than on conceptual understanding results in what Schmidt et al. (1999), analyzing the results of the Third International Mathematics and Science Study (TIMSS), called an unfocused science curriculum in the United States that is "a mile wide and an inch deep."

To complicate matters, science education studies have not always helped to distinguish between and link important ends (learning outcomes that are sought) and means to those ends (teaching resources and strategies such as specific kinds of investigative activities in the laboratory). For example, significant changes in technologies since the 1980s have offered new resources for teaching and learning, but insufficient attention has been directed to critical examination of how these new technologies can enhance or confound experiences in the school laboratory. Further complicating research into school laboratory practices have been ambiguous use of terms such as *inquiry science teaching*, which may refer to teaching science *as* inquiry (helping students understand how scientific knowledge is developed) or teaching science *through* inquiry (having students take part in inquiry investigations to help them acquire more meaningful conceptual science knowledge). Inquiry investigations conducted by novices in school science laboratories differ in important ways from authentic scientific investigations conducted by expert scientists, and to enable development of the science education field, it is important for teachers and researchers in science education to define and use central technical terms precisely and consistently. Engaging students in laboratory *inquiry*, for example, has involved activities ranging from *highly structured* laboratory experiences to *open-ended* investigations in which students explore a question they may have articulated themselves. The nature of the guidance the teacher and the curriculum materials provide for the students is very important to the learning that occurs. Unfortunately, the guidance provided for students has often not been examined or described carefully in studies of laboratory learning; careful reporting of the nature of

that guidance is one important factor in good research and development of laboratory work in science education.

## REVIEWS OF RESEARCH ON THE SCHOOL LABORATORY

The uniqueness of the laboratory as a medium for learning and teaching science has caused it to be the subject of many research studies and several reviews since the 1960s. The reviews referenced in this chapter include those published by Ramsey and Howe (1969), Bates (1978), Blosser (1980), Hofstein and Lunetta (1982), Tobin (1990), Hodson (1993), Lazarowitz and Tamir (1994), and Hofstein and Lunetta (2004). These reviews are sources of many literature citations that have not been included in this chapter because of space limitations.

Prior to the reform movements of the 1960s a latent assumption of many science educators and teachers was that students learn science by verifying or applying ideas in the school laboratory that were taught earlier in class. As noted in the preceding historical overview, curriculum projects developed during the reform movement in the 1960s were intended to promote greater focus on inquiry, interest, and conceptual understanding. A tacit assumption of scientists who led the curriculum reform movement of the 1960s was that students come to understand science ideas simply by performing activities, collecting data in the school laboratory, and then generalizing from the information collected; teachers and the “teacher-proof textbook” provided guidance in the process. Important changes did occur in the development of science curricula, teaching resources, and for a time in science teacher development workshops. However, in general, science teaching has continued to be relatively didactic and focused on delivering information.

Although the 1960s reforms were based, in part, on theories of learning, relatively little research in science education in that decade looked carefully at students’ understanding of science concepts, attitudes, and possible causal factors associated with students’ experiences in the science classroom and laboratory. Following an extensive review of the literature on the school laboratory, Ramsey and Howe (1969) wrote that science educators had come to expect that laboratory experiences “should be an integral part of any science course.” They also noted that the nature of the best kinds of experiences and how these could be integrated with more conventional class work had not been objectively assessed. They claimed that as a result, implications for teaching based on research on laboratory-classroom learning were not available (p. 75).

Between the late 1960s and the 1980s hundreds of research papers and doctoral dissertations investigated variables in settings associated with teaching in the school science laboratory. Bates (1978) reviewed 82 studies on the role of the laboratory in secondary school science programs and wrote that the question of what laboratories accomplish that could not be achieved by less expensive and less-time consuming alternatives needed more research. He wrote (p. 74):

- Lectures, demonstrations, and laboratory teaching methods appear equally effective in transmitting science content;
- Laboratory experiences are superior for providing students skills in working with equipment;

- The laboratory appears to represent significantly different areas of science learning than content acquisition;
- Some kinds of inquiry-oriented laboratory experiences appear better than lecture/demonstrations or verification-type laboratories for teaching the process of inquiry. However teachers need to be skilled in inquiry teaching methods;
- Laboratories appear to have potential for nurturing positive students' attitudes.

Many of the studies on school laboratory learning conducted between 1960 and 1980 tended to assess students' knowledge of conventional science facts. In general, the studies did not take a careful look at the nature of students' learning or their perceptions of the purposes of their laboratory work, and they did not carefully assess students' understanding of the nature of science.

Hofstein and Lunetta (1982) wrote that "Past research studies generally examined a relatively narrow band of laboratory skills and the conclusions that were drawn may apply to a narrow range of teaching techniques, teacher and student characteristics, and learning outcomes" (p. 204). They argued that many research studies conducted since the 1960s suffered from a number of weaknesses, including selection and control of variables, group size, instrumentation selected for the research studies, and control over teacher's behavior and over the students' activities provided by the laboratory. In addition, they wrote that research failed to show simple relationships between experiences in the laboratory and students' learning. Most research studies conducted on the science laboratory failed to show advantages of the laboratory over other science teaching practices, but if differences did exist they were probably masked by confounding variables, by the use of insensitive research instrumentation, and/or by poor research design. For example, only seldom was attention given to the characteristics of the student sample (e.g., cognitive development) or the crucial nature of the teacher's laboratory teaching, expectations, and assessment practices. Hofstein and Lunetta (1982) outlined the need for new research that would provide more information about the important but complex relationships between goals for learning, teacher expectations and behaviors, and student learning outcomes.

The reviews by Bates (1978) and Hofstein and Lunetta (1982) cited several studies indicating that students enjoy laboratory work in some courses and that laboratory experiences have resulted in positive and improved student attitudes and interest in science. Among the studies reviewed, Hofstein et al. (1976) reported that students in Israel rated their personal involvement in the chemistry laboratory as the most effective instructional method for promoting their interest in chemistry when contrasted with teacher demonstrations, presentations, and classroom discussions. Other studies conducted in the 1970s and 1980s made similar claims. Ben-Zvi et al. (1977), for example, reported that chemistry students' personal involvement in chemistry laboratory investigations had been the most effective medium in their chemistry classes for promoting their interest in chemistry when contrasted with teacher's demonstrations, filmed experiments, classroom discussions, and teachers' lectures. In a study that examined why students enrolled in optional advanced high school chemistry courses, one of the key reasons offered was their experience with practical activities in the chemistry laboratory (Milner et al., 1987). These results are similar to findings reported in the United States (Charen, 1966; Johnson et al., 1974; Raghubir, 1979). In Nigeria, Okebukola (1986), using the Attitude toward Chemistry Laboratory Questionnaire (Hofstein et al., 1976), reported that greater partici-

pation in chemistry laboratory activities resulted in improved student attitudes toward chemistry learning in general and toward learning in the chemistry laboratory in particular.

By early in the 1990s, the pendulum of research within the science education literature had moved away from the affective domain and toward the cognitive domain, with special attention to conceptual change. Reflecting this shift, two comprehensive reviews that were published in the early 1990s (Hodson, 1993, and Lazarowitz & Tamir, 1994) did not discuss research focused on affective variables such as attitudes and interest. Nevertheless, some science educators continued to report studies indicating that laboratory work is an important medium for enhancing attitudes, stimulating interest and enjoyment, and motivating students to learn science (e.g., Freedman, 1997; Thompson & Soyibo, 2002). In 2004, the Attitude toward Chemistry Laboratory Questionnaire was administered in a study in which two groups of students were compared (Kipnis & Hofstein, 2005). The first student group performed inquiry-type chemistry investigations, and the second group performed more conventional, confirmation-type activities. Students in the inquiry group developed more positive attitudes toward learning chemistry than did the students who experienced the conventional treatment.

Since the early 1970s, researchers have studied students' perceptions of the *classroom learning environment* and its relationship to outcomes such as student achievement and attitudes (Fraser & Walberg, 1989). A valid and reliable measure for assessing students' perceptions of the *laboratory learning environment*, the Science Laboratory Environment Inventory was developed and validated by a group in Australia and used subsequently in studies conducted in several world locations. Fraser et al. (1993) reported that Australian students' perceptions of the laboratory learning environment accounted for significant differences in the variance in students' learning of science content beyond that attributed to differences in their abilities. Fisher, Henderson, and Fraser (1997) reported significant correlations between students' perceptions of the science laboratory learning environment and their attitudes and science achievement. Similar results were reported in an Australian study by Fraser et al. (1993). A study of this kind was also conducted on high school chemistry in Israel (Hofstein et al., 2001). The study revealed that students involved in a series of inquiry-type laboratory investigations in chemistry found the laboratory learning environment to be more open-ended and more integrated with the conceptual framework they were developing than did the students enrolled in conventional laboratory courses (control). In the inquiry group the gap between the actual learning environment and the students' preferred environment was significantly smaller than in the control group. These findings suggested that some kinds of practical experiences can promote a positive, healthy learning environment.

Tobin (1990) wrote: "Laboratory activities appeal as a way of allowing students to learn with understanding and, at the same time, engage in the process of constructing knowledge by doing science" (p. 405). To attain this goal he suggested that students should be provided opportunities in the laboratory to reflect on findings, clarify understandings and misunderstandings with peers, and consult a range of resources that include teachers, books, and other learning materials. His review reported that such opportunities rarely exist because teachers are so often preoccupied with technical and managerial activities in the laboratory. Similarly, Hodson (1993) suggested that although teachers generally professed a belief in the value of student-driven, open, practical investigation, in general their teaching practices in

the laboratory failed to support that claim. He also argued that the research literature failed to provide evidence that standard school laboratory activities encouraged knowledge construction. He was critical of the research literature: "Despite the very obvious differences among, for example, practical exercises designed to develop manipulative skills or to measure 'physical constraints', demonstration-type experiments to illustrate certain key-concepts, and inquiries that enable children to conduct their own investigations, there is a tendency for researchers to lump them all together under the same umbrella title of practical work" (p. 97). Tobin (1990) wrote that teachers' interpretations of practical activity should be elaborated, made a part of the research design, and reported, because a laboratory session could be open-ended inquiry in one classroom and more didactic and confirmatory in another teacher's classroom. Tobin (1990) and Hodson (1993) were among those who wrote that, in general, science teachers failed to create an environment that encouraged students to make sense of their laboratory experiences, to reflect on their own thinking and to explore new connections that eventually led to the desired conceptual understanding.

Based on their review of the laboratory literature, Lazarowitz and Tamir (1994) joined the long list of authors who indicated that the potential of the laboratory as a medium for teaching science is enormous. They wrote that the laboratory is the only place in school where certain kinds of skills and understanding can be developed. Yet, they are among those who have written that much of what actually occurs in contemporary school laboratory work is not consistent with important purposes of those laboratory activities (Kesidou & Roseman, 2002; Hart et al., 2000). Hodson (2001) wrote that although unique outcomes for laboratory/practical work were articulated in the recent past, the nature of students' experiences in the laboratory and related assessment practices remained relatively unchanged.

Tibergien et al. (2001) and Sere (2002) reported work in a long-term project (Lab-Work in Science Education) conducted in several European nations. They described similarities and differences in science education laboratory tasks in upper secondary schools in Europe. Sere (2002) wrote: "The intention of the [study] was to address the problem of the effectiveness of lab-work, which in most countries is recognized as being essential to experimental sciences, but which turns out to be expensive and less effective than wished" (p. 624). Information on practice was gathered through 23 case studies, surveys, and a tool that helps to map and describe the laboratory work domain. Sere reported that the objectives typically articulated for laboratory work (i.e., understanding theories, concepts, and laws; conducting various experiments; learning processes and approaches; and applying knowledge to new situations) were too numerous and comprehensive for teachers to address successfully in individual laboratory sessions. In response, she suggested that the scope of the objectives for specific laboratory activities should be limited. Science curriculum developers and science teachers should make conscious choices among specific learning objectives for specific laboratory activities and clearly articulate the specific objectives for their students. Sere's "targeted lab-work" project produced a series of recommendations, including the need for each laboratory activity to be supported by a particular strategy organized within a coherent long-term program plan with varied kinds of laboratory work. Subsequently, the Hofstein and Lunetta (2004) review examined themes emerging at the beginning of the twenty-first century. These themes are explored in the section that follows.

## RESEARCH ON THE LABORATORY: AN ANALYSIS OF EMERGING THEMES

Early in the twenty-first century we are in a new era of reform in science education. Once again, the content and pedagogy of science learning and teaching are being scrutinized, and new standards intended to shape meaningful science education have emerged. The National Science Education Standards (National Research Council, 1996) and other science education literature (Lunetta, 1998; Bybee, 2000; Hodson, 2001; Hofstein & Lunetta, 2004) emphasized the importance of rethinking the role and practice of school laboratory work in science teaching. To do so is timely because in recent decades we have learned much about human cognition and science learning (Bransford et al., 2000). In addition, learning through inquiry (National Research Council, 2000) has important potential for teaching science, but it also poses challenges for teachers and learners (Krajcik et al., 2001).

Recent scholarship especially relevant to the school science laboratory has focused on the following themes elaborated in this section:

- Articulating and implementing more explicit goals for student learning;
- Applying learning theory organizers
- Developing classroom communities of inquirers
- Developing students' understanding of the nature of science
- Developing inquiry and learning empowering technologies

### Articulating and Implementing More Explicit Goals for Student Learning

In recent decades, educators have articulated with increasing regularity and clarity that decisions in teaching, assessment, and selection of curriculum resources should be driven by the learning outcomes sought for students. Goals for student learning continue to be explicated, most recently labeled as science standards. As noted earlier in the historical overview of this chapter, expectations articulated for school science laboratory learning since the nineteenth century have included the goals reflected in the first four bulleted items in Table 15.1. Over time, however, understanding of these goals and of how to implement them has developed substantially.

In 1983, the National Commission on Excellence in Education (1983) published *A Nation at Risk: The Imperative for Educational Reform*. This report offered recommendations for schooling in the United States that promoted the movement toward national science standards. Although the goal of promoting understanding of the nature of science has also been articulated for the better part of 100 years, in the last 20 years of the twentieth century, that goal became increasingly prominent. The *Standards* and increasing numbers of publications advocated that school science should enable graduates to understand methods of scientific inquiry, reasoning, and the nature of science (see, e.g., Duschl, 1990; Klopfer, 1969; Matthews, 1994).

Acknowledging the importance of goals for learning, science education researchers increasingly focus on factors associated with learning outcomes, and they try to examine the nature of teaching strategies and behaviors that promote the learning outcomes that are sought. Some have employed new social science research

**TABLE 15.1**  
**Principal Goals for Learning in the School Laboratory**

---

Promote the development of students' scientific knowledge, problem-solving abilities, and habits of mind, including:

- Conceptual knowledge
  - Practical skills and problem-solving abilities; now expanded to include: argumentation from data (*procedural knowledge*)
  - Knowledge of how science and scientists work
  - Interest and motivation
  - Understanding methods of scientific inquiry and reasoning; now expanded to include the nature of science.
- 

methodologies that can shed light on the complex factors associated with learning and teaching science in school settings. Many researchers have also sought theoretical organizers to make sense of particular strategies and to inform curriculum development, teaching, and research. These efforts have occurred while substantive changes have been under way in society, in school and technology environments, and in what we know about teaching and learning science. The importance of keeping learning outcomes in mind is illustrated in John Goodlad's (1983) extensive study of schooling. His critical analysis of observations made in over 1,000 classrooms illustrated the chasm between statements of goals for learning and what so often happens in school laboratory experiences:

One would expect the teaching of . . . science in schools to provide ample opportunities for the development of reasoning: deriving concepts from related events, testing in a new situation hypotheses derived from examining other circumstances, drawing conclusions from an array of data, and so on. Teachers listed those skills and more as intended learnings. We observed little of the activities that their lists implied, and teachers' tests reflected quite different priorities—mainly the recall of information. The topics that come to mind as representing the natural . . . sciences appear to be of great human interest. But on the way to the classroom they are apparently transformed and homogenized into something of limited appeal. (p. 468)

Similarly, research that focused on learning in the laboratory in the late twentieth century reported that mismatches regularly occurred between teachers' perceived goals for practical work and students' perceptions of such activities (Wilkenson & Ward, 1997; Hodson, 1993, 2001). Based on evidence that the goals of instruction are more likely to be achieved when students perceive those goals, Wilkenson and Ward concluded that teachers should be much more attentive to helping students understand the general and specific goals of each laboratory activity. Furthermore, because specific learning objectives are often different from one investigation to another, students should be helped to understand the purposes for each investigation in a *pre-lab* session, and they should review those purposes in *post-lab* reporting and discussion of their findings. However, Hodson (2001) observed that teachers often do not do in laboratories what they say they intend to do. Thus, as Eisner (1985, p. 59) wrote, "In the final analysis, what teachers do in the classroom and what students experience define the educational process."

Earlier, based on analyses of student laboratory guides, Tamir and Lunetta (1981) wrote that, in spite of attempts to reform curricula, students worked too often as technicians following “cookbook” recipes in which they used lower level skills; they were seldom encouraged to discuss hypotheses, propose tests, and engage in designing and performing experimental procedures. Rarely, if ever, were students asked to formulate questions to be investigated or even to discuss sources of error and appropriate sample size. Students’ performance in practical activities generally was not assessed, nor were students asked to describe or explain their hypotheses, methodologies, or the nature and results of their investigations (Hofstein & Lunetta, 1982). Science education research in the 1980s showed that students tended to perceive that following the instructions, getting the right answer, or manipulating equipment and measuring were the principal purpose for a school science laboratory. However, they failed to perceive the conceptual and procedural understandings that were the teachers’ intended goals for the laboratory activities. The students often failed to understand the relationship between the purpose of the investigation and the design of the experiment. Students rarely wrestled with the nature of science and how it underlies laboratory work, including the interpretation of data; they did not connect their laboratory activity with what they had done earlier, and they seldom noted the discrepancies between their own concepts, the concepts of their peers, and those of the science community (see, for example, Champagne, Gunstone, & Klopfer, 1985; Eylon & Linn, 1988; Tasker, 1981). To many students, a laboratory activity has meant manipulating equipment but not manipulating ideas. More recent content analyses of published laboratory guides continue to suggest that students focus on relatively low-level tasks in the laboratory. For example, Domin (1998) analyzed contemporary printed chemistry laboratory guides and reported that they did not appear to actively engage students’ higher level cognitive activities—such as addressing issues related to the assumptions and design underlying the investigation or the scientific justification supporting findings. To remediate discrepancies between goals for learning and the structure of labs and relevant teaching practices, research studies must be conducted to understand the sources of these discrepancies and to develop more effective practices.

To these ends, promising scholarship has ensued. Some of these efforts, linked with learning theory, have focused on helping students articulate their ideas and explanations, reason from data, and improve the quality of their argumentation in school science (Osborne et al., 2004; Kanari & Millar, 2004; Reiser et al., 2001). The research has included the development and study of new software tools designed to support student inquiry and science learning associated with the school laboratory. These activities provide insights for teachers and researchers on the nature and development of students’ understanding as well as new resources for teaching and learning science. This work is elaborated later in this chapter (*Developing inquiry and learning empowering technologies*).

## Applying Learning Theory Organizers

Since the curriculum reform era in the 1960s, science educators have recognized with increasing clarity the importance of identifying theories of learning that can provide guidance for research, curriculum development, and teaching. Developmental

learning theory had a powerful influence on the role of the laboratory and on science education scholarship beginning in the 1960s. While more contemporary theories have been developed, developmental theory can continue to inform teachers' decisions regarding the selection and placement of laboratory experiences to promote the growth of students' reasoning abilities. For example, the three-phase Learning Cycle teaching model (Karplus, 1977; Schneider & Renner, 1980), grounded primarily in developmental learning theory, can guide teachers in providing initial exploration experiences with materials and phenomena for their students that can serve as a foundation for introducing science concepts. In the final application phase of the model, students are encouraged to explicitly link their understandings to questions and new situations. The learning cycle model was studied extensively and shown to promote many science education goals for learning (Abraham, 1982; Ward & Herron, 1980; Purser & Renner, 1983).

In the closing decades of the twentieth century a series of teaching models grounded in learning theories incorporated increasing knowledge of how people learn. These models were designed to guide teachers in selecting, planning, and sequencing their teaching, work in the school laboratory, and interactions with students to promote desired learning outcomes. Nussbaum and Novick (1982), for example, asserted that their model was an improvement on the learning cycle because it emphasized explicit identification of students' conceptual frameworks and their assumptions underlying those frameworks. A goal of their model was to help students become aware of their conceptual frameworks and assumptions and of how their frameworks differed from those of others. Like Erickson (1979), they emphasized the importance of creating conceptual conflict through laboratory experiences with observations contrary to what students tend to expect.

The Generative Learning model (Osborne and Freyberg, 1985) emphasized the need for teachers to consider their own personal explanations of the ideas the students were to study and contrast their ideas with the views of scientists on that topic. They also suggested ways teachers could ascertain the students' thinking on the topic early in the teaching sequence in order to help the students identify differences in their observations and interpretations in laboratory investigation and those of others. The *5-E model* (Bybee, 1997) advocated two phases beyond those of the learning cycle, *engagement* and *evaluation*. The engagement phase is similar to the first phase in the Nussbaum and Novick and the Osborne and Freyberg models in that it emphasizes the importance of engaging students' prior knowledge and experiences. The fifth and final *evaluation* phase reflects constructivist perspectives regarding the tenacity of learners' prior ideas; it involves assessing students' understanding via performance on a relevant task.

Research on the effects of teaching models on learning can have important implications for how teachers should implement laboratory activities. For instance, promoting students' understanding of scientific concepts demands that teachers have a rich scientific understanding of those concepts in addition to the pedagogical understanding and skills needed to use the teaching model (Tobin & Garnett, 1988). Hence, teachers' understanding of relevant science concepts is another important variable that should be, but rarely has been, examined and discussed in research studies on the laboratory. Additional empirical research is needed to examine learning outcomes more carefully and the specific elements of teaching that are most

effective in promoting desired learning before, during, and following laboratory experiences.

When well planned and effectively implemented, science education laboratory and simulation experiences situate students' learning in varying levels of inquiry requiring students to be both mentally and physically engaged in ways that are not possible in other science education experiences. Teaching science as inquiry and through inquiry is at the heart of science education reform documents. Such inquiry reflects what we now know about how people learn science. Understanding how students learn and why they often struggle in learning what teachers intend is the foundation for effective teaching (Bransford et al., 2000). For instance, Driver (1997) noted:

Our optimism about what children ought to be able to do stems perhaps from rather deep seated views about learning. And that as long as the expert tells the story clearly and that the person who is learning is listening and paying attention then they will automatically build up the understanding that the expert has. Now all our current knowledge in cognitive science, and in cognitive psychology, and in science education is telling us that simply does not happen. Children may well be listening, paying attention to what is being said or what they are reading in a book, but they are construing it in different ways to the ways that the teacher intended. And that is the issue we have to deal with.

Constructivist learning theory suggests that learners use ideas and constructs already in their minds to make sense of their experiences. Learning is an active, interpretive, iterative process (Bransford, et al., 2000). Gunstone (1991), however, wrote that helping students develop scientific ideas from practical experiences is a very complex process and that students generally did not have sufficient time or encouragement to express their interpretations and beliefs and to reflect on central ideas in the laboratory. Research on learning in the school laboratory makes it clear that to understand their laboratory experiences, students must manipulate ideas as well as materials in the school laboratory (White & Gunstone, 1992), and they must be helped to contrast their findings and ideas with the concepts of the contemporary scientific community. Manipulating materials in the laboratory is not sufficient for learning contemporary scientific concepts, and this accounts for the failure of "cookbook" laboratory activities and relatively unguided discovery activities to promote desired scientific understanding. Expecting students to develop scientific understanding solely through their laboratory experiences reflects misconceptions of the nature of science (Wolpert, 1992; Matthews, 1994) and how people learn science. Several studies suggested that although laboratory investigations offer excellent settings in which students can make sense of phenomena and in which teachers can better understand their students' thinking, laboratory inquiry alone is not sufficient to enable students to construct the complex conceptual understandings of the contemporary scientific community (Lunetta, 1998). In the laboratory, students should be encouraged to articulate and share their ideas to help them perceive discrepancies among their ideas, those of their classmates, and those of the scientific community. Driver (1995) wrote: "If students' understandings are to be changed toward those of accepted science, then intervention and negotiation with an authority, usually a teacher, is essential."

At the end of the twentieth century there was increasing understanding from cognitive sciences that learning is contextualized and that learners construct knowledge by solving genuine, meaningful problems (Brown et al., 1989; Roth, 1995;

Williams & Hmelo, 1998; Wenger, 1998; Polman, 1999). The school science laboratory can offer students opportunities to have some control of their activities, enhancing their perception of *ownership* and *motivation* (Johnstone & Al-Shuaili, 2001). It can be an environment particularly well suited for providing a meaningful context for learning, determining and challenging students' deeply held ideas about natural phenomena, and constructing and reconstructing their ideas. Though a complex process, meaningful learning in the laboratory *can* occur if students are given sufficient time and opportunities to interact, reflect, explain, and modify their ideas (Barron et al., 1998). Engaging in *metacognitive* behaviors of this kind enables students to elaborate and to apply their ideas; the process can promote conceptual understanding as well as the development of problem-solving skills. The challenge is to help learners take control of their own learning in the search for understanding while providing opportunities that encourage them to ask questions, suggest hypotheses, and design investigations, "minds-on as well as hands-on" (Gunstone, 1991). That theme has been pursued and reported in several research studies, including *Designing Project-Based Science* (Polman, 1999).

In moving students toward more "minds-on" engagement in the laboratory (including problem solving, reflecting on the meaning of data, and decision making, etc.), we now understand that teachers must sequence complex ideas and experiences (scaffolding) in ways that enable students to engage meaningfully in these activities. In doing so, teachers need to pay close attention to students' behaviors and what they are saying. They can then respond with pedagogical decisions that will help students make connections, enabling them to achieve desired learning outcomes. An important area of contemporary scholarship involves the research and development of software tools that support the scaffolding of ideas and promote dialogue. These tools are discussed in the section on Learning Technologies later in this chapter.

Emerging attention to a social constructivist theoretical framework has special potential for guiding teaching in the laboratory (e.g., Tobin, 1990; Lunetta, 1998). Social learning theory emphasizes that learning is situated in interactions with those around us, and conceptual development is associated with the medium of language. Thus, learning depends, in part, on interactions with adults and peers. Social learning theory makes clear the importance of promoting group work in the laboratory so that meaningful, conceptually focused dialogue takes place between students as well as between the teacher and students. Moreover, laboratory experiences in which students discuss ideas and make decisions can present many opportunities for teachers to observe students' thinking as they negotiate meaning with their peers. Carefully observing students' actions and listening to their dialogue creates opportunities for teachers to focus questions and make comments within learners' zones of proximal development (Vygotsky, 1978, 1986; Duschl & Osborne, 2002) that can help the students construct understandings that are more compatible with the concepts of expert scientific communities.

## **Developing Classroom Communities of Inquirers**

The school laboratory is particularly well suited to cooperative investigation of scientific phenomena and relationships when teachers engage their students intel-

lectually as a community of learners. The inquiring community includes students, the teacher, and occasionally expert consultants (Penner et al., 1998; Roth & Roychoudhury, 1993). The importance of promoting *cooperative learning* in the science classroom and laboratory received much attention during the 1980s (e.g., Johnson & Johnson, 1985; Lazarowitz & Karsenty, 1990). Large numbers of studies demonstrated distinct benefits in students' achievement and productivity when cooperative learning strategies were successfully utilized in the classroom-laboratory. Okebukola and Ogunniyi (1984) compared groups of students who worked cooperatively, competitively, and as individuals in science laboratories and found that the cooperative group outperformed the other groups in cognitive achievement and in process skills. Similarly, Lazarowitz and Karsenty (1990) found that students who learned biology in small cooperative groups scored higher in achievement and on several inquiry skills than did students who learned in a large group class setting. Several papers reported that the more informal atmosphere and opportunities for interaction among students and their teacher and peers can promote a healthy learning environment conducive to meaningful inquiry and collaborative learning (Tobin, 1990; DeCarlo & Rubba, 1994). In a study that compared high school chemistry students' ability to formulate questions associated with a science reading and with a science investigation, Hofstein et al. (2005) reported that students who had experience asking questions in a laboratory inquiry-focused course outperformed those in control groups in their ability to ask more and better questions.

The Lunetta (1998) and Hofstein and Lunetta (2004) reviews noted research indicating that the school laboratory offers important opportunities for interaction between students and their teacher and among peers that can be conducive to meaningful inquiry and collaborative learning that results in desired cognitive growth. Research on the school laboratory conducted early in the twenty-first century examined ways to promote and support collaboration among students while they engage in laboratory inquiry or inquiry with the laboratory data gathered by scientists (see, for example, Land & Zembal-Saul, 2003; Edelson et al., 1999). This research has resulted in the development of new software tools that promise to enhance students' inquiry and reflection on the process. Land and Zembal-Saul, for example, reported that use of Progress Portfolio software prompted learners to articulate and connect their experimental findings back to the larger driving questions. "The negotiation and struggle that ensued regarding the significance of the data promoted explanation, justification and reflective social discourse." Research and findings associated with the development of the software tools are discussed in the technology section later in this chapter.

Through the collaboration, reflection, and discussion associated with investigation, students can develop scientific knowledge, and they can begin to glimpse the collaborative nature of an expert scientific community. These are learning outcomes that are now thought to be very important in introductory science. Promoting and examining reflective social discourse in the laboratory is a particularly important area for further science education research, especially since observations of science laboratory classrooms today continue to suggest that insufficient attention is given to promoting collaboration, reflective discourse, and community negotiation.

## Developing Students' Understanding of the Nature of Science

While promoting students' understanding of the nature of science had been articulated as a science learning goal for decades, that goal acquired greater significance (see, for example, Duschl, 1990) in the last 30 years of the twentieth century (see also Chapter 29 in this Handbook). Several reasons relevant to learning in the school laboratory have been discussed in the literature for promoting understanding of the nature of science (Abd-El-Khalick & Lederman, 2000; McComas et al., 1998; Matthews, 1994). Some have argued that appropriate laboratory experiences have an important role to play in developing students' understanding of the nature of science, whereas other evidence suggests that the relatively widespread lack of understanding of scientific philosophical and procedural ideas by both teachers and students has interfered with learning during laboratory inquiry. The outcomes of laboratory investigations in which students have been expected to "discover" accepted scientific relationships have often disappointed students, teachers, and researchers, in part because of mistaken notions regarding the nature of science and how people learn science concepts. Believing that students who carefully perform particular laboratory investigations will come to the same understanding as scientists reflects a naive empiricist view of scientific knowledge (Lederman et al., 1998; Wellington, 1981). Rowe and Holland (1990) described a student's frustration in trying to reconcile science ideas with what is observed in the real world:

What is this game that scientists play? They tell me that if I give something a push it will just keep on going forever or until something pushes it back to me. Anybody can see that isn't true. If you don't keep pushing, things stop. Then they say it would be true if the world were without friction, but it isn't, and if there weren't any friction how could I push it in the first place? It seems like they just change the rules all the time. (p. 87)

This commentary illustrates how understanding aspects of the nature of science is crucial to helping students make sense of their school laboratory experiences. The tendency in scientific writing and science textbooks to idealize conditions in the natural world is counter-intuitive to everyday thinking (Cromer, 1993; Wolpert, 1992; Matthews, 1994; Toulmin, 1972).

Crucial for tapping the potential of laboratory experiences is understanding that the underlying assumptions and theoretical frameworks that shape the understanding and concepts of the expert scientific community are often very different from ideas commonly held throughout the culture; these large differences influence what students observe and the sense they make from their laboratory work. Informed science educators understand that humans tried to understand the natural world for thousands of years prior to the western Renaissance. The subsequent development of contemporary scientific worldviews spanned hundreds of years and resulted in significant changes (paradigm shifts) in our understanding of science concepts and in our understanding of science. The long and counter-intuitive history of science helps to explain some of the misconceptions held regularly by students and some teachers, and the considerable challenges to

be addressed in helping novice learners to understand contemporary scientific concepts.

Making sense of school laboratory experiences often requires that learners and their teachers make conscious efforts to avoid conventional assumptions. Matthews (1994) and others have pointed out that scientific knowledge is based on several assumptions that conflict with commonly held ideas. The following widely held views, for example, can interfere with intended learning in school laboratory settings:

*Processes in the natural world bring about a suitable final state.* Students holding this view may search for explanations that are unnecessarily teleological, thus interfering with their understanding of contemporary scientific explanations.

*Natural processes are activated and controlled by spiritual influences.* This perspective is evident in the difficulty many students and some teachers have in interpreting evidence the scientific community presents in support of biological evolution.

*Knowledge is fixed and unchanging.* This assumption is evident in the difficulty many people have in understanding how well-accepted scientific knowledge based on sound research can be modified on the basis of new empirical evidence or the reinterpretation of evidence gathered in the past.

*Scientific knowledge comes simply from observing natural phenomena.* This assumption is evident in students' difficulties relating formal science concepts to the "real" world. For instance, the student's frustration with objects in motion referenced above (Rowe and Holland, 1990) illustrates how this assumption can interfere with desired science learning.

*Scientific knowledge claims are validated solely by their successful predictions.* Idealized science ideas do not always appear to result in accurate predictions, and some ideas that do provide accurate predictions (e.g., Ptolemaic astronomy) have been abandoned in favor of alternative ideas (e.g., Copernican astronomy). Accurate prediction is part of, but not the only factor in, developing contemporary scientific knowledge.

Many students and some teachers consciously or subconsciously maintain some or all of these assertions while learning and teaching science. If the assumptions are left unexamined, they are likely to interfere with the learning outcomes sought from school laboratory activities. Effective use of laboratory experiences, on the other hand, can help students and their teachers clarify the nature of science and how it differs from other ways of knowing. Informed and relevant discussions about the nature of science in the context of laboratory work can help students make sense of their laboratory experiences and better understand conceptual and procedural scientific knowledge. The interplay between conceptual and procedural knowledge is illustrated in Rudolph and Stewart's (1998) analysis that "conceptually understanding evolutionary biology, and science more generally, requires students to become familiar with the metaphysical assumptions and the methodological process that Darwin laid out. Theoretical context and scientific practice, in this view, are not just interdependent, but really two views of a single entity" (p. 1085).

Duschl (1987) and others have argued that effective inquiry teaching demands that science teachers have an understanding of the nature of science, that is, that an

understanding of relevant philosophical presuppositions is often necessary to conduct laboratory work and to help students interpret results scientifically. Making the most of laboratory experiences requires that both teachers and students understand that many science ideas do not follow simply from observing natural phenomena. What this means for effective school laboratory experiences is that teachers must help their students come to understand the epistemological (how knowledge is constructed and justified) and ontological (nature of reality) assumptions underlying scientific knowledge and the rationale for holding those assumptions while doing science. That said, these issues are complex indeed and warrant further substantial and systematic study of their implications.

A number of recent studies relevant to the school laboratory have focused on enhancing the quality of students' argumentation from data. Kanari and Millar (2004), reporting on how students collect and interpret data, wrote that "an analysis of the sample students' performance on the practical tasks and their interview responses showed few differences in performance when investigating situations of covariance and non-covariation. . . . Investigation of non-covariation cases revealed . . . the students' ideas about data and measurement and their ways of reasoning from data. Such investigations provide particularly valuable contexts for teaching and research" (p. 748). Several of the contemporary studies that examine students' argumentation use new software tools designed to focus students' attention on the ways they justify their own assertions during science investigations. Based on data from a study utilizing such software, Sandoval and Morrison (2002) wrote: "Overall, students held a view of science as a search for right answers about the world. Yet the inconsistency of individuals' responses undermines the assumption that students have stable, coherent, epistemological frameworks. . . . Combined with previous work, our findings emphasize the crucial role of an explicit epistemic discourse in developing students' epistemological understanding." Informed use of this kind of technology tool in teaching has the potential to promote improved understanding of science concepts and perhaps of the nature of science for students. Such tools also offer a window for researchers into students' beliefs, understanding, and how students' understanding can become more scientific.

As noted earlier, research has shown that students are unlikely to develop desired understandings about the nature of science simply by taking part in inquiry experiences. Based on empirical research, Driver et al. (2000) are among those who have suggested that making argumentation a more central and explicit part of learning may improve students' inquiry abilities while supporting their epistemological development. Duschl (2000) wrote that the nature of science can be made explicit when students examine, argue about, and discuss the nature of good evidence and decide between alternatives. Others have written that students learn about the nature of science through an explicit reflective approach (Abd-El-Khalick & Lederman, 2000; Schwartz & Lederman, 2002). Sandoval and Reiser (2004) suggested "engaging students in the reasoning and discursive practices of scientists, not necessarily the exact activities of professional scientists."

Examining these issues is an important frontier area in science education scholarship. Substantive, systematic research is warranted to clarify the complex issues involved. Such research should shed light on how to use school laboratory experiences to help students understand important aspects of the nature of science and on

how to help them apply their understanding of the nature of science in laboratory investigations and in the world around them. Perspectives on the relevant nature of science issues are elaborated in this *Handbook* in Chapter 28, and the development and use of software tools especially relevant to learning in the school science laboratory are discussed in the section that follows.

## Developing Inquiry and Learning Empowering Technologies

In the early 1980s digital technologies became increasingly visible in school laboratories and were recognized as important tools in school science (Lunetta, 1998; Kozma et al., 2000). Much evidence now documents that using appropriate technologies in the school laboratory *can* enhance learning, and important research on learning empowering technologies is the focus of this section. That said, an initial cautionary note is fitting, since evidence also documents that inappropriate use of even simple technology tools has interfered with meaningful science learning (Olson & Clough, 2001; Hofstein & Lunetta, 2004). When a device is introduced prematurely, before students have made sense of the underlying science concepts, there is evidence that the device or tool may serve as a black box that interferes with students' perceptions of what is happening and hinder their understanding of important scientific ideas. To cite one widely viewed example, after having used a bulb holder (bulb socket) in a simple *batteries and bulbs* activity intended to illustrate electric circuits, interviewees in a very well-known video (Annenberg/CPB, 1997) showed clearly that one of the articulate and talented students in an honors high school physics class thought the bulb holder was an essential but mysterious (almost magical) part of the electric circuit. The teacher in the video had made the bulb holders available to help the students construct a simple electric circuit in the laboratory. The student interviewed, however, did not understand the construction and function of the very simple bulb holder. Her failure to have that understanding interfered with her ability to interpret simple observations, to understand the circuit as a whole, and to predict outcomes when the circuit was connected. In this powerful example, if the student had had the opportunity to connect the light bulb in a simple circuit *before* she had access to bulb holders, or if the bulb and bulb holder had been dissected prior to their use in circuits, she then might have perceived the utility and function of bulb sockets that could assist her in connecting and observing bulbs in more complex electric circuits. This video presents very clear and powerful evidence that teachers must seek information about students' understanding of laboratory materials and devices as well as their understanding of the relevant science concepts and then merge that information with the goals sought for students' learning in the laboratory-classroom.

Computer tools, of course, are far more complex and perhaps more "mysterious" than is the functioning of the simple bulb holder that was a principal source of the misunderstanding displayed in the video. Computer tools can promote learning when their role and function are understood. They can be very helpful, for example, in displaying real-time graphic representations and functional relationships. Linked to such graphic displays, the computer can serve as a powerful interfacing tool in the laboratory. However, when a student does *not* understand the purpose and functioning of that interfacing tool (perhaps, for example, if the interfacing de-

vice had been an electric current meter in the electric circuit discussed in the preceding paragraph), the use of the powerful digital interfacing tool at that particular time could have *interfered* with the student's development of the understanding sought by the teacher more than the light socket did.

*Inquiry empowering technologies* (Hofstein & Lunetta, 2004) have been developed and adapted to assist students in gathering, organizing, visualizing, interpreting, and reporting data. Some teachers and students also use new technology tools to gather data from multiple trials and over long time intervals (Friedler et al., 1990; Lunetta, 1998; Krajcik, Blumenfeld, Marx, & Soloway, 2000; Dori et al., 2004). Increasingly, students and their teachers use software to visualize data and functional relationships. Students can examine graphs of relationships generated in real time as an investigation progresses and examine the same data in spreadsheets and in other visual representations. They can use similar software tools such as BGuILE (Reiser et al., 2001), designed for use in biology teaching and learning, to visualize and examine relationships in scientific data gathered by expert scientists in other locations. When teachers and students properly use inquiry empowering technologies to gather and analyze data, students have more time to observe, reflect, and construct the conceptual knowledge that underlies their laboratory experiences. The associated graphics also offer visualization resources that can enhance students' experiences with authentic activities while promoting deeper conceptual understanding (Edelson, 2001). When students have the time and when the activity is valued by the teacher and by high-stakes assessment, students can examine functional relationships and the effects of modifying variables; they can also make and test predictions and explanations. Technologies that offer instantaneous display of data as it is gathered can offer opportunities through which students may be helped to understand systemic functional relationships and more holistic relationships among variables. Using appropriate high-technology tools can enable students to conduct, interpret, and report more complete, accurate, and interesting investigations. Such tools can also provide media that support communication, student-student collaboration, the development of a community of inquirers in the laboratory-classroom and beyond, and the development of argumentation skills (Zemba-Saul et al., 2002).

Two studies are among several that illustrate the potential effectiveness of particular technology in school science. Nakleh and Krajcik (1994) investigated how students' use of chemical indicators, pH meters, and microcomputer-based laboratories (MBL) affected their understanding of acid-base reactions. Students who used computer tools in the laboratory emerged with better ability to draw relevant concept maps, to describe the acid-base construct, and to argue about the probable causes of why their graphs formed as they did. Dori et al. (2004), developed a high school chemistry unit in which the students pursued chemistry investigations with the use of integrated desktop computer probes. In a pre-post design study, these researchers found that students' experiences with the technology tools improved their ability to pose questions, to use graphing skills, and to pursue scientific inquiry more generally.

In addition to developing new applications of technologies that help students gather, visualize, and analyze data, other important software tools have also been designed and developed near the turn of the twenty-first century to empower learning. As noted earlier in this chapter (*Applying learning theory organizers* section), helping students develop understanding of scientific concepts is frequently a very complex task. We now understand that teachers must sequence complex ideas and

experiences in ways that enable students to engage with those ideas through a series of activities and interactions. In contemporary cognitive parlance, teachers and curriculum resources must *scaffold* complex ideas and experiences in ways that enable students to engage, interact, and reflect meaningfully in these activities in order to construct meaningful scientific knowledge. A relatively new area of contemporary scholarship in science education attempts to integrate what we know about how people learn science with the use of new computer software tools that complement and intersect learning in the school laboratory. This research is associated with the design, development, and use of interactive software tools that promote dialogue, relevant activities, and the scaffolding of scientific ideas and students' construction of scientific knowledge (Tabak, 2004; Reiser et al., 2001; Edelson, 2001; Linn, 2000). Davis and Linn (2000) wrote that prompting students (via their Knowledge Integration Environment software) to reflect on their ideas significantly increased performance and knowledge integration. Sandoval and Reiser (2004) wrote that their findings suggest that epistemic tools can play a unique role in supporting students' inquiry and are a fruitful means for studying students' scientific epistemologies.

As noted earlier in this chapter, the use of Progress Portfolio software prompted learners to articulate and connect their experimental findings back to the larger driving questions (Land & Zembal-Saul, 2003). "The negotiation and struggle that ensued regarding the significance of the data promoted explanation, justification and reflective social discourse that can be observed" and studied by teachers and researchers. Related applications of software with important potential to empower student learning include engaging students in using software presentation tools to organize, discuss, and report their investigations, data, findings, and explanations of those findings to share with others. Research on the appropriate use and development of powerful new technology tools is needed to shape the use and development of state-of-the-art technologies, teaching strategies, and curricula that can facilitate important and meaningful science learning.

## TOWARD ASSESSMENT RESOURCES AND STRATEGIES

Over the years several researchers have suggested that the laboratory is not only a unique resource for teaching and learning, but also a unique vantage point for observing students' ideas and for assessing this understanding. There is some evidence that students' abilities in the laboratory are only slightly correlated with their achievement in the sciences as measured by conventional paper-and-pencil tests (Hofstein & Lunetta, 2004). These findings have suggested that students' performance, understandings, and perceptions of the science laboratory learning environment should be assessed with the use of instruments and strategies that are more closely aligned with the unique activities and goals for learning associated with the school laboratory.

In 1970, however, Grobman (1970) identified a major problem in assessing laboratory performance that persists to this day in the United States and in numerous other locations: "With few exceptions, evaluation has depended on written testing. . . . There has been little testing which requires actual performance in a real situation or in a simulated situation which approaches reality . . . to determine not whether a student can verbalize [or identify] a correct response, but whether he can perform an operation, e.g. a laboratory experiment or an analysis of a complex problem."

Bryce and Robertson (1985) were among several who wrote that in many countries, although students spend considerable time engaging in laboratory work, the bulk of their science assessment examines their knowledge divorced from that practical context. The hypotheses and questions students can generate from their laboratory experiences and the laboratory skills they exhibit have all too often been neglected (Van den Berg & Giddings, 1992; Tamir, 1990; Wilkenson & Ward, 1997; Yung, 2001). Gitomer and Duschl (1998) wrote that in science education, the assessment of a student's conceptual understanding has been regularly separated from the assessment of his or her procedural knowledge. They added that although discussions of performance assessment focused on laboratory inquiry skills and understanding, the limited practical assessments employed were influenced by the tradition of practical examinations; the understandings and skills examined were limited. They suggested that assessments should avoid the partitioning of curriculum experiences; curriculum, teaching, and assessment should become better integrated and holistic. The processes of science that are assessed should not be limited only to those involved in specific investigations (Millar & Driver, 1987). Gitomer and Duschl also suggested that students' prior knowledge should be assessed to assist in understanding their behavior during inquiry-type activities.

Bennett and Kennedy (2001) pointed out that because such a wide variety of goals had been articulated for science laboratory learning, it was not surprising to find disagreements in the literature about assessment methods and "what constitutes a reliable and valid assessment of practical abilities." They wrote that areas of discussion included:

- The range and nature of the skills to be assessed;
- The balance between the assessment of prescriptive and investigative tasks; and
- The extent to which the assessment should be holistic or atomistic in its approach.

The Bennett and Kennedy project considered these issues carefully in designing a new model of practical assessment in Ireland. These issues warrant the careful consideration of all test makers, teachers, researchers who inform practice, and policy makers at a time when the assessment of science standards is playing an increasingly important role in shaping the behaviors of teachers and their students in school science. The science education community must develop and use reliable assessment instruments and strategies that are well aligned with the important goals for learning in school science classrooms in general and in laboratory inquiry in particular. The instruments and strategies must also be convenient and manageable for teachers and students, whose time, of necessity, is limited.

Although new instruments must be constructed and validated guided by goals for learning- and data-based research, instruments and strategies *were* developed in the closing decades of the twentieth century to assess the dynamics, the learning outcomes, and the effectiveness of the school science laboratory objectively. Although these strategies and resources have not been widely employed by schools and policy makers, they do offer a foundation for next steps in the research and development of assessment in science education, and they are reviewed here.

Interpreting, explaining, and reporting the results of investigations have generally been important components of student activity in the science laboratory. Stu-

dents' laboratory reports and behaviors can serve as important sources of data for teachers and researchers seeking to make decisions about next steps in teaching, to assess and interpret student performance, and to assess the effects of laboratory experiences on learning. Students' laboratory reports have generally included commentary on *performance* (conducting an investigation; manipulating materials and equipment; making decisions about investigative techniques; and making, organizing, and recording observations) and *analysis and interpretation* (processing data, explaining relationships, developing findings, discussing the accuracy and limitations of data and procedures, and formulating new questions based on the investigation conducted). However, they should also include students' comments on *planning and design* (articulating questions, predicting results, formulating hypotheses to be tested, and designing experimental procedures) and *application* (making predictions about new situations, formulating hypotheses on the basis of investigative results, applying laboratory techniques to new experimental situations [Giddings, Hofstein, and Lunetta, 1991], and justifying assertions). The phases of laboratory activity (italicized above) involve more than manipulation and observation skills; they are important elements of cognitively demanding *procedural knowledge* that includes understanding and sometimes developing investigative design and developing and justifying procedures and assertions about findings. A student's *procedural knowledge* in the laboratory is interwoven with the development of that student's *conceptual knowledge* and understanding of science. Kempa (1986) was one of several who suggested that these four phases of laboratory activity—planning and design, performance, analysis and interpretation, and application—also provided a valid framework for the development and assessment of practical skills.

The Lunetta (1998) and Hofstein and Lunetta (2004) reviews provided numerous citations and discussed alternative strategies for assessing students' performance and understanding in these four broad phases of laboratory activity. The strategies included assessing written and oral evidence and performance in *practical examinations, laboratory reports, portfolios, continuous assessment, and combinations* of these strategies in ways that now include the use of interactive digital technology tools and resources.

*Practical examinations* can serve as valid measures of students' understanding and skill in the *performance* and *interpretation* phases of an investigation, that is, in conducting, decision-making, observing, and making inferences from their observations. As noted in earlier reviews of the laboratory assessment literature (see, for example, Hofstein & Lunetta, 2004), examples of practical examinations reported in published research studies were more visible in the 1970s and 1980s than they were at the turn of the twenty-first century. Practical examinations on some science topics have been useful for teachers and researchers and occasionally in state examinations in some countries, but their use has generally been limited to particular laboratory activities that can be administered easily to students in a restricted time, thus limiting the scope of the activities and the breadth of the assessment. Tamir et al. (1982) developed a Practical Tests Assessment Inventory to standardize the assessment of students' written responses in the inquiry-type practical examination in biology used in Israel. The 21-category inventory included categories ranging from *problem formulation* to *application of knowledge* identified in the students' investigations.

For decades, science teachers have assessed their students' performance in the laboratory via written *lab reports* completed during or after the laboratory activity.

Such reports can offer important data for assessment, but when used in the ritualistic and mechanistic ways that have been so common in many classrooms, the conventional laboratory report reveals little about a student's thinking and understanding. Written evidence of students' thinking and understanding can also be gathered in paper-and-pencil tests designed to assess students' knowledge and understanding of investigative techniques and the scientific procedures, the concepts that underlie the laboratory activity, and their explanations of findings. To date, however, most assessments and grading systems have not examined students' understanding of the research design, the strengths and limitations of the procedures they used, the concepts in which their findings are embedded, and their justifications for their findings. Although there are exceptions to this generalization, many more examples of effective laboratory inquiry assessment practices and carefully validated instruments associated with school laboratory learning are needed in the science education literature. The ritualistic and mechanistic assessment patterns that have been so deadly for meaningful learning in the science laboratory can be changed, of course. When science education research can be applied to inform the providers of high-stakes tests, those who provide support for classroom testing, and teachers, opportunities for more meaningful learning in the school laboratory can follow.

Especially in recent years, some science teachers and researchers have asked students to develop *portfolios* in which the students prepare and collect documents (increasingly using electronic media) throughout an investigation or unit or semester that capture the essence of their investigative work, their understanding, and their justification of procedures and assertions. Such portfolios can help students organize and make decisions about the best ways to report:

- what was investigated and investigative design;
- procedures employed and observations;
- findings and explanations;
- limitations in the findings and new questions.

Portfolios can be important sources of evidence for the assessment of students' performance, activities, understandings, and explanations. Portfolios also provide data about the students' thinking that teachers can use in making decisions about next steps in their teaching in the laboratory-classroom. Progress Portfolio software (Land & Zembal-Saul, 2003) can help students organize, monitor, reflect, and interact with others on the ideas they generate throughout designing, conducting, and determining findings in an investigation. Zembal-Saul et al. (2002) reported that "while engaging in an original science investigation Progress Portfolio assisted prospective teachers in developing elaborated explanations that were grounded in evidence and . . . [in exploring] alternative hypotheses." The Progress Portfolio software was designed "to promote reflective inquiry during learning in data-rich environments." Using such tools prompted "learners to articulate and connect their experimental findings back to the larger driving questions" and to negotiate and struggle with explaining the significance of their data. It also prompted reflective social discourse that resulted in explanation and justification (Zembal-Saul et al., 2002). Progress Portfolio is an example of software used by students in laboratory-classroom activities that can provide teachers and researchers with relatively easy electronic access to student performance data that can also contribute to the assess-

ment of a student's development and progress. Teachers can also use that kind of information for a formative assessment to inform their teaching and their interactions with students.

In an attempt to overcome the limitations of other laboratory assessment methodologies, *continuous assessment* (Hofstein & Lunetta, 2004; Giddings et al., 1991) was designed to serve as a dynamic assessment of students' work throughout a laboratory activity. In this form of assessment the science teacher, researcher, or examiner unobtrusively observes each student during a normal laboratory session and rates him or her on the basis of a prescribed assessment protocol with defined criteria. This system was largely formalized in the United Kingdom by the Joint Matriculation Board (1979). Reflecting the contemporary position that assessment of practical work should be an integral part of the normal science course and not a separate activity, (Denby, 2004) wrote that continuous assessment of students' practical work by their teachers is now required on several occasions throughout the year in the United Kingdom; they must report the variety of practical tasks and skills students have been exhibiting in their science course. Optimally, continuous assessment provides teachers with opportunities to be more directly involved in the practical assessment of their students. However, teachers in the United Kingdom frequently treat the required laboratory assessments separately from conventional practical activities, not in the context of the normal laboratory inquiry and learning, and anecdotal evidence in the United Kingdom suggests that some students engage in very little practical work beyond what is required for their assessment. Thus, what happens in laboratory-classroom practice has often differed from the goals and visions that have been articulated for these efforts.

Science teachers have reported that assessing students during laboratory activities is quite challenging. Teachers often perceive that they do not have sufficient time or skills for evaluating when they also have multiple teaching, management, and safety responsibilities to which they must attend simultaneously (Tamir, 1989). In addition, teachers do not always believe that assessing students' performance in the laboratory should be an especially important part of science assessment. Yung (2001) wrote that teachers in his study in Hong Kong did not believe that assessment of students in the laboratory could improve their teaching and consequently their students' learning. Research examining the issues raised by Yung is needed, with larger samples of teachers in a variety of school settings to obtain more detailed information about appropriate ways to promote and sustain assessment practices that are aligned with the goals for students' learning and that can be managed successfully by teachers.

A long series of efforts have been undertaken to develop and employ multiple methods to assess students in the science laboratory and to increase the reliability and validity of those methods. Recently, Hofstein et al. (2004) used criterion-based *continuous assessment* in an *inquiry-focused* series of high school chemistry courses in Israel that included integrated laboratory activities. Teachers in the study observed individual students or groups working collaboratively. In addition, the teachers examined *hot-reports* submitted regularly by collaborating groups of students in their classes. The *hot-reports* were designed to synthesize the students' experiences, observations, analyses of data, inferences, questions, hypotheses, and plans for pursuing one or more new questions raised by their investigation. Observations of the students' performance in the laboratory, combined with assessment of the students'

*hot-reports*, provided chemistry teachers with valid and wide-ranging information about their students' developing understanding and progress in the laboratory. Continuous assessment in the laboratory is now used in Israel as part of the final examination of the students in this state-approved *inquiry-focused* program. Students in the program are assessed continuously across two high school years (grades 11 and 12) on the basis of their *hot-reports* and teachers' observations of the students' performance in the laboratory. The practical assessment score, based on a performance portfolio prepared by each teacher, contributes at least 25% of each student's total final grade. It is important to note the high commitment of the state and the participating teachers to laboratory work in this project.

The project reported by Bennett and Kennedy (2001) is another showing evidence of a high commitment to laboratory work by the state, in this case in Ireland, and participating teachers. Their study was designed to "evaluate the effectiveness of a new assessment model for practical work." It involved 700 students and 30 schools in Ireland and compared students' written and practical performance associated with their laboratory work in physics and chemistry. Bennett and Kennedy reported that the model developed in their project "provided a reliable and valid assessment of a range of practical abilities, which was also economical of time and resources. Additionally, there was evidence of benefits to the examiners and teachers in terms of their own professional development." Given the substantial commitment of the state and the participating teachers to laboratory work in both the Irish and Israeli projects, it will be important to examine the effects of that commitment on long-term teacher and student behaviors and on multiple issues associated with the nature of the related science learning in years to come.

As noted earlier, limited research has focused on the complex but potentially important intersections between students' understanding of the *nature of science*, how that understanding may influence students' observations and findings in laboratory work, and how the students' understanding of the nature of science may be influenced by laboratory experiences. To develop the knowledge needed to guide relevant curriculum development and teaching decisions, it is important for researchers and teachers to have valid, reliable, and convenient measures of students' understanding of aspects of the nature of science that intersect with practical work in the laboratory. A review of nature of science instruments and associated issues is included in Chapter 28 of this *Handbook*. As noted in that chapter, assessment instruments of this kind are very difficult to develop. However, the task can be accomplished with collaboration among people with expertise in psychometrics, science education, and the philosophy, history, and sociology of science, when the need for the task is understood and supported by the constituencies involved. Research and development conducted by Fraser and a series of colleagues (Fraser, 1998) resulted in the development of the Science Laboratory Environment Inventory (SLEI), discussed earlier in this section and in Chapter 5 of this *Handbook*. Such research is also needed to serve as a foundation for developing assessment protocols that intersect the affective and cognitive domains. Once again, although busy researchers and teachers can use existing resources and strategies to assess students' conceptual and procedural knowledge, understanding of the nature of science, and attitudes associated with *laboratory* learning, the development and use of valid, reliable, and convenient assessment instruments and strategies is a very important area for further discipline-focused research in science education that will guide teaching practice and education policy.

## THE SCHOOL LABORATORY: IMPLICATIONS FOR CLASSROOM PRACTICE AND RESEARCH

In *The End of Education*, Postman (1995) wrote that efforts to improve schooling require attention to the *means* for educating children, but that the “reasons” or *ends* for learning and schooling are far more important. Compelling abstract, metaphysical ends provide meaning and significantly influence education and schooling. However, practical guidance is also needed in shaping both school science reform efforts and moment-to-moment teaching decisions in the science classroom and laboratory. The bulleted goals for learning in the school science laboratory shown in Table 15.1 and discussed earlier in this chapter are important but broad. To guide teachers’ pedagogical decisions and thus to improve learning in complex, busy school laboratory settings, curriculum developers and teachers need to develop more detailed objectives derived from the broader goals; more explicit objectives will also provide guidance that helps students understand the purpose for specific activities and what they need to do consistent with those purposes. Relevant research on laboratory-classroom learning can inform the development of such objectives and teaching strategies.

### Selecting and Promoting Learning Goals for Focused Learning in Specific Laboratory Experiences

Education goal statements in contemporary science education reform documents such as *Project 2061: Science for All Americans* (AAAS 1989), *the National Science Education Standards* (NRC, 1996), and international standards documents reflect the broad goals discussed earlier in this chapter. These goals are best implemented in ways that are particularly relevant to local needs and resources. To these ends, more focused objectives for science laboratory learning such as those shown in Table 15.2

**TABLE 15.2**  
**More Focused Objectives for Student Learning in the School Laboratory**

---

Identify problems for inquiry, suggest strategies for that inquiry, and successfully solve laboratory problems
Participate actively in working toward specific understanding and solutions
Exhibit creativity and curiosity in science inquiry
Exhibit interest and an internal locus of control in science inquiry
Communicate and collaborate in science inquiry
Set objectives, make decisions, exhibit analytical and reflective thinking, and self-evaluate while inquiring and investigating
Retrieve and use current scientific concepts during authentic inquiry
Demonstrate an understanding of the nature of science and its relevance for investigative design, interpreting data, and formulating findings
Make and justify decisions regarding the methodology, data collection, analysis, scientific claims, organization, and presentation of laboratory work
Demonstrate robust understanding of fundamental science concepts ( <i>not</i> simply articulating isolated facts and using mathematical algorithms to solve relatively meaningless problems)

---

should be articulated. Promoting these more focused but still general learning outcomes demands that teachers, curriculum developers, and researchers consider how particular laboratory experiences can promote more explicit, age-appropriate, science learning objectives. They must articulate relevant objectives consistent with desired goals for learning and unique opportunities within specific laboratory activities to guide teachers' and students' decisions and behaviors. Subsequently, the success of laboratory experiences should be examined by the assessment of students' learning associated with the explicit objectives. Decisions regarding selection of laboratory activities and materials, adjustments in the curriculum, and appropriate teacher behaviors and strategies should be influenced by the information gathered from assessments targeted to explicitly stated objectives for student learning in the school laboratory.

### **Selecting and Scaffolding Topics, Ideas, and Laboratory Activities Appropriate for Concept Development**

Important science concepts should be revisited throughout a science course in different and more complex laboratory contexts. Within a course, the selection and sequencing of topics and concepts for student investigation are factors that influence effective teachers' decisions on the selection and use of laboratory investigations. With more deliberate sequential course design and sensitive scaffolding of concepts, students can be encouraged to make more connections between concepts, materials, and contexts. Information about the students' relevant prior knowledge and skills as well as about their ability to handle abstractions, multiple variables, and alternative representations are important factors in the day-to-day decisions of effective teachers. As discussed in the *learning empowering technologies* section of this chapter, this very important area for research and development in science education has led to the production early in the twenty-first century of potentially very helpful software tools designed to support inquiry and the depth and stability of students' concepts and their networks of concepts. These tools should be used with students, and their effectiveness in promoting learning in the laboratory-classroom should be studied very carefully.

To promote conceptual and procedural understanding and engagement, particular laboratory activities must be selected for more thorough investigation in which students experience meaningful inquiry in a time frame that makes sense within the constraints of a school science course. Because in-depth, conceptually focused laboratory study usually consumes considerable time and classroom-laboratory time is of necessity limited, some laboratory activities should be selected for in-depth attention while others are treated less intensively. To conduct those activities effectively, other, less crucial school laboratory activities must be bypassed in favor of more time-efficient alternatives to laboratory teaching, such as simulations and teacher-mediated demonstrations. Many science topics are not readily amenable to first-hand examination in the school laboratory because the materials involved are dangerous to manipulate, very expensive, too large, or too small for students to examine first hand; other important phenomena may take place across time frames that are far too long or too brief to examine in real time (Lunetta & Hofstein, 1991). In deciding what science content is deserving of thorough investigation with mate-

rials in the laboratory and what content may be treated with more limited hands-on experiences, the following questions should be carefully considered:

- What are the principal learning outcomes sought for students in an investigation? Which laboratory activities can successfully promote important learning outcomes, particularly those most neglected in other school science experiences?
- To what extent is the science content in the laboratory experience (including nature of science issues) crucial for scientific literacy? To what extent does that content warrant in-depth investigation when compared with other important content?
- To what extent is the content in the laboratory experience fundamental to one or more science disciplines and extensively linked to other important science concepts? (Content that is well linked to several other important science concepts should normally have higher priority for in-depth investigation.)
- To what extent is the science content difficult to comprehend without concrete experiences that can be used to challenge and extend students' thinking?
- To what extent can students develop meaningful understanding of the important concepts and ideas through a mentally engaging demonstration or simulation, rather than in a more time-consuming, hands-on investigation with materials?
- To what extent are students likely to follow directions relatively mindlessly in pursuing the stated objectives?

In general, science knowledge (conceptual and procedural) that is central in science literacy, fundamental to one or more science disciplines, and difficult to understand without extensive hands-on and minds-on experience deserves in-depth laboratory investigation. On the other hand, "cookbook" verification activities and laboratory experiences that can be taught effectively through teacher-mediated demonstrations, appropriate simulations, and other alternative practical modes of learning and teaching are good candidates for alternative treatment or even for elimination in a conventional laboratory format. Well-conducted, mentally engaging demonstrations and simulations can often be effective and time-efficient, particularly if teachers pose effective questions and scenarios that interest and engage students cognitively. Although the learning outcomes will not be identical, demonstrations can be very appropriate and efficient alternatives to laboratory activities, especially when the instrumentation available for the laboratory normally introduces large measurement error, when special technical expertise is needed to operate those instruments successfully, or when conducting the laboratory activity successfully necessitates particularly heavy commitments of time.

### **Selecting Laboratory Materials to Match Goals for Learning with Students' Needs**

The materials selected for use in a particular investigation often play a very important though complex role in promoting or confounding what students observe and learn. The simplicity or complexity and the novelty or familiarity of the materials and technologies to be used in the laboratory are among the important variables that teachers and curriculum developers must consider to promote meaningful learning. Using equipment and materials that students experience regularly in the

world around them in laboratory investigations can help the students to understand and apply what they are learning in the laboratory. It is important to note, however, that students often bring long-standing misconceptions about the nature of familiar materials with them to school science. These misconceptions can interfere with the ways a student thinks about the materials or equipment, their functioning, and their roles as objects of investigation or as tools in the laboratory. Such misconceptions can influence students' expectations, observations, and understanding of the phenomena they are studying, as illustrated earlier in this chapter when a student's failure to understand the design and purpose of a simple light bulb socket interfered seriously with her ability to interpret a simple electric circuit. Equipment that is novel and not part of a students' prior experience can also influence their learning in the laboratory (Olson & Clough, 2001). When visitors first enter informal environments (a museum, for example), they spend substantial time becoming familiar with that environment before engaging with the exhibits (Falk & Balling, 1982; Kubota & Olstad, 1991). Similarly, when students encounter novel materials during laboratory activity, their attention focuses first on the nature of the novel materials and their functioning Olson (2004). As a result, the students may not focus on important science concepts that the teacher had intended to be a priority. When physics students use a graphing software tool for the first time, for example, their attention may be drawn to the procedures involved in using the software rather than to the graphical representations of the relationships and the concepts the graphing software was intended to illustrate and help them understand. This is but one example of the kind of issue that warrants empirical research to inform good teaching practice.

Johnstone and Wham (1982) wrote that laboratory investigations often overload students with too many variables and too much information to process, whereas Gunstone and Champagne (1990) reported that laboratory work could successfully promote conceptual change, especially if the activities focused on careful treatment of limited *qualitative* tasks. So focusing attention on describing relationships between principal variables and patterns observed in an investigation without the need to attend to multitudes of other details in an investigation can facilitate conceptual understanding at times. When materials are selected to use in laboratory activities, consideration must be given not only to the objectives articulated for students' learning, but also to their prior knowledge and understandings. Therefore, teachers need to help students verbalize their ideas, not only about the relevant science concepts, but also about the nature and function of the laboratory materials to be used in investigating their research questions. Questions that science teachers ask in the laboratory and those they ask students to address in their *portfolios* or *lab reports* can help teachers as well as students to comprehend and explain the investigative procedures and materials used, issues linked to the nature of science, and their understanding of relevant science concepts. With this information, teachers will be in a much better position to select and modify laboratory objectives and activities and to employ more sensitive teaching strategies.

### **Selecting and Modifying Activities to Encourage "Minds-on" Engagement in the Laboratory**

As noted throughout this chapter, goals for learning in science education and knowledge of how people learn should guide teachers in selecting and modifying labora-

tory activities to promote those goals and the more explicit objectives derived from them. When possible, science laboratory activities should encourage students to exhibit the behaviors outlined in Table 15.3. Student behaviors like these can engage students in more meaningful laboratory activities. They are advocated in numerous papers informed by research on learning, and they can be useful for teachers in restructuring their laboratory activities to become more congruent with what we know about learning and goals for student learning. Researchers investigating school science laboratory experiences need to report the extent to which the laboratory activities and teacher-classroom environment engage students in these kinds of decision-making experiences and the effects on learning outcomes for the students.

Multiple studies confirm that the frequently observed ritualistic, even “mindless” student behaviors observed in many laboratory activities stifle students’ personal engagement in decision-making in the laboratory. These kinds of activities

**TABLE 15.3**  
**Student Behaviors to Encourage in Particular Laboratory Activities**

---

Effective laboratory activities encourage students to

1. Explicate the principal question(s) they are investigating
2. Explicate their relevant prior knowledge, e.g., predict outcomes and provide reasoning
3. Employ previously studied science ideas in more complex ways, e.g., determine the products of a chemical reaction with the use of chemical nomenclature, chemical and physical properties, and stoichiometry
4. Invent laboratory procedures. When this is not possible, students should be asked to explain the rationale for steps in the prescribed procedure.
5. Decide what data is relevant and irrelevant; explain what the data means. When students struggle to do this, teachers should ask questions that help the students make progress without making decisions for them.
6. Apply mathematical reasoning to problems. When students are told precisely when and how to use mathematical algorithms to process their laboratory data, then they are unlikely to think conceptually about what they are doing.
7. Set goals, make decisions, and assess progress. Rather than answering all student questions, teachers ask students to explain what they are attempting to do, the procedure they used, what data they collected or are attempting to collect, what meaning they are making from their data, and the reasons for their assertions.
8. Communicate their laboratory work in a clear manner. Rather than prescribe a written laboratory report or portfolio format, have small group and/or class discussions in which the students decide how best to organize and present their research questions, methods, data, interpretations, findings, and new questions. The discussion should include pros and cons of various approaches.
9. Discuss limitations in their sampling, measurement, and data
10. Make connections between science concepts and everyday phenomena. Ask questions that help students observe these relationships
11. Raise new questions suggested by their investigations
12. Reflect on the nature of science. Raise questions that have students consider fundamental assumptions underlying their laboratory work: how theory guided the design and procedures used and their interpretations of data; the role of creativity and ingenuity in their laboratory investigations

---

*Note:* Adapted from Clough (2002).

rarely uncover students' underlying beliefs; they do not encourage students to wrestle with their prior knowledge in making sense of their experiences, and they do not encourage them to reflect on their own thinking. The selection of laboratory activities that actively encourage students to wrestle with science concepts (and hence to better understand them) is one of several important and complex matters. Laboratory activities should be aligned with desired goals for learning, be within learners' zones of proximal development, and require active student engagement. When laboratory activities are outside a student's zone of proximal development, the student has little choice but to follow directions blindly, and the time invested in the laboratory activity is likely to result in learning that is far from the desired goals articulated at the outset.

Laboratory activities that engage the mind as well as the hands have students "thinking out loud, developing alternative explanations, interpreting data, participating in" constructive argumentation about phenomena, developing alternative hypotheses, designing further experiments to test alternative hypotheses, and selecting plausible hypotheses from among competing explanations (Saunders, 1992, p. 140). Students' thinking should be expressed openly and discussed to help students act on their underlying beliefs in the context of alternative explanations; the articulation of students' ideas can also enable teachers to understand and hence to help the students develop deep, scientific conceptual understanding. Because teachers have limited time to interact with all students in a laboratory class, having the students use appropriate electronic tools like Progress Portfolio while conducting their inquiry can assist in facilitating the deep understanding that is consistent with goals for learning. Again, here is an area of contemporary research on science teaching and learning that warrants careful study.

## Selecting Models and Strategies to Guide Laboratory Teaching

The reviews of the school laboratory literature discussed earlier reported a mismatch between the goals articulated for the school science laboratory and what teachers and students regularly do in laboratory activities. Ensuring that students' experiences in the laboratory are aligned with stated goals for learning demands that teachers explicitly link decisions regarding laboratory topics, activities, materials, and *teaching strategies* to desired outcomes for students' learning. Effective laboratory activities require significant student engagement, thinking, and decision-making, but teachers play a crucial role in helping students have productive experiences. The teaching models and strategies teachers employ to guide their behaviors in the laboratory-classroom and the ways in which they interact with students influence the extent to which well-designed laboratory activities promote desired learning. The *learning cycle* and subsequent teaching models were designed to guide teaching that promotes learning.

*Search, Solve, Create, and Share (SSCS)* is a relatively open-ended teaching model (Pizzini et al., 1989) that is well suited for school science laboratory experiences. During the *search* phase, students take part in identifying researchable questions and then in refining them. In the *solve* phase, students in small cooperative groups consider ways to investigate their research questions, using procedures they have

developed. In the *create* phase, the groups prepare their presentations, reporting their research questions, investigative work, results, and conclusions. Each group's presentation is shared in the final *share* phase of the strategy. Pizzini and Shepardson (1992) compared classroom dynamics in a traditional laboratory with that in a SSCS setting. They reported that in the traditional laboratory setting student behavior appeared not to be influenced by the design of the laboratory experience, whereas in the SSCS setting "student behaviors are exhibited in response to . . . the lesson structure—designing a research plan, collecting data, analyzing data, and evaluating" (p. 255). The SSCS teaching strategy helped students learn to ask researchable questions, to design a research plan, and to answer some of those questions. Whereas many teaching strategies encourage students to ask and investigate questions, some strategies like SSCS place greater direct emphasis on expecting these behaviors.

Combining different elements of recommended teaching models can help individual teachers engage students in wrestling with the meaning of laboratory observations. For instance, the *Science Writing Heuristic (SWH)* (Keys et al., 1999) can be effective in promoting thinking, negotiating meaning, and writing about science laboratory activities. The SWH strategy can be integrated with learning cycle approaches and with an SSCS problem-solving approach. The SWH strategy can help students move beyond traditional school science laboratory reports, toward more personal, expressive forms of writing while improving their science understanding (Rivard, 1994). The SWH strategy guides teachers and their students in thinking and writing, and it encourages students to elaborate the links between claims and evidence. An SWH template guides teachers in helping students to negotiate meaning with small groups and with the entire class. A student template incorporates scaffolding questions that form the heuristic: What is the question being investigated? What did I do? What did I see? What can I claim? What is my evidence? What do others say? and How have my ideas changed? These prompts encourage metacognitive behaviors consistent with how people learn and promote many goals articulated for school science laboratory activities. For instance, in a study with grade 6 students, those engaged in the SWH strategy demonstrated higher order cognitive operations when completing laboratory activities, compared with those using a more traditional laboratory report format (Grimberg et al., 2004). Effective implementation of the SWH has been shown to improve grade 7 students' performance on conceptual essay questions focusing on the big ideas of a topic (Hand et al., 2004). Similar results were obtained for freshman university chemistry students' performance on conceptual essay questions and the American Chemical Society semester 1 examination (Rudd et al., 2001; Burke et al., 2003). Based on semester final examinations, the project reported success when the SWH strategy had been used in the lectures of a university chemistry course.

*Predict-observe-explain (POE)* and *think-pair-share (TPS)* are examples of other teaching strategies that can be used effectively alone or in combination with teaching models described earlier to elicit students' thinking and promote minds-on, not just hands-on engagement in school science laboratory experiences. Both POE (White & Gunstone, 1992) and TPS engage students in thinking about a laboratory phenomenon and sharing their thoughts with their classmates and the teacher. POE can be used with an entire class, small groups, or individual students. Having students make a prediction often raises interest in what will be observed and investi-

gated, and in the process, teachers can gain important insight into students' thinking (Liew & Treagust, 1995; Palmer, 1995). When observations do not match students' predictions, cognitive conflict and motivation for learning may ensue. Whether or not students' predictions match what they observe, the most important step of this strategy is the explanation the students provide for their predictions and how they account for observations that deviate from what they had predicted. TPS can be used in small groups and with the entire class when a teacher wants students to contemplate a question or phenomenon individually, then interact with other students to discuss their ideas, and finally share what they think with the teacher, group, or entire class.

A questioning strategy proposed by Penick, Crow, and Bonnstetter (1996) is well suited to school science laboratory investigations because it reminds teachers to determine explicitly what students have done and to help the students recall and use those experiences to speculate, build relationships, create explanations, and apply knowledge. The strategy can be particularly useful to teachers as they work to change their own roles and behaviors during laboratory activities, and it can guide researchers in describing the nature of student and teacher behaviors that may be related to learning outcomes. The examples shown in Table 15.4, while not an invariant step-by-step progression of questions, illustrate how the strategy is useful in the laboratory to ground questions in what students have done and to help the students bridge to more abstract concepts. Even well-written laboratory activities may not enable students to learn with the deep understanding intended by their designers when they are poorly implemented in school settings. Selecting and implementing appropriate teaching strategies can have a powerful influence on the

**TABLE 15.4**  
**Questioning Strategy for School Science Laboratory Experiences**

---

*History*—Questions that relate to students' experience:

What did you do . . . ?

What happened when you . . . ?

*Relationships*—Questions that engage students in comparing ideas, activities, data, etc.:

How does this compare to . . . ?

What do all these procedures have in common?

*Application*—Questions that require students to use knowledge in new contexts:

How can this idea be used to design . . . ?

What evidence do we have that supports . . . ?

*Speculation*—Questions that require thinking beyond given information:

What would happen if you changed . . . ?

What might the next appropriate step be?

*Explanation*—Questions directed to underlying reasons, processes, and mechanisms:

How can we account for . . . ?

What justification can be provided for . . . ?

---

*Note:* Adapted from Penick, Crow, and Bonnstetter (1996).

extent to which learning outcomes sought for students are achieved. In addition, examining the effects of specific teaching strategies and models on student learning should be an important goal for focused research that can inform practice in science education. These are very important tasks not only for science education researchers per se, but also for science teachers and science teacher education.

## ROLE OF THE TEACHER DURING LABORATORY ACTIVITIES

As noted earlier in this chapter, contemporary science concepts rarely emerge from school laboratory experiences and data unless the students have thoughtful conversations with an informed teacher who can help them contrast their ideas with those of the scientific community. Gunstone and Champagne (1990) noted that the need for meaningful interaction and reflection in the laboratory is essentially a call for discussion, “a teaching strategy which has been widely under-used in laboratories” (p. 179).

Windschitl (2002) wrote that “Supporting student learning . . . requires special skills and conditions” (p. 145). These teaching skills are especially important when teachers work with students in the laboratory, and researchers investigating school laboratory experiences should examine and report these “skills and conditions” with special care. Laboratory activities create many opportunities in which the students can describe: what they *see*, what they are *doing*, and how they *explain* these things. Yet, asking thought-provoking questions that help students to articulate their observations, their inferences, and their explanations and to connect these with science concepts they “know” and with the concepts of experts is a particularly important and challenging task for a teacher (Driver, 1995).

Effective teachers encourage students to share their thinking by asking effective questions with appropriate wait time I and II (Rowe, 1974, 1986), carefully listening to students’ ideas and asking for elaboration, acknowledging those ideas without expressing judgment, and responding with further questions and ideas that are based upon the students’ comments. These skills and other complementary teacher behaviors can create mentally engaging and productive laboratory discussions conducive to meaningful science learning. These behaviors are essential *tools* that teachers use to understand students’ thinking during laboratory activities and to help students piece together desired understandings. The importance of these behaviors, especially in the school laboratory, suggests that effective teaching is far more complex and challenging than most observers and even many teachers believe it to be (Clough, 2003; Windschitl, 2002).

This complexity and challenge is illustrated in a short transcript from a case study report adapted from Clough (2003) and shown in Box 15.1. The example illustrates the critical role teachers can play in learning and the importance of the pedagogical practices they use in teaching. The laboratory activity that was the context for Box 15.1 might be perceived by a layperson as simple *hands-on* learning, but to an informed teacher who is sensitive to the nuances of learning and teaching, the learning interactions visible in the dialogue are complex. A careful reading of Box 15.1 shows an expert teacher who worked to understand students’ thinking, challenge misconceptions, and help the student make links to science concepts that led

## Narrative Box 15-1

## One Example of the Teacher's Crucial Role in the Laboratory

Dan was a "good student" who along with his classmates had successfully completed a learning cycle sequence exploring characteristics of chemical change including the conservation of mass several weeks prior to the dialogue below. In that activity, students improved their experimental design several times to prevent escape of the gas produced. With each sequential improvement the "loss" of mass resulting from gas leaking out of the system became smaller. Through these experiences, students came to the conclusion that under perfect conditions (i.e., no substances are lost or gained by the system, perfect balance, etc.) that mass would remain exactly the same before and after a chemical reaction. Dan had appeared to understand a series of activities and discussions that had taken place in the following weeks including balancing chemical reactions, the mole concept, and stoichiometry. Later, the students were enthusiastically attempting to determine the products of that prior chemical reaction using all that they had learned during the entire year in chemistry. Several days into this activity, Dan approached his teacher and the following conversation ensued:

Dan: "Mr. Smith, the mass of my system went down."

Teacher: "How do you account for that, Dan?"

Dan: "A gas was formed and gases have no mass."

Teacher: (Inwardly surprised, but maintaining an accepting and inquisitive outward appearance) "What do you think gases consist of?"

Dan: "Atoms."

Teacher: "What do you know about atoms and mass?"

Dan: "Atoms have no mass."

Teacher: (Doubly surprised and searching for a way to help Dan see his misunderstanding) "Dan, what are you made up of?"

Dan: "Atoms." (Pause, followed by a paradoxical look on his face.) "And I have mass."

In the episode, the teacher kept in mind the overarching goals he had for the students. The teacher's response to Dan reflected an understanding of how people learn and how they often struggle to fully comprehend what the teacher has in mind. To help Dan develop a more scientifically accurate concept, the teacher did not tell Dan how to interpret the data. Instead, he posed a question to have Dan elaborate on his statement. Using non-judgmental, but encouraging non-verbals, the teacher waited again (wait-time II). The teacher's hard won interaction pattern provided Dan with more time to think and talk, while giving the teacher more time to consider what his next move would be. Using positive voice-inflection with a line of questioning he thought would resolve the issue, the teacher continued the interaction while listening intently to Dan's thinking, acknowledging his ideas without judging them, and responding with questions developed from what Dan had said. The teacher reported that while Dan was telling him that *atoms have no mass*, the periodic table of elements was visible to Dan. On it, the atomic masses were clearly displayed, and they were numbers Dan had used consistently in solving stoichiometry problems. Some of those problems had explicitly addressed the mass of reactants and products in the gaseous state, and Dan had solved them successfully.

to more meaningful and comprehensive scientific understanding. Worth noting again is the need for research on learning in the school laboratory that recognizes intricate and intertwined teacher and student behaviors and more clearly articulates the roles of the teacher in promoting meaningful interaction and reflection in the development of more scientific ideas and understanding.

### **TOWARD APPROPRIATE QUESTIONS, METHODS, AND ASSESSMENT SCHEMES IN LABORATORY- RELATED RESEARCH IN SCIENCE EDUCATION**

“At its core, scientific inquiry is the same in all fields. . . . Research . . . is a continual process of rigorous reasonings supported by a dynamic interplay among methods, theories, and findings. It builds understanding in the form of models or theories that can be tested” (Shavelson & Towne, 2003, p. 2). Unfortunately, careful scholarship and student performance data have *not* consistently driven the policies and practices associated with teaching in the school science laboratory. Our review of the literature fails to show many empirical studies that have investigated carefully the causal effects of the objectives, laboratory instructions, teaching models, and teaching behaviors experienced by students in the laboratory on the attainment of explicit objectives for learning articulated for particular laboratory activities or on the broader goals for learning articulated in contemporary science standards. Reviews in past decades have reported disappointment with studies on the laboratory, resulting from (a) failure to explicate goals and objectives for laboratory activities; (b) assessment instruments that were not well aligned with the goals of laboratory work; (c) mistaken notions regarding the nature of science; (d) failure to delineate what the teacher and students were and were not doing before, during, and after laboratory experiences; and (e) other factors discussed in this chapter. Although progress has been made, many of these problems have not been properly addressed. The laboratory presents many opportunities for promoting desired learning outcomes, but what we know about learning and effective teaching has not been visible regularly in many school laboratory settings.

Many variables interact to influence student achievement and attitudes, and searching for single cause-effect relationships in teaching and learning associated with the laboratory is contrary to the complexity that we have come to know is inherent in meaningful science teaching for human learners. Thus, employing research designs that can examine and link complex laboratory-classroom variables to learning outcomes will be a challenging but important goal. To inform practice more optimally, next steps in research on the school science laboratory should include studies that examine multiple interacting variables and research questions to ascertain the nature of their individual and composite effects on students’ science learning. Research on the laboratory in school science should examine the important interacting roles of students’ prior understanding of relevant conceptual and procedural knowledge, students’ understanding of the nature of science, and their understanding and comfort with laboratory technologies, perceived goals and objectives articulated for laboratory learning, the roles played by curriculum materials, teachers’ interactions with students, laboratory assessment systems, the teachers’ scientific and pedagogical knowledge, and other relevant variables. Ultimately, the

science education community should have much more *scientific* information about the nature of the individual and composite effects of these variables on students' science learning to better inform teaching practice and education policy. There is much work to be done.

Research on the school laboratory should also examine some of the very important social and ethical issues that influence teachers' decisions to engage or not to engage their students in laboratory activities. Two examples of important issues that have not been examined and discussed substantively in the literature are concerns about *laboratory safety* and about *valuing living (or formerly living) materials*. Busy teachers who are concerned about promoting humane and scientific habits of mind, values, and inquiry as well as safety must function within schools in which many administrators today are particularly concerned about avoiding potential controversy and litigation while operating with limited budgets. Teachers who are concerned about promoting inquiry as well as the valuing of living things must make decisions about activities to be included or avoided in science laboratory-classrooms. These decisions are made within an array of community values (anti-violence and immature student behavior among them) that influence those decisions. Meaningful research that can inform practice and policy must examine these kinds of issues as well as those in the domain of students' cognition.

One important part of the task is to identify appropriate research designs that can guide next steps in organizing research studies. Research questions, methodologies, and assessment instruments must be aligned in response to the problems and issues discussed in this chapter. Many studies have been conducted with the use of case-study methodologies that have provided information about effects of practices on learning in school laboratory settings. These initial steps have been informative, but it has been difficult to generalize beyond the small samples that were studied. More systematic research, sometimes with complex research designs, is warranted to yield more generalizable findings. The structure and size of many secondary and university science laboratory courses (often with multiple sections) make treatment/control research designs possible. In cases where a large number of students are enrolled, such as in college science courses, *Solomon four-group designs* (Isaac & Michael, 1987) may be appropriate, for example. Structural Equation Modeling (Gall et al., 1996; Hoyle, 1995) and other complex designs might better help science education researchers understand the role of the laboratory in conjunction with other aspects of effective teaching; contemporary social science research designs should be explored and employed. Meta-analytic studies could also provide insight into the effects of specific kinds of laboratory treatments and experiences.

Organizing for larger-scale and longer-term studies of the kind recommended here requires not only the broader expertise that is possible in well-constituted collaborating teams of researchers, but also structures for research that go beyond one classroom and teacher, beyond a single school or community, and beyond classical university science and education departments. Creating and supporting the development of competent, collaborative researchers, research teams, and larger institutional structures sensitive to school and teacher, research and development issues will be challenging. Nevertheless, these are very important tasks en route to conducting research that will properly inform and improve education practice and policy.

## FOUNDATIONS FOR THE TWENTY-FIRST CENTURY: LOOKING TO THE FUTURE

In this chapter, we have reviewed and synthesized multiple activities that have fit within a definition of the school *laboratory* derived from the science education literature and articulated in the introduction to this chapter. *Laboratory activities* have been used in multiple natural science disciplines to teach students of multiple age spans in very different cultural and classroom contexts. In the many studies and varied research settings, important issues and variables intersect. However, there have been many substantive differences in the laboratory settings and in other variables reported. To develop research in the field, the science education community and especially the research community must be careful to explicate detailed descriptions of the participating students, teachers, classrooms, and curriculum contexts in research reports. Among the many variables to be reported carefully are learning objectives; the nature of the instructions provided by the teacher and the laboratory guide (printed and/or electronic and/or oral); materials and equipment available for use in the laboratory investigation; the nature of the activities and the student-student and teacher-student interactions during the laboratory work; the students' and teachers' perceptions of how the students' performance is to be assessed; students' laboratory reports; and the preparation, attitudes, knowledge, and behaviors of the teachers. What do the students perceive they are supposed to accomplish in the laboratory activity? How do they perceive their laboratory performance will be assessed? How important do the students and the teachers perceive the laboratory activities to be? Studies should clearly report the amounts of time students spend in laboratory activities and how those are integrated or separated from other work in the science course. They should distinguish clearly between long-term and short-term student investigations and indicate clearly the numbers and roles of students in each laboratory team. Because substantial differences often are present in different laboratory settings, detailed descriptions of the subjects and contextual details are especially important. To support the development of knowledge that can advance science education by informing curriculum development, teaching and assessment practices, and education policy, it is essential to define technical terms precisely to explicate knowledge in the field; it is also important to use those terms consistently in research reports and in scholarly writing.

In the introduction to this chapter, we articulated a classical definition of school science laboratory activities that would have been appropriate in the nineteenth century and most of the twentieth. We wrote that laboratory activities were learning experiences in which students interact with materials or secondary sources of data to observe and understand the natural world. We also wrote that the increasingly widespread use of digital computing technologies in school science near the turn of the twenty-first century offered not only new tools for gathering, visualizing, and reporting data, but also important simulation resources for teaching and learning science. We have written that work with simulations has helped us to understand that school laboratory activities are themselves simulations of some of the things that scientists do. To teach meaningful science successfully, teachers' decisions must be informed by substantive research on these complex issues. Because citizens in a high-technology society need to understand the important distinctions between real and virtual realities or worlds, that is one more learning outcome that

will come to be expected of science education early in the twenty-first century. Experiences with real and virtual materials in school science have important roles to play in developing the needed understanding.

In the twenty-first century, students will increasingly move their science classes between experiences with actual natural phenomena and the virtual realities that model those phenomena. The distinction between real and virtual tools and phenomena is one more complex and important variable that science teachers in the twenty-first century must consider to promote scientific understanding. The powerful new electronic tools and resources blur the interface between learning in the laboratory with real materials and learning with simulations that are representations of nature. We predict that before long a new goal/standard will emerge as an expectation for science education, that is, *school graduates will discriminate between real and virtual realities*. The school laboratory will have a very important role in the teaching and learning associated with this outcome.

In the twenty-first century, students will increasingly move in their science classes between experiences with actual natural phenomena and the virtual realities that model those phenomena. On some occasions they will process and graphically display laboratory data gathered from the study of real materials, and on other occasions they will process and graphically display data generated by electronic simulations driven by models that have been created by others or by the students themselves. We have reported evidence in the chapter that digital tools in the laboratory at times can help students visualize and understand science concepts, whereas at other times they can seriously confound understanding. Curriculum developers and teachers need to be well informed about these important issues in teaching and learning, and new research is warranted to provide the information needed. The new electronic tools associated with the school science laboratory offer important opportunities for teaching and learning in science; they also offer important opportunities for the scholarly study of learning, students' understanding, and the experiences and teaching prompts that support the development of scientific understanding. For these reasons, the need has arisen for a *new* definition of the school science laboratory that will encompass the simulation of natural phenomena and be appropriate for science education in the twenty-first century.

From a 50-year perspective, considerable progress has been made in the articulation of carefully conceptualized goals for science learning and in what we know about the learning of science. Many now recognize that science curriculum development, science teaching practices, and science education policy should be guided by those goals and by that knowledge. Curriculum development and teaching methodologies reflecting theories of how people learn have begun to be tested on the basis of student performance data, but these research and development activities are not sufficient, given the need to improve education in science and the magnitude of current problems. To achieve what is needed, research and development on these important issues in science education must accelerate.

Science education scholarship to date does provide a foundation for movement toward theories and research that can guide the development of curricula and teaching practices in science education and in the laboratory. Much evidence suggests that carefully conceptualized and carefully delivered laboratory activities are very effective in helping students develop and apply science concepts and procedural knowledge. However, research results have been difficult to interpret because central goals

for learning in the laboratory, assessment measures, and research methodologies have not been well aligned. Contemporary social science research designs must be used to examine complex laboratory-classroom events and an array of variables that are well grounded in theories of science learning and the extant scholarship. To examine the matrix of interacting variables, collaborative research conducted by teams of persons who bring together knowledge and skills in science education, science, and appropriate education research methodologies is warranted.

At the beginning of the twenty-first century high-stakes tests in the United States and elsewhere increasingly drive what school and state administrators, parents, teachers, and students think is important in school science. Because there is a concurrent, widespread perception that what those tests measure is not well linked with time spent on activities in the school laboratory, to expect that students' and teachers' behaviors will shift toward more effective laboratory practices is naïve unless the perceptions change. Significant discrepancies exist between what we know about learning science and current science teaching practices and policy. The policy makers who control the testing programs and those who prepare the tests must become an integral part of more functional efforts to improve the effectiveness of school science.

What we know about science learning and the goals for science learning must be reflected in the science standards, and the standards must be linked to the development of valid and reliable tests. Most assessment of students' understanding and performance in the school laboratory continues to be confined to limited, conventional measures at best. Thus, substantial research and development is needed to create more valid, comprehensive, and useful measures of students' understanding of laboratory *procedural knowledge* and its intersections with the development of students' *science concepts*, their understanding of *the nature of science*, and their *attitudes toward science and the school laboratory*; the results of those efforts must be applied in science teaching practices and policy.

Although many questions about effective school science laboratory experiences remain to be answered, this chapter makes clear that much has been learned about the teaching, curriculum, and laboratory learning environments that promote desired science education goals. This knowledge provides a foundation for research that can inform teaching and curriculum practices and science education policy. The review of literature in this chapter also illustrates the very important and complex nature of teaching in the school science laboratory. Contemporary developments in understanding the nature of science are likely analogous, in part, to contemporary developments in understanding the effects of complex science classroom events on science learning. Overarching claims (pro or con) about the value of school science laboratory experiences are misplaced as myriad variables influence learning outcomes. These interacting variables must be examined carefully to better understand the potential and realities of laboratory experiences.

Much must be done to assist teachers in engaging their students in school science laboratory experiences in ways that optimize the potential of laboratory activities as a unique and crucial medium that promotes the learning of science concepts and procedures, the nature of science, and other important goals in science education. Science education researchers, teachers, curriculum developers, administrators, and policy makers all have important roles to play in these efforts. Understanding and advancing science education learning and teaching, promoting the

development of science curricula, and supporting the development of effective science teachers are very complex activities, and simplistic solutions will be naïve and inadequate. Those important activities must continually be informed and enhanced by excellent research on learning and teaching science.

# CHAPTER 16

---

## Discourse in Science Classrooms

**Gregory J. Kelly**

*Pennsylvania State University*

Educational events occur through communication. Science learning can be conceptualized as students coming to know how to use specialized language, given the constraints of particular social configurations and cultural practices. Across different theoretical traditions, from the sociology and rhetoric of science to studies of classroom interaction, the importance of spoken and written discourse in the production and learning of disciplinary knowledge is becoming increasingly recognized as a salient research focus. The study of discourse, broadly defined, allows researchers to examine what counts as science in given contexts, how science is interactionally accomplished, who participates in the construction of science, and how situated definitions of science imply epistemological orientations. In this chapter, I provide a conceptual overview of the field of discourse studies in science education. My aim is not to present a comprehensive review of all studies, but rather to focus on some of the theoretical approaches, methodological orientations, and substantive findings. Through this selected review, I argue that a discourse analytic perspective provides insight into how the events that make up science education are constructed through language and social processes. The importance of viewing education through this lens of language and social processes is justified by three primary observations. First, teaching and learning occur through processes constructed through discourse and interaction. An empirical focus on the ways language contributes to learning is essential for developing theories of practice for science education. Second, student access to science is accomplished through engagement in the social and symbolic worlds comprising the knowledge and practices of specialized communities. Issues of understanding, appropriating, affiliating, and developing identities for participation in the knowledge and practices of the sciences can be understood through the study of discourse processes. Third, disciplinary knowledge is constructed, framed, portrayed, communicated, and assessed through language, and thus understanding the epistemological base of science and inquiry requires attention to the uses of language. I conclude this review with implications

about how the current body of knowledge suggests future directions for research in discourse processes in science education settings.

Discourse is typically defined as language in use, or a stretch of language larger than a sentence or clause (Cameron, 2001; Jaworski & Coupland, 1999). This definition, while potentially recognizing the need to examine form and function in discourse studies, may not make obvious the relationship of language use to social knowledge, practice, power, and identity (Fairclough, 1995). Therefore, the study of discourse processes in science education should properly include a definition of discourse as using language in social contexts and, as Gee (2001a) argued, connected to social practices, "ways of being in the world . . . forms of life which integrate words, acts, values, beliefs, attitudes, and social identities as well as gestures, glances, body positions, and clothes" (p. 526). For the purposes of this review, I shall leave the definition of discourse broad and consider a range of studies that encompass the many epistemological, ideological, and social dimensions of language use. To maintain focus, I shall consider primarily discourse studies set in educational settings. Furthermore, although the majority of empirical studies related to science education use language, I shall limit my focus to those studies that specifically examine how the form, function, and/or interactional aspects of language are used in an explicit manner. Generally, this means that studies that self-identify as explicitly related to language, literacy, and discourse are more likely to be included in the review.

Studies of classroom discourse in science education have been informed by multiple theoretical traditions and apply multiple methodological orientations. Typically there is a strong tie between the theoretical positions of the researchers and the application and interpretation of a particular research approach. Each theoretical position and manifestation in research entails a certain expressive potential (Strike, 1974), offering a particular set of constructs that allows researchers to speak about certain dimensions of discourse. Furthermore, although theories of discourse may have methodological implications, there is typically flexibility within traditions as to how particular studies are conducted. In this chapter, I make reference to some clearly distinguished theory-method relationships through a review of substantive studies of classroom discourse, rather than describe a set of research methodologies for analyzing classroom discourse separate from the substantial issues of individual studies. Much of the research in science education concerned with discourse processes shows a family resemblance to one or more of a relatively limited number of theoretical traditions, including social semiotics (e.g., Halliday & Martin, 1993; Lemke, 1998), sociolinguistics (e.g., Bleicher, 1994; Carlsen, 1991a), ethnomethodology (e.g., Lynch & Macbeth, 1998; Macbeth, 2000), cognitive science and psycholinguistics (e.g., Yore, Bisanz, & Hand, 2003), rhetoric and writing (e.g., Bazerman, 1988; Keys, 1999a), and critical discourse analysis (e.g., Hughes, 2001; Moje, 1997).

This review of discourse in science classrooms is intended to provide illustrative examples of the range of perspectives and issues. I offer a view of only a limited number of the many studies that could plausibly count as studies of discourse in science classrooms. As many of the authors reviewed have noted, studies of teacher lectures, for example, are not independent of the reading and writing activities in the classroom (e.g., Lemke, 2000; Moje, Collazo, Carrillo, & Marx, 2001; Rivard & Straw, 2000). Student participation in a teacher-directed classroom typically involves attempting to make sense (or not in some cases) of a range of spoken and written texts, signs and symbols, and physical objects, all within a continually con-

structured set of norms and expectations, rights and obligations, and roles and relationships (Gee, 1999; Green, 1983). Similarly, learning to write science/writing to learn science typically involves participation in a range of spoken discourse practices that help make sense of the written texts contributing to the writing goal, as well as any number of participation structures (small group, whole class), cultural expectations, ways of being a student, and so forth (e.g., Kelly, Chen, & Prothero, 2000; Keys, 2000; Rivard & Straw, 2000). Indeed, any issue related to lectures, discussions, writing, or reading in science classrooms typically includes, to some degree, aspects of each of these three categories. For the purposes of this review, I have organized the chapter by studies of spoken discourse, including the topics of classroom teaching, small-group interaction, conceptual change, argumentation, and equity, and studies of written discourse, including the topics of reading and writing science. The research literature will show that there is not a clear demarcation in teacher and student discourse, nor in written and spoken discourse in all instances. Many studies could have been grouped differently.

## STUDIES OF CLASSROOM SPOKEN DISCOURSE

### Discourse Studies of Classroom Teaching

A landmark for discourse studies in science education is Lemke's (1990) *Talking Science: Language, Learning, and Values*. Lemke applied a social semiotic perspective to classroom discourse in a set of studies of secondary science classrooms. Lemke's work began with the premise that science lessons are social activities constructed through human action. These human actions occur with the contingencies of the moment and are generally constrained by activity structures and norms for interaction. Lemke's analysis identified both thematic and organizational patterns in science dialogues in classrooms. The thematic patterns represented the particular semantic relationships comprising the scientific knowledge discussed. This was often in the form of propositional knowledge, controlled by the teacher, with little opportunity for students to take initiatives within the conversations. The examples of classroom discourse demonstrate how these acceptable ways of talking science are tightly controlled through the enforcement of strict uses of language specific to thematic content as interpreted by the classroom teacher. The organization of the discourse often fell into a common pattern of question-answer-response, referred to by Lemke as the triadic dialogue.<sup>1</sup> This triadic dialogue pattern centers control of the direction and thematic content of the lesson on the teacher. Through the analysis of the organizational and thematic patterns and their relationship, Lemke put forth his central thesis that learning science is learning how to *talk* science—that is, observing, describing, comparing, classifying, discussing, questioning, challenging, generalizing, and reporting, among other ways of talking science (p. 1). Lemke explained, "students have to learn to *combine the meanings* of different terms according to accepted ways of talking science" (p. 12, emphasis in original).

---

1. This pattern has been similarly labeled IRE (initiation-response-evaluation) or IRF (initiation-response-feedback); see Cazden (2001), Mehan (1979), and Sinclair & Coulthard (1975).

Lemke (1990) argued that over time the combined effect of strict adherence to patterned language use and tight control of the nature and types of classroom conversation led to a particular ideological positioning of science. The teachers' pedagogical goal of transmitting the propositional content of the products of scientific communities left little room for justification, discussion, and re-examination of science. Students were offered little opportunity to "talk science" and practice making the language of science their own. Furthermore, the disciplinary knowledge was positioned as unassailable, difficult to learn, and reserved for a cognitive elite. Lemke's examination of the discourse processes in science classrooms posed troubling problems for educators. The portrayal of science was ideological in the sense that only one dimension of science (strict use of language in its final form) was made available to students—views of a more social and less secure science were omitted. Consequently, the students may have lost interest in science because of the ways in which science was narrowly framed in the classrooms.

Whereas Lemke (1990) studied ways that teachers talked science, Moje's (1995, 1997) research considered more explicitly how a teacher talked *about* science. By applying a critical discourse analysis framework<sup>2</sup> (Fairclough, 1995), Moje (1995) identified how uses of particular discourse processes (e.g., first person plural, precision in language use, demarcating science from other disciplines) positioned science and science teachers as authorities. In one particular episode described by Moje (1997), a student was requested to repeat his imprecise response three consecutive times. This example illustrated how a teacher's view of the precision required of scientific knowledge was partially responsible for a situation where the power relationships were manifested in the conversation. Rather than viewing scientific practices as a resource for understanding the social practices of a community, the discourse practices were used as a means to enforce the putative exactness and precision of scientists. In these studies, a common theme emerged regarding choices of discourse in science classrooms: The choices of discourse influenced the views of science made available to students. The framing of the disciplines of science emerged similarly in studies of teacher questions, where variables such as teacher knowledge and use of authority became pertinent (Carlsen, 1991a; Russell, 1983).

Much like the social semiotic perspective of Lemke, Carlsen (1991a, 1991b, 1992) applied sociolinguistics to consider the multiple functions of classroom conversations. Carlsen examined the role of teacher subject matter knowledge as a variable in the syntactic, semantic, and pragmatic features of classroom discourse. Carlsen found that teachers' subject matter knowledge of the scientific discipline being taught influenced the extent to which they opened up classroom conversations to student participation, the range and type of questions posed to students, and their willingness to diverge from specific, defined curriculum goals. For example, teachers' questions to students served the immediate function of eliciting a student response to a scientific topic, as well as other functions, such as maintaining control of the students and the range of discussion topics (Carlsen, 1992, 1997). Thus, questions served multiple purposes for science teachers; they had both a locutionary (literal meaning) and an illocutionary (functional meaning) force in the

---

2. Critical discourse analysis examines the role of discourse in society and culture and how discourse plays a role in sociocultural reproduction and change (Fairclough, 1995; Luke, 1995).

conversation. Carlsen's analysis of teacher questioning provided a means of examining how teacher subject matter knowledge (measured independently) influenced the science of the classroom discourse. One interesting finding of these studies was that when teachers taught less familiar subject matter they tended to ask more questions. However, rather than opening up the conversation, these questions tended to be of a lower cognitive level and were fact oriented. Thus, students were put on the defensive by the teachers' questions.

Carlsen's studies of teacher subject matter knowledge and its relationship to choices discourse expanded some earlier findings by Russell. Russell (1983) applied argumentation analysis to the study of teacher questions and found that questioning served to orient the conversation to an unjustified authority of science, rather than to an authority merited by reasons. The studies by Carlsen and Russell corroborate Lemke and Moje's views about the ideological views of science promulgated in schools. Similarly, Cross (1997) identified teachers' support of mythological accounts of science—accounts that fail to consider the problematic nature of science, the influence of funding on science, the role of personal and cultural values, and so forth. Cross attributed the uniformity of teachers' views across cultures to the science socialization processes experienced by teachers and to the professional development of science teachers.

Whereas some studies identified limits to the ways that science was made available to students, other studies showed how access to scientific knowledge and practices occurs through specific, purposeful use of language. For example, rather than finding that questions were often used to control the substance of the classroom conversation (Carlsen, 1991b; Lemke, 1990; Russell, 1983), van Zee and Minstrell (1997) provided a case study of an exemplary physics teacher (Minstrell) who used questions to engage students with scientific knowledge. In this study, the teacher used a questioning method called a *reflective toss*. Unlike the triadic dialogue controlled by the teacher, the reflective toss invited students into the conversation by building on an initial student statement. A three-part dialogic structure consisting of student statement, teacher question, and student elaboration opened up the classroom conversations to serve three emergent goals. The reflective toss served to engage students in a proposed method offered by a student, to begin a refinement process of a previously discussed method, and to evaluate an alternative method. Together these emergent goals served to create discourse events constructed to allow and encourage student participation in the cognitive processes of the lesson.

In another example of teachers using discourse processes to support student learning, Roth's (1996) study of an open-inquiry learning environment considered how teacher-questioning practices were mediated by the situational social context. In this case, the teacher used questioning to scaffold student knowledge through an engineering design unit in a grade 4/5 classroom. Unlike situations where teachers know a preconceived answer to their questions, the teacher in this study generally did not know the requested information, believed the students could provide an appropriate response, was interested in the students' point of view, and believed the students would provide an answer. A typology of the content of the teacher's questions demonstrated a range of knowledge embedded in the conversations generated from these questions. Knowledge of the natural world, design practice, and testing of the designs were central to the classroom discourse. The typology was rounded out by questions relating to students' final products and questions about

the sources of knowledge used and derived from the design experience. The teacher questioning thus served to increase student competence in the requisite engineering knowledge and offered opportunities for students to appropriate the questioning practices.

Gallas's (1995) study of the "science talks" in her first- and second-grade classroom evinced the importance of paying attention to students' ideas and questions in classroom discourse. In her classroom, science was the product of a joint construction of students and the teacher(s) incorporating a child-centered, hands-on approach, emanating from children's questions. The description of these experiences in *Talking Their Way into Science: Hearing Children's Questions and Theories, Responding with Curricula* represents an important shift from engaging students in science through questioning to learning to hear children's questions as a teaching strategy. This shift represents a break in the typical power asymmetries found in science classroom discourse. By developing the norms for discourse of this sort, the classrooms became a community of inquirers "whose interests, questions, and theories emerge from the inside-out, rather than the outside in" (Gallas, p. 101). Emergent curricula were also present in studies of an experienced third- and fourth-grade teacher by Crawford, Kelly, and Brown (2000). In this and a related study (Kelly, Brown, & Crawford, 2000), children's discourse was encouraged through a series of teaching practices that situated the teacher as a co-investigator. By developing a community that valued listening and following through on students' suggestions for next moves in science investigations, the teacher created multiple opportunities for her students to engage in scientific practices and to talk through ideas as a class. Part of the students' discursive practice included generating questions for a participating scientist. In this and other examples, the research focus has shifted from teacher questioning of students to ways in which students learn to pose questions in science contexts (Gallas, 1995; van Zee, 2000).

As illustrated by the previous examples, studies of the discourse processes of science teaching offer a range of views of the inner workings of classroom life. Science can be seen as constructed through discourse processes in these empirical studies. Nevertheless, the ways that science is framed through discourse make available to students a wide range of opportunities to learn specific scientific knowledge and practices. Similarly, although the views of science made available in terms of the conceptual information, the types of permissible discourse structures, and the ways of engaging in the discourse of science show considerable diversity, many of the studies found that limited participation of students in talking science can present an ideological view of science as particularly narrow and authoritarian.

## Knowledge, Discourse, and Conceptual Change

Gallas's studies speak to the issue of translating from the everyday spoken language of students to the canonical discourse patterns typically found in formalized scientific discourse. Discourse-oriented research in science education has provided examples of how to bridge from students' initial knowledge state (i.e., ways of talking about the natural world) to more robust, theoretical language characteristic of professional scientific discourse, as well as examples of how assumptions about

language render the link between knowledge and discourse tenuous. For example, Dagher's (1995) study of analogies, conceived broadly to include metaphors, models, and similes, in teacher discourse in seventh- and eighth-grade science classrooms, identified different ways that teachers bridge from a familiar domain for the student learners (source) to unfamiliar domains (target). Five types of analogies were used by the teachers: compound, narrative, procedural, peripheral, and simple. Interestingly, these types of analogies were used in idiosyncratic ways, and Dagher viewed this diversity of forms of expression as a positive experience for learners. This study also cautioned researchers by suggesting differences in how students viewed analogies, as compared with researchers and teachers.

The interdependence of language use and knowledge is the subject of other discourse-orientated studies in science education. Continuing with the theme of bridging across knowledge domains, Dagher (1994) raises questions about the use of analogies and the meaning of conceptual change for educational research. She reviewed studies of analogy use from a conceptual change perspective and identified different meanings of conceptual change (e.g., replacing students' initial concepts, adding to existing knowledge, providing alternatives to existing concepts). Dagher (1994) suggested that research on uses of analogies extend beyond developing students' knowledge of target concepts and consider the ways that analogies can enhance "creativity, aesthetic appreciation, and positive attitudes" (p. 610). Similarly, Klaassen and Lijnse (1996) caution about the interpretation of classroom discourse from a purely cognitive point of view focused on student misconceptions or alternative conceptions. In this study, an exchange between a teacher and his students is interpreted from three points of view (in terms of teacher analysis, misconceptions, and alternative conceptions) that the authors view as erroneous. They proposed instead to consider the ways in which a dissenting student and her teacher miscommunicate. In the example provided, the two interlocutors in question agreed about the similarities and dissimilarities of a given situation (book-on-the-table condition) but failed to reach agreement about how to characterize the situation in terms of force acting in the relevant bodies. Klaassen and Lijnse argued that the teacher and student did not assign the same meaning to the expression "to exert a force" (p. 129), and, thus, the problem of interpretation revolves around finding common ground that forms the basis for understanding.

The relationship of conceptual change to discourse processes was also examined by Macbeth (2000), who studied the "apparatus" of conceptual change for Karen, a student participant in the Private Universe Project. As is typical of ethnomethodology,<sup>3</sup> Macbeth examines in great detail the practical actions and conversational sequences between Karen and a research interviewer as they participate in a discussion about light. Central to understanding the apparatus of the students' "conceptual change" is the research setting with an ensemble of technologies. This close examination called into question previous assumptions about students' native

---

3. Ethnomethodology is not a research method, but rather an orientation that focuses on the ordinary actions of people as they proceed through everyday life; it studies the methods people use in various contexts to get through the mundane activities in their given situations (Lynch, 1993; Mehan, 1979). Although few discourse studies in science education draw from this tradition, it provides an interesting contrast with other discourse studies.

conceptions and the ways in which these conceptions change through experience. Macbeth demonstrated how Karen, by finding things she could “do in the dark,” showed how “perceptual ‘facts’ are themselves attached to local orders of activity” (p. 253). Macbeth concluded by identifying how the worlds of scientific and ordinary action are continuous and permeable, rather than separate, as sometimes assumed. In another study with an ethnomethodological orientation, Lynch and Macbeth (1998) investigated how a teacher demonstrated science to her third-grade students. In this case, the teacher was shown to position and discipline students as “witnesses” to scientific phenomena through ways of setting occasional confrontations between the students’ ways of seeing and the aimed-for scientific account. This study demonstrated how the mundane discursive tasks of classroom life serve to accomplish science education as situated practice.

Research topics such as teacher framing of disciplinary knowledge, uses of language to control the subject matter, the importance of language for student sense making, and the problematic nature of conceptual change all speak to the intertwined issues of the nature of knowledge and access to knowledge for student learners. These studies identify the importance of discourse processes for understanding how science is interactionally accomplished, how access to the subject matter knowledge occurs through language, and how the disciplines of science are interpreted through ways of speaking about them. Therefore, emerging from the initial studies of science discourse in classrooms are studies centrally concerned with equity, access, and epistemology in education settings. Before synthesizing this literature and its implications for future research directions, I review studies of student (and teacher) discourse in small-group settings.

### **Student Small-Group Discourse**

Whereas the language functions examined in teacher-directed discourse tend to center primarily on the communication of propositional information, and secondarily on the control of social situations, studies of student small-group discourse examine the interrelationship of propositional, social, and expressive functions of language (Cazden, 2001). For example, Anderson, Holland, and Palinscar (1997) studied the interwoven nature of canonical scientific discourse and the social relationships and positioning among students working on an investigation in a small group. In this example, the researchers focused on the negotiated nature of interpersonal relationships, scientific activities, and task requirements for a student, Juan, and his group of classmates. This group of five sixth-grade students observed phase changes in a “barbell apparatus” and was given the task of explaining their observations through the use of a student-designed poster and molecular models. A key finding from the study was that teachers need to develop a sense of communal activity among the students. Opportunities to engage in the scientific discourse were mediated by diverse discursive processes related to negotiation of the task. Thus, understanding access to science required an analysis of the canonical forms of science discourse in the student talk, but also required attention to the students’ personal identities and ways of navigating interpersonal relationships.

The simultaneous construction of propositional, social, and expressive functions of language was further specified in a number of studies involving student

small-group discourse in inquiry-oriented contexts. Hogan's (1999) study considered the sociocognitive roles taken by eighth-grade students through their science group discourse while engaged in a long-term collaborative task related to the nature of matter. This study made explicit connections among the interpersonal and the more content-oriented aspects of scientific discourse, noting how demands on students included both ways of interacting and building consensus. In this case, the demands for interactivity and consensus building proved challenging for the students and may have stood in the way of accomplishing the intellectual task. Similarly, the issues of interpersonal relationships and differential (perceived) status among students engaged in group work were central to two studies by Bianchini (1997, 1999). These two studies drew from sociological theory of expectation states and were designed to create student group work conditions aimed at eliminating disparities of access in linguistically, ethnically, and academically diverse classrooms. Through analysis of students' assessment of peer status, records of group work task behavior, rate of science discourse, and conceptual tests, Bianchini (1997) identified how some students were systematically denied access to materials and participation despite a curriculum and instructional strategy designed to ameliorate such problems. Similarly, Bianchini (1999) found that students of low status as determined by their peers (often students from groups that have historically underachieved in science, including females, Latinos, and African Americans) participated less in cooperative work groups and learned less during the units. Thus, in these studies (Anderson et al., 1997; Hogan, 1999; Bianchini, 1997) and others of student group work (e.g., Hogan, Nastasi, & Pressley, 1999; Kelly, Crawford, & Green, 2001), negotiation of the multiple social and expressive functions such as student roles, individual and collective responsibilities, the nature of the academic task, and the differential status among students were thoroughly tied to the access students had to scientific discourse and, thus, to opportunities to construct institutionally sanctioned knowledge.

Social dimensions of small-group discourse include not only ways of negotiating the interpersonal relationships entailed in group membership, but also the nature of the scientific knowledge in question. The development of explanations that count as science for a given audience is an interactional accomplishment, partially constructed by the nature of the intellectual resources, the status of the knowledge in question, the participant structures, and the goals and purposes of the activity. Herrenkohl and Guerra (1998) designed two interventions related to student roles (groups working with intellectual and audience roles, and others with just intellectual roles) to promote student engagement in the discourse practices of understanding classroom procedures, monitoring comprehension, challenging others' perspectives and claims, and coordinating theories with evidence. Analysis of the speech patterns across the three phases of the inquiry activity (introduction, small-group work, reporting sessions) revealed that students assigned audience roles during spoken reporting sessions initiated more engagement episodes and challenges than students without such role assignment. Furthermore, the teacher discourse was a major mediator of the types of student discourse (e.g., teacher attention to classroom procedures versus scientific discourse practices such as coordinating theories with evidence) and was influenced by the changes in student role taking. Other studies, such as those focused on developing student inquiry, also identify the pivotal role played by teachers' discourse practices in framing students' activ-

ity, focusing student talk on the substantial aspects of science, and allowing space for student-generated discussions (Krajcik et al., 1998; van Zee, 2000)

Research on small-group interaction poses theoretical and methodological challenges for science education. Besides the technical difficulties of recording audibly clear conversations of student talk in busy classroom settings, methodological challenges include choices related to the focus on the discourse analysis (Lemke, 1998) and identification of the relevant semiotic field, given the chosen theoretical orientation and investigative focus. For example, Roth, McGinn, Woszczyzna, and Bou-tonné (1999) drew from multiple data sources recorded in a grade 6–7 classroom to make the argument for the importance of the discursive practices within a community and how a community of practice comes to construct those intellectual resources deemed relevant to the tasks at hand. In this case, Roth et al. (1999) identified how knowing and learning about simple machines was distributed across people, artifacts, social configurations, and physical arrangements. The opportunities for students to participate in the community involved the use of material and symbolic practices, including constructions, measurements, design, and spoken discourse. Thus, this study, like many that consider small-group interaction, recognized the embedded nature of discourse processes and the methodological importance of understanding the community practices.

Researchers concerned with the semiotic field in small-group interaction need to consider discourse broadly, as many studies of small-group work examine student discourse while engaged in hands-on or other investigations with the material world. Two studies make it clear that the multiple resources constructed in time and space in laboratory settings need to be accounted for in research transcripts of student discourse. Roth (1999) and Kelly et al. (2001) identified how hands, arms, eyes, and bodies contributed to the cognition and learning by the participating students and observing researchers. For example, Kelly et al. (2001) identified how eye gaze, bodily orientation and movement, and gestures (such as pointing and motioning) contributed to the semiotic field made available for interpretation of physical motion and graphical representation as students made sense of their own motion and that of other objects in a data acquisition microcomputer-based laboratory. This study identified how community practices provided a framework for conversations, but also how the particular microhistories of small-group interaction served to exclude certain proposed scientific explanations, leading to dissent within small groups.

Whereas laboratory experience in classroom settings has not always led to the cognitive and epistemic goals set forth by educators (DeBoer, 1991; Fairbrother, Hackling, & Cowan, 1997; Meyer & Carlisle, 1996), placing students in apprenticeships in science laboratories offers an alternative set of opportunities. For example, Bleicher (1994, 1996) took a sociolinguistic perspective to examine the cultural practices of scientific research groups with student apprentice participants. Bleicher considered the social and cultural characteristics of everyday laboratory work and how such practices influence student initiation into research groups. By focusing closely on the moment-to-moment interactions in various discursive settings (e.g., lab work, group meetings, student presentations), Bleicher identified how students enter into group practices, identify sources for their knowledge through their apprenticeship activities, and thus learn through participation in scientific inquiry.

Studies of students working in small groups in a variety of interactional contexts demonstrate both the potential to provide opportunities to engage with science not readily available in many teacher-directed events and the possible pitfalls of student-centered discourse. Much like the studies of teacher-directed discourse, examination of small-group interaction identifies two key issues for researchers: the structuring of knowledge through discourse and the potential equity concerns found in how science is constructed through discourse. These two issues surface in studies focused on argumentation and more explicitly on equity. The field of argumentation in science education is concerned with scientific knowledge, evidence, and explanation. Issues of equity transcend the interactional contexts of classroom teaching, small-group work, and writing science and show relevance in the many ways language is used in science education. A small but significant body of research has emerged that considers the ways access to scientific knowledge is mediated through discourse and, in particular, how gender, language, and cultural variation in students' experiences influence success in science. I turn to these fields before reviewing work in written discourse.

### **Studies of Argumentation, Explanation, and Students' Use of Evidence**

*Argumentation* refers to the ways that evidence is used in reasoning. As an analytic tool, argumentation analysis has been applied to examine student reasoning, engagement in scientific practices, and development of conceptual and epistemic understandings (Driver, Newton, & Osborne, 2000; Jimenez-Aleixandre, Rodriguez, & Duschl, 2000; Richmond & Striley, 1996). Studies have included examination of teacher discourse (Carlsen, 1997; Russell, 1983), preservice teacher explanations (Zemal-Saul, Munford, Crawford, Friedrichsen, & Land, 2002), small-group discourse (Kelly, Druker, & Chen, 1998; Richmond & Striley, 1996), and written knowledge (Kelly & Bazerman, 2003). Rationales for the use of argumentation derive from the importance of evidence in science (Bazerman, 1988; Duschl, 1990) and the value of argumentation for unpacking the nature of claims and the warrants for knowledge. Although uses of evidence are often perceived as central for adjudicating among scientific theories, studies of classrooms show that current practices in science teaching offer students few opportunities to engage with scientific evidence, models, and socioscientific issues (Driver et al., 2000).

Research using argumentation analysis begins with a normative model. One model is Toulmin's (1958) layout of arguments. Central components of an argument following Toulmin's model are relevant data, a claim asserted by the author, and warrants supported by theoretical backing. This way of laying out an argument offers some theoretical guidance but does not attend to how the discourse features are argued *in situ*. Nevertheless, application of Toulmin's layout of arguments to teachers' discourse allowed researchers to assess the extent to which authority in the classroom was derived from evidence or social standing (Carlsen, 1997; Russell, 1983). In another application, Bell and Linn (2000) adapted the Toulmin method for analysis of student argumentation. In their study of middle-school students' argument construction, Bell and Linn sought to scaffold student knowledge integration

through uses of explanation and evidence with the SenseMaker argument-building tool. This study identified a range of types of arguments formulated by students and how the nature of students' beliefs about the nature of science was associated with characteristics of the arguments.

Sandoval (2003) provided another argumentation analysis approach based on scientific explanation, in which evidence is considered in the context of building and assessing models. Sandoval's study of students' understanding of natural selection, using the ExplanationConstructor computer program (as part of the Biology Guided Inquiry Learning Environments [BGuILE] project), examined the causal claims made by students and the ways in which these claims were warranted. Results showed how students were able to adopt explanatory goals and how attention to epistemic practices in specific domains can direct student inquiry to focus on evidence. A similar model was developed by Zembal-Saul et al. (2002) to study uses of explanations by pre-service science teachers. In this study, the software associated with the BGuILE project was similarly shown to support the articulation of evidence-based arguments. Additionally, the study demonstrated ways that the arguments could be improved and the important role the instructor had in supporting students' argumentation.

Argumentation theory has also been applied to students' conversations while they are engaged in science investigations. For example, Richmond and Striley (1996) analyzed students' use of evidence in 10th-grade integrated science and found that although students were able to use evidence, the results varied across student groups. The differential opportunities for demonstrating scientific understanding were constructed in part by the emergence of the social roles of the student group members, particularly as related to the student groups' leadership roles. In another study, Jimenez-Aleixandre et al. (2000) applied argumentation analysis to student conversations about genetics. By focusing on the argumentative operations proposed by Toulmin (1958) and a set of epistemic operations, including induction, deduction, causality, and plausibility, Jimenez-Aleixandre et al. distinguished engagement in scientific practices from narrower engagement in the specified school task. In another example of the opportunities afforded by first-hand experience with phenomena, the relationship of talk and action was investigated by Abell, Anderson, and Chezem (2000). In this study, the discourse of a teacher and students during a third-grade unit focused on sound was investigated to consider ways in which teachers can place greater emphasis on evidence and explanation. Although the pedagogical goals were only partially met, the study (Abell et al., 2000) showed how students can be introduced to using evidence in arguments and how student inquiry requires both practical experiences and talk about these experiences (Mortimer, 1998).

Three studies of argumentation analysis applied to university writing extended Toulmin's (1958) model and brought into consideration more linguistically oriented methods for analyzing evidence use. Kelly and Takao (2002) introduced an analytic tool to assess university oceanography students' use of evidence in writing. Recognizing that evidence chains typically span multiple epistemic levels of claim, Kelly & Takao evaluated how students were able to tie specific claims about data representations to claims about geological features and theoretical claims about abstract entities such as terrestrial plates. This model was extended to consider the lexical cohesions tying claims together to form an argument and to recognize the rhetorical

moves required of the particular academic task (Kelly & Bazerman, 2003; Takao & Kelly, 2003).

## Issues of Access and Equity

Discourse plays a central role in the mediation of knowledge in classrooms. To understand the ways in which students get access to knowledge, and to consider the knowledge that counts as science in given circumstances, researchers have approached issues of equity from a language point of view. Discourse studies of classroom interaction shed light on the ways in which science is framed, who gets to speak about what regarding science, and how issues of language use, choice, and variation represent instances of identity construction. The interactional aspects of classroom life are crucial for understanding how students' opportunities to succeed in science may be limited. For example, a needs assessment of Hispanic/Latino students in elementary science classrooms in the Southwest region of the United States found that these students were less likely to have access to appropriate science materials (e.g., culturally sensitive textbooks, laboratory apparatus) and were less likely to participate in student-initiated classroom interactions, including hands-on experiences and collaborative group work (Barba, 1993). Given such inequalities, a number of scholars examined variations in culturally and linguistically diverse populations and proposed methods to ameliorate inequities in science education.

Lee and Fradd (1996) studied the interactional patterns of fourth-grade student dyads and teachers in three populations: bilingual Spanish, bilingual Haitian Creole, and monolingual Caucasian English speakers. Lee and Fradd drew from theories of cultural congruence that consider the linguistic and social competence required for participation, recognizing that discourse processes presuppose and entail values, beliefs, culturally based interactional patterns and ways of organizing knowledge. Through the use of three science tasks (weather phenomena, simple machines, and buoyancy), Lee and Fradd were able to ascertain differences in discourse patterns across the populations. These differences were found in both categories of discourse patterns, such as turn taking, unit of discourse, and nonverbal communication, as well as categories of task engagement, which included methods for completing the task, mode of teacher guidance, teacher reinforcement, and student initiative. The study pointed out that students "may have difficulty deciding when to talk, how to present their ideas, and how to demonstrate their understandings" (p. 292). These difficulties may be exacerbated when students' cultural ways of interacting are not consistent with some standard ways of using scientific discourse in a broader community. The interactional differences thus extend beyond the substantive scientific content of the conversation. In a related study for a similar student population, Lee (1999) examined how students' worldviews influenced their ways of talking about a natural disaster (Hurricane Andrew). In this case, variations were found in how students attributed the cause of the hurricane; higher SES students and Caucasian students were more likely to describe the causes of the hurricane in terms of natural forces, whereas lower SES students, girls, and African American and Hispanic students included people, nature, and supernatural forces as playing a role in causing the natural disaster (p. 214). The study by Lee shows how student-derived discourse patterns used in classrooms represent a heteroglossia of languages and cultures, and

how taken-for-granted interactional patterns, not attending to the multiple ways of speaking and being, may limit access for students.

Some of the most interesting work regarding language minority students and bilingual students has emerged from the Cheche Konnen project (Ballenger, 1997; Roseberry, Warren, & Conant, 1992; Warren, Roseberry, & Conant, 1994). Cheche Konnen, Haitian Creole for "search for knowledge," was chosen for the name of a group of teachers and researchers collaborating to address issues of access in bilingual classrooms. The project draws theoretically from theories of discourse, science studies, and culture and is aimed at transforming science classrooms. For example, Ballenger's study of multigrade (5–8) bilingual Haitian students demonstrated that, by allowing students to deviate from the standard structure of classroom discussion, the teacher provided multiple opportunities for students to use everyday discourse in constructing scientific knowledge. This change in discourse pattern allowed students to interact more directly, addressing claims made by other students without the intervention of the teacher. The pedagogical foci of this and other related studies shift from transmitting knowledge to engaging students in the scientific practices of argumentation and persuasion and appropriating scientific discourse (Roseberry et al., 1992; Warren & Roseberry, 1995). Engagement in scientific practices and appropriation of scientific discourse are served by designing educational experiences derived from students' experiences and lifeworlds, such as examination of the safety of the schools' water supply or bacteria levels in a local pond. By situating students as inquirers who pose questions, find evidence, and communicate results, these studies point to directions for pedagogy that recognizes both the language diversity found in many urban U.S. schools and the usefulness of scientific concepts for problem solving.

Gender equity is also a concern for science education (Baker, 2002). While the long-standing issue of gender inequity in participation and affiliation in science has been noted (Baker, 1998), most research paradigms have examined the issue in terms of cognitive, attitudinal, and epistemic dimensions of students, teachers, and science (Kahle & Meece, 1994). Furthermore, discourse-oriented studies of classroom interaction have only begun to examine the ways in which interactional patterns in science classrooms may be discriminatory to female students. Nevertheless, gender-based interactional patterns have been considered both in teacher-student discourse patterns (Barba & Cardinale, 1991) and in small-group contexts, either as a central focus (Alexopoulou & Driver, 1997) or as part of broader equity concerns (Bianchini, 1999; Lee, 1999).

Gender differences have been identified in ways in which teachers interact with female and male students and how talk and kinds of talk are distributed among members of science classrooms. For example, in a study of teacher-student questioning interactions in secondary science classrooms, Barba and Cardinale (1991) found that female students had fewer interactions with teachers and were posed less cognitively complex questions. These questioning patterns signal views of competence among the students and may contribute to both male and female students' views about who can and should be successful in science. At the elementary school level, Kurth, Kidd, Gardner, and Smith (2002) studied the discourse patterns of two grade 1/2 combination classes in a professional development school during whole-class conversations to consider variation in the use of paradigmatic (persuasion through formulating an argument) and narrative (story-based, valued for lifelikeness) modes of discourse among students. The analysis considered variations over

time, across topics (life or physical science), and by gender. This study examined discourse patterns in more detail than the study of Barba and Cardinale (1991) and led to similar results. The male and female students were not found to show qualitative differences in the uses of narrative and paradigmatic features of discourse; however, male students in both classrooms “obtained more opportunities to practice their use of narrative and paradigmatic discourse either by receiving more speaking turns or expressing more language feature per turn” (Kurth et al., p. 814). As with the case of linguistic minority students, issues of access included the interactional dimensions of discourse.

Gender differences were also found in more complex social interactions, such as those found in small-group interaction. Alexopoulou and Driver (1997) examined gender differences in the discourse of secondary school Greek students working in small groups. Both group composition (self-selected, single-sex groups) and group number (two or four members) were relevant variables. The discourse analysis, like other studies of small-group work (e.g., Bianchini, 1997; Richmond & Striley, 1996), made evident an interaction in the organization of the social activities and the discussions of the substantive science issues. Analysis attentive to gender identified how male groups used confrontation to progress through ideas, whereas female groups sought to maintain consensus among members (Alexopoulou & Driver, 1997).

The issues of gender-oriented discourse patterns intersect with other issues, such as ethnicity and class, and interestingly, in some instances, subject matter (Hughes, 2001). As differences have been found in male and female students’ orientation to science, potential affiliation based on the nature of science presented (Barton, 1998), and cultural variation in discourse patterns regarding phenomena (Lee, 1999), a number of questions are raised as to how research on attitudinal and cognitive variation can be informed by detailed discourse analysis of the interactional events. Discourse analytic research methods may provide new interpretations of equity and associated constructs such as identity, agency, and attribution of success by students, teachers, and researchers.

## STUDIES OF LEARNING AND TEACHING WRITING AND READING SCIENCE

Periodically, scientific literacy is put forth as a rationale for reform in science education (American Association for the Advancement of Science [AAAS], 1993; DeBoer, 1991; National Research Council [NRC], 1996). Typically, this notion of literacy is quite broad, involving understanding of science concepts, reasoning, and science-technology-society issues, and is tied to notions of citizenship. However, other research focuses more specifically on the reading and writing of science (see special issue of the *Journal of Research in Science Teaching* [Yore, Holliday, & Alvermann, 1994]). A review of literacy by Norris and Phillips (2003) sets these conceptions in clear relief. Norris and Phillips (2003) define the *derived* sense of scientific literacy as encompassed in being knowledgeable, learned, and educated in science and *fundamental* science literacy as coming from the ability to read and write on the subject of science. They argued further that scientific literacy in the fundamental sense, focused on reading and writing texts, forms a basis for understanding science in ways that serve the broader societal goals of scientific literacy. Nevertheless, what counts as the relevant texts in even relatively straightforward science lessons is interac-

tionally accomplished and subject to the contingencies of the particular interaction context. For example, Lemke (2000) identified the multimedia literacy demands of a science lesson that include interpretation of verbal discourse of the teacher and other students; paralinguistic features such as voice quality and pacing; images from a calculator, overhead transparency, and blackboard; writing, diagrams, and mathematical symbols; and manipulation of demonstration apparatus, among others. Much like studies of classroom discourse that depend heavily on various written forms, studies of reading and writing often consider the interaction of written and spoken language (Keys, 2000; Rivard & Straw, 2000). Therefore, the question of what counts as reading, writing, and text is not as obvious as may appear at first glance. Choices regarding the textual forms of science and education lead to theoretical questions.

For the purposes of this review, I shall focus specifically on reading and writing issues identified in the literature that examine written orthographic text. The rationale for this choice is twofold. First, applying functional linguistics to textual features of written science in textbooks and professional scientific papers, Halliday and Martin (1993) identified how written science depends often on unique linguistic features such as interlocking definitions, technical taxonomies, lexical density, syntactic ambiguity, and semantic discontinuity, which pose challenges to student learning. Second, written discourse has played key roles in the history of scientific communities, particularly as related to the development of persuasive texts centered on experimental evidence (Bazerman, 1988; Harris, 1997). Within science education, research on writing in science education has created an extensive body of research (e.g., Hand & Prain, 2002; Hand, Prain, Lawrence, & Yore, 1999; Keys, 1999b, 2000; Keys, Hand, Prain, & Collins, 1999; Prain & Hand, 1999; Rivard, 1994). This research is becoming increasingly integrated with studies of classroom spoken discourse (e.g., Keys, 1997; Rivard & Straw, 2000), thus identifying the important ways in which communication systems work within particular communities of practice. Ultimately, studies of writing and reading in science merit their own extensive review, such as those found in Prain and Hand (1996) and Glynn and Muth (1994).

## Reading and Science Learning

One dimension of scientific literacy concerns developing the processes associated with certain tools, procedures, and strategies involving the interpretation of written texts. The value of being able to ascertain and comprehend the meaning of science concepts from printed materials is one central component of science literacy. Issues of meaning making with such written material often center on the important role textbooks play in classroom communication (Hand et al., 1999). Parallel to comprehension, learners' relative ability to communicate ideas in clear and coherent language (to a given audience) emerges as another key dimension to scientific literacy. Meaning making with written texts and communicating through spoken and written discourse provide ways for students to develop conceptual understanding and for teachers to assess student learning.

Yore et al. (2003) provided an extensive review of literacy in science education. In this review they noted the many early studies of reading that concerned the "readability formulae, reading skills tests, text analysis, page format, and end-of-

text questions" (pp. 697–698), and later studies, influenced by constructivist cognitive theories, sought to examine the many ways that reading was part of a broader communicative context of norms, practices, and actions. These later studies consider how textual materials interact with spoken discourse, readers' metacognition, and science inquiry activities (Yore et al., 2003). Therefore, the emerging view of literacy understands reading as an "interactive and constructive process for meaning making constrained by criteria for good inferences in a sociocultural context" (Hand et al., 2003, p. 612). Although it is not possible to review the full body of research on reading in science (e.g., Yore et al., 2003), I provide a short review of three bodies of literature related to reading in science: how students develop meaningful understanding from science textbooks, how text can be used to support conceptual change, and how readers understand popular reports of science.

In their 1994 review of research on reading and writing to learn, Glynn and Muth (1994) suggested that science curricula can be "placed on a continuum from text-book driven to teacher driven" (p. 1061). In this continuum, the authors suggested that the textbook can potentially serve as a reference source in a teacher-driven curriculum, or as "the engine that drives the curriculum" (p. 1062) in a textbook-driven curriculum. The teachers' outline for instruction, use of videos, transparencies, laboratory activities, among others, are all products of the textbook's design in a textbook-driven curriculum. The significance of the textbook in classroom learning extends beyond its direct influence on student comprehension of the subject matter, as it typically serves a guideline for instructional choices and for the sequencing of learning events. With the textbook having such a significant role in the learning process, the students' ability to negotiate meaning through textbook instruction becomes a crucial skill in science classroom learning (cf. comprehension of spoken discourse in Lemke, 1990). Therefore, Glynn and Muth provide analysis of three reading strategies aimed at making learning from textbooks meaningful and conceptually integrated.

Other studies of reading in science are derived from a conceptual change point of view. These studies, reviewed extensively by Guzzetti, Snyder, Glass, and Gamas (1993), involved interventions aimed at using text to promote conceptual understandings. Pedagogical strategies derived from reading research included uses of refutational texts, pedagogies aimed at activating student initial knowledge through texts, and variations of textual forms, for example, contrasts between narrative and expository texts. A general finding from these studies was that text could be used to eradicate students' misconceptions when refutational texts were used with other strategies to promote cognitive conflict. Early science education research tended to examine reading within the context of broader pedagogical practices such as the learning cycle, uses of bridging analogies, and conceptual conflict. These studies were less able to identify particular reading strategies as relevant variables because of the confounding nature of studying reading embedded in broader instructional strategies (Guzzetti et al., 1993).

An additional area of interest for research on reading in science is the use of multiple, alternative sources for texts. Much like the uses of textbooks and refutational texts, the interpretative dimensions of sense making are identified as crucial for effective uses of sources other than books. Wellington and Osborne (2001) provide a number of examples of types of texts that can be used in learning science such as newspapers, tabloids, and pamphlets from advocacy groups. The use of popular accounts, for example, can give students reason to examine issues related

to the nature of science. For example, Norris and Phillips (1994) used a study of grade-12 science students reading popular reports on science to consider the issues of knowledge and expertise in interpreting texts. Although the study found that students overestimated the reported truth of scientific claims and failed to understand the extent to which science is textured, the authors point to epistemological issues involving how students' views of knowledge influence what they learn about science. Norris and Phillips argued that scientific literacy needs to include not only understanding of science concepts, but also a pragmatic understanding of how scientific texts' structures and intentions can be ascertained. Included in this understanding would be developing competence in the metalanguage of science—that is, making sense of justification and evidence in the argumentative structure of science—and understanding how to value and temper scientific expertise (Norris, 1995).

### **Learning to Write Science and Writing to Learn Science**

Research on writing represents another dimension to discourse studies in science education. Much like the other discourse theories presented in this review, research on writing is informed by multiple theoretical traditions and offers a wealth of empirical studies examining the significance of writing on the learning process (Hand et al., 2003; Hildebrand, 1998; Keys, 1997, 1999b; Rivard, 1994). Prain and Hand (1996) presented a review of the literature on writing for learning in secondary science that provided a broad framework for understanding this literature. This review illustrated variations in thinking about written discourse. Prain and Hand argued there are three major schools of thought, modernist (advocating student use of technical scientific language), constructivist (advocating writing to bring about student understanding of scientific concepts), and postmodern (advocating genres that make visible the sociological aspects of scientific representation in written forms). They built on previous work to present an expanded model of elements for writing for learning in science that included relevant issues related to writing topic, type, purpose, audience, and method of text production. Advocates of student learning of the genre conventions of science (e.g., Halliday & Martin, 1993)—in a sense, a modernist view—and those seeking to understand the value of adhering to a scientific genre for its value in learning while incorporating constructivist pedagogy (e.g., Keys, 1999a) share a common perception regarding the value of science, for access to institutions of power or to powerful knowledge.

One specific outcome of studies of writing to learn in science was the development of the Science Writing Heuristic (Keys, 2000; Keys et al., 1999). The Science Writing Heuristic comprises two components, one oriented to helping teachers develop activities to promote laboratory understanding and another focused on assisting students in developing explanations with their peers (Keys, 1999b). In one study (Keys et al., 1999) the Science Writing Heuristic was shown to develop important attributes in student understanding, including reflection of self-understanding, meaning making with scientific data, and construction of logical-semantic relationships between events. Keys's (2000) study of an application of the Science Writing Heuristic considered how writing about investigations in a scientific genre served student learning. The study drew from the knowledge-transforming model created by Bereiter

and Scardamalia (1987), which considers both the content problem space and the discourse problem space. The writing under these conditions is posited to serve student subject matter learning. Keys's study showed evidence that for some students the interaction of content and discourse influenced students' reasoning about data. The study thus poses important questions about the interaction of genre knowledge, rhetorical forms, argumentation patterns, and scientific knowledge. Prain and Hand (1999) also investigated the uses of the Science Writing Heuristic by considering students' perceptions of writing for learning. They found that students had difficulty understanding how knowledge claims were established in science and how writing could serve as an epistemological tool.

The interaction of spoken and written discourse surfaced as a key dimension in understanding student learning. Rivard and Straw (2000) used a quasi-experimental design to identify the roles of talking, writing and talking, and writing on science learning. Their study focused on middle-school ecology lessons and sought to decipher the various roles of discourse processes on student learning. By separating students into various treatments, they reported that student talk was important for sharing, clarifying, and distributing knowledge, whereas writing helped the development of more structured and coherent ideas for the participating students. Instructor roles have also been shown to influence the nature of writing and perceptions students have of the writing task. Chinn and Hilgers (2000) found that professors of college science writing could provide students with ways of relating their writing to a professional context through supportive feedback and conferencing.

Hildebrand (1998) offered an argument for expanding the academic genre of scientific writing. Her contention was that classroom science writing is hegemonic. As an alternative, she suggested that a pedagogical approach be explored that would allow individuals to apply personal perspectives to scientific writing, which would incorporate the contexts of critical, creative, affective, and feminist pedagogies. Underwriting this perspective is the notion that expanding the genre conventions could potentially address the needs and abilities of students disenfranchised by current writing practices in science classrooms. Similarly, Hanrahan (1999) documented ways that affirmational dialogue journal writing both encouraged students to participate more actively in science and provided alternative ways for students to express their concerns about science and the particular class. Hanrahan made the argument that journal writing can contribute to the development of more democratic and collaborative classrooms. Across the different perspectives there is a recognition that writing needs to be viewed from a situated perspective, acknowledging variations in the educational purposes and tasks, as well as student knowledge and background, particularly as experience with linguistic forms that may be tied to students' identity and agency (Chinn & Hilgers, 2000; Gee, 2001b).

## **FUTURE DIRECTIONS AND CHALLENGES FOR THE STUDY OF DISCOURSE IN SCIENCE EDUCATION**

In this section, I build on lessons learned from discourse studies in science education and point to potential avenues for future research. Studies of discourse in science

classrooms have contributed to understanding how learning occurs through language, how access to knowledge derives from participating in the social and symbolic worlds, and how disciplinary knowledge is constructed through language. Of the many important future directions for research in discourse studies in science education, I name six: (a) student understanding, participation, and affiliation; (b) equity and access; (c) sociocultural theories of learning; (d) language use and knowledge; (e) student achievement and policy; and (f) teacher education. After reviewing these future research directions, I note some methodological challenges for discourse studies in science education.

A common theme across studies of teacher discourse, small-group discourse, and reading and writing has been the ways in which specific linguistic features of canonical science serve to limit students' understanding, participation, and affiliation in science. Furthermore, the syntactic features of science language are not the only impediment to student understanding. The particular grammatical forms associated with science discourse do not appear to be isolated from the many other uses and purposes for language use. Thus, studies of classroom life identify how cognitive learning is embedded in and mediated through social interaction and cultural practices. The uses of language in schooling serve many purposes for speakers and hearers, with issues of student identity, cultural knowledge, and idiosyncratic ways of talking science surfacing often as unresolved topics for further investigation. Both tensions and bridging strategies were found between students' ways of talking and the thematic content of science found in teacher discourse and textbooks (Gallas, 1995; Lemke, 1990). Tensions derived from students' knowledge and discourse as compared with the ways this knowledge and discourse are valued by educational institutions proved relevant to issues of access and equity.

Issues of equity, with particular concern for examining language variation across gender, ethnicity, and class, were closely tied to understanding the relationship between students' talk and canonical science as manifested in classroom life. Discourse-oriented studies show how educational opportunity (or lack thereof) for students is socially constructed in discourses of schooling. Closely tied to issues of identity and agency (Brown, 2004; Reveles, Cordova, & Kelly, 2004), analysis of the discourses of schooling needs to consider the ways in which students are positioned among themselves, the teacher, and the putative knowledge (Hughes, 2001; Luke, 1995; Moje et al., 2001). Discourse variations and choices among repertoires of ways of speaking need to be investigated for language minority students; students of differing ethnicity, language, and culture; and others marginalized by current instructional practices.

Educational events, predominately discourse events of some sort, were shown to encompass cognitive, social, and cultural dimensions of knowing and learning. Although sociocultural theories of learning are entering the field (Duschl, 1998), there is a lack of science education research examining how sociocultural psychology can be informed by studies of science discourse processes in schooling and how the creation of new educational contexts for learning can be informed by sociocultural theory. Although the potential for fruitful interaction was indicated across instructional strategies, the research in small-group work was the most explicit about how discourse processes were framed by textual, interactional, and cultural variables (e.g., Hogan, 1999; Kelly et al., 2001; Kurth, et al., 2002; Roth et al., 1999). Understand-

ing how learning can be viewed over time within activity systems remains an area for future research in science education.

Studies of language in use in science classrooms presuppose assumptions about knowledge. Some common background knowledge is required for participants in a discourse event to achieve some mutual understanding. Minimally, such knowledge concerns the uses of language, the nature of the conversation within the sociocultural backdrop, the purposes of the interchange, and the phenomena under consideration. Studies of classrooms have noted the ways that scientific knowledge is framed by discourse and how, in the process, science is often portrayed in an ideological manner (e.g., Lemke, 1990; Moje 1995; Sutton, 1996). Simply, discourse processes send messages about the nature of science. These messages may be mediated by choices in pedagogy. Whereas the ideological images of science have been identified to some extent, more normative visions of science have received less scrutiny. An emerging group of studies, however, considers the epistemological assumptions of classroom discourse and opens the way for implications about the pedagogies of inquiry-oriented science (Hammer & Elby, 2003; Kelly et al., 2000; Sandoval, 2003). In many cases, these pedagogies are supported by educational technology.

The body of literature on discourse processes in science education treats student acquisition and understanding of science in a variety of ways. Whether the study of teacher discourse or students' learning to write in scientific genres, student learning is central to concerns about uses of language. Although these studies often focus on the details of student uses of specialized language, there has been an absence of consideration of how such studies may influence educational policy (Hand et al., 2003). Part of the absence is due to focus. Whereas discourse studies often examine the micro-worlds of everyday life, policy concerns typically focus on broader more blunt measures of success. Therefore, an important area for research will be ways that studies of language use can influence policies that often have great influence on classroom life.

Teacher education is an important part of research in science education, although there have been relatively few studies of the discourse of teacher education. Two sorts of studies seem to emerge from this review. First, there is a need to continue studies of teacher education (e.g., Bianchini & Solomon, 2003; Zembal-Saul et al., 2002). Much of the work of teacher education has not been documented in the same detail as studies of science classroom discourse. Nevertheless, the work of teacher education has developed specialized language to accomplish the tasks of learning through teaching. The discursive work of teacher education needs to be examined. Second, there is a need to consider ways that discourse studies of spoken and written texts can be used to effectively inform teacher education. Creating a database of classroom events for examination and reflection by teachers and teacher educators would facilitate the uses of results of discourse studies to improve classroom teaching and learning.

Instructional issues such as discourse variation, access, identity, and the embeddedness of talk in social action pose methodological challenges for future research, particularly as many nations face increased pressures to produce quantifiable measures of learning. These methodological challenges are at least threefold. First, the research reviewed in this chapter made clear that understanding instances of talk required understanding the social practices of the participants, established

over time, through multiple media. Therefore, as discourse studies in science education move to consider further the cognitive, social, and cultural dimensions of schooling, research methods will have to become more comprehensive in scope. These methods may require additional intellectual resources across subject matters of science, social science fields, and importantly those from the relevant community of the learners. Second, the embodied nature of discourse suggests that studies need to attend to interaction in greater detail, drawing from the intellectual resources of multiple theoretical points of view. This requires detailed analysis of verbal and nonverbal communication and the multitude of texts, images, inscriptions, and graphic representations. Third, discourse analytic work needs to find ways to tie the micromoments of interaction to institutional issues, and ultimately to educational policy. This may require the development of further systematic methods for investigation, but also strategies for communicating to those who influence education on a broad scale. Despite such challenges, the study of discourse offers much hope for improving our understanding of the ways in which science education is interactionally accomplished.

### ACKNOWLEDGMENTS

The author wishes to thank Bryan Brown for helping to identify the articles presented in the review and for many conversations about students, discourse, and identity. In addition, the author wishes to thank Judith Green and Jacqueline Regev for comments on an earlier version of this chapter. Thanks also to Carolyn Wallace and Larry Yore, who reviewed this chapter.

# CHAPTER 17

---

## Digital Resources Versus Cognitive Tools: A Discussion of Learning Science with Technology

Nancy Butler Songer

*University of Michigan*

Over the past two decades, computers and network technologies have become commonplace in many aspects of our work and personal lives. Despite widespread use of technology by scientists across many disciplines, computers and network technologies are often underutilized and poorly integrated into core science education activities in K–16 classrooms. How can this underutilization be explained? This chapter discusses research studies associated with technological tools for learning science relative to meaningful use of technologies in science classrooms. In particular, the chapter presents a framework for examining whether a technological tool is a cognitive tool for meaningful use of technology focused on specific audiences, learning goals, learning activities, and learning performances. To provide discussion for this perspective, examples of technologies associated with four areas of learning science are presented and discussed relative to the Cognitive Tools Framework, and implications revisit the question of underutilization of technology in science classrooms.

Technology permeates many dimensions of our work and personal lives. Evidence of this is apparent in the many instances of technology that are sometimes taken for granted or invisible to us, including cars, telephones, household appliances, and toys (Tinker & Vahey, 2002). Increasingly, institutions and industries are being dramatically altered through the integration of computers and network technologies such as the Internet. Daily business in banking, the postal service, the stock market, and neighborhood grocery stores has changed substantially as a result of computers and network technologies. With the integration of technology as an increasingly ubiquitous and essential component of our daily lives comes speculation about even more and profound alterations in how we will live, work, and

play in the future. To quote *New York Times* columnist Thomas L. Friedman on technology, “Clearly it is now possible for more people than ever to collaborate and compete in real time with more other people on more different kinds of work from more different corners of the planet and on a more equal footing than at any previous time in the history of the world—using computers, e-mail, networks, teleconferencing, and dynamic new software” (Friedman, 2005, p. 8).

Like their adult counterparts, American children are also incorporating the Internet into their daily lives for many different purposes. One recent study documented that 78% of American children ages 12–17 go online on a regular basis (Levin & Arafeh, 2002). However, as research studies in education document, increasing levels of computer use do not necessarily translate into increasing use of technology in American schools. Recent studies document that in many cases across a wide range of varieties of settings, schools are struggling to implement widespread adoption of computers and network technologies into mainstream classroom activities (e.g., Levin & Arafeh, 2002; Cuban, 2001). Although policy makers and the general public generally agree that K–16 students need many and varied productive experiences learning with and by technology (e.g., United States House of Representatives, 2001; Department of Education, 2004), most educators agree that much remains to be understood relative to the productive integration of technology into today’s classroom activities. Concerning the use of technology within specific content areas such as science, as discussed in this chapter, a gap exists between technology for doing science and technology for learning science. What do we know about using technology to learn science, and how can this gap be bridged and understood?

This chapter investigates whether technology is underutilized in American science classrooms and, if so, what we can learn from exemplary cases of learning science with technology to guide more widespread integration. The chapter begins with a definition of technology in schools, followed by a discussion of the possible underutilization of technology in American science classrooms. Subsequently, the chapter will present a framework for understanding the lack of utilization of technology for productive learning in science classrooms and several exemplary cases.

## **ARE TECHNOLOGIES UNDERUTILIZED IN SCIENCE CLASSROOMS?**

According to the U.S. Department of Education (2003), technology in schools consists of six categories, including (1) computers and computer-driven equipment; (2) servers, routers, and other equipment that support wired and wireless communication; (3) telephone-based technology; (4) display equipment used in classrooms; (5) infrastructure of wires and cables; and (6) software applications and programs. This chapter uses the following working definition of technology: computers, network technologies, and education-based software associated with categories 1 and 6 above.

According to the Department of Education, American schools have nearly ubiquitous access to computers and the Internet; 99 percent of American schools are connected to the Internet, with a 5:1 student-to-computer ratio (Department of Education, 2004). In addition, computer use is widespread; 90 percent of American

children between 5 and 17 use computers on a regular basis (Department of Education, 2004). Interestingly, computers are increasingly a resource that is not limited to older students or adults; one study documents the largest group of new Internet and computer users as children aged 2–5 (Department of Education, 2004).

On balance, although statistics suggest that access and use are widespread, other studies investigating meaningful use of technology to learn science or other subjects suggest that the presence of computers in schools does not necessarily imply productive use of technology within classrooms (e.g., Department of Education, 2004; Cuban, 2001). In one study, although access to computers in school was widespread, most teachers and students used computers infrequently, such as once a month or less, and the majority of uses were focused on mundane or routine tasks (Cuban, 2001).

Science education researchers provide possible explanations for the lack of widespread integration of technology into science learning activities. Concerning Internet-based materials, some researchers suggest that limited use might be a result of poor quality of available web-based science material for K–12 science learning. Linn, Davis, and Bell (2004) state that despite nearly universal Internet access in classrooms, much of the Internet-available material is of questionable scientific content or appropriateness. Others attribute low use to the limited availability of software that is well integrated into curricular programs (U.S. Department of Education, 2003) or that promotes critical thinking (Lee & Songer, 2003). In addition, classroom teachers describe a gap between building or district expectations in their use of technology and the support structures needed to successfully integrate technology into their classrooms (American Association of University Women, 2000).

Collectively, research studies suggest that although computers and network technologies are available in nearly all American schools, the literature in science education suggests that there may be many factors that contribute to the underutilization of technology in American science classrooms. One approach to teasing out the underutilization of technology is to define exemplary roles and activities for the use of technology to learn science. This approach provides one means to begin to address and overcome the barriers impeding meaningful use of technology in science classrooms.

## WHAT ROLE DOES TECHNOLOGY PLAY IN SCIENTIFIC LITERACY?

A discussion of exemplary uses of technology to learn science begins with a discussion of how we define learning or knowing science. What is science literacy? As defined by the National Science Education Standards (National Research Council, 1996, 2001), scientific literacy includes both science content knowledge (declarative facts and conceptual knowledge) and reasoning knowledge such as analyzing data, building explanations from evidence, and engaging with scientific questions. In the National Science Education Standards, a central component of scientific literacy is the appropriate use of technology to support learning goals (Bransford, Brown, & Cocking, 2000; National Research Council, 1996). But what is meant by “appropriate use of technology”?

To investigate this question, we look first at how professional scientists use technology. Scientists utilize technology for many specific purposes involving working with and developing both science content and scientific reasoning skills. For example, scientists utilize computers and network technologies for advanced analysis, data modeling, and data representation. A scan of research articles from a recent edition of *Science* magazine reveals several examples of essential use of technology by scientists, including simulation modeling to explain patterns in complex ecological systems at various levels of organization (Grimm et al., 2005) and DNA analysis of ancient artifacts to characterize evidence of human evolution (Haak et al., 2005). These examples represent scientists using technology to develop both scientific content knowledge (generating patterns about complex ecological systems) and scientific reasoning skills (e.g., analyzing data; making hypotheses based on empirical data).

Similarly, students' experiences with technology in science classrooms have resulted in the productive use of technology for both content and reasoning in the form of modeling (Gobert & Pallant, 2004), data analysis, and data representation. Examples of technology to guide content development in atmospheric and environmental science and reasoning in terms of making hypotheses based on empirical data are the methods developed by Edelson and Reiser (2006) in which students use technological tools to analyze historical data on climate (WorldWatcher) or ecosystems (Galapagos Finches).

Additional examples in science education provide research-based means of technologies that can be utilized to guide the scientific reasoning we desire among K–16 students. Using technology to guide the development of reasoning can take many forms, including resources that provide (a) organized dialogue with peers and/or scientists towards collaborative understandings (O'Neill and Gomez, 1998; O'Neill, 2004), (b) scaffolded guidance in the development of scientific explanations (e.g., Explanation Constructor by Reiser, 2004), or (c) guidance in reflection on steps taken and progress within more open-ended investigations (e.g., WISE by Linn & Slotta, 2000; Knowledge Forum [formerly called CSILE] by Scardamalia & Bereiter, 1994; Symphony by Quintana et al., 2002).

## A SHIFT IN RESEARCH FOCUS

An interesting commonality of the set of research studies briefly mentioned above is the emphasis on the role of technology as a resource for complex reasoning in science, including reasoning such as data analysis (e.g., WorldWatcher), the development of explanations (e.g., Explanation Constructor), or reflection (e.g., WISE). This emphasis on the role of technology as a resource for scientific reasoning is a shift from earlier studies of technology in schools that focused on counting and numbers, either amount of access to technology or amount of use. Shifting the research on technology from counting studies to quality and character of use is a major undertaking and shift in research emphasis. Why is this shift necessary or desirable?

Leaders analyzing the needs of educated citizens of the future, such as Susan Patrick, the Director of Educational Technology for the United States Department of Education, document a need to focus on the transformation of technology for educational purposes as opposed to focusing on the mere placement or integration of

technology into schools, “The paper-based system does not make any sense to kids who are coming up in school. Is our educational system geared towards innovation? Do we want an 18th-century model or a 21st-century model for our schools? The 18th-century model is the one we have now. . . . The ed-tech community loves the term ‘integration’. But our schools need transformation not integration” (NSTA Reports, 2005, p. 1).

Similarly, a group of researchers from diverse educational perspectives has discovered that previous examinations of the allocation of educational resources such as curricular programs provided insufficient information to explain student outcomes (e.g., Cohen, Raudenbush, & Ball, 2000). These researchers argue that a more extensive examination of the use of the materials in particular learning contexts is needed to understand the value of the learning resource and the best means of widespread incorporation. Will a similar shift in research focus toward a critique of the use of technology in particular science education settings yield new insights into the best means to overcome the underutilization of technology to learn science? Might this kind of analysis that goes beyond counting studies yield insights into what is meant by the “appropriate use of technology” (National Research Council, 1996)?

In choosing any focus, important trade-offs are required. Focusing this chapter on the quality of use of the technology as opposed to counting studies eliminates a discussion on several other topics associated with learning science with technology that might have been addressed in this chapter. This shift in focus disallows, for example, a detailed historical review of trends in technology and science education over the past several decades. Luckily, this topic is well represented elsewhere (see Linn, 2003, for a good example). Similarly, this chapter does not provide an extensive list of all of the possible technological tools that are available for teaching or learning science. On balance, this chapter focuses on a particular thesis and an associated framework for analyzing the character and quality of the use of technology for learning science. This focus sacrifices some dimensions of breadth to allow a greater discussion of depth focused around the particular perspective of the quality of the use of technologies for learning science. In addition, the chapter provides insight and discussion associated with a handful of exemplary cases of the meaningful use of technology to learn science that will help shed light on principles that might guide more widespread productive use of technology for learning science.

## Digital Resources and Cognitive Tools

To begin our discussion of the use of technology for learning science, we present two critical and contrasting definitions. A Digital Resource can be defined as any computer-available information source containing facts, perspectives, or information on a topic of interest. Digital resources often contain valuable information, such as science information presented in the form of text, pictures, simulations, video, or other interactive formats. The National Aeronautics and Space Administration (NASA) article describing a newly discovered planet candidate in the constellation Hydra, *Hubble’s Infrared Eyes Home in on Suspected Extrasolar Planet* ([www.nasa.gov/home/hqnews/2005/jan/HQ\\_05012\\_hubble.html](http://www.nasa.gov/home/hqnews/2005/jan/HQ_05012_hubble.html)), is an example of a valuable digital resource. Figure 17.1 presents a sample from the NASA article digital resource.

The image shows a screenshot of a NASA website page. At the top left is the NASA logo and the text 'National Aeronautics and Space Administration'. To the right of the logo are links: '+ Text Only Site', '+ Non-Flash Version', and '+ Contact NASA'. Further right is a search bar with the text 'FIND IT @ NASA:' and a '+ GO' button. Below the header is a navigation menu with links: '+ ABOUT NASA', '+ LATEST NEWS', '+ MULTIMEDIA', '+ MISSIONS', '+ MY NASA', and '+ WORK FOR NASA'. On the left side of the main content area is a vertical sidebar with a '+ Home' link. The main content area is titled 'NASA NEWS' and features an article dated 'Jan. 10, 2005' by 'Dolores Beasley' from 'Headquarters, Washington'. The article title is 'Hubble's Infrared Eyes Home in on Suspected Extrasolar Planet'. The text of the article describes how the Hubble Space Telescope (HST) is providing evidence for a candidate planetary companion to a brown dwarf star. It mentions that astronomers at the European Southern Observatory's Very Large Telescope (VLT) in Chile detected the planet candidate in April 2004. The article also discusses the use of Hubble's Near Infrared Camera and Multi-Object Spectrometer (NICMOS) and the challenges of observing such distant objects. The article concludes by stating that the candidate planet and dwarf are in the nearby TW Hydrae association of young stars.

FIGURE 17-1. NASA article describing new planet candidate as example of a digital resource.

In contrast, a Cognitive Tool is defined as a computer-available information source or resource presenting focused information specifically tailored for particular learning goals on a particular topic of interest for learning by a particular target audience. An example of a cognitive tool is the BioKIDS Sequence of CyberTracker (Fig. 17.2), a modification of the original Sequence of CyberTracker (Fig. 17.3), designed to suit the learning goals of sixth-grade students studying a particular biodiversity unit called BioKIDS ([www.biokids.umich.edu](http://www.biokids.umich.edu)).

To further define these constructs, we provide comparisons of digital resources and cognitive tools in three major areas. The first area is Audience/Knowledge. A digital resource is designed for a general audience to serve a range of possible roles. In reviewing the full NASA article available on the NASA website, it is not difficult to imagine scientists, high school students, teachers, and other adults reading this article and finding it to be of value. In contrast, a cognitive tool is designed for a specific audience and is focused on a particular knowledge goal. For example, the BioKIDS Sequence of CyberTracker is software specifically designed for the col-

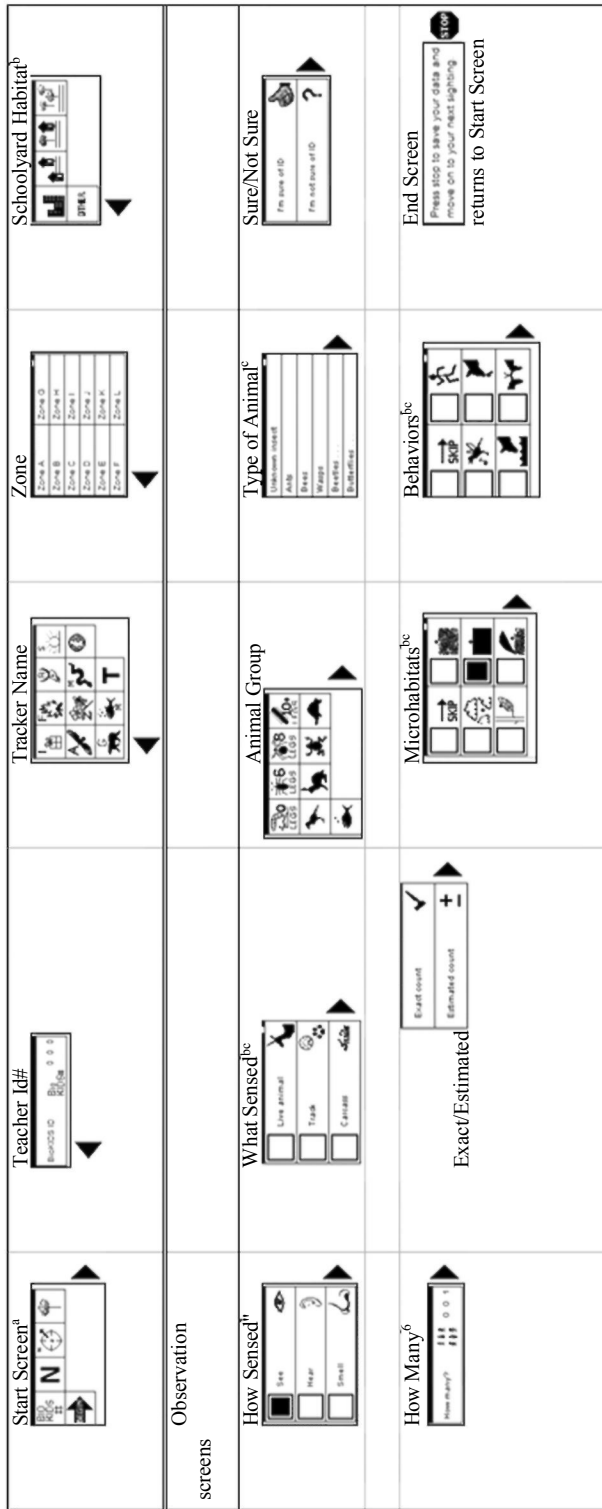

FIGURE 17-2. The BioKIDS sequence, as an example of a cognitive tool.

FIGURE 17-3. Sample screens from CyberTracker sequence for gathering field-based animal data.

lection of schoolyard animal data by fifth- and sixth-graders in Midwestern states. Unlike the original CyberTracker sequence, the BioKIDS Sequence has a limited set of data types and a limited range of animals available for entry (e.g., Michigan-based animals). These limitations allow more focused data collection and more focused learning around particular curricular goals.

A second area of comparison between digital resources and cognitive tools is the area of Learning Activities. Digital Resources do not specify how the particular resource is to be used for learning. For example, the NASA article may be used by scientists for a range of purposes and by high school students for a completely dif-

ferent set of purposes. In contrast, cognitive tools are designed to be used in particular ways to achieve particular learning goals. Our example cognitive tool, the BioKIDS Sequence, is used by fifth- and sixth-graders to achieve specific learning goals focusing on gathering data, data analysis, and ecology that are articulated in the curricular activities aligned with the national (NRC, 1996), state, and district science education standards.

The third area of comparison is Learning Performances. As a result of the lack of specificity with regard to audience and activities, digital resources also do not specify the kinds of products learners produce as a result of working with the digital resource. With the NASA article, a high school student might use this article for a report in an astronomy class; however, the performance or outcome that student develops as a result of the use of the article will likely never be known by NASA or any source associated with the digital resource. In contrast, the products that result from the use of the cognitive tool can be examined and evaluated, as well as compared with the original predictions about audience and learning goals. With the BioKIDS Sequence, research studies provided empirical evidence of the usability and learning outcomes associated with the use of this tool (see Parr, Jones, and Songer, 2004).

An interesting outcome of the comparison of digital resources and cognitive tools in the three areas of audience, activities, and performances is what kinds of conclusions can be drawn about the value of the technology for learning. In the case of digital resources where audiences, activities, and performances are not articulated, no clean comparisons can be made between intended goals, activities, and products to determine relative “learning success” with the digital resource. It is worth noting that this lack of specificity relative to knowledge, activities, and performances might be one explanation for why some earlier studies intending to evaluate the “learning success” of technologies were not successful.

In contrast, when comparisons of audience, activities, and performances are made relative to a cognitive tool, empirical evidence can be gathered on the degree to which intended goals are demonstrated by actual outcomes. This information can serve as empirical evidence of both the effectiveness of the resource and the empirically driven redesign of the resource. With the BioKIDS Sequence, data on student accuracy of data collection, analysis, and use of data for the development of scientific explanations can be compared with the original estimations of learning goals and audience. Subsequent redesign of the cognitive tool can then be performed, resulting in stronger learning outcomes and more meaningful use of the technology.

In summary, we developed definitions of digital resources and cognitive tools and developed three areas in which we contrast digital resources and cognitive tools. The next section outlines a framework for the examination of technologies relative to their potential as a cognitive tool and the potential transformation of digital resources into cognitive tools.

## **Transformation via the Cognitive Tools Framework**

The cognitive tools framework allows a detailed examination of a particular technological resource relative to its predicted role and value in learning science. The development of this framework draws from work in related areas, such as design of

high-quality assessment instruments that are well matched to instruction (National Research Council, 2001). Similar to other frameworks and drawing on the three areas of comparison outlined earlier, the examination of a technological tool via the Cognitive Tools Framework involves an examination relative to three dimensions of the learning experience: (1) target audience and learning goals, (2) the identification of specific learning activities that are performed with the digital resource, and (3) the articulation of particular learning outcomes, such as student performances that are produced as a result of use of the technology within the particular learning context.

As outlined in the previous section, digital resources often provide a rich scientific milieu with strong but unrealized or unfocused potential as a way of learning science. An examination of a digital resource in the three focus areas outlined earlier can lead to the development of a more focused technological tool targeted for a particular audience, learning goal, task, and outcome.

In many cases, it may be advantageous for science teachers or researchers to work from these existing rich scientific resources in the development of cognitive tools for learning science. In these cases, it might be advantageous to redesign the tool in particular ways, such as transform the digital resource into a cognitive tool following the steps of the Cognitive Tools Framework. Figure 17.4 presents the cycle of activities involved in the transformation of a digital resource into a cognitive tool following the Cognitive Tools Framework.

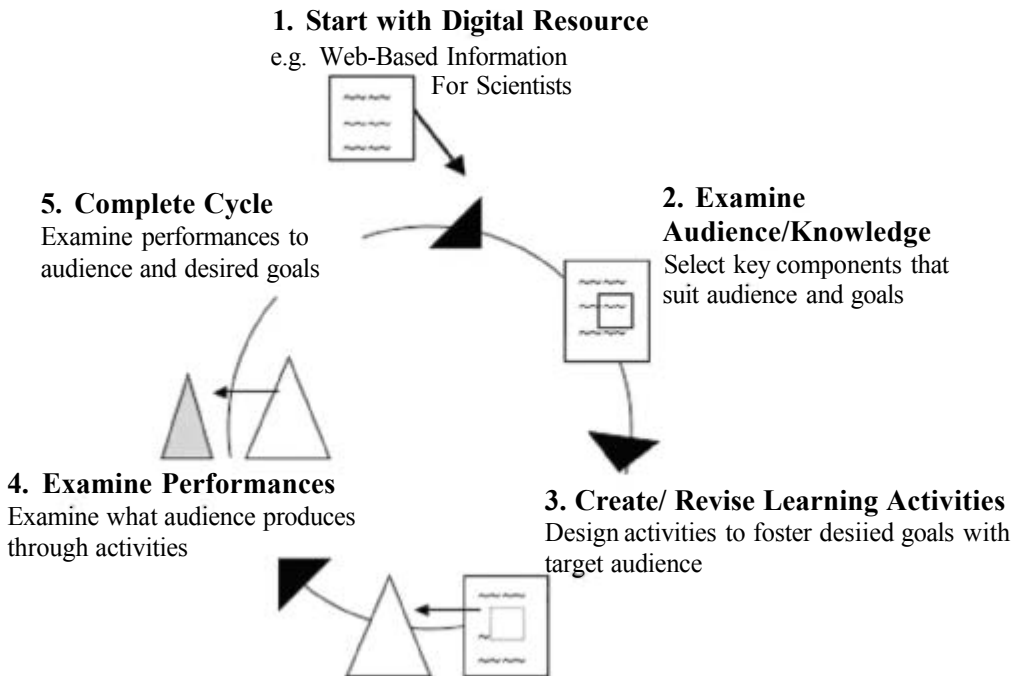

FIGURE 17-4. Steps involved in examining or transforming a digital resource into a cognitive tool via the Cognitive Tools Framework.

The framework consists of examination in three areas. Examination relative to *Audience/Knowledge* refers to a clear definition of the target audience (age, abilities, prior knowledge, and beliefs) as well as learning goals (science content, scientific reasoning, beliefs/attitudes about science) associated with the use of the digital resource. *Learning Activities* refers to the specific tasks that the target audience will perform with the digital resource. Note that the digital learning activities must correspond directly to the audience and learning goals in the Audience/Knowledge area. *Learning Performances* refers to the specific products that are generated by the student as a result of interactions with digital learning activities. Note that digital learning performances should be a clear demonstration of the knowledge outlined in Audience/Knowledge. Correspondence between the three areas of the framework provides a stronger prediction that learning with the resource will achieve desired goals.

### **Why Transform Digital Resources into Cognitive Tools via This Framework?**

We present the idea of transformation of digital resources into cognitive tools via the Cognitive Tools Framework as one means to examine technological resources focused on learning science. We also present this framework to use in guiding the redesign of a digital resource into a cognitive tool that may more feasibly contribute to the intended learning goals outlined.

The idea of transformation to cognitive tools builds from the work of others who developed instructional design frameworks to guide design decisions for educational technologies (e.g., Schwartz, Lin, Brophy, & Bransford, 1999; learner-centered design by Soloway, Guzdial, & Hay, 1994). In addition, this work builds from the recent trend of developing educational technologies to be tailored to specific topics, populations, or disciplines (Linn, 2003). In these studies, expertise on how individuals learn was incorporated with human-computer interface expertise on how individuals interact with technology, to produce guidelines for the design of learner-focused technologies. For example, the work by Soloway and colleagues (Soloway et al., 1994) incorporated components of learning theory such as “learn by doing” with expertise about interface design, resulting in concrete issues to be addressed when designing for learners. Some of these issues included a focus on understanding, motivation, design for a diverse audience, and software that is sensitive to learners’ growth of understanding. In the work of Soloway and colleagues (1994) and others, the task of articulating guidelines for the design of technologies focusing on learners and the subsequent evaluation based on these criteria was considered essential to making informed decisions about the role of technology in learning science.

The work here also involves an analysis of software presentation and the role of technology; however, the Cognitive Tools Framework provides more specificity about the areas of necessary focus, as well as an emphasis on transformation as opposed to the nascent creation of new educational technologies.

Concerning areas of focus, an essential area for the Cognitive Tools Framework is the area of audience/knowledge. Examination of a technological resource via the Cognitive Tools framework requires a detailed understanding of knowledge to be

learned and, ideally, the placement of the target concept in a sequence of concepts to be learned by the target audience. Without an articulation of the knowledge (e.g., facts, conceptual understandings, reasoning skills) and sequence of target science concepts, appropriate design decisions cannot be made that will determine whether the technology might be valuable as a learning resource within this learning environment and for the particular target audience.

Building cognitive tools from digital resources using the Cognitive Tools framework also takes into account the idea that many existing digital resources have strong educational potential that can be used as a foundation for a more focused Cognitive Tool. Many rich resources that contain excellent scientific material already exist, yet they are often unusable in their current form because of their unfocused, narrowly focused, or overly technical presentation. Guidelines for the productive reworking of these resources could expand the potential repertoire of productive learning resources for pre-college science students. In addition, transformation using the Cognitive Tools framework may be simpler than creating educational software products from scratch, particularly when a rich resource in this topic area already exists.

### **AN EXAMINATION OF SCIENCE LEARNING WITH TECHNOLOGY VIA THE COGNITIVE TOOLS FRAMEWORK**

This section explores cases of technology in the research literature relative to the Cognitive Tools Framework. To begin this examination, it is necessary to identify the kinds of science knowledge we might wish technology to support. The National Science Education Standards suggest that in order to develop scientific inquiry abilities in K–12 education, learners should be engaging with rich scientific questions, gathering and analyzing data, formulating scientific explanations from scientific evidence, critically examining relevant data and explanations, and communicating scientific claims, evidence, and explanations to others (National Research Council, 2000).

Drawing from these dimensions of scientific inquiry, we select four areas that are considered essential in developing scientific knowledge where we believe technology can play an essential role:

- a. Learners think critically and logically about scientific ideas and compare them with real-life conditions.
- b. Learners critically evaluate and communicate scientific ideas.
- c. Learners formulate scientific explanations from evidence.
- d. Learners use appropriate tools to gather, analyze, and interpret data (National Research Council, 2000, p. 19).

In the following section, we identify categories of technologies that might be fruitful in supporting each learning dimension. The learning dimension and their associated technologies are represented in Table 17.1.

The following sections present exemplary cases of associated technologies and learning dimensions. The discussion of each case focuses on the role of the technology in the learning environment relative to the learning dimension specified and

**TABLE 17.1**  
**Learning Dimensions and Their Associated Technologies**

<i>Learning dimension</i>	<i>Associated technologies</i>
Learners think critically about scientific ideas and/or compare with real life conditions	Modeling, simulations, and visualization tools
Learners critically evaluate and communicate scientific ideas	Online critique and discussion resources
Learners formulate knowledge such as scientific explanations from evidence	Online scaffolding tools
Learners using appropriate tools to gather, analyze, and interpret data	Computer-based data collection and analysis

the components of the Cognitive Tools Framework. A discussion focused on the areas of the Cognitive Tools Framework allows a review relative to the tools' use as a cognitive tool for learning science by a particular audience as opposed to digital resource. In each technology category, the cases discussed are only some of the possible resources that might have been selected from the research literature; thus this discussion is not intended to be a comprehensive review of all of the possible technologies that might have been discussed.

### **Thinking Critically with Modeling, Visualization, and Simulation Tools**

In learning science, it is frequently not possible to manipulate objects first-hand in order to develop deep conceptual understandings of scientific concepts. Sometimes the necessary materials are very toxic or costly. Other times, resources are too large or too small to work with first hand, as when a class studies the movement of solar systems, weather systems, or individual electrons.

Digital resources transformed into cognitive tools can help science learners to experiment and think critically about real-life phenomena through study in controlled, hypothetical or virtual environments. Subsequently, learners can compare what they have learned in the hypothetical or virtual environment with real-life phenomena.

One example of a case where technology can support students in thinking critically and logically about complex systems is in the use of computer models, such as models of very large and complex three-dimensional systems. The Virtual Solar System (VSS) project supports students in the creation and analysis of three-dimensional models of the solar system that simulate the relative rotation, size, and distance between planets (e.g., Keating, Barnett, Barab, & Hay, 2002). In this study, specific curricular activities were developed to complement the visualization tools to support undergraduate students' abilities to visualize abstract three-dimensional concepts leading to more sophisticated understandings of basic astronomy concepts. Research on the development of students' explanations for the seasons, the phases of the moon, and eclipses reveals significant improvements in students' understandings of these concepts as a result of the construction and analysis of solar sys-

tem models. In this case, the researchers articulated the target audience and learning goals, the learning activities, and the learning performances to facilitate VSS 3D models. The models served as cognitive tools for critical thinking about sun-moon-earth concepts through students' visualization of abstract concepts about the solar system from a range of reference points or perspectives (Keating et al., 2002). Students' ability to run tests and view a three-dimensional system from a range of reference points allowed students to use the cognitive tool as an interactive representation of the actual scientific phenomena, which facilitated greater understanding of the scientific concepts than might be available with a non-interactive two-dimensional textbook picture or model. The emphasis on the needs of the audience, learning goals, specific activities, and specific performances facilitated the technology's use as a cognitive tool as opposed to a mere digital resource.

Another exemplary case of a cognitive modeling tool is the case of ThinkerTools (e.g., White & Frederiksen, 1998). Grounded in theories of learning, ThinkerTools was designed with a coordination between the three elements of the Cognitive Tools Framework: audience/learning goals, activities, and performances. Middle school students are guided in physics problem solving as they are also guided in the development of metacognitive skills about their own learning process. Learning outcomes, on measures of conceptual understanding of physics, applied physics, and attitudes about science, all demonstrate significant gains. Similarly, a third modeling tool focused on middle and high school students creating dynamic models of plate tectonics phenomena, leading to the development of sophisticated conceptual understandings of basic geology and the value of models (Gobert & Pallant, 2004). Again, the coordination of audience/learning goals, activities, and performances facilitated the possibility of students' demonstrating strong learning outcomes with this cognitive tool.

### **Critically Evaluating and Communicating Scientific Ideas with Online Scaffolding Tools**

Many network technologies are interactive and therefore provide possible opportunities for learners to critically evaluate and communicate their scientific ideas with others. Some technologies facilitate feedback and variations of tutoring, including feedback built into the tool (e.g., intelligent tutors), whereas others facilitate feedback and communication of individuals through the tool (e.g., Scardamalia & Bereiter, 1994). In one exemplary case, students using the interactive tool called Computer Supported Intentional Learning Environment (CSILE) demonstrated significantly higher scores on standardized tests and demonstrated greater depth in their explanations than students without CSILE (Scardamalia & Bereiter, 1994).

Discussion tools (e.g. online tools that provide opportunities for individuals to discuss, collaborate, or share ideas or materials) also can serve as rich examples of cognitive tools that can help learners critically evaluate or communicate their ideas about science. In one exemplary case, Guzdial and Turns (2000) discovered that computer-mediated discussions that focused specifically on topics related to class learning goals (e.g., the Audience/Knowledge area) were more effective than discussions with a more open discussion format. The Multimedia Forum Kiosk (MFK; Hsi & Hoadley, 1997) supported much greater participation by a more widely rep-

representative part the class as compared with participation levels in a more traditional classroom discussion. Similarly, a tool focused on supporting ongoing conversations between mentors and students can support guidance in science concept development, reasoning skills, or more productive views of the nature of science (e.g., Bruckman, 2000; O'Neill & Gomez, 1998). In these cases, special attention to Cognitive Tools Framework areas, such as those tailored to online discussions and learning goals or tailoring activities for more anonymous participation (Hsi & Hoadley, 1997), resulted in strong desired outcomes (productive views of the nature of science, conceptual development, high participation levels).

In a contrasting case of critical evaluation and communication of scientific ideas, the Kids as Global Scientists' live prediction tool was used to support globally distributed middle school students' predictions of tomorrow's weather. Once weather data was reviewed and predictions were communicated, these predictions were evaluated relative to the actual weather outcomes through feedback by online atmospheric scientists (Lee & Songer, 2003). In this case, the online prediction environment provided opportunities not just for the development of conceptual knowledge but also for the introduction of real-time problem solving for students ("bringing real world problems into the classroom for students to explore and solve"; Bransford et al., p. 207). On balance, because of the complexity of the real-world situation, the Audience/Knowledge component of the Cognitive Tools Framework has to be carefully matched to the learner's prior knowledge and abilities for maximum effectiveness (Lee & Songer, 2003).

### **Formulating Knowledge Such as Scientific Explanations with Online Scaffolding Tools**

A third category of technologies that can support productive learning of science is online scaffolding tools. Online scaffolding tools can provide a range of different kinds of scaffolding. Scaffolding is commonly defined as the process used by a learner to assist in solving problems or performing cognitive tasks that are too difficult to perform on their own (Wood, Bruner, & Ross, 1976; Quintana et al., 2004). In the case of technologies for learning science, scaffolds are commonly present in the form of written prompts, links, or diagrams that are built into the software to guide students in up to three different types of scientific knowledge development: conceptual knowledge development, reasoning skills such as the development of an evidence-based explanation, or understanding the nature of science.

Zemal-Saul and Land (2002) provide evidence of an online scaffolding tool that helps prospective teachers to construct scientific arguments related to physics concepts. Using the Progress Portfolio tool developed by Loh and colleagues at Northwestern University (Loh et al., 1997), teachers were provided with online guidance in two areas: the organization and reflection on evidence from experiments, and the development of scientific explanations based on evidence. An examination of the preservice teachers' performances after they used Progress Portfolio demonstrated that the cognitive tool provided valuable assistance in guiding the target audience in the interpretation of their results and in developing iterative refinements of their scientific explanations. In both of these examples, it appears that the matching of learning goals (reflection on data collected; development of strong scientific

explanations) to the observed performances allowed a more detailed explanation of the ways in which the cognitive tool was and was not leading to the desired outcomes.

In two different papers, Davis (2003) and Reiser (2004) discuss research results with middle and high school students to explore differential benefits of online scaffolding tools for knowledge formulation such as scientific explanations. Davis (2003) explored different kinds of online problems to guide eighth-graders' reflection. She discovered that when working with complex problem situations, students using generic prompts developed more coherent understandings than students using directed prompts. In contrast, Reiser (2004) presents a review of research results from studies exploring online scaffolding tools. Taking a bird's-eye view of these studies, Reiser discusses two ways in which online scaffolds can assist students in learning science. These ways are to a) structure the learning task itself and b) problematize essential scientific content. Reflecting on these research results relative to the Cognitive Tools Framework, one hypothesis is that Davis's generic (2003) and Reiser's scientific content scaffolds (2004) appear to define but do not overly restrict key dimensions of the knowledge dimension, so that the learning activities and learning performances can be coupled accordingly.

### **Using Cognitive Tools to Gather, Analyze, or Interpret Data**

The fourth area of learning science in which technology can play essential roles is in the gathering and analyzing of scientific data or information. A relatively new and promising area for the use of technology in learning science is the use of small handheld computers such as personal digital assistants (PDAs) for quick data gathering and feedback associated with teaching and learning environments. As one example of this use, in Project WHIRL: Wireless Handhelds in Reflection on Learning (Penuel & Yarnell, 2005), teachers use handheld computers and the benefits of interactivity and feedback to improve their ability to rapidly assess student learning within their classrooms.

A second example of technology for data collection and analysis is CyberTracker, the tool presented earlier. CyberTracker (Fig. 17.2 and [www.cybertracker.co.za](http://www.cybertracker.co.za)) is an icon-based software tool that runs on PDA computers to support professional African animal trackers in quickly recording and identifying animals in the field. Recognizing early on the learning potential of the CyberTracker digital resource for use by middle school students, researchers began to explore the transformation of this tool into a tool better suited for use by middle school students in Michigan. The examination of how to transform CyberTracker followed the Cognitive Tools Framework.

First, researchers investigated CyberTracker for audience/knowledge. At the onset, the icon-based, data entry format of CyberTracker was a good fit for the target audience of language-diverse fifth- and sixth-graders in the Midwestern states. On balance, the learning goals were focused on ecology and the inquiry reasoning of building scientific explanations, as outlined in the National Science Education Standards (National Research Council, 1996). The original CyberTracker sequence contained prompting for data collection that was irrelevant to these learning goals.

Therefore the transformation of CyberTracker relative to audience/knowledge required little adjustment in the area of language for the target audience; however, large adjustments were necessary to focus the data collection to support content development in ecology and inquiry reasoning associated with building scientific explanations from evidence (Songer, 2006).

For all of our learning goals, the collection and organization of accurate scientific data were essential. Therefore, step three of the transformation of CyberTracker via the Cognitive Tools Framework involved the design of learning activities that focused on children’s accurate data collection of animal data in their schoolyards. This transformation step involved both a reworking of the manner in which animal entries were organized in animal groups, as well as a streamlined sequence of data entry focusing on a small number of types of data focused around key unit concepts (habitats, animal group, animal, number, and zone). Figure 17.2 illustrates an example of the CyberTracker sequence after transformation via the Cognitive Tools Framework, now called the BioKIDS Sequence.

Finally, an examination of CyberTracker was performed relative to the third area of learning performances. This examination involved analysis of the products students generated from their data collection with the BioKIDS Sequence to determine if the information would support their ability to reach the desired learning goals. Figure 17.5 displays the student data collected by sixth-graders in one schoolyard in the Midwestern United States with the use of the BioKIDS sequence.

## DISCUSSION

This chapter began with a discussion of the rapid integration of technology in our lives and the comparative underutilization of technology in science classrooms, despite a growing integration and use of technology by children outside of classroom walls. A majority of large-scale research on technology and science education contributes information largely associated with numbers (e.g., access, frequency of

Habitat	Animal Group	Animal	How Many?	Location (Zone)
 Short grass	 Insects	Unknown beetle	13	A
 Short grass	 Insects	Bee	2	F
 Bare ground	 Mammals	Norway rat	1	D
 Bare ground	 Mammals	Fox squirrel	1	F
 In the well	 Myriapoda and Crustaceans	Centipede	2	E
 Under rock or log	 Annelids and Mollusks	Earthworm	1	D
 In the air	 Insects	Bee	1	A
 Single tree	 Birds	American robin	1	F

FIGURE 17-5. Sample habitat summary for Michigan-collected animal data.

use); few studies provide an analytical lens to help explain why technology is underutilized in science classrooms. This is the case despite high-profile requests for research studies that investigate technology designed with the principles of learning in mind:

[T]he process of using technology to improve learning is never solely a technical matter, concerned only with properties of educational hardware and software. . . . Good educational software and teacher-support tools, developed with a full understanding of principles of learning, have not yet become the norm. Software developers are generally driven more by the game and play market than by the learning potential of their products. . . . Much remains to be learned about using technology's potential: to make this happen, learning research will need to become the constant companion of software development. (Bransford et al., 2000)

Addressing this issue of the examination of learning principle-driven technologies first hand, this chapter presents an analytical framework and a discussion of several exemplary cases designed or transformed with respect to audience, learning principles, and outcomes. Through the presentation of the analytical framework and associated cases, the chapter discusses the factors necessary in the design or transformation of learning-associated cognitive tools to learn science. The Cognitive Tools Framework identifies areas of examination necessary for either design or transformation of a digital resource into a cognitive tool, so that the technological resource can have a greater potential to contribute toward strong learning outcomes. The Cognitive Tools Framework and exemplary cases discussed present a perspective on how technological tools can be designed or transformed so that the gap in utilization in classrooms can be understood and overcome.

Each of the exemplary cases discussed illustrates means by which technologies can be designed to focus on issues of audience, knowledge, learning activities, and performances. In many of these cases, the technology was evaluated, and strong learning results that support the value of a cognitive tool as opposed to merely a digital resource were found. For example, empirical results conducted with the designed cognitive tool ThinkerTools demonstrate middle school students' significant gains on a variety of physics concepts relative to peers and older students (White & Fredricksen, 1998). Similarly, empirical results on the transformed cognitive tool the BioKIDS Sequence demonstrate high levels of usability by fifth- and sixth-grade students and strong learning outcomes, both understanding of science content and scientific reasoning (Songer, 2005; Parr, Jones, & Songer, 2004). Interestingly, although the idea of designing or transforming technologies to be cognitive tools is one that has been around for a while, a review of the literature in science education suggests that greater empirical evidence of learning outcomes relative to cognitive tools is needed.

In conclusion, we encourage additional research to examine issues associated with the design of cognitive tools for learning science, including studies that utilize quasi-experimental comparative designs to examine the relative value of different designs relative to the factors of the Cognitive Tools Framework. With the continued small amount of research studies that examine learning-focused technologies, it will remain difficult to respond to critics who claim there is little empirical evidence to support the widespread use of technology in science classrooms. Further-

more, without a solid research base on learning-focused technologies, it will be impossible to make informed decisions on how and when to use technology for learning science. We also encourage additional research to examine the potential of technology for the learning of science, such as research that couples learning research with research on software and resource design. Coupled research of this kind is necessary to understand the effective use of technology in science classrooms and the transformations necessary to develop powerful cognitive tools to advance the learning of science by all learners.

# CHAPTER 18

---

## Elementary Science Teaching

**Ken Appleton**

*Central Queensland University, Australia*

This chapter is about research related to the teaching of science in the elementary school, that is, to students from 5 to 12 years of age. This age range covers grades 1 to 6 or 7 in most education systems. In some countries, particularly those with an English (UK) heritage, this level of schooling is called *primary school*; and to complicate things further, the term *middle school* is used for students aged 10 to 15 years in a number of education systems. For consistency, in this chapter I use the term *elementary school* for grades 1 to 7.

In many countries science in the elementary school is a relatively recent addition to the curriculum, in most instances having been introduced in the decade or two following World War II. Prior to this, any science was essentially nature study. Furthermore, elementary teacher preparation in universities has tended to be a more recent phenomenon and is still to be achieved in a number of countries. Elementary teacher preparation in science, particularly in universities, consequently does not have a long tradition. Because educational research tends to be done by university professors engaged in teacher preparation, research into elementary science teaching remains an emergent area. Fortunately, some research into lower secondary school science has application to the upper elementary grades and has provided a boost for research in elementary science.

Over the last few decades, there has been an increasing amount of research into elementary science teaching, so I have been necessarily selective. I have chosen to review work published over the last decade, mainly in journals, and tried to avoid major overlap with other chapters in this *Handbook*; though for some topics that cross schooling and cognate boundaries, that is unavoidable. My selection and comments naturally reflect my own views and beliefs about research and elementary science teaching.

I have organized the chapter under headings that summarize the main trends in relevant research over the last decade, which, not surprisingly, mirror some chapters in this *Handbook*. The headings are also comparable to several sections in the previous *Handbook* (Gabel, 1994), making the choice of concentrating on research

during the last decade more appropriate. I have deliberately omitted a section on learning (see Chapters 2–7), though key ideas about learning surface in several sections. I begin with a consideration of trends in elementary science education research, then discuss the context for teaching and learning, moving on to consider the teacher, the curriculum, assessment, pedagogy, and finally future research directions. The research into elementary science teacher preparation and professional development has its own extensive literature (see Chapters 34–39), so it is referred to only incidentally.

## TRENDS IN RESEARCH INTO ELEMENTARY SCIENCE TEACHING

Research into elementary science teaching is not immune from the pressures and influences on research into schooling more generally, and science education more specifically. The current, dominant social issues such as political demands for accountability in education, maximizing student learning outcomes, and social justice are demanding the attention of educational researchers. However, a majority of elementary science education researchers have moved to academia after commencing their careers as elementary teachers and subsequently undertaking doctoral studies. They therefore tend to have an interest in the type of research that will make a difference in the classroom. The research literature therefore abounds with investigations focusing on the pedagogical application of theories of learning, enhancing conceptual learning of science, current practices in science teaching, and ways of addressing the identified problems in elementary science teaching and learning through pre-service and in-service teacher education. Studies dealing with the larger social agendas and those that might inform policy making are less frequent. Perhaps this is understandable, given that elementary science is just one part of the overall elementary school context, so policy and social issues impinge more broadly on all aspects of the elementary school rather than just one subject. Yet a consequence of this is that elementary science education researchers are largely reactive to policy changes and do not help shape them. This is particularly significant when policy changes affect science teaching and learning in a detrimental way. In making this comment, I acknowledge that merely doing research does not guarantee that it informs policy—networking and lobbying are perhaps even more critical. But having research findings is a necessary starting point.

Over the last few decades there has been a change in the type of research conducted. With the growing popularity of constructivist views of learning in elementary science, I have noted a corresponding shift in epistemological beliefs held by elementary science education researchers from positivist views to constructivist views, and within constructivism, from cognitive to social constructivism. A consequence has been a growing tendency for researchers to select interpretive research designs rather than the experimental designs that dominated educational research 30 years ago. The shift in constructivist views has also resulted in a change from research involving clinical interviews to probe understandings to case studies of social settings and influences. This means that a change has also been under way in the type of research questions asked by researchers. Questions like, *Which teaching strategy is more effective?* and *What misconceptions do these students hold in \_\_\_?* are

rare nowadays, whereas questions such as *What aspects of the teaching strategy enhance students' learning?* are more common. The trend is toward trying to understand the complexities of the learning and teaching interface. Instead of trying to control variables, there is a preference to describe how they interact. Instead of describing problems in teaching and learning, there is a preference to understand how the problems come about and how to reduce the likelihood of their occurrence. Such trends are particularly evident in the context of elementary science teaching.

## THE CONTEXT FOR TEACHING AND LEARNING ELEMENTARY SCIENCE

Science in the elementary school is framed by the social and cultural context of elementary schooling. This varies considerably from country to country, despite some similarities in tradition and practice. An overriding tradition is that elementary schooling's major priorities are literacy and numeracy, with other subjects taking second place. Such traditions and perceived priorities have consequently shaped research into elementary science teaching. Inasmuch as science is a relatively new elementary curriculum area with low priority, two major research foci have been science teaching practices in the elementary school, and teacher preparation and professional development in elementary science education. Other influences on elementary science research have tended to flow from science education research in the secondary school and from research into learning. Most researchers investigating elementary science teaching have had their thinking framed by historical developments in elementary science education research and science education research generally. My own thinking has, for example, evolved from a concern for the state of elementary science teaching to an emphasis on process skills, to cognitive constructivism and emergent pedagogies, to a more social constructivist orientation, and finally to a focus on standards-based conceptual learning and teaching. Within these trends has been an ongoing and overarching interest in elementary science teacher preparation and professional development. My research practices have correspondingly evolved from quantitative, quasi-experimental studies to qualitative studies taking a constructivist perspective, with a heavy reliance on case-study techniques. Many of my colleagues throughout the world have taken a similar journey.

Understanding the context of schooling is an essential starting point for making sense of research in elementary science. Science in the elementary school is one of a number of subjects that are usually taught by a generalist teacher. Research into the social and cultural setting of science in the elementary school is consequently a subset of a vast literature that cannot be reviewed in a chapter such as this (see the special issues of *Journal of Research in Science Teaching*, volume 36 issue 3 and volume 38 issue 5).

A defining set of studies about the context of science teaching and learning was conducted by Nuthall (2001). He reported the effect on student learning in science and social studies of the intersecting variables of the instructional social setting, peer-peer social interaction, and internal cognitive processing and attending behaviors of students. He used multiple data sources from intensive and extensive observation of classroom events over several weeks, including interviews, and artefacts. He tracked conceptual development in students by identifying each concept intro-

duced during teaching and categorizing each item of data from the focus students into the respective concept. He was thus able to construct a time-event overview of experiences for each student that influenced that student's learning of each concept. In his studies, he highlighted how each of these variables can dramatically influence the learning that occurs. Consequently, I refer to his studies in a number of places in this chapter.

Although not addressed by Nuthall, it is critical to note that students' internal cognitive processing and attending behaviors are derived from their cultural and linguistic backgrounds (Warren, Ballenger, Ogonowski, Rosebery, & Hudicourt-Barnes, 2001). These influence considerably the nature of previous experiences students bring to the learning situation and consequently what they learn (Nuthall, 1999). They also influence the types of social interactions that can occur within a small group of students (Kurth, Anderson, & Palincsar, 2002). Peer-peer interactions are largely invisible to the teacher in a busy classroom, particularly when small groups are working on activities or projects, but can either enhance or interfere with learning (Kurth et al., 2002; Nuthall, 2001; Ritchie, 2002).

It is such considerations that, I believe, have caused many researchers in elementary science education to move away from experimental and quasi-experimental studies toward qualitative ones, because these are variables that cannot be controlled and are usually hidden in experimental statistical error estimates. Nuthall (1999) makes the point, for instance, that what students learn from a lesson is not related to their ability, but to how they interact with and interpret learning experiences. Large-scale experimental designs cannot control for such a variable, but they can be identified and described with the use of qualitative data. A further example of this trend in research is presented in the next section, on the elementary science teacher.

## THE ELEMENTARY SCIENCE TEACHER

Early research into elementary science teaching tended to use self-report surveys of teacher practice. Later studies have focused more on understanding classroom events from both the teachers' and students' perspectives.

### Current Practice

Current practice in elementary science has been an ongoing research topic for decades, and despite huge efforts it seems that little has changed.

### Teacher Avoidance of Science

That elementary teachers tend to avoid science has been an issue for a long time. For instance, Tilgner (1990) commented that the situation had not changed in 20 years, and in the decade since, there have been continuing reports along similar lines across the world (e.g., Goodrum, Hackling, & Rennie, 2001; Harlen, 1997; Harlen & Holroyd, 1997; Lee & Houseal, 2003; Osborne & Simon, 1996; Schoon & Boone, 1998). The main issues identified in research over the decades are that ele-

mentary teachers tend to have limited science subject matter knowledge, limited science pedagogical content knowledge (PCK) (Shulman, 1986), and low confidence/self-efficacy in science and science teaching, with the consequence that many avoid teaching science. Harlen (1997) identified six avoidance strategies used by teachers:

1. avoidance—teaching as little of the subject as possible,
  2. keeping to topics where confidence is greater—usually meaning more biology than physical science,
  3. stressing process outcomes rather than conceptual development outcomes,
  4. relying on the book, or prescriptive work cards which give pupils step-by-step instructions,
  5. emphasising expository teaching and underplaying questioning and discussion,
  6. avoiding all but the simplest practical work and any equipment that can go wrong.
- (p. 335)

Factors related to the school and/or school system, such as resources, time (both personal and class schedules), and personal and system perceptions of the importance of science in the elementary school, are cited as other reasons for limited teaching of science (e.g., Appleton & Kindt, 1997; Goodrum et al., 2001; Levitt, 2001).

Harlen also cautioned that, although some teachers are more confident about teaching science, avoidance behaviors allow them to teach a form of science with which they are comfortable, and therefore they do not see their science teaching as problematic. In self-report surveys, these teachers may appear as confident, regular teachers of science. However, King, Shumow, and Lietz (2001) found that there was a considerable discrepancy between teachers' views of their own practice in elementary science and the views of science educators who observed their teaching. What the teachers saw as inquiry, the science educators saw as expository. This has implications for research that relies solely on teachers' self-reporting of their science teaching practice.

A consequence of elementary teachers' limited science knowledge and low confidence in teaching science is a tendency for them to use teaching strategies that allow them to maintain control of the classroom knowledge flow, but which are often not appropriate ways of engaging students in science (e.g., Skamp, 1993; Woodbury, 1995). In a case study of a grade 4/5 teacher, Roth (1996) found that "the teacher's competence in questioning was related to her discursive competence in the subject-matter domain" (p. 709), but also noted the complex interaction of content knowledge and context. A naïve solution to this problem has been to demand that elementary teachers take more science content in their pre-service preparation. However, Roth noted that "subject-matter competence in and of itself was insufficient" (p. 731), and others (e.g., Morell & Carroll, 2003; Skamp & Mueller, 2001) have shown that more content knowledge, of itself, does not necessarily help teachers use strategies appropriate to recent reform initiatives (National Research Council, 1996). Schoon and Boone (1998) suggested that there may be key, fundamental misconceptions held by some elementary teachers, characteristic of a lack of understanding of foundational ideas in science, that particularly affect their self-efficacy. They suggested that misconceptions in other, more minor, ideas in science have less impact.

Even when science is taught in elementary classes, the way it is taught can be problematic. D. P. Newton and Newton (2000), for instance, concluded that there was little causal reasoning promoted in the science classes studied: "teachers' discourse was often largely confined to developing vocabulary and descriptive understandings of phenomena and situations. Often, there was little evidence of an oral press for causal understanding . . . with its persistent emphasis on reasoning, argument and explanation. The teachers who gave least time to causal questioning in their oral discourse also tended to be amongst those who did not provide a practical activity" (p. 607). Newton and Newton also noted that the more science studied in high school by the teacher, the greater the tendency for them to engage the students in causal reasoning. Such an emphasis in teaching conveys inappropriate views of the nature of science. Chinn and Malhotra (2002), for instance, argued that "the epistemology of many school inquiry tasks is *antithetical* to the epistemology of authentic science" (p. 175, emphasis in the original).

Teachers' perceptions of themselves as learners, of learning and of epistemology, also influence their teaching. For instance, Laplante (1997) reported that two grade 1 French immersion teachers tended to present science information from books during science lessons. The knowledge they presented was descriptive and anecdotal. Laplante attributed this to their epistemological beliefs about science. They saw themselves, and their students, as consumers of science, rather than inquirers in science. "They put scientists on a pedestal and consider them to be gifted with cognitive abilities they and their students do not possess" (p. 290). The tendency for elementary teachers to hold and convey inappropriate views of science has been noted by others (e.g., Watters & Ginns, 1997). These views are passed on to students. For example, grade 4 students saw science with "an inductivist, empiricist view of scientific inquiry, a view in which we approach knowledge of the world through an unbiased accumulation of data" (Varelas, Becker, Luster, & Wenzel, 2002, p. 867).

However, perceptions held by elementary teachers that they are somehow inadequate in doing and teaching science are unfounded. Harlen (1997) reported that, "[w]hat holds back teachers' understanding is not ability to grasp ideas but the opportunity to discuss and develop them" (p. 336). Indeed, Summers, Kruger, and Mant (1998), among many others, have reported how appropriate professional development can transform elementary teachers' science teaching practices. With appropriate professional development, teachers can make their own personal curriculum and pedagogical decisions for effective teaching of science and can even devise different pedagogical pathways for achieving the same learning goals for students (Kruger & Summers, 2000). However, not all teachers are able to make the same progress—not because of ability or lack of it, but because they tend to hold beliefs more or less consonant with reform moves (Levitt, 2001). Levitt categorized elementary teachers, after professional development in reform science, as being traditional, transitional (moving toward reform), or transformational (transformed their teaching to be consistent with reform initiatives). Their alignment with reform beliefs determined the extent to which their science teaching was reform-oriented.

Even if elementary teachers hold beliefs consistent with reform initiatives, they are not always able to make the transition to such teaching themselves. Ramos (1999) reported that most of the teachers she surveyed believed that constructivism was the best basis for teaching science but felt that external constraints prevented them from

teaching this way. On the other hand, some teachers appear to be able to use their general pedagogical knowledge to teach science effectively (Kelly, Brown, & Crawford, 2000), despite limited knowledge and perceived constraints. Some use knowledge from other subjects: Flick (1995) reported how a teacher used language pedagogical skills to encourage discussion and exploration in science in a grade study of the solar system. Some teachers who teach science use constructivist principles such as eliciting children's ideas as a basis for their teaching, though their facility in doing this depends on their science content knowledge (Akerson, Flick, & Lederman, 2000). In their study, Akerson et al. (2000) described how the least-knowledgeable teacher of the three studied inhibited students' further sharing of ideas by the nature of her responses to the students. This, however, could be due to the fact that she was also a beginning teacher and had limited general pedagogical knowledge.

Given the incidence of science avoidance in the elementary school, it is tempting to attribute this to an anti-science attitude among teachers. However, even though many elementary teachers have limited science knowledge and avoid teaching it, Cobern and Loving (2002) reported that the teachers in their study were not "anti-science."

Making changes to the school and system context through, for example, proactive school leadership can change the teaching of elementary science in a school (Spillane, Diamond, Walker, Halverson, & Jita, 2001). In this study, school administrators successfully embarked on a deliberate process to develop the human capital within the school, with an emphasis on providing resources and improving pedagogy for science. Support from administrators and colleagues within the school as well as from personal friends/family has been identified as an important factor in helping even very capable beginning teachers to be effective in their own classroom teaching (Martinez, 1994).

The research into science teaching practices reveals a fairly depressing picture. A naïve reaction is to blame elementary teachers for not doing their job properly. However, the overwhelming majority are doing the best they can under the circumstances.

## Gender Trends in Science

In the last decade, there have been relatively few studies on gender in elementary school science that give a new or different perspective (see Chapter 11 for a full discussion). Some studies show ongoing gendered preferences about science—boys toward science and physics, girls away from science and toward biology (Farenga & Joyce, 1997; Johnson, 1999; Stark & Gray, 1999). Liu and Lederman (2002) noted that girls' and boys' informal writing in science differed in both style and content. They concluded that "[g]irls seemed to personalize their knowledge more; they perceived science as a social activity involving fun and communication, appreciated the importance of science as a practical field, wrote in greater detail, and preferred to write about plants, animals, and topics relevant to their lives" (pp. 264–265). By contrast, "[b]oys' writing was condensed and formal, and contained the technical attributes normally ascribed to scientific writing. They also seemed to have a more imaginative perspective of science, to prefer informative tasks, and to write significantly more about technological applications in the physical sciences" (p. 365). It appears that socialization into such interests starts early, as parents give

kindergarten girls three times as many opportunities to take part in biological activities than in physical science activities (Johnson, 1999). In a different vein, Warwick, Stephenson, and Webster (2003) reported that boys had greater difficulty expressing their understanding in writing than girls, but whether this is also a consequence of socialization is unknown. An apparent decline in boys' performance over recent years has generated controversy in the media and is an emergent research area.

## Generalist/Specialist Science Teaching

One way of addressing difficulties generalists experience in teaching science is to appoint science specialists in elementary schools. However, there is limited research specifically focusing on specialist science teachers. Most reports that I have found tend to have a different research focus, such as professional development, and mention incidentally that the teacher was a specialist.

*Specialists in science.* There are ambiguities in the literature in defining science specialists, as some label generalist teachers who take school leadership in science curriculum as specialists (Schwartz & Lederman, 2000; Spillane et al., 2001), some refer to generalists who have studied more science (e.g., D. P. Newton & Newton, 2000), and some think of those who take science exclusively (e.g., Owens, 2001). Those who take science exclusively also tend to be well qualified in science and elementary science and take curriculum leadership within the school for science (Schwartz & Lederman, 2000). I prefer this view of a science specialist, and call generalists who take some initiative in science, science curriculum leaders. Sometimes a school administration may deliberately invest resources in science by appointing a science specialist for the school. In some education systems, science specialists are appointed for middle school classes, but this is the exception rather than the rule.

Where specialists are appointed, it is important to choose the right people. Beeth (Beeth, 1998b; Beeth & Hewson, 1999) reported a study of an exemplar specialist teacher who achieved high-quality learning outcomes with her students. The teacher reportedly had considerable subject matter knowledge, excellent pedagogy, and extensive science pedagogical content knowledge. However, not all specialists fit this pattern. Owens (2001), for instance, had a specialist teacher in her sample of teachers who was not well qualified and held beliefs about using the textbook that were similar to those of many other generalist teachers. In fact, a generalist teacher who had the most pre-service and in-service experience in science was best able to use writing effectively within a broader inquiry framework. In this case, there was no advantage in this teacher being a specialist. In one of the few studies of any advantage in appointing science specialists, Schwartz and Lederman (2000) compared the views of science and teaching practices of elementary science specialists in grades 4 to 6 with generalist teachers' science teaching. They concluded that "elementary science specialists may be more 'effective' than elementary science teachers in implementing the reforms vision" (p. 191). Another study by Jones and Edmunds (2006) compared the effect on science in three different schools that employed specialists and science curriculum leaders. While the effect of a science curriculum leader was positive, science had a higher profile in the school where there was a specialist.

### *Turn teaching by generalists (swapping subjects)*

In many schools there is usually little leadership support for science compared with mathematics and language arts. Leadership involvement tends to be limited to human and material resource allocation, not instructional leadership (Spillane et al., 2001). If any leadership is provided at all, it is left to classroom teachers acting as science curriculum leaders, who receive little acknowledgment or time release. These actions “reinforce the belief that science is not important” (p. 925).

A common occurrence is an informal arrangement between two or three teachers to divide subjects between them (Summers et al., 1998; Watters & Ginns, 1997), which I call turn teaching. That is, teachers who lack confidence in science may negotiate with more confident colleagues to teach their science for them. This is another form of science avoidance (Harlen, 1997).

## THE ELEMENTARY SCIENCE CURRICULUM

### Curriculum Influences

There are numerous influences on the curriculum that can be broadly categorized as cultural, systemic, and those internal to the teacher. Cultural influences include predominant views of science, teaching, learning, and schooling held by different community sectors, including students. Systemic influences include school traditions and practices; choices of instructional materials; and mandated curricula, standards, and testing regimes. Those internal to the teacher include aspects of teacher knowledge and self-confidence discussed above.

### Cultural Influences

Research into cultural influences on the elementary science curriculum, apart from a focus on equity and “science for all,” tends not to be published in mainstream science education journals. Nor have I found research into curriculum design for elementary science. Official curriculum documents issued by education systems tend to assume a “one size fits all” policy, regardless of the suitability of the curriculum for different cultural groups within their jurisdictions. Zubrowski (2002) argued for a different curriculum structure based on a social constructivist view of learning, situated cognition, but did not relate this specifically to cultural issues. In the special issue of *Journal of Research in Science Teaching* (volume 36, issue 3, 1999) on science education in developing countries, issues of curriculum and pedagogical appropriateness were raised. See also the special issues on culture and language (volume 38, issue 5, 2001) and on urban science education (volume 38, issues 8–10, 2001).

### Views of “Best Practice” in Science Education

One of the few studies that considered different cultural groups was conducted by Hayes and Deyhle (2001). They suggested that notions of what science education is best for different cultural groups depend on differing views of what constitutes best practice in science education. Views of best practice are determined, in part, by

cultural views of learning, teaching, and authority; available resources; and current practices.

## Systemic Influences

**Curriculum—scope, sequence and scheduling.** Very little has been researched in this area in recent years. Tytler and Peterson (2000) suggested that some topics in science, specifically evaporation, are too complex for young students, such as first-graders, to grasp, possibly because the necessary mental models require mastery of linguistic/conceptual tools not yet accessible to the students. Significantly, their data did not support the notion of “readiness” that is still prevalent in many early childhood settings.

There is a major implication of Nuthall’s (1999) work for scheduling of science lessons in the elementary school. He found that for students to commit something to long-term memory, they need a minimum of three or four experiences with it. Furthermore, he found that a part of memory is used as a staging point before some experience is committed to long-term memory. He called this short-term memory, distinguishing it from traditional definitions of short-term memory in psychology. Significantly, memories of classroom experiences remain in this short-term memory for a maximum of two days before they are lost. By implication, to maximize student learning, science lessons (and/or homework or similar tasks) dealing with the same information need to be scheduled within two days of the previous lesson. In some education systems, science is officially scheduled for one to two hours per week, and the consequent common practice of timetabling one science class a week militates against effective science learning.

## Types of Instructional Materials

Instructional materials used by elementary teachers consist of three main types: textbooks, teacher guides and resources, and supplementary materials for student use. Textbooks are common in countries such as the United States and Canada and tend to lead to heavy reliance on text reading and limited hands-on, inquiry teaching (Mastropieri & Scruggs, 1994). Teacher guides and the like, common in Britain, Australia, and New Zealand, are used as sources of activity ideas (Appleton, 2002; Appleton & Asoko, 1996). Supplementary materials such as trade books and newspapers are used generally either to supplement textbooks or activities that work, or as a basis for language-oriented science—a form of avoidance of hands-on science (Harlen, 1997).

**Textbooks.** Mastropieri and Scruggs (1994) compared text-based curricula with activities-oriented curricula. They highlighted the limitations of textbooks and the advantages of hands-on activities. Texts “convey science content information through reading and interpretation of the printed word. This approach also reflects an emphasis on vocabulary learning and factual recall of text-based information . . . Activities . . . are almost exclusively paper-and-pencil tasks” (p. 82). In contrast, activities-oriented curricula depict “science as an ongoing process of exploration and discovery, rather than a content domain to be memorized. Tests . . . tend to be performance-based measures that assess student understanding of the unit’s central

concepts. Activities with real materials and apparatus replace paper-and-pencil activities" (p. 83). They also commented that both types of curricula require specific support for children with disabilities, though text-based curricula present particular problems for students with disabilities that influence reading ability.

In another examination of textbook elementary science, Chinn and Malhotra (2002) devised a way to analyze text-based inquiry tasks and compare them with authentic science. They concluded that "the inquiry activities in most textbooks capture few if any of the cognitive processes of authentic science" (p. 204) and that "school tasks may actually reinforce an unscientific epistemology" (p. 213). As part of this concern, they commented that textbook inquiry activities differed little from those included in other teacher resource materials, with recent innovative materials faring somewhat better: "our analysis of recent tasks developed by researchers shows that there is still room for improvement even in these outstanding, cutting-edge inquiry tasks" (p. 205). However, creative and effective use of textbooks is possible, as reported by Candela (1997).

**Teacher resources.** Teacher resources can be published sets of materials or eclectic collections from a variety of sources. Published sets seem to be useful to experienced teachers, but not so useful to beginning teachers. Watters and Ginns (1997) told how a grade 4 teacher used *Primary Investigations* (Australian Academy of Science, 1994) as a resource and found it helpful, but Appleton and Kindt (1997) reported that, compared with more experienced teachers, beginning teachers tended to find the official teacher guides of limited use (Appleton, 2002). Note that when schools adopt *Primary Investigations*, they are expected to engage teachers in professional development in its use, whereas official curriculum guides are frequently distributed to teachers with limited or no professional development. Other studies have also highlighted how professional development associated with the use of teacher guides can result in effective science teaching (e.g., Appleton, 2003; Hunt & Appleton, 2003; Kruger & Summers, 2000).

Some publishers, particularly in the the United States, provide complete curriculum packages, including equipment, to accompany teacher guides. These "kit"-based materials, such as *Science and Technology for Children* (National Science Resources Centre, 2002), provide pedagogical ideas for teachers that are derived from research findings. Complete curriculum packages like this are seen as one way to minimize the difficulties experienced by elementary teachers trying to teach science. There is limited, current, independent research into the efficacy and cost-effectiveness of kit programs compared with other forms of curriculum and teacher support. This is a potentially fruitful area of research, particularly where policy direction may be needed for education systems. However, to influence policy, research designs would need to be carefully crafted.

**Other resources.** Vaughan, Sumrall, and Rose (1998) reported how pre-service teachers, in-service teachers, and students all made effective use of newspapers to enhance science teaching/learning. Positive attitudes to their use were also reported, though they were found to be most effective in upper grades.

Nonfiction science books, usually called trade books, are another resource that teachers use—usually by having students do "research" into the current science topic. However, such trade books seldom focus on providing explanatory under-

standings (L. D. Newton, Newton, Blake, & Brown, 2002), which suits many elementary teachers' current practices.

### **Teacher Choice of Materials**

Although the use of science textbooks is common practice in countries such as the United States and Canada, I found no studies about how teachers and schools make choices of texts to use. However, in countries such as Britain, Australia, and New Zealand, where teachers use a variety of resources, there have been a number of studies about resource selection (e.g., Appleton, 2002; Appleton & Asoko, 1996; Appleton & Kindt, 1997; L. D. Newton et al., 2002; Peacock & Gates, 2000), though only a few commented on how teachers made their choices. For instance, Appleton and Asoko (1996) reported that a teacher chose hands-on activities from resource materials, using criteria such as how manageable he thought activities would be in the classroom, whether they would teach the students something, and his perception of whether they would interest his students. As Appleton (2002) later elaborated, teachers chose such "activities that work," using these and further criteria, including whether equipment was readily available, whether there was a clear outcome or result from the activity, and the extent to which they lent themselves to integration (see below). How teachers select trade books was also the subject of a study by Peacock and Gates (2000). They reported that newly qualified teachers' selections of trade books "do not simply relate to problems of children's interaction with text, but also to teachers' perceptions of the demands placed on themselves" (p. 165). That is, they were mindful of work demands and classroom management issues. They further commented, "neither the nature and depth of the science content nor the quality of the representations of science concepts played a part in influencing their selection and use of text" (p. 165).

To explore how elementary teachers used supplementary material to their textbooks, David P. Butts, Koballa, Anderson, and Butts (1993) surveyed 125 primary (early grades) and 150 intermediate teachers over two years. They reported that some teachers supplement their textbook with other materials for alternative and additional instructional ideas:

If teachers believe that science topics are of interest to their students and that these topics will help their students achieve goals in science that the teachers value and that are part of the expected curriculum, then teachers will find time to schedule the use of these materials with their students. The teachers' internal beliefs about what is beneficial for their students linked with the external constraints of their students' interests and the expected curriculum are the factors that govern a teachers use of instructional materials . . . teachers are not likely to use these resources if they believe that they do not fit the "gotta do's" of the expected curriculum. (p. 357)

### **Mandated Curricula, Standards, and Tests**

Given that reform movements in elementary science education have been in progress in many countries for at least a decade, there has been limited research into how teachers are responding to these initiatives. Harlen (Harlen, 1997; Harlen & Holroyd, 1997) claimed that concerted efforts in in-service teacher education in England and Wales have resulted in some improvements in elementary science,

though there is still a long way to go. In Australia, reports are beginning to emerge that show that, with extensive support, some teachers have successfully engaged with new elementary science curricula (e.g., Appleton, 2003; Hunt & Appleton, 2003; C. M. Peers & Watters, 2003). In the United States and other countries, there have been similar reports of success with helping teachers use more inquiry-based teaching (e.g., Feters, Czerniak, Fish, & Shawberry, 2002). However, I have attended conferences such as AERA and NARST, where teachers also recount horrific stories of curriculum limitation, dispirited teachers, and jaded students constrained by so-called reform high-stakes testing regimes; but little of this has actually been published. Bianchini and Kelly (2003), in a study of the effects of the California standards, concluded that the standards were limiting curriculum and teacher flexibility. Lee and Houseal (2003) saw standards and benchmarks as an external constraint to effective science teaching. Given the limited research available, it seems that the implementation of benchmarks and testing regimes in some education systems is working against the very reform moves (National Research Council, 1996) that they are supposed to support. More research into the consequences of the reform initiatives on elementary science teaching and learning needs to be published.

### Cross-Disciplinary Teaching

Cross-disciplinary teaching in science can take two forms: general science and teaching across disciplines. In general science, the traditional science disciplines are combined into science topics or themes, such as *Change*. Activities within a topic or theme may include identifiable components of traditional science disciplines, but these are subservient to the topic or theme. Arguments for general science in the elementary school tend to be based on notions of learning, curriculum philosophies, or curriculum constraints rather than research evidence of learning outcomes. Many instances of so-called general science, however, are really taught as traditional discipline strands with more contemporary names, such as "Natural and Processed Materials."

Teaching across disciplines, or, as it is more commonly called, curriculum integration, is a common feature of the elementary curriculum, particularly in some countries such as the United Kingdom, Australia, and New Zealand. Unfortunately, there is no consensus about what "integration" means (Hurley, 2001; Venville, Wallace, Rennie, & Malone, 2002), other than that some or all subjects are taught together or in association with each other in some way. In a meta-analysis of research into integration, Hurley identified five different categories (with specific reference to science and mathematics) that lie along a continuum ranging from sequential planning and teaching to the subjects being taught together in "intended equality" (p. 263). Venville et al. reported a number of similar categorizations in the literature but chose not to present their own findings as a continuum, "because of the implication that more integration is synonymous with better integration" (p. 76).

A common curriculum organization for integration has been the use of themes, like *The Sea*, or *Our Body*. Other organizers such as projects or problem solving have been suggested. However, I believe that such organizers do not readily fit the reform outcomes/standards-based science curricula that are now common. There consequently needs to be a more sustained research effort into reform-consistent integrated curricula that enhance science learning as well as learning in other subjects. This reflects the dilemma of curriculum approach conflicts noted by Venville

et al. (2002), who published a recent review of research into integration from a science perspective.

Their review provides an excellent overview of research findings, so just a brief summary of their conclusions is presented here. After noting the variety of forms of integration, Venville et al. (2002) concluded that reasons for integrating subjects included epistemological, practical, and motivational arguments. Regarding the last, they raised the question of whether improved student engagement is necessarily a product of integration or some other variable such as better teaching. They also concluded that integration was “difficult to implement and maintain in school environments” because “integrated curricula challenge many aspects of established practices, rituals, beliefs and hierarchies of traditional school establishments” (pp. 76–77). In terms of student learning, integration provided benefits in motivation, interest, and development of higher order cognitive skills, at a cost of conceptual understanding of science (and other subject) content knowledge. Decisions to integrate were therefore difficult to justify from a traditional subject perspective, but could be justified from different philosophical or epistemological perspectives, such as humanism or holistic learning.

Research on integration of science with other subjects has tended to date to cluster around mathematics (Hurley, 2001; Pang & Good, 2000), language arts (Akerson & Young, 1998), and design technology (see below), with more isolated reference to science and other subjects such as art (e.g., Lach, Little, & Nazzaro, 2003), social studies (e.g., Buxton & Whatley, 2002), and physical education (e.g., Buchanan et al., 2002). A lot of published material on integration with particular subjects tends to focus on exhortations and arguments for integration, and ideas for how to do it, rather than research findings.

## **Integration with Mathematics**

Reports of research into science and mathematics integration feature regularly in *School Science and Mathematics* (e.g., see the reviews by Hurley, 2001, and Pang & Good, 2000), a journal committed to encouraging such integration. In her meta-analysis, Hurley reported that, compared with traditional instruction, student achievement in science tended to be greatest when science and mathematics were more fully integrated. However, achievement in mathematics was more limited.

## **Integration with Language**

Much has been written about the integration of science with language and, in particular, about the potential benefits for science achievement. This is such a central issue that a chapter has been devoted to the topic in this volume (see Chapter 3), so is not discussed further here.

## **Integration with (Design) Technology**

There are three approaches to science and technology integration:

- Equal emphases on science and technology. Jane and Jobling (1995) described an integrated science/technology unit in grade 5. Benefits included high levels of engagement and metacognition, and integration of learning outcomes.

- Emphasis on technology. Ritchie and Hampson (1996) described an inter-linked science and technology unit, where the main focus was technology. Some science was apparently also learned, though the report did not document what.
- Science through technology. Technology as a way of accessing science was described by Benenson (2001) and Roth (2001). That is, science was taught through technology.

## Information Technology

Information technology (IT) (that is, computers and the like) has been used as a pedagogical aid in elementary science (see also Chapter 17). Research reports usually recount how IT has been used to support science teaching and include an evaluation. Sometimes a contemporary theoretical stance, such as conceptual change theory or writing to learn, is adopted; sometimes there is no clear theoretical base. Evaluations vary considerably in what is evaluated and in the degree of rigor of the evaluation. IT use in elementary science tends to fall into the categories of email (Jarvis, Hargreaves, & Comber, 1997), the world wide web (Mistler & Songer, 2000), computer tutorials (Biemans, Deel, & Simons, 2001; Shimoda, White, & Frederiksen, 2002; Williams & Linn, 2002), computer tools such as word processing and publishing (Nason, Lloyd, & Ginns, 1996), and computer simulations (Barnett & Moran, 2002; Raghavan, Sartoris, & Glaser, 1998).

## ASSESSMENT IN ELEMENTARY SCIENCE

Assessment in science has come under considerable scrutiny in recent years (see Chapter 32). There were two notable research projects (Bell & Cowie, 2001a, 2001b; Black, Harrison, Lee, Marshall, & Wiliam, 2002) and a comprehensive discussion (Fraser & Tobin, 1998) on classroom assessment in science worth mentioning, even though they did not exclusively focus on the elementary school. A major study of formative assessment in grades 7–10 science was reported by Bell and Cowie (1997, 2001a, 2001b). The other, by Black and associates (Black et al., 2002), looked at assessment more generally. Both studies included the effect of teacher professional development in assessment.

### Formative Assessment

Teachers use formative assessment to gauge students' initial conceptions prior to teaching, their developing understandings, and progress toward learning goals, and to obtain feedback about their teaching to inform future teaching decisions (Bell & Cowie, 1997, 2001a). Others have highlighted that identifying elementary students' pre-instructional conceptions is an important part of formative assessment and is essential for deciding on subsequent pedagogy (e.g., Summers et al., 1998; Turner, 1997). Specific techniques, often adapted from research, have been used to elicit students' conceptions prior to and during a pedagogical sequence. These include concept maps (Stoddart, Abrams, Gasper, & Canaday, 2000), interviews (Turner, 1997), and drawings (Edens & Potter, 2003). Another technique for

eliciting preconceptions involved showing students a cartoon illustrating a science phenomenon, in which several students commented on what they thought would happen, or why it was happening (Keogh & Naylor, 1999). Students were asked to discuss the ideas presented and decide which idea might be better. These concept cartoons, as they were called, were found to be useful for identifying student conceptions and initiating subsequent student investigation sequences.

Others have advocated identifying students' conceptions as part of the normal pedagogical sequence rather than using a specific technique prior to commencing teaching. Pedagogical approaches discussed below that do this include the 5Es (Blank, 2000), KWHL (Iwasyk, 1997), and the interactive approach (Chin & Kayalvizhi, 2002; van Zee, Iwasyk, Kurose, Simpson, & Wild, 2001; Watts, Barber, & Alsop, 1997). A more general inquiry approach incorporating several investigative techniques embedded in pedagogical sequences was outlined by van Zee et al. (2001). Another strategy reported by Palmer (1995) was POE (Predict, Observe, Explain). Students' predictions about what would happen in a particular scenario and their explanations for why they made the prediction provided insights into their initial conceptions.

A caution was sounded by McGinn and Roth (1998), which was also reflected in the study by Jones, Carter, and Rua (2000), that strategies used to elicit students' conceptions influence what is revealed of students' ideas. That is, different strategies/techniques reveal different aspects of students' ideas. It is therefore unwise to over-rely on one specific technique for eliciting students' ideas, especially in research.

## Self-Assessment

Self-assessment has not been a major focus of elementary science research. Stow (1997) described grade 4/5 students using concept maps as a self-assessment tool. Benefits included motivation (on seeing learning growth, but dependent on successful completion of concept maps) and metacognition, in that "children . . . analyse[d] their own thinking, enabling them to identify their strengths and weaknesses and set themselves future learning targets" (p. 15).

## Summative Assessment

Traditionally, summative assessment has not been strongly emphasized in elementary science. When it has been conducted, teachers have often used end-on written tests that focus on recall, or students' recordings in science notebooks. There has been, however, a trend toward conceptual learning and therefore assessment of students' science understanding (Harlen, 1998). External, benchmarked testing has been a relatively recent occurrence that has stimulated some teachers into examining their own assessment practices. Many elementary teachers need considerable help in moving toward more effective assessment practices, particularly those that focus on conceptual learning.

An important principle recently advocated in assessment has been that assessment tasks must be authentic—that is, they should relate to the real world of the student in a meaningful way (Gitomer & Duschl, 1998; Kamen, 1996). With the notion of authenticity, there is the idea that assessment should be embedded as part of the pedagogy rather than tacked on at the end of a unit of work (Kamen, 1996). That

is, some formative assessment can be used effectively for summative purposes (Bell & Cowie, 1997, 2001a) and documented with the use of a system such as portfolios (Gitomer & Duschl, 1998). However, change in assessment practices cannot occur in isolation from other aspects of pedagogy and teachers' views of teaching and learning. As Kamen noted, "real reform for a teacher's practice comes from a deep understanding of conceptually based science learning" (p. 875).

## Assessment Techniques/Strategies

Traditional pen-and-paper tests, especially multiple-choice tests, are not necessarily the best way of ascertaining students' understanding in science. For instance, Nuthall and Alton-Lee (1995) found that students used a variety of strategies to answer test questions in science and social studies, including recall and deducing answers from related knowledge and experience. Totaled scores from such tests were not necessarily considered a measure of the students' learning. Regarding multiple-choice tests, Kamen (1996) concluded that, "[i]n many cases it is asking too much of a fourth-grade student to read a question about a difficult concept, read several answers written by someone else, and choose another person's best answer" (p. 869).

McGinn and Roth (1998) compared different assessment strategies with grade 6/7 students' understandings about levers, showing that students' responses varied according to the strategy and context. That is, the students' learning was context-dependent in a situated cognition sense. They noted that the students relied heavily on available resources in giving explanations for novel situations. Generalizations, they suggested, come after "individuals have great familiarity with a large number of contexts" (p. 829). They too were critical of standard pen-and-paper tests and suggested varied assessment techniques that contribute to the compilation of portfolios. Tytler (1998) also commented about situation-specific conceptions developed by students. This was further supported by Raghavan et al. (1998), who commented on how the assessment question used in their study showed the context-specific nature of learning. Students understood buoyancy in liquids, but some had not transferred this to fluids (balloons in air).

Jones, Carter, et al. (2000) also reported how different assessment techniques elicited different types of knowledge. Concept maps elicited pre-instructional schemas, multidimensional scaling and card sorting elicited conceptual organization for clusters of concepts, and interviews and class dyad discourse elicited processes and prior knowledge used in interpreting experiences. Choosing the most appropriate assessment techniques for the teaching/learning context is therefore critical.

Other summative assessment techniques and strategies reported include concept cartoons used by teachers for summative assessment (Keogh & Naylor, 1999) and concept maps. Stoddart et al. (2000) developed a system of analyzing concept maps for assessment purposes, using a rubric to quantify the quality of understanding demonstrated by the student in a concept map.

## A Final Caution

Summative assessment is frequently in a written form, but there are some reports of gendered differences in using this medium. For example, Warwick et al. (2003) noted

that boys, especially those in grade 7, had difficulty expressing their understanding in written form compared with the understanding evidenced in their speech. Boys therefore may under-perform in written assessment tasks, compared with girls, even though their understanding may be similar.

## PEDAGOGY FOR LEARNING IN SCIENCE

Pedagogy that leads to conceptual learning has been a dominant focus in research into elementary science teaching. This has arisen from the misconceptions research of the previous decade, the pre-eminence of constructivist views of learning, and reform movements such as the National Science Education Standards (National Research Council, 1996). There has been limited research into affective learning, despite theoretical views and research that recognize that affect and cognition are closely intertwined (e.g., Varelas et al., 2002).

### Inquiry

I have included inquiry because it is a key component of the U.S. standards (National Research Council, 1996) and because the term is used widely in the literature. However, there is considerable overlap with other sections in this chapter and other chapters in this *Handbook* (see Chapter 27), especially those dealing with specific strategies like the learning cycle (Parker, 2000). A difficulty is that there is no consensus on what constitutes inquiry, apart from attempts to define it in the standards—perhaps because it is a term that has been used extensively for many years. I personally find the notion of *working scientifically*, described in most Australian curricula (Curriculum Corporation, 1994), to be preferable. There is a close link between inquiry and the nature of science (see Chapter 28).

Butts and associates (D. P. Butts, Hofman, & Anderson, 1993, 1994), in their studies, demonstrated that hands-on experiences, of themselves, are insufficient to develop understandings in 5/6-year-olds. Specific pedagogical sequences involving exploration and discussion of ideas, “instructional conversations,” are also needed. Nor does mere engagement in inquiry ensure that students will learn about the nature of science (Khishfe & Abd-El-Khalick, 2002). An explicit, reflective focus on the nature of science needs to be included as part of the inquiry pedagogy for this to occur. However, this may be a cultural phenomenon, as Liu and Lederman (2002) found that gifted grade 7 Taiwanese students “appeared to have basic understandings on several aspects of NOS . . . [Even though] science is largely taught by delivering scientific facts written in textbooks as absolute knowledge” (p. 120).

Meyer and Woodruff (Meyer & Woodruff, 1997; Woodruff & Meyer, 1997) reported that students aged 8–13 engaged in generating explanations with a form of inquiry called “consensually driven explanations.” Students conducted activities and then discussed ideas/explanations in small groups; then these groups shared and justified their explanations (undergoing several cycles). Meyer and Woodruff saw this as a process of socially constructed knowledge-building.

An important part of inquiry is that the teacher is clear about the conceptual learning goals. Flick (1995) commented on how a grade 4 teacher taught inquiry with a conceptual focus, starting with students’ ideas and building on these. This

included her clear identification of what she wanted the students to learn. This is consistent with the research reported by Nuthall (2001).

Inquiry in the form of research-based projects is a common strategy (Nason et al., 1996), but there are uncertainties about its effectiveness (Nuthall, 1999, 2001). The learning tends to be superficial (Moje, Collazo, Carrillo, & Marx, 2001) and, according to Nason and associates, not conducive to conceptual learning, because the students focus on completing the project and therefore use superficial processing strategies. Furthermore, where students divide aspects of the task, Nuthall reports that the students only learn about the part of the task that they concentrated on, even though there may be in-group and whole-class sharing of findings.

The recent trends toward inquiry, conceptual learning, and standards have tended to cause teachers to scaffold or carefully structure lessons to maximize learning of target concepts. A cautionary note about highly structured pedagogy, however, was sounded by Tomkins and Tunnicliffe (2001), who found that, at least in some topics, sustained periods of undirected observation may later help students when formal instruction commences. This is consistent with constructivist views of learning.

## Conceptual Change

The notion of conceptual change had its origins in the misconceptions research that reached its heyday during the 1980s. It emerged initially as a cognitive conflict-based teaching strategy specifically designed to address the perceived problem of students developing misconceptions (e.g., Hewson, 1981). Subsequent research led to doubts about the efficacy of such strategies, leading to reconsiderations of the notion of conceptual change. Limón (2001) provided a comprehensive review of conceptual change research, and Chapter 2 in this *Handbook* also review the area. Georgiades (2000), among others, has taken the argument beyond cognitive conflict, suggesting that a more appropriate focus would be the transfer and durability of scientific concepts, through metacognition (also see Hewson, Beeth, & Thorley, 1998). Limón outlined three ways of initiating conceptual change that have been reported: cognitive conflict, sharing and justifying ideas, and using models and analogies. I would add a fourth: scaffolding a series of learning experiences that may include a mix of these and other activities (Appleton, 1997). A discussion of these four categories is used to structure the remainder of this section.

## Cognitive Conflict

Cognitive conflict originated in the Piagetian idea of disequilibrium (Piaget, 1978). Although comparative studies of teaching strategies based largely on cognitive conflict still occasionally surface, researchers over the last decade have realized the inadequacy of the strategy and have tended to include other teaching and learning experiences as well. Summarizing the situation in the special issue of *Learning and Instruction*, Caravita (2001) said that “cognitive conflict, although not disproved as the main condition producing reorganization of knowledge, is no longer seen as the result of crucial experience. It is considered as dependent on many psychological and personal factors that the instructional intervention can only partially address and control in the classroom” (p. 428).

There has also been discussion about whether misconceptions are consistent theories held by students, or are context-dependent, and therefore whether conceptual change entails major restructuring of schema. Tytler (1998) concluded that conceptual change is not necessarily a change of consistent theories, but that conceptions tend to be context-dependent and can sit alongside each other. He suggested that, because “the extension of a generalizable conception to new phenomena can involve significant difficulties related to the way situation-specific factors cue particular concepts . . . conceptual change should be viewed as a case-by-case phenomenon rather than an adjustment in mental structure” (p. 922), but this would depend on what is meant by “mental structure.” For instance, the neo-Piagetian idea of minitheories suggested by Claxton (1990) would be consistent with Tytler’s conclusion. Tytler also noted that older children are better at extending generalizations.

### Small-Group Interaction—Sharing Ideas

In contrast to the notion that cognitive conflict is necessary for conceptual change, researchers following a more social constructivist theoretical position suggest that students sharing ideas in science is a critical part of conceptual change, or, as most of these researchers would prefer, conceptual development. For instance, Carter, Jones, and Rua (2003) suggested that giving explanations to a group partner may affect students’ cognitive growth. Weaver (1996) concluded that hands-on activities combined with discussion and reflection can promote conceptual change and that learning is enhanced if students find the topics interesting and relevant to their daily lives or experience. Most reports about students sharing ideas have it as one component in a sequence of other experiences (see scaffolded instruction below). For instance, Meyer and Woodruff (Meyer & Woodruff, 1997; Woodruff & Meyer, 1997) incorporated into their pedagogical scaffold small-group work directed toward students’ deriving a consistent explanation of experiences. Mutual co-construction of explanations was a key component that they claimed mirrored discourse by scientists. Barnett and Morran (2002) also described a curriculum that scaffolded grade 5 students’ learning about the Earth-Moon system, using a structured sequence of activities that included opportunities for students to present their understandings to peers during class discussions and students reflecting on their own learning progress. They believed that “conceptual understanding is an evolutionary process that emerges from a complex interplay between prior understanding and the context in which learning occurs” (p. 860; see also diSessa & Minstrell, 1998). Similar approaches have been suggested by others (e.g., Beeth, 1998b; Carter et al., 2003; Fellows, 1994; Mason, 2001; Meyer & Woodruff, 1997; Woodruff & Meyer, 1997).

In mechanics, a quasi-experimental design with grade 5 students was used to explore the role of small-group interaction in conceptual change (Vosniadou, Ioannides, Dimitrakopoulou, & Papademetriou, 2001). They attributed the significant conceptual gains that they observed in the experimental group to “complex changes in . . . class dialogue . . . when the students are explaining their point of view, or when the teacher is obliged to explain what he means because these [*sic*] is no established common language between him and the children . . . [and] when the teacher uses empirical observations to lead children to induce theoretical abstractions” (p. 417). They referred to these processes as “negotiation of meaning” (p. 417) between teacher and students,, and between students. Whether this is possible with

younger students, such as first-graders, is not so clear. Shepardson (1996) reported how a grade 1 teacher appeared to hold views that her students could not engage in this type of activity, preferring to have them engage in activities that encouraged individual work, even though they were seated in small groups. Her interactions with the students also tended to be with individuals, rather than with groups. Her discourse with students focused on observations, thinking, science ideas, and terminology, rather than developing understanding. Whether the teacher's view reflected her own perceptions of her students' capability or what they were actually capable of is consequently unclear. Other studies (see below) suggest that young students are capable of developing understanding of science ideas.

Students giving explanations to peers in small groups needs careful consideration, as this may lead to rote learning by less able pupils who defer to those they see as more capable (Nuthall, 1999) or result in disrupted learning from some students' inability to negotiate their way through peer interactions during group work (Nuthall, 2001; see below).

## Models and Analogies

There is convincing evidence that, when used appropriately, analogies can enhance learning (e.g., Yanowitz, 2001). In another example, Heywood and Parker (1997) concluded that "combining, building on, moving between analogies and rigorous examination of ideas through practical activity enhances learning" (p. 882). However, they warned that the purposes of analogies may be perceived differently, depending on participants' views of learning in science, and that to be useful, the limitations of analogies must be recognized by participants.

Analogies and models can be teacher generated or student generated. Examples of effective teacher analogies used in elementary science include the following:

- Thorley and Woods (1997) described a specialist grade 5 teacher's conceptual change unit on electricity. A key component was student construction and evaluation of mental models. They concluded that analogies were valuable in helping students articulate "diffuse" theories about electricity.
- Barnett and Morran (2002) used computer models for the Earth-Moon system.
- Summers et al. (1998) reported how grade 7 students found a bicycle chain analogy for electric circuits helpful.
- Glynn and Takahashi (1998) used a text and graphic-based analogy of a cell (factory) to help grade 8 and 6 students successfully learn the functions of a cell.

Examples of encouraging the generation of student analogies include the following:

- Raghavan et al. (1998) had grade 6 students construct and test their own models of floating and sinking, using computer software.
- Penner, Giles, Lehrer, and Schauble (1997) described how grade 1–2 children constructed models of elbows. A design pedagogy was used so students could see for themselves the limitations of modeling. Penner et al. also discussed the application of the pedagogy to learning about the nature of science (specifically, modeling in science).

- Students' model building can take several other forms. Students in grades 4 and 5 who constructed their own drawings of ideas extracted from an explanatory text showed better conceptual understanding than those who copied an illustration and those who wrote a summary (Edens & Potter, 2003). Similarly, Gobert and Clement (1999) found that grade 5 students generating diagrams while reading expository text about plate tectonics reached a better understanding than those who merely read the text or who wrote summaries, even though the summaries contained more references to domain-specific information than the diagrams. Tomkins and Tunnicliffe (2001) highlighted the usefulness of students generating their own "mental models" from investigations, discussions, and reflective diaries when making predictions.

The effective use of analogies requires particular care in the development of appropriate pedagogy. For instance, Heywood and Parker (1997), who explored students' understanding of analogies of electricity, concluded that the base of the analogy must be within the students' experience for them to understand the target idea. Shepardson, Moje, and Kennard-McClelland (1994) highlighted how fifth-grade students had difficulty relating an experimental analogy on air pressure (a boiled egg being pushed into a milk bottle by air pressure) to their study of the weather. Boulter, Prain, and Armitage (1998), who reported a study of a Moon eclipse by 9–11-year-olds, commented on how students need to understand the characteristics of a model for its use to be effective:

[A]n individual would need an understanding of what a model is, an understanding of how analogies are formed and evaluated, and a knowledge of existing conceptual models in the same or other field. The evidence is that an understanding of these notions of model is slow to develop (Grosslight et al. 1991), that many people have little idea either of what the process of drawing an analogy involves or of what other models are already available (Duit 1991). (pp. 493–494)

Furthermore, Abell and Roth (1995), in a study of grade 5 students' learning about trophic relations in a terrarium community, emphasized that it is important for students to construct their own representations, such as diagrams and analogies, before the scientific model is presented.

### **Scaffolded Instruction (cf. Inquiry)**

Scaffolded instruction is based on the idea of cognitive development rather than cognitive change. All scaffolds begin with establishment of the students' pre-instructional conceptions and use a sequence of learning experiences that build on these ideas, usually helping students specifically consider how their ideas stand up to the evidence from investigations, the ideas of others, and scientific thinking (e.g., Abell & Roth, 1995). There also should be a focus on helping students clarify their learning goals and take ownership of their learning. For instance, Summers et al. (1998) told how a grade 7 teacher who had received intensive professional development used an effective scaffolding strategy by drawing on most of these principles. Fellows (1994, p. 999) concluded that the activities chosen must "directly relate to [the students'] initial conceptions and goal conceptions." However, scaffolded learning experiences that build on students' initial conceptions do not necessarily

ensure success. For instance, Brickhouse (1994) reported limited learning of shadow phenomena with a grade 3 class, in a study of light and shadows. The pedagogical sequence was devised collaboratively by the classroom teacher and a Curriculum Development Lab researcher and was taught by both. Given the expertise that went into the planning and delivery of the unit, the issue of what might be the most effective scaffolds for particular target understandings and initial conceptions, and how teachers can make appropriate choices between competing pedagogical ideas, is a major one. This is related to the teacher's science pedagogical content knowledge, and it highlights questions of how elementary teachers with limited science PCK can teach most effectively, how science PCK is communicated to other teachers, and the extent to which teacher guides and professional development can help teachers extend their science PCK (Appleton, 2006).

Making appropriate pedagogical choices is important. For instance, Shepardson (1997) highlighted how the pedagogy and experiences provided to students determine what they learn. He suggested that planning with the "bigger conceptual picture" in mind was necessary, and specific attention needs to be drawn to aspects of the object of study on which conceptual understandings can be built. This is problematic when many elementary teachers do not have a clear idea of what the bigger picture looks like and may not have a clear idea of what the students need to attend to.

An important consideration is that the scaffold must both link several lessons and structure the detail of each lesson. Appleton (1997, 2002) emphasized that "units that work" are necessary to adequately employ constructivist strategies. This is supported by Nuthall's (1999) work on student learning. Using carefully structured learning experiences to encourage active engagement by students in thinking about activities was also advocated by D. P. Butts et al. (1993, 1994).

Different *types* of scaffold, discussed below, are required to sequence lessons in a unit, sequence detail within a lesson, and make decisions about moment-by-moment lesson transactions.

*Scaffolding units of work by sequencing experiences and lessons.* Appleton (2002) suggested that there needs to be a focus on units that work that include a scaffolded lesson sequence (see, for example, Appleton, 1993; Huber & Moore, 2001). Examples such as the interactive approach are discussed below. Although cognitive conflict per se is no longer considered adequate to generate conceptual change, discrepant events that generate this have been a suggested component of a scaffolded sequence of lessons, usually as the initial lesson (e.g., Appleton, 1995; Meyer & Woodruff, 1997).

*Scaffolding strategies and experiences within lessons.* Scaffolded sequences may include experiences such as students

- expressing and supporting their ideas,
- making and testing hypotheses and predictions,
- investigating in small groups,
- comparing ideas, giving scientific explanations and suggesting models, and
- presenting and debating ideas and conclusions in the whole class (Vosniadou et al., 2001).

Teacher demonstrations and explanations can also be used effectively (Shepardson et al., 1994).

*Scaffolding lesson transactions.* Moment-by-moment interactions with students involve questioning, probing ideas, giving explanations, and the like (Appleton, 1997). This is a direct application of a teacher's science PCK (Appleton, 2006).

*Other components of a scaffold.* Student writing can be another important component of a scaffold (see also the section on writing). In a grade 5 conceptual change unit on electricity taught by a specialist teacher, students constructed and evaluated mental models (Thorley & Woods, 1997). Students first wrote explanations and then discussed them. Thorley and Woods commented, "it was not uncommon for [the students] to change their ideas in mid-discussion. Talking allowed them the opportunity to reassess what they had written and often produced a change in their perception of the problem, concept, or definition" (p. 241).

Teacher questioning can also play a critical role (Harlen, 1998). Beeth (1998b; Beeth & Hewson, 1999) reported how a highly effective teacher used a scaffold of questions to help students think about their activity work and relate it to their existing and developing ideas. The questions, which have a metacognitive emphasis, were

1. Can you state your own ideas?
2. Can you talk about why you are attracted to your ideas?
3. Are your ideas consistent?
4. Do you realise the limitations of your ideas and the possibility they might need to change?
5. Can you try to explain your ideas using physical models?
6. Can you explain the difference between understanding an idea and believing in an idea?
7. Can you apply intelligible and plausible to your own ideas? (Beeth, 1998b, p. 1093).

Three assertions about using teacher questions were made by van Zee et al. (2001):

- "We elicited student thinking by asking questions that develop conceptual understanding" (p. 176), in order to elicit students' experiences (e.g., "What can you tell me about the moon?" [p. 177]), and diagnose and further refine students' ideas (e.g., "What is your evidence for that idea?" [p. 177]).
- "We elicited student thinking by asking students to make their meanings clear, to explore various points of view in a neutral and respectful manner, and to monitor the discussion and their own thinking" (p. 178).
- "We elicited student thinking by practicing quietness as well as reflective questioning" (p. 181), that is, by using wait time, listening to students, providing information only as needed, and encouraging students to think things out for themselves.

***Scaffolded student material.*** Scaffolds have been constructed with the use of written materials and/or information technology. Sneider and Ohadi (1998) reported on teachers' use of an astronomy unit (Great Explorations in Math and Science) in grades 4–5 and 7–8, with a scaffolded pedagogy embedded in the written materials used by students. Teachers were provided professional development to support their teaching. There was evidence of considerable conceptual learning in students. In another study, a curriculum designed to scaffold (my term) grade 5 students' learning about the Earth-Moon system by a carefully structured sequence of activities incorporated "class discussions, whole and small group activities, individual activities, and three-dimensional (3-D) dynamic computer models" (Barnett & Morran, 2002, p. 859). The computer models were designed to develop understandings and build on what students already knew so they could relate new ideas to existing ones and experiences. Biemans et al. (2001) also reported the use of a computer-based scaffold for activating students' prior knowledge and supporting conceptual change as they processed expository text.

## **A Final Caveat on Scaffolding**

Scaffolding has become a popular notion in elementary science education, for many good reasons. For instance, it emerges from social constructivist views of learning that are almost universally supported, and there is research evidence that a scaffold used appropriately can enhance student achievement. However, when a scaffold is so directive that it inhibits learning for some students, there may be a problem. Warwick et al. (2003) raised this issue with respect to scaffolded writing in science used to enhance procedural understanding: "the question of 'scaffold or straightjacket' is an important one, particularly for higher ability pupils" (p. 184). Tomkins and Tunnicliffe (2001) also cautioned against the teacher being so intent and goal directed, that he/she does not listen to students and give them intellectual space: "If teachers take a less instrumental attitude to what is learned and allow a longer gestation time for considered pupil observation and familiarization, it may be conducive to allowing hypotheses to emerge more naturally. We assert that much of this 'pupil talk' or 'diary reflection', which is seemingly inconsequential, is in fact of considerable learning value" (p. 811). More research is needed on the nature and effectiveness of scaffolds for all students for units of work, lessons, and lesson interactions.

## **Metacognition**

A different emphasis on conceptual change not included in Caravita's (2001) categorization has been made by a number of others, who have drawn on the notion of metacognition as an aid to conceptual change. Beeth (1998a) reported how a metacognitive emphasis on the perceived status of ideas, using the notions of intelligibility and plausibility (Hewson & Thorley, 1989), can aid learning (see also Beeth, 1998b; Beeth & Hewson, 1999). Others (such as Blank, 2000; Hewson et al., 1998) have also supported a metacognitive emphasis in pedagogy. A relevant series of studies on metacognition in the junior high school, the Project to Enhance Effective Learning (PEEL) (e.g., Mitchell & Mitchell, 1997), has been omitted from this review.

## Writing

Writing is usually considered a complementary component to other pedagogies in elementary science and is frequently implemented in conjunction with students sharing ideas. This area has been extensively reported in the literature and is discussed in Chapter 3 of this volume. Writing, however, is an important part of the elementary school curriculum; so selected aspects of this research are touched on in this chapter. It is taken as a given that writing, used appropriately, may enhance students' conceptual learning in science. The reader may also wish to consult a comprehensive review of writing in science compiled by Rowell (1997) and the special issue of *Journal of Research in Science Teaching*.

### Writing Is Difficult for Pupils

Warwick, Linfield, and Stephenson (1999) reported that elementary school students find it easier to express science understandings verbally than in writing, partially because they and teachers have different purposes in speaking and writing. Providing more structure for students' writing tasks in science can help (see also Warwick et al., 2003, below). Patterson (2001) described ways to scaffold students' science writing during different aspects of writing and added to the claims that writing enhances understanding:

[f]or pupils at the early stages of literacy development, this research has demonstrated that support at the sentence level, through the provision of appropriate sentence connectives, can transform writing from descriptions and statements of facts to that which includes explanation. . . . Support at the text level is beneficial to pupils who are proficient at structuring sentences, but have difficulties organising their ideas into extended pieces of scientific writing. Context mapping has been shown to be an effective scaffold during the drafting stage of writing. (pp. 15–16)

In an attempt to help African American students engage more meaningfully with writing in science, Varelas et al. (2002) described a strategy that encouraged students to use genres familiar to them, such as rap songs and plays, instead of the more formal school science genres. They concluded that the strategy provided such students with an effective discourse genre that helped them construct meaning for the phenomena under study, but did not provide them with facility in scientific discourse.

### Science Notebooks

Science notebooks are used extensively in elementary schools in my state, Queensland, Australia. In my numerous discussions with elementary students, many have told me that they dislike science because of the large amount of writing that they have to do. This often constitutes copying notes (frequently using headings like "Aim, Equipment, Procedure, Results, Conclusions") from the chalkboard into their science notebooks. No wonder they are bored! If this entrenched tradition of science notebooks must continue, they need to be used more effectively for student learning. Even where notebooks are constructed by students themselves, they do not necessarily enhance learning. For instance, Baxter, Bass, and Glaser (2001) ex-

amined students' notebook recording of work on electric circuits in three grade 5 classes in two schools. Videotapes of lessons were also taken. No written feedback was given to students about their writing. They found that recording in notebooks "gave little indication of the quality of student thinking or understanding" (p. 138). Not surprisingly, what the students recorded in their notebooks was dependent on the classroom context: specifically, the teachers' directions and what the teacher attended to. Their conclusion was that

[w]e found that aspects of science instruction that teachers attend to (procedures, results) appear in some detail in students' notebooks, but the use of data recording as a platform for thoughtful reflection, hypothesis generating, and the synthesis of ideas was generally absent. Teachers use notebooks to monitor what students are doing, and students, when prompted by their teachers, use the notebooks to remind them of what they have done. (p. 138)

Similarly, other aspects of the classroom context that influence writing were reported in a study where students accessed a variety of written sources (Shepardson & Britsch, 2001). The students' journal writing was influenced by the available science texts.

Student-centered notebooks, also reported by others (Caswell & Lamon, 1998; Shepardson & Britsch, 2001; Tomkins & Tunnicliffe, 2001), can be effective if used by students as research journals to record their thinking and ideas. Usually, text is accompanied by students' drawings, diagrams (Edens & Potter, 2003), or concept maps. Computers may also be used to aid writing. In such writing tasks, consideration needs to be given to the age of the students, both in terms of their writing capability and in the ways that they interact with the world. For instance, Shepardson and Britsch (2001) described how young students contextualized their science experiences by relating to three different "worlds" or mental contexts: a) imagination, b) previous experience, and c) the science investigation itself. Although imaginative play is considered a legitimate component of informal early childhood classes, it is not usually endorsed in formal schooling, where the teacher's focus tends to be on the science investigation. Older students seem to be better attuned to the expectations of the teacher. For example, when older students were left to their own devices during a science investigation, they recorded observations including anatomical and behavioral features of animals (Tomkins & Tunnicliffe, 2001). That is, if students are familiar with a teacher-classroom culture, it is unnecessary to provide a "tight" scaffold for writing, especially in the early phases of a unit. Building on work by Gott and Duggan (1995), Warwick et al. (2003) used writing frames embedded in worksheets as prompts for grade 4, 6, and 7 students when planning investigations and recording results. They took a particular focus on teaching students about the use of evidence in drawing conclusions. The frames were varied to suit the age group. Examples of frames are (pp. 176–177):

- We are trying to find out. . . (gr. 4)
- We made the test fair by. . . (gr. 4)
- These results tell me that. . . (gr. 4)
- By carrying out these measurements we are able to find the connection between . . . and . . . (gr. 6)
- My results are accurate and reliable because. . . (gr. 7)

Warwick and associates (2003) concluded that discussion and collaboration focusing on the prompts in the frames were necessary for them to be effective—the worksheets could not just be handed to students. Furthermore, they concluded that,

[i]t is therefore essential for the teacher to:

- have a clear understanding of the objectives of the lesson;
- share both the learning objectives and the assessment criteria for the session with the pupils;
- be clear, in the structure of any writing frame, about which concepts of evidence are to be focused upon;
- understand his/her role in scaffolding the pupils' experience through use of the writing frame; and
- understand the central importance of social interaction to learning, and therefore to encourage pupil-pupil and pupil-teacher collaboration. (p. 182)

Even though the studies by Warwick et al. (2003) and Tomkins and Tunnicliffe (2001) differed in the degree of scaffold/support provided to students, a common component was the use of writing as a reflective tool, in which discussion played a major part.

## **Teacher Feedback**

It is commonly accepted that the teacher should provide written feedback on elementary students' writing in science, but this presents potential difficulties for both teachers and students. Owens (2001) studied the written feedback that four grade 4/5 teachers gave to three pieces of grade 5 student writing in science. One teacher was a science specialist. Owens reported that:

- No two teachers defined or used science writing in the same ways.
- Most teachers found responding to science writing to be a frustrating process.
- All of the teachers assumed the students could read and write non-fiction science paragraphs and were uncomfortable with evidence that this might not be the case.

She further concluded, "The teachers' individual definitions of science predisposed them to either accept or reject the processes of science writing as supportive of science learning" (p. 33).

## **Writing to Learn**

A key purpose for writing in elementary science is as an aid to arriving at conceptual understanding in science (e.g., Fellows, 1994; Mason, 2001; Tomkins & Tunnicliffe, 2001). Writing for understanding is usually part of a scaffolded sequence of experiences. Writing, however, can have multiple purposes. Mason (2001) described how students wrote on several occasions for different purposes, such as writing for prediction, expressing intuitive ideas on a topic, communicating what is temporarily understood or what puzzles, recording changes of ideas, and giving final explanations of a phenomenon. The students were told not to worry about

spelling, grammar, or even how good the idea was, as this writing was for a different purpose: learning science.

A key component of writing is to clearly identify the audience, which is usually the teacher. A different audience for some grade 6 students' writing reported by Fellows (1994) was themselves: they wrote notes to themselves, in order to explain their ideas. These notes were used as a basis for discussions with others. Fellows concluded, "writing ideas to themselves to explore and share informally with peers, reflecting on the ideas to reproduce new writing, and talk about the ideas with other students appeared to be important mechanisms for conceptual change" (pp. 998–999).

## Specific Strategies

A number of specific pedagogical approaches and strategies for elementary science have been reported in the literature. Some are related to conceptual change, and all have a conceptual learning focus. In this section I outline research on the use of some of these strategies.

***Dramas/simulations (often a specific type of model analogy).*** Bailey and Watson (1998) used a simulation game to develop ecological concepts in 11-year-olds. Affective development was an important component. A comparison of the experimental group's post-test scores on understandings with a control group suggests that the strategy was also highly successful in developing understanding. In a South African context, grade 5 students used both videotapes and comics portraying puppets working on problems and confronting common misconceptions (Rollnick, Jones, Perold, & Bahr, 1998). It was considered important to have both formats available to suit the variable resources available in South African elementary schools. The initiative was deemed successful in helping students learn science concepts. There are some parallels in this idea with Concept Cartoons (see Keogh & Naylor, 1999, below).

***Small-group work.*** Small-group work, preferably in a hands-on activity context, is an accepted practice in reform elementary science, partly because it is seen as analogous to high school laboratory work. However, small-group work, particularly where equipment is involved, can be difficult for some teachers because of management issues (e.g., Appleton & Kindt, 1997). Management problems can be reduced with the use of cooperative learning principles. For instance, Watters and Ginns (1997) told how a grade 4 teacher learned to use the *Primary Investigations* (Australian Academy of Science, 1994) cooperative learning strategy, involving defined roles for group members (manager, director, speaker). A confident but traditional teacher, she made the transition to small-group work in science and was enthusiastic about it. However, even though she successfully had the students working in small groups, she did not necessarily use strategies to develop understanding.

Small-group work can also be problematic for students in two ways: 1) where social interactions and/or cultural expectations subvert or interfere with learning (e.g., Gray, 1999; Kurth et al., 2002; Nuthall, 1999, 2001; Ritchie, 2002), and 2) where the students construct their own purpose, different from the teacher's, for the activity—such as to complete the worksheet or finish the activity first (Nuthall, 2001).

Tasker and Freyberg (1985) first highlighted this problem, but there has been limited subsequent research into how to resolve the issue. Both of these issues were also highlighted by Anderson, Holland, and Palincsar (1997), who noted that “interpersonal relationships among students and their interpretations of the task requirements led to the scientific activity being appropriated largely by the most academically successful member of the group” (p. 359). This raises the issue of status within groups, discussed below.

How students are grouped, and students’ status within the group, are important considerations. In studies of ability-paired dyads (by reading scores), Carter and Jones (Carter et al., 2003; Carter & Jones, 1994; Jones & Carter, 1994) concluded that grade 5 students achieved best when high-ability students were paired with low-ability students. There was no difference in the science achievement of high-ability students, whether they were paired with another high-ability student or a low-ability student, but the nature of their interactions differed considerably. In both cases, they had greater opportunity for speaking and working with equipment. However, low-ability students paired with a high-ability student achieved better than when paired with another low-ability student. Low-ability dyads tended to be off-task and inattentive when the teacher gave instructions, and spent considerable time negotiating group roles.

Rath and Brown (1996) identified six ways that students engage with materials during hands-on group work. Termed “modes of engagement” (p. 1087), they are:

- Exploration—Finding out about the phenomenon and studying its basic properties.
- Engineering—Using properties of the phenomenon to make something happen.
- Pet care—A personal connection to the object of study focused on nurturing.
- Procedural—Using the phenomenon as a support for imitation and step-following.
- Performance—Soliciting attention, using the phenomenon or object of study as a prop.
- Fantasy—An imaginative play activity that builds on some aspect of the phenomenon or object of study.

They cautioned that not all modes promote conceptual learning, and there may be cross-purposes between students in a small group. Some modes of engagement used by grade 2 and 5 students are gendered (Jones, Brader-Araje, et al., 2000). In the Jones, Brader-Araje et al. study, males tended to explore/tinker, whereas females tended to follow the teacher’s instructions. Social interactions within the group were related to these gendered modes of engagement, competition for materials, and competition for power and status (see also Nuthall, 2001; Ritchie, 2002).

In the elementary school, status of students can be attributed on the basis of perceived academic prowess or cultural factors. Consequently, students in the same group do not necessarily do the same thing, partially because of differences in social interactions and differences in whether and how they engage with the materials. Bianchini (1997) highlighted this in a study of a grade 6 life sciences class. Even with an experienced teacher using an accepted small-group model, access and achievement of all students was limited. She concluded that, “despite a curriculum and instructional strategy designed explicitly to meet the needs of those tradition-

ally positioned on the periphery of science, student differences in participation and in academic achievement remained" (p. 1062). Higher-status students in a small group, despite specific steps taken by the teacher, continually excluded low-status students. In a later report, she made three recommendations for refining group work to address status issues: "the consistent implementation of interventions designed to ameliorate status differences; the strategic assignment of procedural roles to ensure student access to group materials, discourse, and decisions; and the overturning of students' conventional notions of intelligence—what they think it means to be smart" (p. 577).

***Problem solving and discrepant events.*** Students working on genuine, puzzling problems (not the application of algorithms) can be an important component of a scaffold, especially as an initiating activity, though they have also been used at other critical times throughout a sequence of lessons (Meyer & Woodruff, 1997). One highly effective way of generating such problems within a classroom environment is to use discrepant or counterintuitive events. Discrepant events had their origins in Piagetian (Piaget, 1978) ideas of disequilibrium. Highly refined by Suchman (1966), they have been a consistent component of science pedagogy since (e.g., Friedl, 1995; Huber & Moore, 2001). Use of discrepant events has been recommended because they can be highly motivating (Friedl, 1995; Suchman, 1966), though the pedagogy in which they are used can have different effects on students' learning (Appleton, 1995). Appleton reported that a common behavior by students experiencing a discrepant event is to try to find a solution to the perceived problem(s) by relating the event to memories and seeking information. However, the information sources and strategies that they can use are constrained by the classroom context, in particular, the teaching strategies used. For instance, although the puzzling effect of a discrepant event that is conducted as a teacher demonstration may be high, students may have limited means of gaining further information about the problem because of the constraining effect of a highly teacher-controlled strategy. If the teacher provides an explanation immediately after demonstrating the discrepant event, learning is limited. By comparison, students working in small groups with the discrepant event have the opportunity to obtain information by discussing ideas and exploring the materials directly (see, for example, Huber & Moore, 2001).

## The Learning Cycle and Its Variations

The main pedagogical approach suggested in the *Science Curriculum Improvement Study* (SCIS) materials was called the learning cycle (Karplus & Thier, 1967). Over the years, this approach has remained both a valued pedagogy for inquiry and a subject of research. It has also been modified as a consequence of further consideration of constructivist ideas of learning (see below). Some argue that the approach or its variations should be used to structure a lesson (e.g., Koch, 2002); others argue that it should be used to structure a unit of work (e.g., Appleton, 1997).

The SCIS learning cycle had three main phases: exploration, concept introduction, and concept application. In revising the Learning Cycle, Barman (1997) suggested four phases: investigative, dialogue, application, and assessment, with constant evaluation and discussion being a central component. Another revision (Blank, 2000) had a metacognitive emphasis, resulting in four phases: concept exploration,

concept introduction/status check, concept application/status check, and concept assessment/status check. The notion of status introduced here reflects the idea that different concepts are ascribed different levels of status by learners, with intelligibility and plausibility influencing this (see also Beeth, 1998a). A key component of Blank's first phase was students making explicit their prior knowledge of the topic, which sets the scene for later consideration of the status of their developing ideas. In a comparison study with students using the SCIS strategy, Blank concluded that, although students using the revised strategy did not show greater content knowledge, they did experience more permanent restructuring of their understandings.

Another version of the SCIS approach, called the 5Es model, has become popular for scaffolding units of work in science (Appleton, 1997) and has been used in curriculum projects like *Science for Life and Living* (BSCS, 1992) and the Australian adaptation, *Primary Investigations* (Australian Academy of Science, 1994). Derived from constructivist considerations, it has been described in detail by Bybee (1997) and has been the subject of some studies (e.g., Boddy, Watson, & Aubusson, 2003). The 5Es approach derives its name from the five phases: engagement, exploration, explanation, elaboration, and evaluation. Boddy et al. (2003) reported that "[s]tudents found the unit of work fun and interesting and were motivated to learn while others said they were interested and motivated because they were learning . . . [and that] the unit of work . . . promoted higher-order thinking" (p. 40).

## Students' Questions

Using students' questions as a basis for science investigations in the elementary school is a form of curriculum negotiation and is an attempt, in part, to address the confusion over the purpose of investigations discussed earlier. This work builds on earlier studies of the interactive approach (also called question raising) in the Learning in Science (Primary) Project (Biddulph & Osborne, 1984) and has been advocated by a number of authors since (e.g., Appleton, 1997; Flear & Hardy, 2002; Gallas, 1995).

Keys (1998) explored the reasoning strategies of grade 6 students as they created their own questions and plans for investigations. Ideas for questions came from varying the initiating activity or from the students' own imaginations. Some questions led to experimental investigations (variables), and some to descriptive investigations (describing characteristics of events). Reasoning included translating ideas embedded in the questions into physical objects/events. Keys reported that the students' ability to control variables varied, so teachers had to change their practice to encourage social interaction and encourage students to evaluate their choice of variables. Management of different groups pursuing different questions was problematic for the teachers. Another issue for the teachers was that they had to accept the fact that not all students would learn the same thing.

Others (Chin & Kayalvizhi, 2002; Gibson, 1998; Iwasyk, 1997; van Zee et al., 2001; Watts et al., 1997) have explored eliciting students' questions to initiate investigations. Grade 6 (Chin & Kayalvizhi) and grade 1 (Watts et al.) students asked questions better suited to investigations after their teachers provided examples. Group discussion also helped. The teacher providing an introductory focus was also useful (Watts et al.), though not necessary (Chin & Kayalvizhi). Iwasyk (1997)

added a variation to question-raising by having kindergarten and grade 1 students also discussing answers to their questions as they investigated them. In groups, a student acted as “teacher” or “leader,” and the others asked questions as part of a discussion to clarify ideas. She used a strategy, KWHL, to structure the unit—K (What do I Know about), W (What do I Want to know about), H (How can I find out about), L (What did I Learn about). KWHL was also used to elicit students’ questions and encourage discussion of their answers in another study (van Zee et al., 2001). They identified four conditions that encouraged students to raise questions:

- setting “up discourse structures [KWHL, brainstorming] that explicitly elicit questions” (p. 166),
- engaging “students in conversations about familiar contexts in which they had made many observations over a long time period” (p. 168),
- creating “comfortable discourse environments in which students could try to understand one another’s thinking” (p. 171), and
- establishing “small groups where students were collaborating with one another” (p. 174).

Gibson (1998) described another variation of the approach by having students suggest and discuss answers to other students’ questions.

### Identifying Students’ Initial Ideas

This is a common theme in many teaching approaches emergent from constructivist thinking and from the 1980s misconceptions research. It is a basic plank of many approaches, such as the conceptual change approaches, as well as the 5Es, KWHL, and interactive approaches. A variety of techniques have been suggested that can be used to identify students’ pre-instructional ideas for guiding subsequent teaching. Summers et al. (1998), for instance, reported how a grade 7 teacher actively sought students’ ideas and used these as a basis for her teaching. There was evidence of effective learning. Other possible strategies for eliciting students’ ideas include the following:

- Open-ended teacher questions can be effective (Harlen, 1998), particularly if the teacher probes students’ answers for deeper explanations.
- Students raising questions provides a window into their existing ideas (Iwasyk, 1997; Watts et al., 1997). Asking them to also suggest answers/explanations provides even better windows (Gibson, 1998). See also the original work by Biddulph and Osborne (1984).
- Turner (1997) reported how teachers used interviews and observations of students’ explorations to research students’ ideas about food and health during professional development sessions. The teachers saw this as a useful pedagogical tool to find out what the students knew and used it to shape subsequent pedagogy.
- Keogh and Naylor (1999) reported on the use of concept cartoons to identify student conceptions, generate student discussion of ideas, and subsequent investigations exploring alternative ideas.

- Concept maps were used to identify student understandings (Stoddart et al., 2000).
- Students' drawings were used to access their ideas (Edens & Potter, 2003). Having students explain their drawings is even more effective.

## FUTURE RESEARCH DIRECTIONS

The research reviewed in this chapter has demonstrated that considerable gains in our understanding about the teaching/learning nexus in elementary science have been revealed over the last decade. Given the impetus in this research, it will doubtless continue over the coming decade, with further potential to inform elementary science curriculum and pedagogy.

Over the last few years, research into the benefits or otherwise of standards reforms have begun to appear in the literature. Further work is needed, including research that has a focus on:

- curriculum design—especially integration,
- conceptual learning,
- identifying clear learning goals,
- determining appropriate scaffolds for pedagogy in different contexts,
- assessment in authentic contexts,
- reporting student progress to carers and parents,
- the validity and appropriateness of large-scale testing and possible alternatives,
- helping teachers make pedagogical shifts arising from the above, and
- ways of introducing large-scale change in elementary science teaching in education systems that are cost-effective.

As mentioned in the introduction to this chapter, there has been little research in elementary science that has been conducted to inform and shape policy. This is not to say that the research being conducted is not valuable, and cannot be used to inform policy. Perhaps one way forward is to engage in research in partnership with policy-makers so there is a greater likelihood that research questions that they feel are valuable are addressed, and they are more likely to be aware of the research findings and recognise their validity.

In preparing this review, I noticed that much of the research was conducted in upper elementary science classes, that is, was situated in the middle school. The number of studies of grades 1 to 3 was relatively small in comparison, either because fewer studies are being conducted at these grade levels, or because they are being reported in early childhood journals that I missed. If there are fewer studies, this could be because elementary science researchers:

- have a greater interest in middle school science compared with science in the early grades;
- do not feel that they have expertise in the early grades;
- find it more difficult to collect reliable data in early grades, compared with middle school grades;

- have difficulty framing worthwhile questions for research into science in early grades; or
- do not consider science learning and teaching in early grades so important and worth studying.

There clearly needs to be more research into science in the early grades (Fleer, 2006), especially to explore aspects such as curriculum integration, theoretical frameworks for research, learning in the early grades, and pedagogy to enhance learning.

## ACKNOWLEDGMENTS

Thanks to Valerie Akerson and Keith Skamp, who reviewed this chapter.

# CHAPTER 19

---

## Interdisciplinary Science Teaching

**Charlene M. Czerniak**

*University of Toledo*

Although the topic of curriculum integration has been around for more than 100 years, its popularity among educators has been renewed in the last few years. The notion of connecting subject areas has substantial face validity, because it makes common sense. In real life, people do not separate their daily tasks into separate subjects; therefore, it seems only rational that subject areas should not be separated in our schools.

Some authors propose that the integration of subject areas helps students learn to think critically and develop a general core of knowledge necessary for success in the future (Carnegie Council on Adolescent Development, 1989). Curriculum integration advocates speak of the numerous advantages integration offers in helping students form deeper understandings, see the “big” picture, make curriculum relevant to students, build connections among central concepts, and become interested and motivated in school (Berlin, 1994; George, 1996; Mason, 1996). Advocates also maintain that curriculum integration is supported by societal reasons; traditional curriculum is not relevant to students and does not concentrate on genuine problems and issues.

Those who back curriculum integration also assert that it is anchored in psychology and human development. In defining constructivism, Brooks and Brooks (1993) remark that deep understanding is formed when students make connections between prior knowledge and new experiences—meaningful learning occurs when they see relationships among ideas. Cohen (1995) asserts that thematic teaching is supported by brain research, and Beane (1996) states that people process information through patterns and connections rather than through fragmented snippets of information.

However, after a century of calls for integrated approaches, some educators question the merit of integration and cite the paucity of research supporting it over traditional methods. Educators attempting to implement an integrated curriculum confront this critical issue and a number of other equally important ones. In this

chapter, a brief history of curriculum integration is provided, and various issues are discussed, including the lack of a consistent definition of integration, the role of integration in school curriculum, advantages and disadvantages associated with integration, and problems commonly encountered in trying to implement an integrated curriculum. These issues are critical to the understanding and implementation of integration and present areas for future research that can help elucidate the value of integrated approaches.

## RATIONALE

Justification can be found in the literature to support both traditional subject matter separation and integrated curriculum. Academic scholars have traditionally structured knowledge within the major disciplines recognizable today (science, mathematics, social sciences, and language arts). Some academics believe that academic disciplines are a powerful way to organize knowledge. For instance, Gardner and Boix-Mansilla (1994) declare that academic disciplines “constitute the most sophisticated ways yet developed for thinking about and investigating issues that have long fascinated and perplexed thoughtful individuals . . . (and) they become, when used relevantly, our keenest lenses on the world” (pp. 16–17). Educators who desire to keep subject disciplines separate fear that attempts to integrate subjects sometimes result in topics being left out of the curriculum and gaps in student understanding of important concepts. Berlin and White (1992) reported that Wingspread conference participants feared that the merging of the disciplines might cause people to lose important philosophical, methodological, and historical differences between the two subjects.

In contrast, others (e.g., Perkins, 1991) considered academic disciplines as “artificial partitions with historical roots of limited contemporary significance.” Mason (1996) described the present-day school curriculum as moribund—a regression to the factory system, where students proceed down a hallway to the next class. Mason pointed out that although our factories today have changed, our schools remain out of sync with society and real life, where knowledge and skills are not separated. Some stress that the curriculum needs to be transformed because science is divided into 25,000 to 30,000 research fields, and data generated by this research is presented in over 70,000 scientific publications (Hurd, 1991). Science is no longer differentiated by distinct disciplinary lines such as biology, chemistry, geology, and physics, and demarcations between the sciences are blurred to form new fields such as geophysics and computational chemistry. Hurd recommended that science educators integrate the science curricula, because science in daily life is not separated or compartmentalized. He argued that traditional discipline-bound, fact-laden science courses are too narrow in scope to teach students how to learn in today’s world, where science, technology, and societal issues are all interrelated.

McBride and Silverman (1991) summarized literature on integration of science and mathematics dating to the early twentieth century and concluded with four primary reasons for integrating the subjects:

1. Science and mathematics are closely related systems of thought and are naturally correlated in the physical world.

2. Science can provide students with concrete examples of abstract mathematical ideas that can improve learning of mathematics concepts.
3. Mathematics can enable students to achieve deeper understanding of science concepts by providing ways to quantify and explain science relationships.
4. Science activities illustrating mathematics concepts can provide relevancy and motivation for learning mathematics. (pp. 286–287)

## BRIEF HISTORY

Although disciplinary knowledge has been developed for centuries and shapes the basis for exploring a particular area of knowledge, integration of subject areas has also been discussed for over 100 years. Berlin (1994) noted that since the early twentieth century the School Science and Mathematics Association has published numerous articles on the topic. In 1903, as Moore was retiring as president of the American Mathematical Society, he provided momentum to the reform efforts of that time by devoting part of his presidential address to mathematics in secondary education. He called for “the unification of pure and applied mathematics” and “the correlation of the different subjects” (Moore, 1967). Beane (1996) summarized several historical references to integration during the progressive era in U.S. education in Kilpatrick’s work in the 1920s, Hopkin’s efforts in 1937, and writings of John Dewey in the 1930s. A 1927 third-grade integrated unit on the study of boats on the Hudson River in New York is outlined in Cremin’s (1964) book. Beane states that the word *integration* first appeared in *Education Index* in 1936.

Hurley (1999) summarized several additional periods in U.S. history where integration was used: the core curriculum in the 1940s and 1950s, the curriculum improvement projects in the 1960s and 1970s, the science-technology-society (STS) movement in the 1980s and 1990s, the middle school movement, and most recently the national standards established by various professional organizations.

For science education, the curriculum improvement projects were a particularly important period in history where curriculum integration took a foothold. Lehman (1994) stated that numerous curriculum projects were developed with the intent to integrate science and mathematics. Examples of projects (and contemporary offshoots) designed to integrate the curriculum include the Minnesota Mathematics and Science Project (Minnemast, 1970), the Unified Science and Mathematics for Elementary Schools Project (USMES, 1973), Nuffield (1967), Lawrence Hall of Science’s Great Explorations in Math and Science Project (GEMS) (Lawrence Hall of Science, 1984), Fresno Pacific College’s Activities That Integrate Mathematics and Science (AIMS Educational Foundation, 1986, 1987), and the University of Chicago’s Teaching Integrated Mathematics and Science Project (TIMS) (Institute for Mathematics and Science Education, 1995).

### Middle School and Early Childhood Education Movement

Curriculum integration is a cornerstone of efforts aimed at creating schools focused on the developmental needs of students. The National Association for the Educa-

tion of Young Children (NAEYC) and the National Middle School Association (NMSA), organizations specializing in instructional practices appropriate for the education of young children and young and early adolescents, respectively, publish numerous materials to guide teachers in the selection and use of materials for young children and adolescents. Curriculum integration is stressed in various NAEYC reports (1987), and the NMSA book titled *A Middle School Curriculum: From Rhetoric to Reality* (Beane, 1993, 1997) argues for integration around personal and social concerns that interest adolescents and young adults. *This We Believe* (NMSA, 1982, 1995) argues for developmentally responsive middle schools where curriculum is challenging, integrative, and exploratory. Numerous NMSA resources support curriculum integration (Bean, 1997; Brazee & Capelluti, 1995; Erb, 2001; Nesin & Lounsbury, 1999; Smith, 2001; Stevenson & Carr, 1993), and the *Middle School Journal* devotes considerable space to articles on curriculum integration (see, for example, the November 2001 issue).

## National Standards

In the last decade, almost all national reform efforts have stressed the need to make connections among subject areas (National Council of Teachers of English, 1996; National Council of Teachers of Mathematics [NCTM], 1989, 2000; National Council for the Social Studies [NCSS], 1994; National Research Council [NRC], 1989; NRC, 1996; National Science Teachers Association [NSTA], 1996; Rutherford & Ahlgren, 1990). Integration or thematic instruction is often used as a key idea in school reform efforts. The BSCS group (1994) summarized in a questionnaire ten common reform strands, and thematic instruction is one of the common elements of reform. For example, Crane (1991) described a restructured high school science curriculum focused on four themes of change, interactions, energy, and patterns. Similarly, Greene (1991) described a science-centered reform at the elementary school level.

In the early 1990s, the NSTA's *Scope, Sequence and Coordination* project (NSTA, 1992) recommended replacing traditional high school discipline curricula with four years of integrated science. In 1996, NSTA published a position statement on interdisciplinary learning in grades PreK–4 that represented the thinking of members of a variety of professional organizations (NCTM, NCTE, IRA, NSTA, NCSS, Speech Communication Association, and Council for Elementary Science International) that met to develop guidelines for integrating curriculum. This position statement addressed some of the matters raised by Berlin and White's (1994) integrated science and mathematics model, because it focused on ways of learning and knowing, process and thinking skills, content knowledge, attitudes and perceptions, and teaching strategies.

The national standards movement in the last ten years has once again increased emphasis on integration. *Science for All Americans* states, "The alliance between science and mathematics has a long history, dating back centuries. Science provides mathematics with interesting problems to investigate, and mathematics provides science with powerful tools to use in analyzing them" (pp. 16–18). The National Science Education Standards (NRC, 1996) maintain, "Curricula often will integrate topics from different subject-matter areas—such as life and physical sciences—from different content standards—such as life sciences and science in personal and social

perspectives—and from different school subjects—such as science and mathematics, science and language arts, or science and history” (p. 23). The Science Education Teaching Standards (NRC, 1996) declare, “Schools must restructure schedules so that teachers can use blocks of time, interdisciplinary strategies and field experiences to give students many opportunities to engage in serious scientific investigation as an integral part of their science learning” (p. 44). Finally, the Science Education Content Standards (NRC, 1996) state, “The standard for unifying concepts and processes is presented for grades K–12, because the understanding and abilities associated with major conceptual and procedural schemes need to be developed over an entire education, and the unifying concepts and processes transcend disciplinary boundaries” (p. 104).

NCTM (2000) emphasizes, “School mathematics experiences at all levels should include opportunities to learn about mathematics by working on problems arising in contexts outside of mathematics. These connections can be to other subject areas and disciplines as well as to students’ daily lives” (p. 65).

The National Council for the Social Studies (NCSS, 1994) cautions against integration for its own sake, stressing, “Unless [programs] are developed as plans for accomplishing major social studies goals, such programs may focus on trivial or disconnected information” (pp. 165–166), but NCSS has also published resources promoting integration that is in alignment with the NCSS Standards. For example, Sandmann and Ahern’s (2002) book, *Linking Literature with Life*, is a resource for integrating the NCSS standards and children’s literature for middle grades. The Science-Technology-Society (STS) movement in the 1980s and 1990s also renewed the call for integration, with particular emphasis on the societal implications of science and technology.

Elementary educators viewed the whole language movement in the 1990s as a way to integrate across content areas (Willis, 1992). Others advocate the use of language arts strategies to help teachers develop science literacy (Akerson, 2001; Dickinson & Young, 1998). Dickinson and Young (1998) comment that science and language arts goals are complementary, and language arts can provide the tools for science inquiry.

Some educators claim that technology serves as a catalyst for integration across the curriculum (Berger, 1994), and recent studies suggest that technology has enhanced integration between science and mathematics by facilitating collaboration, providing real-world contexts for problem solving, removing limits on instructional time, and offering students opportunities to apply knowledge to real problems (Pang & Good, 2000).

## Focus in Teacher Education

One criticism of teaching in an integrated fashion is that teachers aren’t prepared to teach this way. Hurley (2003) mentioned that although there have been appeals for integrated approaches for years, it is only a recent development that integrated methods courses have been offered at universities. The need to be skilled in integrated approaches is underscored in the National Science Education Standards, which state, “Integrated and thematic approaches to curriculum can be powerful; however they require skill and understanding in their design and implementation” (p. 213).

With teacher education in mind, Hurley conducted a study examining the presence, value, and reasoning behind universities offering integrated science and mathematics methods courses. The reasons those universities reported offering integrated methods courses include new state and national standards, program reorganization, constructivist reforms, and the literature on integration. Akerson (2001) also affirms that educators have implemented integrated curricular ideas into their methods courses at universities in an effort to help teachers meet the state and national standards. Beane (1996) declared that integration is now found in university courses and even college degrees.

### UNFOCUSED DEFINITION

Despite the plea for integration, many have argued that few empirical research studies support the assertion that integrated approaches are more effective than traditional, discipline-based teaching. A summary of articles from the 1991 Wingspread conference on integration found that of 423 articles summarized, 99 were related to theory and research, and only 22 were research-based articles (Berlin, 1994). Lederman and Niess (1997) echoed concerns that research supporting the use of integrated instruction or thematic curricula is almost nonexistent. Czerniak, Weber, Sandmann, and Ahern (1999) summarized literature on the integration of science and mathematics with other subject areas and concluded that there are few empirical studies to support the notion that an integrated curriculum is any better than a well-designed traditional curriculum.

A possible explanation for the dearth of empirical research on integration is a conceptual one that clouds the generation of research questions. At the fundamental level, a common definition of integration does not seem to exist that can be used as a basis for designing, carrying out, and interpreting results of research. Davison, Miller, and Metheny (1995) appealed for a definition of integration, stating, "Few educators would argue about the need for an interwoven, cross-disciplinary curriculum, but to many, the nature of the integration in many interdisciplinary projects is not readily apparent. A more pervasive problem is that integration means different things to different educators" (p. 226). Hurley (2001, 2003) concluded after a comprehensive study, however, that an agreed-upon definition of integration could not be found.

Despite Davison, Miller, and Metheny's (1995) request for clarification, this elusiveness is evident in the sheer number of words used to convey integration: *interdisciplinary*, *multidisciplinary*, *transdisciplinary*, *thematic*, *integrated*, *connected*, *nested*, *sequenced*, *shared*, *webbed*, *threaded*, *immersed*, *networked*, *blended*, *unified*, *coordinated*, and *fused*. Lederman and Niess's (1997) editorial in *School Science and Mathematics* explained that many educators use the terms *integrated*, *interdisciplinary*, and *thematic* synonymously, and this only compounds the confusion and limits the ability to adequately research the topic.

The tendency to use the words *integrated*, *interdisciplinary*, and *thematic* synonymously may be a result of the fact that little agreement exists regarding the definition of integration. Berlin and White (1992) reported that a group of 60 scientists, mathematicians, science and mathematics educators, teachers, curriculum developers, educational technologists, and psychologists assembled at a conference funded by the National Science Foundation (NSF) were unable, after three days of deliber-

ation, to reach a consensus on the definition of integration of science and mathematics. The group proposed an operational definition: "Integration infuses mathematical methods in science and scientific methods into mathematics such that it becomes indistinguishable as to whether it is mathematics or science" (p. 341).

Historical references to integration (Hopkins, 1937, as cited in Beane, 1996) defined integration as problem-centered, integrated knowledge. Beane (1996) used four characteristics to define integration: (a) curriculum that is organized around problems and issues that are of personal and social significance in the real world, (b) use of relevant knowledge in the context of topic without regard for subject lines, (c) knowledge that is used to study an existing problem rather than for a test or grade level outcome, and (d) emphasis placed on projects and activities with real application of knowledge and problem solving. He maintained that other forms of integrated curriculum (such as parallel disciplines or multidisciplinary curricula) still focus on separate content areas and, therefore, are not fully integrated.

To distinguish between *integration* and other terms, Lederman and Niess (1997) defined *integration* as a blending of science and mathematics to the point that the separate parts are indiscernible. The metaphor of tomato soup was used: The tomatoes cannot be distinguished from the water or other ingredients in the soup. They defined *interdisciplinary* as a blending of science and mathematics where connections are made between the subjects, but the two subjects remain identifiable. The metaphor used is chicken noodle soup, where you can still distinguish the broth, chicken, and noodles. Jacobs (1989) described interdisciplinary as "a knowledge view and curriculum approach that consciously applies methodology and language from more than one discipline to examine a central theme, issue, problem, topic, or experience." Lederman and Niess (1997) defined *thematic* as a unifying topic used to transcend traditional subject boundaries.

## INTEGRATED CURRICULUM DESIGN

Educators espousing integration have provided a variety of curriculum design options. Beane (1995) recommended that curriculum integration must have social meaning, and, therefore, design begins with "problems, issues and concerns posed by life itself" (p. 616). The notion of organizing a science and mathematics curriculum around projects as a relevant way to connect science, mathematics, and events outside of the classroom was a consensus of the NSF-sponsored Wingspread conference (Berlin & White, 1992). Venville, Wallace, Rennie, and Malone (1998) identified technology-based projects, competitions, and local community projects as forms of curriculum integration. More recently project-based science has been suggested as a methodology for curriculum integration because its key features (driving questions, student engagement in investigations, communities of learners collaborating together, use of technology, and creation of artifacts) are all congruent with integrated approaches. Rakow and Vasquez (1998) stated, "Project-based integration may be the most authentic form of cross-curricular integration because it involves students in real-world learning experiences. In project-based integration, students investigate real issues in real contexts."

Jacobs is well known for her work on curriculum integration. In 1989, she presented a continuum of curriculum design options that move from discipline-based to parallel disciplines, multidisciplinary and interdisciplinary units or courses, inte-

grated day, and complete program integration. Underhill's (1995) editorial illustrated six perspectives on science and mathematics integration that echo some of the alternatives presented in Jacob's (1989) continuum: math and science are disjointed; there is some overlap between science and math; math and science are the same; math is a subset of science; science is a subset of math; and there is major overlap between science and mathematics. Brown and Wall (1976) presented a similar vision of science and mathematics integration in which mathematics and science (on opposite ends of the continuum) are taught for their own sake; science is guided by math; math is guided by science; or science and mathematics are blended with each other.

Davison, Miller, and Metheny (1995) identified five different models of integration: discipline specific (i.e., two or more branches of science—integrating life and chemical science), content specific (combining related objects from several disciplines—combining mathematics with science), process (using skills such as collecting data, analyzing data, and reporting results to examine real-life situations), methodological (i.e., the learning cycle model as a good way to solve problems in science), and thematic (selecting a theme, such as sharks, and teaching academic concepts around the theme). Projects such as AIMS and GEMS are good commercial examples of curricula that focus on integrating science and mathematics by using process skills, such as observing, classifying, and analyzing (Roebuck & Warden, 1998).

A similar continuum of integration for science and mathematics, ranging through independent mathematics, mathematics focus, balanced mathematics and science, science focus, and independent science, was developed by Lonning and DeFranco (1997) and Lonning, DeFranco, and Weinland (1998). They suggested that readers should ask two questions when planning an integrated curriculum: "What are the major mathematics and science concepts being taught in the activity?" and "Are these concepts worthwhile? That is, are they key elements in the curricula and meaningful to students?" (p. 214). Likewise, Huntley (1998) presented a mathematics and science continuum on which the ends of the spectrum represent separate subject area teaching and the center represents integration of the two subjects. However, Huntley extended the Lonning and DeFranco model by emphasizing that the center point, integration, occurs only when science and mathematics are dealt with in a synergistic fashion. Francis (1996) extended the mathematics and science continuum by proposing a connections matrix that integrated mathematics and science standards to integrate the curriculum.

Hurley (2001) conducted a study to determine the types of integration that have historically been used and found five major types of integration: sequenced (science and mathematics are planned and taught one preceding the other); parallel (science and mathematics are planned and taught together); partial (the subjects are taught separately as well as integrated); enhanced (one of the subjects is the major discipline being taught and the other is added to enhance the other); and total (science and mathematics are taught equally together). She found that no form of integration ever totally dominated in any period of history from the 1940s to 1990s.

## RESEARCH ON INTEGRATION

Most of the literature on curriculum integration could be characterized as testimonials, how-to's, or unit/activity ideas. For example, a thematic approach is used in

all K–8 classrooms where teachers report student excitement and the teacher’s cooperative spirit (Peters, Schubeck, & Hopkins, 1995). School Science and Mathematics Integrated Lessons (SSMILES) are published in *School Science and Mathematics*. For example, McDonald and Czerniak (1998) describe activities developed to integrate science and mathematics around the theme of sharks. Descriptions abound of integrated methods, units, and processes used with preservice and inservice teachers and K–12 students (Francis & Underhill, 1996; Sandmann, Weber, Czerniak, and Ahern, 1999; Stuessy, 1993). Some articles discuss integrated arts and science undergraduate courses (Deeds, Allen, Callen, & Wood, 2000).

In the last five years, a greater amount of research-based literature has surfaced focusing on integration. Concerned with the lack of empirical evidence supporting the integration of science and mathematics, Hurley (2001) used mixed methodology to review 31 studies with reported outcomes conducted between 1935 and 1997. She used Study Effect Meta-analytic (SEM) methods to review the quantitative aspects of these studies, and she used grounded theory to analyze the qualitative portions of these studies. Hurley’s review found quantitative evidence favoring integration and qualitative evidence revealing the existence of multiple forms of integration. Most of the published empirical research studies on integration reviewed in this chapter support its use. A number of K–12 studies sustain the notion that integration helps students learn, motivates students, and helps build problem-solving skills. Studies regarding teachers’ reactions to integration focus on teacher beliefs and attitudes, subject matter knowledge, and obstacles faced when in the implementation of integrated approaches.

## Student Achievement and Affective Gains

Meier, Nicol, and Cobbs (1998) state, “Without evidence that integration will produce improved student performance in mathematics and science, little change can be expected” (p. 439). This call for research that provides evidence of student performance through the use of integration has been met somewhat in the last few years.

Green (1991) reported that student achievement scores significantly improved after a year-long restructuring to connect science to all subject areas. Seventy-eight percent of students had improved NAEP scores in science, exceeding the NAEP nationwide figures. Teachers and principals also reported success with educationally disadvantaged students and indicated that real-world integration accelerated the rate of language acquisition for bilingual students. Stevenson and Carr (1993) reported increased student interest and achievement in integrated instruction. Similarly, Vars (1991) and Beane (1995) reported that interdisciplinary programs produced higher standardized achievement scores than did separate-subject curriculum. These authors also acknowledged that the interdisciplinary curriculum is frequently embedded into other reforms such as block scheduling and multi-age grouping, and therefore it is difficult to separate the effects of integration from those of other reform strategies. Zwick and Miller (1996) found that Native American students using an outdoor-based integrated science curriculum outperformed their peers using a traditional curriculum on the California Achievement Test 85 (CAT). Similarly, McGehee (2001) described the development of a problem-solving framework

for interdisciplinary units used with minority students in a northern Arizona summer academy that found evidence of student success based on artifacts from student projects.

Studies that examined student gains made in curriculum improvement projects or a commercial integrated curriculum convey positive results. Shann (1977) explored the effect of the Unified Science and Mathematics for Elementary Schools (USMES) program and noted an increase in students' content knowledge and problem-solving skills. Additionally, there was an increase in students' self-worth, socialization ability, and excitement for learning. Goldberg and Wagreich (1989) report increased academic achievement in the Teaching Integrated Mathematics and Science (TIMS) program. Similarly, Berlin and Hillen (1994) report increased cognitive, motivational, and attitudinal outcomes for fourth-, fifth-, and sixth-graders using the Activities Integrating Mathematics and Science (AIMS) program.

A number of studies focused on affective gains made in the use of integrated curricula. Friend (1985) reported that students exhibited an appreciation of science as a result of an integrated mathematics/science program. McComas (1993) and Bragow, Gragow, and Smith (1995) confirmed that thematic units had a positive impact on student attitudes and interest in school. Barb and Landa (1997) state that when focused on a problem worth solving, interdisciplinary units motivate students to learn. Integrated science and reading instruction was also found to affect motivation (Guthrie, Wigfield, & VonSecker, 2000).

Hurley (2001) conducted a comprehensive study of integrated curricula from the early twentieth century to the present. Small student achievement effect sizes were found for both science and mathematics in studies from the 1930s to 1950s, and medium effect sizes were found for studies in the 1960s and 1970s (mostly curriculum improvement projects). Small effect sizes were found for studies published in the 1980s and 1990s. Student achievement effects were higher for science than for mathematics in integrated courses, especially when mathematics was used to enhance science or when the two subjects were totally integrated. Student achievement effects were higher for mathematics when mathematics was planned in sequence with science, but the subjects were taught separately—first mathematics and then science. Qualitative analyses found positive evidence for integration, attendance, student enthusiasm, and student engagement.

Hurley's (2001) meta-analyses of the effect of each type of integration on student achievement revealed differences. Sequential instruction resulted in positive effect sizes for science and mathematics, with mathematics effect sizes being larger. Parallel (but separate) integration had negative effect sizes for both science and mathematics, indicating that students achieved more in traditional instruction. Partially integrated and partially separate integration had small positive effects for science and mathematics. Enhanced instruction had a medium positive effect size for science and small effect sizes for mathematics. Total integration of science and mathematics had a large effect size for science and a small effect size for mathematics.

It may be more difficult to flesh out the effectiveness of integration on college-age students because of the limited number of integrated programs in universities, but McComas and Wang (1998) summarized a few studies of college-age students that demonstrated greater achievement or interest in science when it was presented as an integrated program rather than a traditional sequence.

## Teacher Knowledge and Attitudes

A number of studies examined teachers' knowledge of and attitudes toward using integrated strategies. Although integrated techniques have been used for years in pre-K–12 schools, the integrated teacher education methods course at the university level is a more recent phenomenon. Nonetheless, studies can be found at both the preservice and inservice levels, but the findings for the effectiveness of integration are mixed.

### Preservice Teachers

Conclusions from earlier studies of preservice teachers were based more on anecdotal examinations than outcome measures. For example, Lehman and McDonald (1988) studied the perceptions of preservice teachers toward integrated mathematics and science and found that preservice teachers had a greater familiarity with integration than practicing teachers, and mathematics teachers were concerned with covering the curriculum if they used an integrated approach. Lonning and DeFranco (1994) developed an integrated science and mathematics methods course, and anecdotal surveys and course evaluations indicated that students' attitudes toward the course were positive and students were enthusiastic about the course. Haigh and Rehfeld (1995) described the integration of a secondary mathematics and science methods course, and they report that surveys of students' opinions were generally favorable. Although the authors describe how they evaluated the course, no evidence is provided as to the merits of integration over separate courses.

Briscoe and Stout (1996) describe the integration of math and science through a problem-centered methods course. Using data from qualitative analyses, the authors describe problems preservice teachers had with problem solving, but it is unclear whether or how these were different from learning problem solving in separate mathematics and science methods courses. Kotar, Guenter, Metzger, and Overholt (1998) describe a teacher education model for curriculum integration that they used at California State University, Chico, but no evidence is provided about the effectiveness of the model. Conversely, Stuessy and Naizer (1996) report gains in reflection and problem solving after students completed an integrated mathematics and science methods course.

In a study of a team-taught middle-level mathematics and science methods course, Koirala and Bowman (2003) found that preservice teachers appreciated the emphasis on integration and had a better understanding of integration. An absence of integration was sometimes found because some science and mathematics concepts did not lend themselves to integration. As a result, students were frustrated at the tension between subjects. Furthermore, students at some middle schools seldom taught in an integrated fashion in their field experiences or student teaching, and these students tended to lose their appreciation for integration. In contrast, Hart (2002) studied preservice teachers' beliefs and practice after participating in an integrated mathematics/science methods course and found that beliefs and teachers' reported classroom teaching behaviors were consistent with program and reform goals.

Hurley (2003) studied methods course offerings and found that most universities reported that their integrated science and mathematics methods courses were

summer courses, grant-funded projects, or experimental. Few universities had integrated courses at the time of study, but several had integrated science and mathematics Master's degree programs. Hurley's study found that surveyed universities' reported successes included teachers gaining science and mathematics concepts and reasoning, positive preservice teacher attitudes and enthusiasm, improvement in higher order thinking skills in science, improved teacher reflectivity, and success in connecting theory to practice. Failures and challenges included difficulties in communication among teaching partners, lower higher order thinking skills in math, teachers' lack of content knowledge to integrate, overcoming influence of supervising teachers in field experiences, mathematics attitudes transferring to science, concern about coverage of curriculum, and challenges with enacting reforms.

## Inservice Teachers

Few studies on inservice teacher education focused on teacher knowledge or pedagogical skill. More commonly, studies reported teacher beliefs and attitudes. Again, findings are mixed regarding the effectiveness of integrated strategies.

In one of the few studies on teacher knowledge and instructional skill, Basista, Tomlin, Pennington, and Pugh (2001) evaluated an integrated professional development program and found significant gains in understanding of content and confidence to implement integrated science and mathematics in their teaching. Similarly, Basista and Mathews (2002) discovered that a professional development program for middle grades science and mathematics teachers (intensive summer institute, academic year support, and administrator workshops) increased teachers' content and integration knowledge, increased pedagogical knowledge and implementation, increased administrator awareness of science and mathematics standards, and helped support teachers as they implemented practices during the school year. Teachers in a collaborative professional development project that integrated science with mathematics, using language arts and technology, displayed increased levels of competence and confidence in the use of technology to teach science and mathematics (Cleland, Wetzel, Zambo, Buss, & Rillero, 1999).

Differential effects on students were found, depending on how the teacher implemented integrated curriculum and instruction. Waldrip (2001) found that primary teachers perceived that they implemented integration in their classrooms, but the actual level of implementation influenced the students' learning. Use of a science theme without strong connections to language and mathematics was less effective, whereas strong connections to other subject areas helped studies attain a deeper level of understanding.

To a greater extent, the research on inservice teachers focused on their beliefs, attitudes, and perceived barriers of integration. Watanabe and Huntley (1998) reported that mathematics and science educators in a NSF-funded project had many of the same beliefs about integration as other classroom teachers. Middle-level mathematics and science teachers thought that connecting mathematics and science helps students with tangible examples of mathematics, that math helps students become familiar with science relationships, and that connections provide relevancy and incentive for students.

Teachers in a Maryland NSF-funded project saw some barriers to integrated instruction, including the conflict over time in the school day and coverage of con-

tent, students not desiring to see connections between the subjects, the teacher's lack of subject matter knowledge in both subjects, and teachers feeling uncomfortable with teaching the subject for which they were not originally prepared or certified (Watanabe & Huntley, 1998). Likewise, Keys (2003) reported that despite holding similar beliefs, elementary teachers used integration to compensate for lack of knowledge to teach science, whereas secondary teachers did not consider integration because it limited the amount of time needed to cover the curriculum. Wieseman and Moscovici (2003) also describe the challenges that inservice teachers face when implementing interdisciplinary approaches.

Czerniak, Lumpe, and Haney (1999) found that teachers generally have positive beliefs concerning the use of thematic units, but negative attitudes toward integration also exist. In general, K–12 teachers believed that thematic units in the classroom have the ability to foster student excitement and interest in learning science. Although some teachers believe that integration can make science more meaningful to students because students see connections between the sciences and other subject areas, others were concerned that thematic units would water down the curriculum. Teachers were concerned that it would be time consuming and difficult to use thematic units, especially because integrated curriculum materials are not abundant. The teachers specified that a number of variables would be needed (but unlikely to be available) to help them use thematic units (resources including funding, curriculum materials, supplies and equipment; staff development; less emphasis on testing and assessment; team teaching; administrative support; and a course of study that stressed integration). Although not surprising, it was revealed that teachers of lower grade levels have greater intentions to implement thematic units in their classrooms than teachers of upper grade levels.

Finally, in a study conducted among 400 schools in Missouri, Arredondo and Rucinski (1996) discovered differences among rural and low-SES schools regarding curriculum integration. They found that a high percentage of rural, low-SES schools are not involved in any type of curriculum integration. In schools where there is a high use of integrated curriculum, teachers reported greater involvement in decision-making processes at the school—perhaps indicating their involvement in school reform efforts.

## DISADVANTAGES OF CURRICULUM INTEGRATION

Critics of integration purport that there is insignificant evidence to support the belief that integrated approaches are any more effective than traditional, separate subjects. George (1996) summarized assertions about integration not corroborated by research:

1. Addresses the real-life concerns of students better than traditional curriculum
2. Presents greater opportunities for problem solving
3. Promotes student's independent learning
4. Offers more effective involvement with the environment and society
5. Provides more opportunities for student involvement in planning the curriculum along with the teacher

6. Allows teachers more opportunity to be “facilitators of learning”
7. Permits learning in greater depth; makes deeper connections
8. Presents students with opportunities to capitalize on prior learning more effectively
9. Allows for more application of curriculum outcomes to real life
10. Supplies more concrete experiences for slower learners or more enrichment opportunities for more able students
11. Encourages greater transfer or retention of learned information
12. More effectively rejuvenates and energizes career teachers with new experiences
13. Helps provide greater achievement, personal development, or harmonious group citizenship

From a theoretical perspective, Lederman and Niess (1997) commented that research on integrated instruction seems to demonstrate that science and mathematics instruction is severely restricted because the concepts included are narrowed to a specific framework. Evidence of this, they stated, is the disappointing achievement results associated with the STS approach. The argument was made that each discipline possesses unique conceptual, procedural, and epistemological differences that cannot be addressed through an integrated approach, and thus it is preferred that connections be made among topics, with each subject area retaining its own identity.

Roth's (1994) experience teaching a fifth-grade unit around the theme of 1492 supports Lederman and Niess's assertions. Roth's experiences were frustrating, because the science content was confined to the theme, and attempts to integrate science into the theme often distorted and diminished the science content she hoped to teach. Davison, Miller, and Metheny (1995) asked the following questions in reference to concerns about integration of mathematics and science: “1) To what extent can these integration efforts represent bona fide integration of science and mathematics? 2) To what extent has the integration of science and mathematics been merely cosmetic?” (p. 226).

Mason (1996) listed a number of logistical problems that may be disadvantages for using integrated strategies. For instance, mathematics concepts are sequential, and adding mathematics concepts as bits and pieces in the curriculum could confuse students if they lack the prerequisite knowledge and skills. In other words, adding mathematics here and there for the sake of integrating might leave wide gaps in the subject matter and student understanding. Additionally, Mason described a typical example of integration at the elementary school level, such as “the rain forest,” and argued that students are typically asked to graph the number of endangered species. He cast doubt on the value of making dozens of graphs. Mason also asserts that many teachers, in an effort to force integration, trivialize the content. For example, “A poem about photosynthesis may not help one understand photosynthesis as a process, or poetry as a genre” (p. 266). Gardner and Boix-Mansilla (1994) concur with Mason by stating that prerequisite skills are often needed before students can use an integrated curriculum, and schools typically do not have time to both teach skills and put them in an integrated curriculum.

Thus, if integration becomes contrived and formed around trivial themes, children may not have the prerequisite background. The *Professional Standards for Teach-*

*ing Mathematics* state, “The content is unquestionably a critical consideration in appraising the value of a particular task” (NCTM, 1991). Despite the fact that NCTM stresses content, Roebuck and Warden (1998) declare that few curriculum materials use the content of science or mathematics as a focus of integration. Lonning and DeFranco (1997) maintain that integration is justified only when connecting science and mathematics concepts enhances the understanding of the subject areas. To avoid a shallow curriculum that lacks meaning, they suggest that some concepts and skills are better taught separately. They advised that teachers should avoid forced integration. Similarly, the National Council for the Social Studies (1994) warned:

Integrative aspects have the potential for enhancing the scope and power of social studies. They also, however, have the potential for undermining its coherence and thrust as a curriculum component that addresses unique citizen education goals. Consequently, programs that feature a great deal of integration of social studies with other school subjects—even programs ostensibly built around social studies as the core of the curriculum—do not necessarily create powerful social studies learning. Unless they are developed as plans for accomplishing major social studies goals, such programs may focus on trivial or disconnected information. (pp. 165–166)

Several research studies support the claim that integration is no more effective than well-planned traditional curricula. St. Clair and Hough (1992) stated that few studies support interdisciplinary curriculum results in gains in student achievement. Similarly, Merrill (2001) found no significant achievement gains in high school students exposed to an integrated technology, mathematics, and science curricula.

## **Obstacles to Enacting Integrated Units**

One of the true tests of any educational idea is that it can be successfully implemented in schools. McBride and Silverman (1991) cautioned that a number of problems must be addressed before integrated instruction becomes commonplace:

1. In most schools, students formally encounter the science and mathematics curricula organized and taught as separate subjects.
2. More instructional time is required to teach mathematics concepts through science concepts.
3. Classroom management can be more complicated when students are engaged in integrated science and mathematics activities than when they are solely engaged in whole class mathematics instruction.
4. Many teachers do not have science materials to utilize in mathematics instruction.
5. Few teachers have access to or are aware of curriculum materials that integrate science and mathematics.

Meier, Nicol, and Cobbs (1998) also pointed out that there are a number of barriers to integration: the content barrier (science and mathematics topics don’t always integrate well without one subject leaving gaps), teacher knowledge barrier (secondary teachers prepared in one subject, state licensure often isn’t integrated,

elementary teachers have limited subject matter knowledge about how to integrate), teacher belief barrier (inservice teachers think the curriculum is already crowded; preservice teachers don't know about integrated curriculum; and math teachers are less likely to integrate than science teachers), school structure barriers (schedules, different teachers without common planning time, tracking students, supplies/materials, and assessment), and curriculum barriers (standardized tests cover separate subjects, don't measure higher order thinking skills associated with integration).

Lehman (1994) discovered that in spite of positive perceptions about integration, teachers' views do not carry over into their practice. Teachers often believed there was no time to add integrated ideas into an already overcrowded curriculum, and they were not aware of integrated resources. Similarly, Watanabe and Huntley (1998) reported that although teachers in the Maryland Collaborative for Teacher Preparation had positive attitudes about connecting science and mathematics, some had problems enacting the curriculum. Some teachers were concerned with the amount of time it took to infuse integration into an already crammed curriculum. To counter the content coverage concern, Beane (1995) maintains that the separate subject curriculum is already too dense and not everything is covered now. He argued that curriculum integration allows the most important and powerful ideas in the discipline to surface. Pang and Good (2000) mention that the current U.S. curriculum is already fragmented and unfocused, and therefore any attempts to integrate a coherent content would be difficult.

Concerns about time may be related to the structure of the school day—especially in high schools where the organization does not allow time or structure to integrate (Jacobs, 1989; Venville, Wallace, Rennie, & Malone, 1998). Unless teachers team teach (an approach popular in middle schools), they rarely have the opportunity to work with other teachers outside of their discipline (Mason, 1996). More recently, block scheduling is seen as a format that allows for reforms such as integration (Canady & Rettig, 1996).

In summarizing Lynn A. Steen's presentation at the 1991 Wingspread conference, Berlin (1994) cited inadequate teacher preparation as one cause for lack of integration. Steen declared that few science teachers, with maybe the exception of chemistry and physics teachers, have enough mathematical background to integrate advanced mathematics with science, and few mathematics teachers would be able to teach even one science subject area. Similarly, Lehman (1994) stated that less than 50% of 221 preservice and inservice teachers surveyed believed they had sufficient content background to integrate science and mathematics. Mason (1996) also suggested that many teachers do not know how to create an integrated curriculum, and, thus, teacher education may be one problem contributing to the limited implementation of integrated curriculum (Roebuck & Warden, 1998). Generally, preservice teachers do not take integrated classes in their general studies, and they do not experience integrated methods. As a result, they do not know how to integrate across the curriculum (Mason, 1996). In most states, teachers (especially secondary teachers) are licensed in specific disciplines and, therefore, do not possess the knowledge needed to integrate with other subject areas.

Student assessment is viewed as an impediment to enacting an integrated curriculum, since standardized tests measure, for the most part, disciplinary knowledge (Berlin & White, 1992; Mason, 1996). Although the standards movement (NCTM, NRC, NCSS, NCTE/IRA) is moving along disciplinary lines, it encourages

integration. Standards and tests, however, do not exist for integrated ideas, and as a result, national trends will likely fail to support integration—especially with testing guidelines established in the No Child Left Behind legislation (<http://www.nochildleftbehind.gov>).

Finally, a few studies indicate that curriculum integration poses difficulties for teachers that might affect the quality of instruction. McGehee (2001) summarized problems that occurred among instructors teaching together and found that instructors needed to work out issues among themselves (i.e., some dominating lectures and separating their subject area). Hurley (2001) discovered that integration of science and mathematics took more time, was a challenge to teachers, and resulted in less time being spent on mathematics. She also observed that integrated courses developed by classroom teachers were less effective in affecting student achievement than commercially designed curriculum materials.

## CONCLUSION

A number of implications can be drawn from this literature review. These implications provide foci for science educators to provide leadership in clarifying issues, challenging basic assumptions, and solving problems associated with integrating science with other subject areas. In spite of a plethora of literature about the benefits of curriculum integration and some recent research-based studies to support this belief, additional research would be useful to verify these benefits and determine whether the results can be used to inform school-based practices.

There continues to be a lack of consensus regarding the definition of integration. Models presented in the October 1998 special issue of *School Science and Mathematics* provide a catalyst for this discussion, but the debate continues (Hurley 2001, 2003; Pang and Good, 2000). Elucidation of definitions may help science educators eliminate confusion when discussing curriculum and instructional approaches that endeavor to integrate curriculum. Moreover, a clear-cut definition could provide the stimulus for the design and completion of further research regarding the impact of integrated curriculum.

A few STS and project-based curriculum projects focus on issues as a means to integrate across the curriculum and make science relevant to real life. However, most integrated curricula, particularly commercial curricula, concentrate on process skills and give little attention to using science or mathematics content as the curriculum's central focus. Thus, the implication is that educators continue to search for good curriculum materials that provide sufficient, high-quality science and mathematics content.

Problems regarding the structure of the school day need to be overcome before integration becomes commonplace in schools. In the last few years, many U.S. schools turned to block scheduling as a way to provide teachers, particularly at the middle, junior, and high school levels, with larger portions of time to teach (Canady, 1995; Canady & Rettig, 1996). The block schedule typically provides a 90-minute segment of time rather than the traditional 45- or 50-minute class periods, and this format may give teachers the time needed to integrate the curriculum.

Hurley (2003) identified some benefits of teacher education models designed to prepare teachers to integrate the curriculum but also noted that integrated methods

courses are atypical. A few new studies support curriculum integration in professional development models (Basista, Tomlin, Pennington, & Pugh, 2001; Basista & Mathews, 2002). To better prepare preservice and inservice teachers to design and implement integrated units, they must be familiar with state and national reform recommendations, receive instruction in the integration of science and mathematics, and learn about integrated curriculum resources. It is also important that teachers experience courses where team teaching is used so that they have a better understanding of the collaborative processes needed to enact integrated strategies (Lehman, 1994; Mason, 1996).

The pressure of high-stakes standardized tests continues to be a limiting factor in implementing an integrated curriculum, and recent No Child Left Behind legislation may only exacerbate the problem. Because most standardized tests examine content separately, educators are doubtful about whether the knowledge and skills learned in an integrated fashion would transfer to these tests. One may conclude that for integration to be widely accepted in a standards environment, either standardized tests need to measure knowledge and skills associated with learning in an integrated manner or integrated units developed commercially and by teachers need to contain assessments consistent with those in the standards and on high-stakes tests.

It is paradoxical that despite the interest in integrated approaches over the last 100 years, standards today for each discipline remain separate (e.g., NCTM, NRC's *National Science Education Standards*, NCTE/IRA, and NCSS). If progress is to be made in moving integrated instruction into the mainstream, discussions need to occur among leaders of professional organizations to establish standards for integrating content areas.

Finally, Pang and Good (2000) perhaps best summarize the challenges surrounding attempts to integrate across the curriculum and the need for additional research:

These issues suggest that integration of mathematics and science is one of the most daunting tasks educators face. There is no magic formula for completing the task except collaborative efforts among various disciplines and personnel. The more communication is opened about successes and failures of integration, the more significant progress can be made toward identifying what teachers are expected to teach and students are expected to learn through integrated curricula. In order to help all students become more scientifically and mathematically literate, a goal most reform documents advocate, more focused attention about integration of curriculum and instruction is necessary. (p. 78)

## High School Biology Curricula Development: Implementation, Teaching, and Evaluation from the Twentieth to the Twenty-First Century

**Reuven Lazarowitz**

*IIT, Israeli Institute of Technology, Haifa, Israel*

This chapter is divided into two sections. The first part provides a description of the high school biology curricula taught in the twentieth century and presents the factors, which in the author's opinion, have contributed to the creation of these different study programs, based on the rationale described by Tyler (1960). The development of high school biology curricula during the past century will be depicted on the basis of two assumptions: one, that there is a high correlation among biology research, biology content structure, and biology high school curricula; and two, that new high school curricula in biology were affected by changes in society's daily life, in the high school student populations, research in science education in biology, and learning theories and pedagogy. All of these changes required modifications in the education of pre-service and in-service biology teachers; the latter issue is beyond the scope of this chapter. This section includes a short report based on selected studies of formative and summative evaluations, which investigated the implementation of the new programs in teaching biology in high school.

The second section encompasses several subjects investigated in teaching and learning biology that have had an impact on students' achievement in the cognitive, affective, and psychomotor domains. Because the new biology curricula emphasize

the teaching of concepts and principles, the subjects were selected according to their relation to the "unifying themes in biology" (Schwab, 1963, p. 31), the seven levels of biological organization (Schwab, 1963, pp. 15, 16, 17), and the "fundamentals themes" in Nuffield Biology (Nuffield Foundation, 1966, p. 1). This section concludes with suggestions as to what kinds of curricula, learning materials in biology, and types of studies we need in order to address the issues of student heterogeneity in our schools, as well as their needs, interests and abilities, in order for them to master the knowledge and skills needed to cope with our highly scientific and technological society.

### TYLER'S RATIONALE FOR CURRICULUM DEVELOPMENT

Based on Tyler's Rationale for Curriculum Development, the concept of a course of study can be defined as a sequence of planned science topics to be taught in relation to a specific subject matter, for a particular age group of students, accompanied by recommendations as to what to teach in the classroom and laboratory. The planned curriculum recommends several textbooks written according to its organization, with suggested modes of instruction, learning, evaluation, and grading of students.

In 1960 Tyler published a monograph titled *Basic Principles of Curriculum and Instruction*, which was later revised by Madaus and Stufflebeam (1989). The study grew out of the problems brought on by the depression, one of which was the great increase in the number of youth attending high school (many of whom would have preferred to go to work but were unable to find employment) (Tyler, 1966). The motivation of the study was an attempt to define three key points with respect to qualitative education:

1. *Clarification of purpose*, which included a) selection of learning experiences, b) the organization of these experiences, and c) the assessment of progress toward the attainment of the school's objectives.
2. *A program's objectives should be clarified through the learner's studies and studies of contemporary life.*
3. *Objectives should then be screened through a) the school's philosophy of education, b) theories of learning, and c) suggestions from subject matter specialists.*

Four divisions of curriculum inquiry were outlined:

1. What educational purposes should the school seek to attain?
2. What educational experiences can be provided that are likely to help attain these objectives?
3. How can these educational experiences be effectively organized?
4. How can we determine whether these objectives are being met? (Tyler, 1966)

Tyler's Rationale for Curriculum Development (1966) served as a tool for analyzing high school biology curricula developed in the twentieth century.

## SECTION I: A DESCRIPTION OF THE HIGH SCHOOL BIOLOGY CURRICULA OF THE TWENTIETH CENTURY

### **The Content-Oriented Curriculum in Biology**

The first science study program, which we refer to as “the content-oriented curriculum,” prevailed from the beginning of the twentieth century until the 1960s. It was characterized by its content structure sequence. The sequence of the science topics reflected the syllabi of the courses taught at the university level (DeHart Hurd, 1961) and represented the patterns and processes used in science research at that time, and the content knowledge structure (CKS) of any particular science as it was known.

In the field of biology the main body of knowledge included major topics such as invertebrates and vertebrates in zoology, lower and higher plants in botany, and the structure of the human body. Each organism was presented in sequence as to its morphology, anatomy, physiology, growth, development, and reproduction. Various aspects of their relationships with the environment were mentioned together within a classification approach. Each organism was introduced with a short description of the cell structure and function. This information could be found at the beginning of each textbook. Microbiology, genetics, ecology, and evolution were complementary subjects. The main biology research was aimed at learning about organisms and their classification, with the appropriate physiology aspects as far as the current knowledge in chemistry and physics permitted. This was the biology CKS of the curriculum, which was reflected in the textbooks. The textbooks depicted a sequence of cells from unicellular to multicellular organisms at different levels of sophistication.

### **Research in Biology that Affected the CKS**

The research in cell theory, for instance, was based on a sequence of technology developments, starting with the development of microscopes and what they allowed people to see. Zacharias Janssen built the first simple microscope with only one set of lenses in 1590. Following this, in 1670 Anton van Leeuwenhoek developed a microscope that could magnify objects as much as 270 times, enabling him to see bacteria, protozoa, sperm cells, red blood cells, and yeast cells. In 1665, Robert Hooke, who was a physicist, put two sets of lenses together, thus building a compound microscope. He examined a thin piece of cork and found that it was built of walled structures; he named these empty boxes “cells.” Based on these earlier technologies, in 1831, Robert Brown found that in living plant cells, small spherical structures could be detected, and he decided to call these nuclei. In 1838 Matthias Schleiden concluded that all plants are composed of cells. During the same period Theodor Schwann, while studying animal tissues, came to the conclusion that animals are also built of cells. One can see that there is a strong correlation between the technologies developed at that time and the possibility of more sophisticated research in biology. Thus, already in the nineteenth century a reciprocal impact existed between research in science and technological development. Any separation between the two, thereafter, has been artificial and the result of people’s decisions alone.

Another factor that had great influence on the development of the science of biology's content structure were the advances in maritime technologies that made possible the great global expeditions led by two scientists: a) Carolus Linnaeus (1707–1778), a Swedish botanist and zoologist who firmly established the binomial system of plant and animal nomenclature in the 1750s; and b) Charles Darwin (1809–1882), a naturalist who while on the ship the *Beagle* traveled around the world between 1831 and 1836 and collected a vast number of specimens of skeletons and creatures. On his return, and based on his collections, he made public a notebook, which contained his observations on the changes of species. *Origin of Species*, published in 1859, had an enormous effect on human thought. This was the most significant book of the nineteenth century (Alexander, 1953, p. 204). Consequently, the research conducted by biologists helped them develop theories on the sequence of evolution of plants and animals, and their classification, anatomy, physiology, reproduction, and genetics. One may say that all of this research was primarily based on the two monumental works published by Linnaeus and Darwin. It also formed the biological sciences content knowledge structure that existed until the 1960s. This SCK was the foundation of the science programs taught at universities and in high school science classes, and all of the textbooks students in both places used reflected it.

### **Content-Oriented Curriculum and Methods of Instruction**

The modes of instruction used in this type of curriculum, the first generation of the high school curriculum, were primarily expository. Teachers lectured and asked questions, while students had to listen and sometimes were allowed to answer. Student-student interactions in the learning process or any process of inquiry rarely occurred. One may therefore conclude that listening and memorization skills were emphasized rather than skills of learning, or seeking for knowledge, exchanging ideas, taking responsibility, etc. This was a teacher-centered instructional activity in which students remained passive. In the late 1980s Shulman (1987) defined the subject matter of the curriculum as content knowledge (CK). The nature of laboratory work was essentially aimed at proving what had already been learned (Lazarowitz & Tamir, 1994). Evaluation and grading procedures were based on tests with open questions in which students were asked to write their answer in a narrative mode; few tests used multiple-choice questions. The questionnaires referred mainly to the cognitive levels of knowledge and understanding. Higher cognitive levels such as application, analysis, synthesis, and evaluation were mostly ignored. Most of the examinations and tests were assessed in a summative approach and used only for grading purposes.

In Fig. 20.1, the structure of the content-oriented curriculum in biology, as it was used in many countries, is presented with its suggested sequence of the subjects to be taught in high school (grades 9–12), as was customary from 1900 to 1965. Whereas in the United States biology was taught in grade 10 only, with electives in the 11th and 12th grades, in Europe and Israel, biology was taught in 9th to 12th grades, depending on the schools' structures, their curriculum, and students' choice in what science subject to be assessed in their matriculation examinations.

	<u>Grade</u>
* The Cell Theory	9 <sup>th</sup>
* Invertebrates: Morphology, Anatomy, Physiology, Reproduction	9 <sup>th</sup>
* Vertebrates: Morphology, Anatomy, Physiology, Reproduction	10 <sup>th</sup>
* Human Body: Morphology, Anatomy, Physiology, Reproduction	10 <sup>th</sup>
* Botany: lower Plants and Higher Plants	9 <sup>th</sup>
* Microbiology	9 <sup>th</sup> -10 <sup>th</sup>
* Genetics	11 <sup>th</sup>
* Ecology	11 <sup>th</sup>
* Evolution	12 <sup>th</sup>
* Classification of Plants and Animals	11 <sup>th</sup> -12 <sup>th</sup>

#### Weekly time-table

<u>Grade</u>	<u>classroom</u>	<u>laboratory</u>
9 <sup>th</sup> and 10 <sup>th</sup>	2 periods	1 period
11 <sup>th</sup> and 12 <sup>th</sup>	3 periods	2 periods

All students in 9<sup>th</sup> and 10<sup>th</sup> grades learned Biology

In 11<sup>th</sup> and 12<sup>th</sup> grades - only those students who chose to study biology for the matriculation examinations.

FIGURE 20–1. The content knowledge structure in biology and high school biology curriculum as it was used in Europe and Israel 1930–1970.

## The Inquiry-Oriented Curriculum in Biology

In the late 1960s, a second generation of high school curriculum was developed, which we call *inquiry-oriented*. It was based on the concept of inquiry as suggested and developed in the book by Schwab and Brandwein (*The Teaching of Science as Inquiry*, 1962; see also *Inquiry* by Gagne, 1963; Rutherford, 1964). This approach had its roots in the educational and philosophical theories developed in the monumental manuscripts written by Dewey (*The Theory of Inquiry*, 1938) and by Bruner (*The Act of Discovery*, 1961). These theories were incorporated into Schwab's book *Biology Teachers' Handbook* (1963), which can be considered to be the foundation for all inquiry-oriented curricula, the Biological Sciences Curriculum Study (BSCS) textbooks, and the *Invitations to Inquiry*.

## New High School Science Curricula

What was the trigger for the development of these new curricula? There was, and still is, a tendency to explain it by the fact that the satellite Sputnik had been launched by the Russians in the early 1960s, causing the United States to feel inferior for not having been the first country to launch a satellite. As a result, the Americans began

an inquiry to find out why they had lost the race into space. They concluded that the high school science curricula did not reflect the knowledge of sciences as they had been known to scientists in the 1960s and was not being taught in the same way as science was practiced. Scientists and educators attempted to explain that the lack of updated science curricula and inadequate methods of instruction were responsible for the American “inferiority,” and consequently there was a dearth of high school graduates who were well versed in the sciences. Indeed, there was a shortage of students in the science faculties, which resulted in a lack of scientists. This, together with a scarcity in research funds, led to a reduction in the numbers of researchers in the sciences and applied technology. Politicians and educators called for radical changes in high school science curricula, and adequate budgets were allocated by the American federal government for the development of satisfactory science curricula, in order to solve this problem. Can we say that Sputnik was the only factor behind the radical changes, which occurred in the second generation of high school science curricula, or were there additional reasons for these changes? The answer lies in scientific research.

### **Science Curricula, Technology, and Societal Issues**

This chapter cannot refer to the societal issues following World War II without touching on their effect on Americans. In the United States, the aftermath of World War II saw an enormous change in students’ attitudes toward the sciences and technology, because of what they thought was the misuse of technology during the war. In the postwar period, they felt that the achievements of science and technology were not being used to solve social problems or to improve the life of people living under low economic conditions. It is possible that the students’ sensitivity had a significant influence on their decision about whether to study science.

Another issue that arose in the 1960s was that scientists and science educators tried to separate science from its technological applications. This trend had a huge impact on the new science curricula, which did not include any aspects of technology. This issue was addressed later in the third generation of curriculum, the problem-oriented one, where this unnatural separation between science and technology was corrected.

### **The Impact of Chemistry and Physics on Research in Biology**

Chemistry and physics played a major role in biology research from the 1940s to the 1960s and later. Two main developments contributed to the changes in the biology CKS: one was based on biology research and the other was based on the use of advanced technology developed in chemistry (working with labeled atoms) and physics (the development of the electronic microscope). Until the late 1930s, radioactive isotopes were not commonly used to probe physiological processes below the macromolecular level. Developments in biochemistry enabled scientists to use labeled isotopes and to track the path of atoms in molecules of amino acids, proteins, nucleic acids, fats, and sugars, etc. Thus a new window of knowledge was opened, laying the foundation for molecular biology.

An example from the research in plant physiology can illustrate the impact of the use of an isotope. This example is adequate for the high school curriculum, since it can demonstrate to students how research is advancing by giving a historical view of the new methods used in the laboratory. The process of photosynthesis, until the 1940s, was taught as a process in which the chlorophyll in green plants, in the presence of light energy, liberates free oxygen and produces sugar from water and carbon dioxide. The source of the oxygen was explained to be the CO<sub>2</sub> molecule, which is broken down to liberate the oxygen and the carbon, and together with the molecule of water formed the skeleton of the sugar molecule. The chemical equation was very simple:

It was only around 1939 when biochemists were able to add the isotope O<sup>18</sup> to water and carbon dioxide, to label water H<sub>2</sub>O<sup>18</sup> and CO<sub>2</sub><sup>18</sup>, that they were able to demonstrate that the oxygen released in photosynthesis came from water, whereas the carbohydrate that was formed contained the O from CO<sub>2</sub>. This finding was further proved by the Hill reaction, where Hill showed that isolated chloroplasts or even fragments of them, when illuminated, can liberate oxygen from water while the hydrogen is transferred instead to the carbon dioxide, to some artificial acceptor added to the system (e.g., ferricyanide, quinone, coenzyme1):

(Harder, Schumacher, Firbas, & Denffer in Strasburger, 1965, p. 256).

In the 1950s the path of carbon in the photosynthesis process was described and the DNA model was suggested. The electron microscope enabled scientists to see cell ultrastructures, and organelles and membranes were more accurately described in their distinct molecular parts.

Consequently, the metabolic paths of proteins, amino acids, sugars, and fats in the cell were depicted as well, and step by step all of the physiological processes that occur in cells were described at the molecular level, parallel to the description of all of the ultrastructures, achieved with the help of the electron microscope. These two methods—labeled atoms and electron microscopy—technological in nature, when combined together made possible sophisticated biological research, changing the face of biology CKS in the middle of the twentieth century. The use of advanced technology in biological research has clearly shown the strong, inseparable relationship between science and technology. At the macro level, studies in ecology integrated with mathematical optimal methods in the framework of the ecosystem added new dimensions to field studies.

## The Development of the Biological Sciences Curriculum Study in the United States

The newly accumulated body of knowledge induced changes in the corpus of the biology CKS, and scientists started to present it, using seven levels of biological organization (LBO). The seven LBO are molecular, cellular, tissue and organs, organisms, societal, communal, and biome. Unity is highest at the molecular level, com-

mon to all living creatures, and diminishes toward the last level, the biome. In contrast, diversity is lowest at the molecular level and increases through the levels, reaching the highest order of diversity at the biome level.

Figure 20.2 presents the new biology CKS in accordance with scientific research in the 1960s, together with its relationship to the cognitive learning demands of high school students.

The changes in biology CKS led to changes in curricula, and the three versions of the Biological Sciences Curriculum Study (BSCS-1968) represent the classical examples of the second generation of high school science curricula. All three versions that were developed around the seven LBO required an inquiry mode of learning and teaching. Each version emphasized the seven LBO at different levels of depth and sophistication:

- BSCS, *Biological Science: An Inquiry into Life—The Yellow Version* (1968), emphasized developmental and evolutionary aspects of biology. In this respect this curriculum was the closest version to the content-oriented curriculum, and it is therefore understandable that it was the one most adopted by schools and teachers in the United States and other countries.
- BSCS, *Biological Science: Molecules to Man—The Blue Version* (1968), emphasized molecular biology. It was the most revolutionary curriculum in that period.
- BSCS, *High School Biology—The Green Version* (1968), which emphasized the ecological aspects the most, was primarily adopted by rural schools in the United States and agricultural high schools in other countries.

Figure 20.3 displays the comparative characteristics of the CKSs emphasized by the two generations (content-oriented and inquiry-oriented) of high school curricula.

In addition, other texts were developed: (a) a textbook for low academic achievers, titled *Biological Science: Patterns and Processes* (1966) (the text was minimal and

FIGURE 20-2. The content knowledge structure in biology from the inquiry-oriented curriculum.

FIGURE 20-3. The seven levels of biological organization as emphasized in BSCS— inquiry curricula vs. traditional content oriented curriculum. (Schawb, 1963, pp. 15, 16, 17).

the experiments were integrated within the text), and (b) BSCS: *Interaction of Experiments and Ideas* (2nd ed., 1970). This textbook was written in a purely inquiry mode; the experiments were integrated into the text and presented research problems in biology in a manner that required students to suggest solutions and ideas and to perform experiments in order to find answers. The textbook was developed for use in the 11th and 12th grades.

### The Pedagogical Approach in the BSCS Textbooks

The content knowledge component of the BSCS textbooks emphasized the teaching of concepts and principles in biology, including a new concept, inquiry. Teachers were asked to create classroom learning environments in which students had “to search and seek” for knowledge, using the reasoning procedure and inquiry skills of scientists in their research. Students were required to use skills such as problem identification, formulation of hypotheses, planning and experimenting, collection of data and results, analysis of the results, planning, and designing and reading graphs and tables based on the results. Students were asked to draw conclusions and infer, in the hope that in this manner they would be able to identify new problems to be researched. Educators and sociologists hoped that students would use these acquired skills in their daily lives as an objective method of solving personal and societal issues. Unfortunately, no studies were carried out to establish if skills mastered in science were successfully transferred and used in daily life.

## Summary of the Inquiry-Oriented Curricula

Following the Sputnik crisis and increased scientific research in biology, the science community was able to suggest new curricula. National committees consisting of scientists, educators, science supervisors, and science teachers were convened and asked for their input. The new curricula were expected to present the new achievements in sciences, and it was hoped that the committee members would be able to suggest methods of instruction and learning that would reflect the way science was carried out, researched, and studied.

Students were not required to perform pure research, but only to use inquiry skills in their learning (Schwab, 1963; Rutherford, 1964). In investigations carried out in the laboratory, students were not compelled to discover new facts unknown to science, but to seek existing knowledge in an explorative mode of learning. Later in the 1980s, Shulman (1987) called this component of any curriculum the “pedagogical content knowledge” (PCK), which was added to the content knowledge part.

The three BSCS versions were predicated on the seven levels of biological organization as presented in Fig. 20.2 and the “Unifying Themes in Biology” (Schwab, 1963, p. 31):

1. Change of living things through time: evolution
2. Diversity of type and unity of pattern in living things
3. The genetic continuity of life
4. The complementarities of organisms and their environment
5. The biological factors of behavior
6. The complementarities of structure and function
7. Regulation and homeostasis: preservation of life in the face of change
8. Science as inquiry
9. The history of biological conceptions

## The Implementation of the BSCS in the United States and Evaluation Studies

The changes in biology CKS since the 1950s has had an enormous influence on high school curricula, biology education, and teaching and learning strategies. These changes required formal and summative evaluation studies, which in turn required new modes of assessment and grading as well as new tests. These tests were aimed at evaluating academic achievement; mastery of skills in the cognitive, affective, and psycho-motor domains; and attitudes and classroom learning environment, to name a few areas. The years 1960 to 1975 represent one of the most active phases in biology education in the United States. The cooperation among biology scientists in colleges and universities, science educators, and high school biology teachers reached a high level that was unknown until then.

The new biology curricula, comprising all the versions of the BSCS, additional learning material that had been developed, the second course, and the biology teachers’ handbook were used in schools all over the United States. BSCS materials were

used in in-service and pre-service courses in the education of high school biology teachers. DeHart Hurd (1978) called this period “the Golden Age of biological education” in the United States. Between the years 1959 and 1975, some 15 million high school students learned biology through one of the available BSCS programs. In the academic year of 1970–1971, 50% of the high school student population (of the 2,729,306 who learned biology) studied using a BSCS variant (DeHart Hurd, 1978, p. 42). The massive implementation of this new curriculum required evaluation studies, which were carried out by graduate students for their M.Sc. and Ph.D. degrees and by science educators in the United States and all over the world. In his chapter, DeHart Hurd (1978) reviewed this vast mass of studies on the implementation of the BSCS programs, as well as general studies in biology education, and succeeded in condensing all of the findings under a large number of sections.

In the present chapter, limited as we are in space, it is impossible to present all of the findings, but we strongly suggest reading the original chapter on the golden age of biology education, which includes two sections. The first one prepares the reader by providing the information needed to relate to the studies and consists of the following parts: new programs and student enrollments; growth of research in biological education; selection of investigations for review, analysis, and organization of investigations; the conceptual base for biology teaching; and developing interpretative theories. This section introduces readers to the development process and rationale of the BSCS curricula, as well as to how the studies were selected for the review.

The second section presents the nature of the studies reviewed, such as comparative analysis of learning outcomes among students enrolled in BSCS courses and those who took conventional biology programs, students’ achievements, changed attitudes, inquiry skills acquired, and subject matter mastered by the methods of pre- and post-testing. The basic assumption was that teachers who adopted the BSCS textbooks and understood the goals of the theories would assimilate them, would master the required teaching behaviors, and would teach according to the inquiry mode. However, studies clearly indicated that this was not the case. Gallagher (1967) found that the individual teacher interpretation of the new method of teaching biology by inquiry actually directed their behavior in the classroom. The other studies reviewed in the second section compared BSCS with other biology curricula, teaching by inquiry, students’ attitudes, the use of BSCS textbooks, students learning biology, the appropriate grade level for teaching biology, biology teachers and their education and behavior, learning conditions, the laboratory and the teaching of inquiry method, student-teacher interaction in the laboratory, and evaluation studies on the BSCS implementations in Australia, Israel, and other countries. The studies’ results did not show a clear picture of the superiority of one curriculum or one method of teaching over another curriculum and mode of instruction. We can assume that the expectations of the newly implemented educational theories embedded in the BSCS program were high because of the enthusiasm.

This huge wave of studies had its advantages and disadvantages. The advantages were the immense number of studies, which provided a multitude of findings and thus helped build a body of knowledge related to the development and implementation of new curricula and the BSCS learning materials, including all of the issues related to these processes.

## **BSCS Curricula, Academic Achievement, and Mastery of Inquiry Skills**

What might be the reasons for the fact that the studies that investigated the implementation of BSCS programs reported contradictory results? For one, numerous research projects were carried out by graduate students who were fulfilling the requirements needed to obtain their degrees, so the studies were of a one-time nature, without any continuity or sequence that could encompass connected variables and amass results that might build a body of knowledge. A complete list of results on a set of related tested variables may portray a picture in which one result may compensate for another one. The sporadic selection of the problems to be investigated simultaneously in many places actually inhibited the possibility that each science education center would specialize in the study of one variable, laterally and in depth; for example, the study of science teacher education for teaching in an inquiry mode from all possible angles and points of view was not conducted. When a new curriculum is implemented the list of variables to be studied can be very long: students' learning, achievement and mastery of skills, etc. Studies were not replicated in order to ensure more reliability than that of a single study's results. Tamir and Jungwirth (1975) suggested that longitudinal studies are needed when comparative research is carried out. When one variable alone is studied, there is a danger of ignoring other variables that may have a lateral impact on understanding and interpreting the results. For instance, while investigating a certain school population—both high and low achievers—for its academic achievement, mastery of skills, and attitudes while using any BSCS program, one might ignore other characteristics, such as cognitive stages, learning styles, learning environments, and students' preferences, choices, and needs.

## **Comparative Studies in Science Education**

*Students.* A problematic issue in any comparative study is how to compare the academic achievements of two different groups of students. For instance, how do we weigh one group of students who learned in a BSCS program (group *a*) against another group that learned biology traditionally (group *b*)? From the beginning group *a* is at a disadvantage. It must learn a new topic by a new method; group *b* has to learn the new topic only, since its members are accustomed to the traditional method of teaching and learning. The assumption that, by learning a new topic in an inquiry method, students will simultaneously master the knowledge and the inquiry skills needed to study the new topic is questionable and is not founded on research. Therefore, one cannot expect that group *a* will do better than group *b*. In the optimal situation, the two groups may well achieve the same level. In their book *The Jigsaw Classroom*, Aronson, Stephan, Sikes, Blaney, and Snapp (1978) suggested that when we want to investigate the academic achievement of students who learn in a cooperative small-groups method compared with students learning in an expository mode, we have to take care that the students should first master the needed skills of helping behavior and learning cooperatively. Only then can they learn the

new topic and can their achievements be compared with those who learned by a traditional method.

*Teachers.* The issue of teachers is another important variable when one investigates their impact on students learning a new curriculum such as the BSCS programs. One cannot circulate an instrument on teachers' attitudes or investigate their impact on students' achievement while ignoring the teachers' past education, knowledge of science, personalities (openness vs. closeness), personal interpretations of a new CKS, and new theories and strategies of teaching, learning, and assessment as well as their attitudes toward the new method in whose development they were not involved. A single teacher cannot be an agent of change in his/her school without the cooperation of the other teachers, the principal, and other school officials or without being involved in setting the teaching timetable.

Teachers cannot be asked to introduce new curricula or new teaching strategies in their classrooms without being involved in one way or another in developing them and in the issues of the implementation process itself (from the pedagogical, educational, and administrative points of view) before they start to use them. The danger of imposing a new curriculum on teachers from top to bottom is that this will push them back from their third stage, the impact stage in their professional development in which s/he can focus on students' needs by adapting teaching modes to their learning styles. Thrusting a new curriculum onto teachers may shunt them back to the self stage (survival), in which they focus on their personal problems, classroom management and discipline, teaching a lesson, and student-teacher interaction. Such a situation invites objections, resistance, antagonism, and failure (Fuller, 1969; Bethel & Hard, 1981).

Teachers' knowledge of the classroom learning environment (learning settings) and their understanding and knowledge of the nature of their student population were also ignored in most studies, and only one variable was investigated. The interrelationships between the variables, whether constant, independent or dependent, must be taken into account when explanations and interpretations are made. This can be done only when a chain of consecutive studies on interrelated variables is carried out, and a whole picture is constructed, based on a set of study results in one science education center. Otherwise, we get broken and unrelated pieces of information that cannot contribute to the construction of a body of knowledge on a particular subject.

## **The Nuffield Project in Biology in the United Kingdom**

The Nuffield curriculum in biology featured particular characteristics based on a different philosophical approach, which was used because of the structure of the English school system (Nuffield Foundation, 1966). The English school system consists of three parts: elementary school (1st to 5th grades), high school (6th to 10th grades), and sixth lower and upper forms (11th and 12th grades). In this chapter we refer only to the high school level. The biology curriculum was updated with the CKS of the 1960s and 1970s as then known to scientists. It had several major charac-

teristics: it was divided into five parts for the five high school grades and two additional advanced courses for the sixth-form students who had chosen to study biology for their matriculation examinations. *The sequence of the textbooks* for every grade was as follows:

*Nuffield Biology Text 1. Introducing Living Things (6th grade)*

*Text II. Life and Living Processes (7th grade)*

*Text III. The Maintenance of Life (8th grade)*

*Text IV. Living Things in Action (9th grade)*

*Text V. The Perpetuation of Life (10th grade)*

The structure of the course centered around 11 fundamental themes, which recur repeatedly throughout the five years (Nuffield Foundation, 1966, p. 1):

1. Cycles of matter and energy
2. Structure and function
3. Interaction of organism and environment
4. Integration and homeostasis
5. Replication
6. Variation
7. Adaptation
8. Natural selection
9. Classification
10. Man
11. Mathematical relationships and experiments.

*Time allotment:* During the first two years: two single periods per week. During the remaining three years: three periods per week (one double and one single)

### **Instructional Strategy**

*The synopsis* of the course clearly indicates that the books were divided into five parts: the first two parts can be regarded as introductory, and the remaining three constitute the next intermediate phase. The introductory phase is characterized by a broad general approach to the subject. In the intermediate phase the treatment becomes more quantitative, with greater emphasis on experimentation and reasoning.

The learning material was written according to the expected cognitive stage of the pupils in each grade. In this way, the sophistication level of the learning material increased with the grade age. In addition, each chapter was written as a sequence of texts integrated with experiments. Accordingly, the text included concepts and principles in biology, introduced facts, and raised problems that had to be solved by the performance of an experiment. The experiment results provided answers, which, in turn, led to a new problem, which had to be solved. The activities ensured that no one could skip a text or omit performing an experiment, because the two were interconnected. Teachers and the students were requested to follow the suggested sequence.

The pedagogical approach used in the textbooks ensured that the inquiry mode of learning accompanied the learning process. Each student textbook was provided with a teacher's handbook in which, for every chapter, additional scientific information, experiments, and suggested modes of instruction were available. Thus, teachers had the needed accurate science knowledge for any particular subject and were encouraged to add more experiments to their curriculum, if time was available. They were allowed to choose the teaching strategy that matched their students' needs, their cognitive stage, and the subject being taught.

### **Sixth Lower and Upper Forms (11th and 12th Grades)**

For the students who studied biology for their matriculation examinations, advanced courses were available based on two textbooks: 1. *Teachers' Guide to the Laboratory Guides, Volume I.* a) Maintenance of the organism; b) Organisms and populations; and *Volume II.* a) The developing organism; b) Control and co-ordination in organisms (Nuffield Advanced Science, 1970). The units covered all of the biological levels of organization and illustrated the major concepts and principles in biology, such as structure and function, organisms and their environment, processes of physiology and behavior, the genetic and evolutionary continuity of life, matter and energy cycles, homeostasis, and the development and uniqueness of the individual. In both textbooks, biological subjects and problems were presented to students who were asked to perform inquiry experiments in the laboratory.

The sequence in each subject was composed of four components: a) Principles, where items of information were presented, leading to a biological problem; b) Teaching procedure with associated materials; c) Practical problems related to the investigated subject; and d) Questions and answers, in which student-student and student-teacher interactions occur. Experimental results led to the need to read biology texts, in which more problems were raised in order to be solved. The inquiry mode of learning and performing of experiments transformed the class (no more than 12 students are in a sixth-form class) into a small group of learners who led discussions among themselves, or with the teacher. The teacher never lectured, but rather constituted a source with whom to exchange ideas and to consult, and from whom to receive support during the process of inquiry and learning.

The goals of the advanced courses were to learn rather than to be taught, to understand rather than to amass information, and to find out rather than be told (Biological Science: Nuffield Advanced Science, 1970; Teachers Guide I, Young, p. VI).

### **The Adaptation of the BSCS, Yellow Version in Israel**

The inquiry-oriented curriculum project was implemented in Israel between 1964 and 1970. *BSCS: Biological Science; An Inquiry into Life (Yellow Version, 1968)* was translated and adapted for Israeli high schools by a team of 25 biology teachers under the leadership of Professors Alexandra Poljakoff-Mayber, Clara Chen, and Ehud Yungwirth at the Department of Biology of the Hebrew University in Jerusalem, and Professor Haim Adomi from the Oranim Teachers College in Kiryat Tivon.

The CKS in biology of that period as presented in the seven levels of biological organization had raised several questions regarding pedagogical aspects of instruc-

tion. Since biology is taught in the United States in 10th grade only as an introductory course, its adaptation in Israel and Europe raised a series of problems, among them the fact that biology in the latter two countries is taught in grades 9 through 12. Following the implementation of the CKS, one of the main problems was the higher level of the learning material, especially the requirements in biochemistry knowledge, which 9th-grade students, on the one hand, were required to assimilate. On the other hand, for 11th- and 12th-graders, the need for learning material at a higher level quickly became apparent. The two main questions were: a) What should be the appropriate sequence of the LBO to be taught in the 9th, 10th, 11th, and 12th grades, respectively, since we know that all of the students in grades 9 and 10 learn biology but very few will continue to study advanced courses in biology in grades 11 and 12? and b) What are the appropriate LBO to be taught to a certain grade, when we have to match students' cognitive stages with the cognitive demands required by the learning material? Since we cannot expand on this issue in this chapter, we only mention the fact that young students who were still in the cognitive concrete operational stage found the content of the levels of biological organization at the reduced level very difficult. For them, probably the most adequate levels are the holistic ones, whereas for the students in grades 11 and 12 the reduced levels suited their cognitive stage. This problem requires a separate debate on how to match learning material to students' cognitive development, age, grades, learning theories, and learning styles.

### **The Implementation of the BSCS Curriculum in Israel**

The teachers who implemented the BSCS chapters in their classes provided feedback that was used for the content validation process. Names of the plants and the animals were replaced by those of Israeli endemic organisms. Formative evaluation was carried out during the two years of the implementation process by Tamir and Yungwirth (1975). The formative evaluation and the feedback provided by the teachers served for the revision of the translation and adaptation of the learning material. Based on the experience of 25 teachers in their classrooms, in-service training courses were organized in four areas of the country in which teachers, who wanted to adopt the new curriculum in their schools, participated. The courses were led by biology university professors, their role being to update the participants in biology content knowledge, and by teams of biology teachers from the original group of the 25 teachers, as their pedagogical and didactic experience gained during the first two years of implementation (in instructional modes, the integration of the learning in the classroom with the performance of the experiments in the laboratory, assessment, evaluation, and grading procedure) was practical guidance for the novices. This course of action was based on Francis Fuller's (1969) findings that the implementation of a new curriculum or a new method of instruction will be successfully carried out if schoolteachers are the agents of change rather than external factors. Teachers tend to trust their colleagues, rather than experts, on learning theories, and strategies of instruction and assessment, evaluation, and grading.

The in-service training course was organized in the following manner. During the first meetings the professors and the teachers from the original group, who pre-

sented the new curriculum, were the most active participants, and the novices were passive. Thereafter, the latter began to participate actively by preparing lessons from the BSCS units, peer teaching, and performing experiments, followed by discussions regarding the implementation process in their classes. In addition, conducting laboratories as well as issues of evaluation, assessing, and grading were discussed. By the end of the course the biology professors and the original group of teachers were in the background while the participating teachers took over all the activities. Only teachers who participated in these in-service training courses, which lasted almost two months during the summer vacation, and took two more short courses of two weeks each during the academic year (during the Hanukah and Passover breaks), were allowed to join the new curriculum in biology, to implement it in their schools and have their students take the BSCS matriculation examination at the end of 12th grade. Furthermore, these teachers were provided with weekly (in five different locations) additional training sessions, at which time they heard lectures on new topics in biology and feedback on the matriculation exams. The teachers shared experiences and participated in didactical and pedagogical discussions about how to teach new topics in biology or any other issues. Teachers expressed satisfaction that opportunities were provided where they could enrich their knowledge, exchange ideas, listen, and find that they were not alone with their problems. This enabled them to seek solutions together. Later on, the Ministry of Education and Culture developed a method to recompense these teachers with an increase in their salaries according to the number of in-service courses in which they participated. It should be mentioned that almost eight years passed until the entire population of biology teachers joined the BSCS curriculum and that during these years, two curricula in high school biology and two kinds of matriculation examinations were in use. The stipulation required of the biology teachers who wanted to introduce the inquiry curriculum into their classes was their active participation in the in-service training courses and the school principals' agreement to provide an adequate laboratory schedule, equipment, biological and chemical materials, and the aid of a laboratory technician. This long period of transition ensured the successful implementation process of the Inquiry Biology-Oriented Curriculum in Israel under the leadership of Professor Tamir and his colleagues. This was a process that the teachers chose to undertake on their own and was based on learning, experience, and support, and was not imposed on them.

Consequently, there was a need to translate several chapters from the *Interaction of Experiments and Ideas* (2nd ed., 1970) for use in the 11th and 12th grades. For low academic achievers in grades 9 and 10, *Biological Science: Patterns and Process* (BSCS, 1966) was translated and adapted as well.

## **The Inquiry Matriculation Examinations in Biology in Israel**

The new inquiry-oriented curriculum in biology required a new approach to examining students. Rather than testing for the memorization of facts and information, students were assessed on the application and mastery of inquiry skills, on higher cognitive skills such as critical thinking, problem solving, and affective skill such as responsibility in the learning process (Lazarowitz, 2000).

The matriculation examinations had four parts:

1. *A written test* (3 hours) assessed by the Ministry of Education, comprising three sections:
  - a. 30 multiple-choice questions to assess students' knowledge of the seven levels of biological organization, aimed at evaluating them on the six cognitive levels (Bloom, 1956): knowledge and understanding (low cognitive levels) and application, analysis, synthesis, and evaluation (higher cognitive levels).
  - b. Six to nine open-ended questions in which students were required to demonstrate knowledge of plant and animal physiology by relating an inquiry approach to the questions. Students were meant to answer the questions in a way that would show their mastery of the inquiry skills.
  - c. An "unseen" section in which students were required to analyze a portion of a real research paper published in Israel, using the inquiry skills mastered in the classrooms and laboratory practical work.
2. *Laboratory work*. Performance of an unknown experiment in which students had to identify a researchable problem in biology, based on a written question. Students were required to suggest a hypothesis and an experiment to be performed in order to prove the hypothesis. Following the examiner's approval, students performed the experiment; collected data, which had to be put in tables and graphs; and analyzed the results. Students then wrote a summation in which they demonstrated biological knowledge in physiology and mastery of practical and inquiry skills in laboratory work.
3. *The identification of an unknown plant*, in which they described the structures of the flowers, stem, leaves, roots, fruits, and seeds and, by using a taxonomic key book, found the scientific names of the family, genera, and species to which the plant belongs.
4. *An ecology project*. Students selected a biology subject to be investigated during one year of field observations that were reported in a portfolio. It was assumed that students choosing a subject and studying outdoors would develop learning responsibility, along with skills of observation, data collection, and care for the environment. As a consequence, students decided on what scientific topics and data they would examine. This reduced to the minimum the anxiety factor during the oral examination. It was also expected that their motivation would increase and that they would develop positive attitudes toward nature and the environment.

### **Summary of the Inquiry-Oriented Curriculum Implementation**

In the content-oriented curriculum the emphasis was on the sequence of biological knowledge that reflected the evolutionary and classification research in biology. The emphasis in the inquiry-oriented biology curriculum was on updating the content knowledge based on the seven levels of biological organization, from the mol-

ecular to the biome, reflecting biochemistry, biophysics, and ecological and ecosystems research in modern biology. An additional emphasis was given to the pedagogical aspects in which the pure inquiry mode of learning was recommended.

Research in biology led to changes in the CKS in biology as a subject matter, which in turn triggered modifications in the structure of the biology curriculum based on the seven levels of biological organization. Parallel to the changes in the CK and changes in the biology curriculum, changes in the nature of the student population and society occurred too. These transformations required developments in learning theories, instructional strategies, and methods of learning, evaluation, and assessment. All these have enabled teachers to not only test students' academic achievements but also their mastery of inquiry skills, attitudes toward science and understanding of the process of science, and their cognitive, affective, psychomotor, and social skills, which were assessed in the classroom and in practical laboratory work (Tamir & Glassman, 1971; Tamir, 1974; Tamir & Jungwirth, 1975; Lazarowitz & Tamir, 1994; Lazarowitz, 2000).

## **Inquiry Curricula and Heterogeneous Student Population**

Were the BSCS programs and other curricula of the 1960s and 1970s suitable for the whole student population, which became more and more heterogeneous? What are the characteristics of a heterogeneous student population? We know that students differ in their cognitive operational stages, abilities, learning styles, preferences, choices, interests, and needs.

Although the inquiry curricula were updated in relation to the subject matter and asked for an inquiry mode in teaching and learning, they were not made suitable for a heterogeneous student population. In order for all students to function in a scientific and technological society, they had to be able to take a democratic stand on societal issues based on literacy and not on prejudices, naïve knowledge, and misconceptions. Moreover, it had to be recognized that only a small portion of students aspire to an academic career; the majority need an academic education in order to find a job in the market. The inquiry-oriented curricula did not address these issues, and a call for developing a curriculum to lead educators and students into the twenty-first century went out. Science curricula of the 1960s and 1970s represented distinct, well-defined disciplines.

In his paper, *The Crisis in Biology Education*, Yager (1982) noted that most curricula of the 1970s, the BSCS programs, the Human Science Program-HSP (BSCS), the Outdoor Biology Instructional Strategies-OBIS (Lawrence Hall of Science), the Biomedical Interdisciplinary Curriculum Project-BICP, and others were challenged regarding their appropriateness. The public was concerned about the inclusion of sensitive subjects such as sex, reproduction and social issues, and evolution, since these were the topics relevant to the students' needs. Yager (1982) mentioned that biology teachers were used to relying for the majority of their teaching on textbooks, which determined the content of their classes and directed their teaching. Biology teachers did not make curriculum decisions related to the biology programs to be used in their classrooms, and the act of selecting a textbook itself was a significant educational reform for them.

## Biology Textbooks Used in High Schools

Three major textbooks were used in high schools in the United States, *Modern Biology* (Holt, used by 40%) and the *Yellow and Green Versions* (BSCS, also used by 40%). In other countries the books used were translations of the BSCS versions in an adapted form or books written locally that used an inquiry approach. Regarding the instructional strategies practiced in the classrooms, Yager (1982) remarked that teaching science by inquiry, a major goal stated by the BSCS in the 1960s, was rarely observed in the classrooms. In the classroom teachers tended to emphasize information related to the terminology and definitions, whereas the nature of the laboratory work was demonstrations and confirmation, which was contradictory to the principles of investigation and inquiry. Biology in the school program did not relate to applications, to current issues, to individual students' needs, or to career awareness. The teachers' main concern was with the academic preparation of students, not with other aspects later raised by Yager and Hofstein (1986). In his paper, Yager (1982) stated that the optimal state of biological education would also include the need to relate to human adaptation, the inquiry process, decision making, values, and ethical and moral considerations of biosocial problems. These issues, he felt, are as important as biology content knowledge. Other aspects he mentioned were teaching and learning settings (individualized and cooperative work), new modes of testing and evaluation, and the use of biology to interpret personal and social problems and issues. The inclusion of human welfare and progress in biology teaching is also of great importance. Finally, Yager wrote that one has to see science education in a continuum change, like science itself. All of these aspects should be reflected in "a curriculum problem oriented, flexible and culturally as well as biological valid" (Yager, 1982, p. 332). Therefore, it was decided to call the third generation of biology curricula the problem-oriented curriculum. This new approach has been leading us into the new millennium.

## The Problem-Oriented Curriculum in Biology

Since the 1990s, new approaches in science curricula have been started, and we now present examples of how Yager's ideas were implemented in the third generation of biology curriculum in Israel. Student populations are heterogeneous in terms of learning styles, cognitive stages, abilities, choices, preferences, and needs. In the high school student population here we have two very well-defined, main groups studying biology. In grades 10 through 12, only 15% of the students continue to study biology at the three- and five-point levels for the matriculation exams. This follows their participation in an integrated course given in a thematic approach that includes some aspects of science, technology, and society (STS) in junior high school in grades 7 and 8. Eighty-five percent of high school students do not continue to study any science or technology subjects after grade 9. With these students in mind, Harari's report (1993) recommended that every student in high school who does not choose to study a science should be provided with science and technology literacy embedded with societal aspects. It was assumed that science and technology have a reciprocal influence, and both have an impact on human life and society, the computer being one example of this. In order to produce citizens who are literate in science

and technology, the goals of the curricula should give greater emphasis to societal issues and not concentrate only on preparing students for academic careers. The nature of a desired science curriculum that can fulfill students' needs was defined by Yager and Hofstein (1986). The four main goals were presented in their paper under the title *Features of a quality curriculum for school science*:

1. Emphasis on science as preparation for further academic study of a discipline has been a major focus of curricula of the past.
2. Major concerns in science are seen as a means of encountering and resolving current societal problems.
3. Means for attending to the personal needs of students.
4. Means of approaching greater awareness of career potential in science, technology and related fields, suggesting goals that may be far more important than the traditional goal of academic preparation for future courses. (Yager & Hofstein, 1986, p. 134)

Therefore, the problem-oriented curricula in biology called for a differential approach. First, it advocated a flexible curriculum, which answers the first goal in Yager and Hofstein's paper (1986). This curriculum may consist of many independent learning units from which teachers choose the units that are most appropriate for their goals, the ones they prefer to teach, and those that meet students' preferences, interests, and needs. Sometimes students can participate in this process. Any sequence of several units studied can provide the students with an entire biological picture. Each learning unit can be replaced from time to time, and each unit can be updated, so the need to change the entire curriculum at once no longer exists. This approach was suggested for students who would be taking the matriculation examination in biology at the end of 12th grade (about 15% of the high school population). Second, it recognized the need for a curriculum for the remaining 85% of students that would address Yager's other three goals: science as relevant to societal problems, and students' needs and awareness of professional career potential while learning sciences. This curriculum was built of independent units, written in a thematic content of biology, chemistry, physics, and technology with societal aspects, thus having a flavor of the STS approach. Therefore, only science and technology subjects, which could have a common background and could be integrated, were selected.

### **Matriculation Exams and Learning Units**

The following curriculum was offered to the students who wanted to take the matriculation examination in biology. For grade 10 the following units (called basic topics) were offered:

1. Communication, regulation, and coordination in plants and animals
2. Microorganisms
3. Reproduction systems in plants, animals, and the human body
4. Processes and metabolism in the cell

5. The organism and the environment
6. Transport and mediation systems in plants and animals
7. Darwin and theories on the origin of species and evolution

Teachers and students were allowed to choose three out of seven learning units to be studied during the academic year.

The following units were offered to grade 11 and 12 students according to their level of matriculation examinations. Learning units for the three-point academic level (basic topics) were:

1. Heredity
2. Energy transformation in living creatures
3. Any two learning units not chosen in 10th grade, bringing the studies to a total of four units.

At the three-point academic level, the matriculation examinations were aimed at assessing students on a) quantitative treatment of data, b) attainment and use of inquiry laboratory skills, and c) classification and identification of plants and animals and mastery of knowledge of the four learning units. Learning units for the five-point academic level (extended topics) were:

1. Heredity
2. Regulation and mechanisms of plant development
3. Photosynthesis
4. Microorganisms
5. Cell communication
6. Physiological systems in animals: respiration and secretion

The matriculation examinations were aimed at assessing students on a) quantitative treatment of data, b) an ecology project, c) plant identification and classification, d) inquiry laboratory work, e) mastery of knowledge of three out of the six units, and e) two learning units not chosen in grade 10.

### **Curriculum Offered to Students Not Taking a Science Discipline**

This curriculum was built around learning units, their role being to provide students with scientific and technological literacy and mastery of skills in the cognitive, affective, and psychomotor domains. The units were written using a thematic approach, integrating biology, chemistry, physics, and societal aspects based on the STS approach (Bybee, 1987). About 20 units were developed, and teachers and students chose five of them to be studied in grades 10, 11, and 12. Each unit was structured so that it could be taught in 30 to 45 periods (two periods in the classroom and one in the lab). We present four of them here.

## Human Health and Science

These learning units developed by Huppert, Simchoni, and Lazarowitz (1992) included health science subjects. The course was developed based on studies in which it was found that high school students (12 to 16 years old, girls and boys) were interested in learning subjects related to their bodies, everyday life, food, health, and the environment (Lazarowitz & Hertz-Lazarowitz, 1979; Baird, Lazarowitz, & Allman, 1984; and Bybee, 1987, who included human health and diseases in his list of the most important societal issues).

The Human Health and Science subunits were written in an STS approach for a two-year biology course, three periods per week, to be used by comprehensive high school students. The learning material consisted of five modules: a) Human Energy Expenditure, b) Organ Transplantation, c) Human Reproduction, d) Diseases of Modern Civilization, and e) Addictive Substances. Each module included the relevant biology content and physiological processes, and aspects of chemistry, physics, and technology applications, which included moral and ethical issues. The various ways of learning included laboratory work, recorded lectures, reprints of articles in science journals, computer simulations, classroom and group discussions, and films. Each module contained two learning units.

Two units from different modules are presented here to illustrate the ways in which STS was integrated:

### *Module 1. Human Energy Expenditure. Learning Unit B: The Fat and the Slim*

STS topics	Descriptions
Biology:	Digestions and absorption. Sugar metabolism
Chemistry:	Structure of sugars and fats. Cholesterol
Physics:	Heat and temperature. Energy in food
Technology:	Recording metabolic rates. Modern agriculture technology
Society:	Obesity. Anorexia nervosa. Dietary habits. Malnutrition

### *Module 2. Organ Transplantation. Learning Unit A: The Heart*

STS topics	Descriptions
Biology:	The cardiovascular system. Cardiovascular diseases
Biochemistry:	Neuro-hormones
Physics:	Blood pressure. Electrical activity of the heart
Technology:	Electrocardiogram. Artificial pacemakers. Heart surgery. Coronary angioplasty. Artificial heart
Society:	Organ donors. Religious, ethical, moral, and scientific rules for determination of death

A detailed description of the modules, subunits, learning topics, learning activities, assessments procedures, formative evaluation, and discussions regarding the development and implementation problems as well as the educational values of teaching biology in an STS approach may be found in Huppert, Simchoni, and Lazarowitz (1992).

## **Ionizing Radiation: Uses and Biological Effects**

The learning unit *Ionizing Radiation: Uses and Biological Effects* (Nachshon, 2000) was written in a thematic and STS approach and included related subjects: a) the physics-chemistry of ionizing radiation—the particle radiation of Alpha and Beta rays, electromagnetic radiation, gamma and X-ray radioactive phenomena and background radiation; b) biological aspects—the effects of radiation on different levels of biological organization: the molecules (DNA molecules), organelles, cell, tissues, and organisms; c) the technological aspects—radioisotopes as energy and radiation sources, the food industry, science research, the range of medical uses of X-ray photography and computerized tomography (CT); and d) societal aspects and issues—uses of ionizing radiation for human needs, the use of radioisotopes for diagnosis and treatment in nuclear medicine, the use of nuclear power for electricity (advantages and disadvantages), and the use of this energy as possible weapons of mass destruction, the process of mutation, and the relationship between cancer and damage repair mechanisms and ionizing radiation's immediate effects and long-term effects, which may affect cell life cycles. The implementation and evaluation in grades 10 and 11 revealed that students' fluency and elaboration on ideas were higher while they learned in cooperative groups rather than as individuals. One-third of the students asked higher order questions, and the questions of the other students were mainly on the knowledge and comprehension levels. Half of the students were interested in the physics of ionizing radiation and activities aimed at developing creative thinking. Students preferred to learn the subjects in the thematic mode, in group activities, and most of them mentioned the importance of the diversity in instructional strategies that were used. The academic achievement of students in control groups, who learned chemistry and physics subjects in a disciplinary approach, was significantly lower, whereas the achievement of those who studied the subjects in the STS mode was higher. All students mentioned that learning about nuclear and ionizing radiation and their uses for human needs in a thematic approach and STS mode helped them to overcome their fears, which had been based on a lack of knowledge and prejudice (Nachshon & Lazarowitz, 2002).

## **Microorganisms**

This learning unit was written in the STS approach in Arabic and Hebrew for 9th-grade Israeli and Arab students (Khalil, 2002a, 2002b). The learning unit was structured around two main biological principles: the unity of life in the world and the relationship between structure and function. The problems raised in the unit were concerned with health issues, environment, microorganisms, and drainage canalization between neighborhood villages. This unit enabled us to investigate achievement in the cognitive and affective domains as well as attitudes toward the preservation of the environment, and understanding and peace between people who live close to each other. The following topics were included in the learning unit: microorganisms and their structure, the physiological processes, microorganisms' role in the food web, carbon and nitrogen cycles, the food industry, the environment, and the level of the health of society. The unit helped students to master practical skills in laboratory work and to develop scientific thinking and problem-solving

skills. The learning tasks included individual and small-group instructional settings, utilizing a variety of teaching and learning methods in the classroom and laboratory. Students read scientific essays, watched videos, played group games, went on group field trips, visited food industries, and searched for information from different sources (e.g., the Internet and libraries). The learning unit was introduced to the students in a manner designed to raise their motivation. It was practical, was connected with daily life, and dealt with societal issues. In this way the relationship among science, technology, environment, and society was emphasized. It was assumed that students would develop positive attitudes and be able to judge objectively the problems involved in the preservation of the environment, while understanding the important role of microorganisms in the life cycle. The outcomes in the cognitive and affective domains were obtained by analysis of students' portfolios written while they studied in the classroom, in the laboratory, and during the execution of their homework. The results showed that students gained in their academic achievement, developed positive attitudes toward the environment, and understood the role that people have in preserving nature and its relation to peace (Khalil & Lazarowitz, 2002).

## SECTION II: BIOLOGY TEXTBOOKS AND HIGH SCHOOL

In his paper, Yager (1982) stated that the existing biology curriculum was textbook-centered and inflexible, and only biological validity was considered. Biological information was given in the context of the logic and structure of the discipline. While citing others, Yager mentioned that biology as it appeared in the school program was pure in the sense that few applications for it were presented, and it did not focus on individual students' needs and paid little attention to current issues and career awareness (Harms & Yager, 1981; Yager, Hofstein, & Lunetta, 1981). Citing the NSF Status Studies of 1976, Yager (1982) stated, "Biology in the school program can be characterized by one word, textbooks." The biology textbook determined the content to be taught, the order, the examples, and the applications of the content, which directed and controlled the teaching strategies. Teachers had faith in textbooks and used them 90% of the time. Teachers did not make curricular decisions about the biology programs in their classrooms, and one of their major involvements was in the "initial choice of the textbook."

Yager (1980) pointed out the need for new learning materials, which can be adapted to local situations, including new instructional strategies and models of implementation. As mentioned previously, Yager's (1982) remarks were the impetus for the development of the biology problem-oriented curricula and the learning units, geared toward students studying for biology matriculation exams or students anxious to acquire scientific and technological literacy. The learning materials in the learning units were written in an experimental mode in order to attend to the issues raised by Yager (1982) and Yager and Hofstein (1986). The learning units (textbooks) comprised a flexible and differential biology curriculum for diverse student populations. They had specific content based on the "unifying themes in biology" (Schwab, 1963), but at different levels of depth and sophistication. Teachers and students were able to choose the learning units, which included integrative topics in sciences

and technology embedded with societal issues, designed to raise students' awareness of academic and professional careers and to help them master the cognitive and affective skills that they would need. Teachers were able to decide what kind of instructional strategies, learning settings, modes of assessment, evaluation, and grading to use. The textbook remained the center of teachers' instruction and students' learning, and it is interesting to compare past studies that related to the role of textbooks with recent investigations that looked into the reasons behind teachers' choice of learning units that they made when making their curricular decisions, following the adoption of the biology problem-oriented curriculum.

### **Biology Teachers' Perceptions of the Textbooks' Role**

An analysis of 22 high school biology textbooks carried out by Rosenthal (1984) revealed that between 1963 and 1983 the awareness of societal issues decreased. Nevertheless, when compared with other texts, Rosenthal mentioned that BSCS textbooks were preferential in both quantity and quality in terms of their treatment of science and society. In general, she noted that biology textbooks tended to avoid questions of ethics and values, and that the interdisciplinary nature of problems was neglected. Although between the 1960s and 1970s there was an effort to make the biology textbooks relevant to students' personal and social needs, there was, nonetheless, a decline in the emphasis on societal issues. Understanding the relationships between science and society is necessary in order for citizens to be able to make decisions and deal with problems in an effective and constructive manner, which is so necessary in a highly scientific and technological society (Aikenhead, 1980). Biology teachers themselves are divided over how much attention to allocate to societal issues (Rosenthal, 1984). DiGisi and Willet (1995) reported that biology teachers modified their use of textbooks according to the academic level of the biology class they taught. They expected that students with higher academic levels would learn from classroom instruction and independent reading, and they understood that those with low academic levels rely only on what is taught in the classroom. Their main observation was that "biology teachers viewed both reading and inquiry activities as important to learning biology, but they appeared unsure of how to incorporate reading comprehension strategies into their science instruction" (DiGisi & Willet, 1995, p. 123). In a study conducted by German, Haskins, and Auls (1996), laboratory manuals in biology were evaluated as to how well they promoted the basic and integrated science process skills that are involved in scientific inquiry. They found that in some manuals there are some efforts to integrate science process skills, but in general they require students to use their knowledge and experience by asking questions, solving problems, investigating natural phenomena, and suggesting answers and generalizations.

Thus the issues raised by Yager (1982) regarding the role of textbooks and how teachers use them in their instruction are still valid today. In their paper, Stern and Roseman (2003) mentioned that the textbooks they analyzed were updated in terms of the scientific content knowledge and full of declarations regarding the cognitive goals to be mastered by the learners, but were very lacking in the inclusion of the products of the research in science education; in other words, they were in need of

didactic pedagogical knowledge of how to use the content in a variety of teaching and learning strategies and learning settings. The question arises as to whether teachers can make curricular decisions choosing the learning unit and the topic to be taught and decide upon what strategies to use, so that the curriculum fit their personality as well as the students' pedagogical needs. Because schools and teachers "are still relying on textbooks as the primary source of the classroom curriculum, which strongly influence students' learning through their impact on the teachers," Stern and Roseman (2004) assumed that "curriculum material can and should play an important role in improving teaching and learning." In their opinion, textbooks that score high on the PCK, according to their criteria, should assist teachers in selecting the content and adapting the relevant pedagogical knowledge, and that this discernment and judgment will be reflected in their teaching.

### Reasons for Choosing Textbooks and their Selection

What are teachers' perceptions of the textbooks, and their reasons for selecting them for their classrooms? In two studies, teachers were asked about their reasons for choosing learning units for preparing students for the matriculation exams and the criteria for their selection. In her study Agrest (2003) found that biology teachers tended to choose the subjects for the matriculation exams primarily from the basic learning units, presented in descending order: Organisms and their Environment; The Cell; Heredity; Transport and Mediation Systems in Plants and Animals; Microorganisms; Reproduction Systems in Plants, Animals, and the Human Body; Energy Transformation in Living Creatures; Evolution; Communication, Regulation, and Coordination in Organisms. The expanded learning units chosen, in descending order, were: Physiological Systems in Animals: Respiration and Secretion; Heredity; Photosynthesis; Microorganisms; Regulation and Mechanisms of the Plant Development; and Cell Communication. While the main concerns of the scientists regarding the learning units were with regard to the scientific content and the methods of scientific thinking, most of the teachers' concerns were focused on the pedagogical aspects.

In a second study, Wagner-Gershgoren (2004) clustered the teachers' criteria for choosing and evaluating biology textbooks into three groups:

1. Scientific content: The teachers attributed the highest degree of importance to the quality of the scientific content (including considerations of being up to date; precision, reliability, and trustworthiness; organization of the information; clear explanations; innovation; relevancy to the individual and daily life; interest; and quotes from studies and articles).
2. Technical aspects: The teachers attributed the highest degree of importance to the format of the book (language, aesthetics, morphological organization of the material, color and formatting of the text).
3. Didactic aspects: The teachers attributed the highest degree of importance to illustrations and organization of data (illustrations, pictures, graphs, flow charts, and schemes and tables).

All of the considerations were presented in descending order of importance.

## Teaching Concepts and Principles in Biology

One of the main goals emphasized in biology curricula is the teaching of concepts and principles. When we analyze the “unifying themes in biology” (Schwab, 1963, p. 31), we find that this is a list of concepts presented in a set of biological principles. The main and ultimate expected result of any effective biology teaching and learning is the students’ mastery of and ability to use biology concepts and principles in their learning. In his paper, Yager (1982, p. 331) stated that a “closer look at biology textbook reveals some important generalizations, and typical textbooks emphasize new words or concepts, often as many as 30 on a single page.” A typical science textbook for middle or high school, according to DeHart Hurd, Robinson, Connell, and Ross (1981), includes 2500 new words. This amount is nearly double the number of new words required from a person of the same age when he or she is learning a foreign language. In science education literature we see studies on concept formation, concept mapping, conceptual change, misconceptions, etc. Because these studies are reviewed in other chapters, we refer here to how a concept is taught and formed in biology.

### Concepts and Names

What is the definition of a concept? Is there a distinction between the word *concept* and a name of an object? Are “new words” equivalent to the word concept? When can we refer to a word as a concept and when we do refer to it as a principle? Confusion often exists in the use of all of these terms. When we talk and teach about a specific amino acid, sugar, starch, chloroplasts in the green cell of a leaf, mitochondria, a specific tissue of plants or animals, organelles in a cell, an organ, a specific system within an organism, an organism or the human body, it may be that these are “new names” for our students, a new language. Yet these new words represent objects, which can be seen, either with the help of a microscope, in a picture, or with our eyes; we can check and measure them; we can depict their characteristics or learn about their properties by performing chemical and other laboratory experiments. We can use our senses to learn about them, and, therefore, they are objects to which we can give names, and consequently, they are not concepts. We can learn about these objects, can classify and organize them into groups such as amino acids, organelles, cells, families genera and species, or name specific physiological processes performed by these objects or substances, respiration, photosynthesis, reproduction, and so on. These are the concepts learned, and they include names of objects, which were investigated and their specific structures, properties, characteristics, and physiological processes were identified, learned, and grouped. Each group can be given a specific name due to common characteristics of its members, which represents a mental activity. At the same time each group is different from another group, inasmuch as they differ in their characteristics. Facts are elicited through the use of discriminative mental activity, as a result of which a new grouping will form under a different umbrella and be given a different concept name. Accordingly, these are not concrete or abstract concepts. They are objects, which can be studied and their characteristics learned. There are objects for which we need technological aids in order to see and learn about them, and others that require the use of our senses, but they continue to be real at the concrete level. Students master the new words, the

new language, based on experience, and they proceed to deal with and learn about them as well as use related concepts.

## Models of Teaching Biological Concepts

According to Novak (1965), in order to understand a given discipline, one must do more than just memorize statements that summarize the concepts in a topic. Students have to find out how the concepts were derived and elaborated in order to meaningfully understand them so they can grasp the discipline structure. In other words, Novak understood concepts to be generalizations of aspects of the physical or biological biome, which are composed of individual facts and emotional experiences, such as the concept of osmosis or evolution, which represent a group of related facts that stand for a composite of knowledge (Novak, 1965). Concept formation, according to Novak (1965), goes through several steps: a) experience a student stores as cognitive information; b) storage of affective information; c) and the processing of all of the information. A detailed psychological description of the formation of concepts can be found in Novak's (1965) paper, and readers are invited to study this article.

According to Koran (1971), in biology, concepts represent natural objects such as mammals, invertebrates, amino acids, and autotrophs, and events such as dehydration, synthesis, oxidation, reduction. We can add physiological processes such as respiration, photosynthesis, and reproduction. When we use the term *amino acid*, it is understood that we are not referring to a single object but to a class of objects or to groups. Koran distinguished along a continuum between the concept of all amino acids and a specific amino acid. Each amino acid has COOH and NH<sub>2</sub> at the opposite ends of the molecule, and between them each amino acid has a different chemical structure. We can group under the concept of amino acid any compound that shows this chemical structure; a specific amino acid is a fact or object that can be studied and its characteristics learned (Koran, 1971). In the process of concept formation, two distinct activities are involved. When we group all of the organic compounds, which have at their opposite ends the chemical structures COOH and NH<sub>2</sub>, under the name of amino acids, we are generalizing. However, when we distinguish between these molecules and a molecule of sugar, which does not possess COOH and NH<sub>2</sub>, we are undertaking a discriminative mental activity (Mechner, 1965). These two mental activities of generalization and discrimination are the major components of concept formation. Providing adequate examples of what a concept includes is as important as providing examples of what it does not include, according to Koran (1971).

Koran, Koran, Baker, and Moody (1978), and Koran, Koran, and Baker (1980) provided many more examples of concept formation in different fields of biology, together with models of teaching using the inductive and deductive modes of instruction and learning.

## Concepts and Teaching Biology

Concepts, accordingly, do not represent concrete entities but are created in the human mind, following a learning process, and are, therefore, abstract. It is obvious that we, as teachers, usually start teaching first by presenting the concept, which

requires an abstract operational activity, which immediately breaks down the communication between the teacher and the students. We do not have a common language with the students, because as far as they are concerned, we are speaking a "new language" with which they have not had any prior experience. Following the introduction we proceed to present the objects or to perform an experiment, which are at the level of a concrete operational activity. Although the direction of the learning process as depicted (the deductive approach) is adequate for students who are in a formal cognitive stage and who can cope with this mode of instruction, most students are in the concrete cognitive stage, and the opposite direction is more appropriate for them. First, they have to be introduced to the object, learn about its characteristics, or perform an experiment in order to accumulate information and knowledge about it. Only then can we introduce the names of all the information mastered under the name of the concept, which represents all of the learning activities that have just occurred (the inductive approach). Topics, which are at the reduction level, such as molecules of glucose or macromolecules of starch, for example, since they are names of objects, can be taught by the inductive approach. Starch (an object) can be seen and its characteristics can be learned, being an object that is well known to students from their daily life experiences. Afterward we can relate to its components, the molecules (a concept) of glucose (an object), and as such the deductive approach is desirable. This is the way scientists investigate a phenomenon.

For instance, only after using a microscope and finding out that all organisms are built of microstructures did they refer to some common characteristics of the "cell" concept. The microstructure, the cell, represents an entire organism; when grouped together, the cells represent a structure, the tissue of an organism. Once having made these observations, scientists realized that every unicellular organism or any group of cells that form a tissue have a specific structure and perform a specific physiological activity, and that a relationship exists between the two. With this deduction, the basic principle in biology of structure and function emerged. Scientists can and do communicate among themselves using the word *cell*, without the necessity of explaining again and again all the knowledge related to this concept, because all of them know what the concept "cell" means. In essence, a concept such as a cell is an economical way of communication among people who have a common background of experience and knowledge, following a process of learning.

This is not the situation that may exist between the teacher and his/her students. The teacher has all the knowledge behind a concept, whereas for the students this is a new word, and they first have to attain this knowledge in order to be able to use the new concept. Thus, when the teacher starts to teach by first presenting the concepts to be learned by the students, instead of creating learning settings in which the learners will come into concrete contact with the objects to be studied, by observing, measuring and experimenting, perceiving and conceptualizing, they generally lose their audience. Nonetheless, even when these two steps, perception and conceptualization, are experienced in the correct sequence, students may still not attain the knowledge and grasp the concept. They must be taken through a third step application. Here learners have to show that they can use the new knowledge in a new learning situation. Only then can we say that learning has occurred. This learning process can be illustrated as follows.

### **First Step: Perception**

This is a concrete learning process. The teacher presents a biological problem that can be solved by making observations regarding objects or by performing an experiment. Students collect information and data and construct their knowledge.

### **Second Step: Conceptualization**

This is a formal (mental) learning activity. Students and the teacher hold class discussions, using the knowledge mastered in the perception step, and by discrimination and generalizing mental activities, they summarize the accumulated information under one name. For example, if the problem investigated is how plants nurture and they learn about the structure of leaves and perform experiments with chlorophyll, sugars, glucose, starch, solar energy, etc., they can group all of this acquired knowledge under the concept name of photosynthesis.

### **Third Step: Application**

Students receive variegated leaves (the leaves have areas with chlorophyll that are green, and areas without chlorophyll that are albino). The question posed is: Can we find starch in both areas? In order to find an answer, students have to use their knowledge regarding the role of chlorophyll, solar energy, and the production of starch, in a new situation. Depending on how their students resolve the question, the teacher will know if their students mastered the knowledge.

### **Learning Difficulties in Biology**

The CKS of the high schools' biology curricula is based on the seven LBO. This organization of the biological content is logical from the evolutionary point of view and represents areas of research and instruction. The concepts and principles presented in most of the LBO require students to be in the formal operational stage of learning and thinking in order to successfully cope with them. In their studies Johnstone and Mahmood (1980), Steward (1982), Finely, Steward, and Yaroch (1982) and Friedler, Amir, and Tamir (1987) reported that several biological topics were identified by their level of difficulty in terms of instruction by teachers, as well as the difficulty students encountered while learning these subjects. The concepts were water transport in organisms, osmosis and osmoregulation, the chemistry of respiration and photosynthesis, energy cycles (ATP, ADP), cell respiration, protein synthesis, mitosis and meiosis, enzyme structure and function, the chromosome theory of heredity, and Mendel's laws of genetics and multiple alleles. According to Klinckman (1970), the LBO might be one of the reasons for these difficulties. Young learners and less academically able students may be able to achieve higher scores if they study biology topics that lie within the levels of organisms, population, and community (holistic subjects). Conversely, they may encounter substantial difficulties in learning concepts related to molecules, cells, tissues, and organs. Another reason for their problems in understanding may be the abstract level of concepts such as photosynthesis, respiration, enzyme activity, dominance and co-dominance, and sex linkage.

## Learning Biology and Students' Cognitive Stages

Students' ability to deal with formal concepts in a meaningful manner was found to be correlated with their cognitive operational stage. This assumption was supported by Shemesh and Lazarowitz (1989) in a study with students (ages 15 to 16). These researchers found that, following lessons on the respiratory system, results showed a positive correlation between students' cognitive stages and their achievements, and that only learners at the concrete cognitive stage made errors. Lawson and Thomson (1988) investigated students' misconceptions about natural phenomena. They hypothesized that in order to overcome their mistaken beliefs, learners must be made aware of scientific knowledge and must be able to generate the logical relationships among the evidence and alternative conceptions. The results indicated that the reasoning ability of seventh-grade students, who were assessed by having them write an essay on principles of genetic and natural selection, was the main factor related to the number of misconceptions held. These two studies indicate that relationships do exist between achievement in biology and students' mastery of formal cognitive stages. Students found to be at the concrete cognitive stage were not able to go beyond the given data in a problem situation, and the inferences they drew, even when they remembered all the necessary facts, were directly related to what they had actually observed. It seems that the lack of formal reasoning skills constrained these students' capacity to encode formal concepts and to process complex information. Only a few students at the formal cognitive stage were able to meet the high criteria of relational or extended abstract responses (Shemsh & Lazarowitz, 1989).

As such, the main question asked is, can we teach biological concepts to high school students at any age, or should one delay teaching them until they reach the appropriate formal cognitive stage, when we assume that learners will be able to cope with the concepts? To answer this question we will relate to several studies. The study by Penso and Lazarowitz (1992) looked at students (ages ranged from 17.5 to 18.5) who were given a test, which included 18 multiple-choice questions. In order to identify difficulties in learning biology and to locate the mistakes made by students in the process of choosing the correct item, they were asked to justify their choice. Their justifications were compared with a justification key prepared by the researchers. This is a method that provides teachers with a remedial teaching tool and helps students analyze their answers and master the correct knowledge. The remedial teaching can take place when the evaluated tests are returned to the students and both they and the teacher engage in a constructivist mode of learning. Students can realize that the test is used not only to give grades (as a punishment tool), but as a learning process from which all can profit. It was also determined that students can overcome test anxiety and develop positive attitudes toward the teacher, the subject matter, and, consequently, the learning process, when their justifications are compared against a justification key. All of the details of the study procedure and the biological content of the questions, the answers, and the analysis can be found in the researchers' paper (Penso & Lazarowitz, 1992).

In another study, Lawson and Worsnop (1992) reported that teaching a learning unit to high school students on the topics of evolution and natural selection yielded the following results: the instruction did not produce an overall shift toward a belief in evolution; reflective reasoning skill was significantly related to the students' initial scientific beliefs and to gains in declarative knowledge but not significantly

related to changes in students' viewpoints. One of the difficulties in teaching evolution in high school is the fact that we can neither illustrate nor concretize the evolutionary process in the laboratory. In order to overcome this obstacle, Ron and Lazarowitz (1995) conducted a study among 12th-grade students in which the topic of evolution was taught in an instructional mode of cooperative groups. The topics learned were Lamarck's, Darwin's, and neutral theories; punctuated equilibria; genetics diversity; natural selection; specialization; and phylogenesis. The results showed that students' academic achievement was higher than that of the control group. The explanation for this was based on the fact that cooperative learning facilitates students' verbal interaction and construction of the knowledge, based on group products. Can ninth-grade students identified as being in the concrete operational stage learn the concept of pH, which requires formal operational ability? In their study, Witenoff and Lazarowitz, (1993) found that when the laboratory worksheets according to which students performed the experiments are restructured according to Farmer and Farrell's (1980, p. 64) suggestions, and taught in cooperative groups, they achieved significantly higher grades than the control group. It can be seen that when the cognitive operational stages of students are identified and the learning material restructured in order to fit their cognitive stage and learning style, they can succeed. Identifying students' cognitive stages not only provides additional independent variables, but also helps teachers analyze the learning difficulties their students encounter and adjust the learning material, the instructional methods, and the learning environment to their needs and thus facilitate successful outcomes. Biology teaching and learning in classrooms and in the lab present many opportunities for evaluation and grading procedures, in addition to the use of classical tests following the instruction of a unit (Lazarowitz, 2000; Lazarowitz & Tamir, 1994).

## Evaluation and Grading

Finally, we relate to the issue of students' evaluation and grading. A single study performed by Welicker and Lazarowitz (1995) is presented. A learning unit on the "Cardiovascular System with Health Aspects" was implemented in 10th-grade classes, and through the learning experiences in the classroom and laboratory work, a multidimensional learning environment was created. Students were able to demonstrate a variety of competencies, which were observed by the teachers and evaluated with the use of a multidimensional performance assessment instrument. This instrument served as a tool for an authentic evaluation of students' abilities and mastery of inquiry, psychomotor, and team working skills. The multidimensional evaluation system, which was used during the process of teaching and learning in the classrooms and laboratory work, was shown to be a qualitative and dynamic tool of assessment and may provide teachers with an alternative performance evaluation in addition to summative tests.

## CONCLUSIONS

In this chapter, I preferred to make a historical summary of the achievements made during the second half of the twentieth century in the development, implementation, and teaching of biology curricula in high schools all over the world and to pay

tribute to the modern science educators who contributed so much to our field. The inquiry mode of teaching and learning; the study of cognitive skills and cognitive stages, conceptual change and formation; and the learning settings of individual, cooperative, and computer-assisted learning developed during the twentieth century, to mention just a few, are milestones pointing the way toward the new century. In the twenty-first century we have to grapple with the issue of teaching sciences to a heterogeneous student population in order to spread scientific and technology literacy and enable these young men and women to participate in a continually evolving society. Only by appreciating and knowing the past can one look to the future.

The reader, then, in my opinion, after reading this chapter will have a basic understanding of where research on science education has been and the directions in which it may be going.

Having said this, I point out to the reader that there are several reviews that present the topics investigated in teaching biology, some of them in specific chapters in this book and others I now mention briefly. The interested readers may look at Lawson (1988), who mentioned the research aimed at improving biology teaching. Lawson found that two major theories dominated these studies. The first, proposed by Ausubel, is a theory of verbal learning on ways students acquire specific biological concepts, and the second is Piaget's developmental theory, which focuses on ways students acquire and use general scientific reasoning patterns. The research on laboratory practical work was summarized by Lazarowitz and Tamir (1994). The research studies on teaching biology in cooperative small groups were reviewed by Lazarowitz (1995a, 1995b) and by Lazarowitz and Hertz-Lazarowitz (1988).

The topics of Concept Mapping in Biology from different angles, the nature of biology knowledge, misconceptions in biology, language, analogy and biology, concept circle diagramming as a knowledge mapping tool, and more topics are presented in *Mapping Biology Knowledge* by Fisher, Wandersee, and Moody (2000).

## Recommendations

As we embark on the twenty-first century, it is becoming clear that biology curricula should serve not only the students who are pursuing academic careers, but also the remainder of students, who are the majority (almost 85%) and whose needs are different.

A differential approach in developing biology curricula, which will provide an answer to our student populations who differ so much in their needs, must be adopted. It is imperative to integrate all of the findings of our research in science education, in textbooks, in pre-service and in-service courses in a more rigorous way, so that teachers will have the tools for the instructional process to help students enjoy and profit from the learning of science and technology. If we want to be relevant to students' needs as future citizens who will have to function in a highly scientific and technological society, then an integration of the sequence of topics to be taught and learned with a new pedagogical and didactical approach should be developed, implemented, and evaluated. The pedagogical and didactical approach should include a variety of instructional strategies and learning settings. The issue of ethics and values cannot be ignored and should be integrated into textbooks and the education of biology teachers. The results of a study by Lazarowitz and Bloch

(2005) have shown that teachers, while teaching genetics, genetics engineering, molecular biology, and evolution topics, are primarily concerned with the CKS and much less with the aspects of ethics, moral, values, and societal issues, which derive from scientific research and daily life. In this troubled world, one may ask if it is not the educational role of teachers at all levels, from K to 12th grade and in the universities, to address these issues while teaching the sciences and technology, biology in particular. These new approaches are opening new frontiers for science education research in the twenty-first century and becoming more relevant to a heterogeneous high school student population.

## ACKNOWLEDGMENTS

Thanks to Anton Lawson and James Wandersee, who reviewed this chapter.
