PNF techniques are superimposed on movement and posture. Among these techniques are basic procedures considered essential to the PNF approach. Two procedures, verbal commands and visual cues, were discussed previously. Other procedures are described in the following sections.

Manual contacts refer to the placement of the therapist's hands on the client. These contacts are most effective when applied directly to the skin. Pressure from the therapist's touch is used as a facilitating mechanism and serves as a sensory cue to help the client understand the direction of the anticipated movement.[97] The amount of pressure applied depends on the specific technique being used and on the desired response. The location of manual contacts is chosen according to the groups of muscles, tendons, and joints responsible for the desired movement patterns. If the client is having difficulty reaching to comb the back of the hair because of scapular weakness, the desired movement pattern is D_2 flexion. Manual contacts should be on the posterior surface of the scapula to reinforce the muscles that elevate, adduct, and rotate the scapula.

Stretch is used to initiate voluntary movement and enhance speed of response and strength in weak muscles. This procedure is based on Sherrington's neurophysiologic principle of reciprocal innervation.[84] When a muscle is stretched, the Ia and II fibers in the muscle spindle send excitatory messages to the alpha motor neurons, which innervate the stretched muscle. Inhibitory messages are sent to the antagonistic muscle simultaneously.[26]

When stretch is used in the PNF approach, the part to be facilitated is placed in the extreme lengthened range of the desired pattern (or where tension is felt on all muscle components of a given pattern). This range is the completely shortened range of the antagonistic pattern. Special attention is given to the rotatory component of the pattern because it is responsible for elongation of the fibers of the muscles in a given pattern. After the correct position for the stretch stimulus has been achieved, stretch is superimposed on the pattern. The client should attempt the movement at the exact time that the stretch reflex is elicited. The use of verbal commands also should coincide with the application of stretch, to reinforce the movement. Discrimination should be exercised with the use of stretch to prevent an increase in pain or muscle imbalances.

Traction facilitates the joint receptors by creating a separation of the joint surfaces. It is thought that traction promotes movement and is used for pulling motion.[97] In activities such as carrying a heavy suitcase or pulling open a jammed door, traction can be felt on joint surfaces. Although traction may be contraindicated for clients with acute symptoms, such as after surgery or a fracture, it can sometimes relieve pain and promote greater ROM in painful joints.

Approximation facilitates joint receptors by compressing joint surfaces. It promotes stability and postural control and is used for pushing motion.[97] Approximation is usually superimposed on a weight-bearing posture. For example, to enhance postural control in the prone-on-elbows posture, approximation may be given through the shoulders in a downward direction. As part of a home program to enhance proximal stability, Leticia could play board games on the floor with her children in weight-bearing positions such as prone on elbows or side-sitting. A weighted vest could be used in place of the therapist's manual contacts to provide approximation.

Maximal resistance involves Sherrington's principle of irradiation—namely, that stronger muscles and patterns reinforce weaker components.[84] This procedure is frequently misunderstood and applied incorrectly. It is defined as the greatest amount of resistance that can be applied to an active contraction while allowing full ROM to occur, or to an isometric contraction without defeating or breaking the client's hold.[97] Maximal resistance is not the greatest amount of resistance that the therapist can apply. The objective is to obtain maximal effort on the part of the client because strength is increased by movement against resistance that requires maximal effort.[34]

If the resistance applied by the therapist results in uncoordinated or jerky movement or if it breaks the client's hold, too much resistance has been given. Movement against maximal resistance should be slow and smooth. To use this technique effectively, the therapist must sense the appropriate amount of resistance. For clients with neurologic impairment or pain, the resistance may be very light, and light resistance is probably maximal for the client's needs. The therapist's manual contacts may offer light resistance that actually assists by providing the client with a way to track the desired movement. In the presence of spasticity, resistance may increase existing muscle imbalance and thus needs to be monitored. For example, if an increase in finger flexor spasticity is noted with resisted rocking in the hands-knees position, resistance should be decreased or eliminated or an alternate position should be used.

Techniques

Specific techniques are used in conjunction with these basic procedures. A few have been selected for discussion. These techniques are divided into three categories: those directed to the agonists, those that are a reversal of the antagonists, and those that promote relaxation.[97]

Techniques Directed to the Agonist

Repeated contractions is a technique based on the assumption that repetition of an activity is necessary for motor learning and helps develop strength, ROM, and endurance. The client's voluntary movement is facilitated with stretch and resistance, using isometric and isotonic contractions. This is also referred to as the **contract-relax** (CR) method where the targeted muscles for lengthening are contracted by the client against resistance for a short period of time.[36] Following the contraction against a stable resistance (isometric contractions), stretch is gently applied to lengthen the targeted muscle. The process of repeatedly contracting against a force and then relaxing and stretching has been effective in increasing muscle length. Repeated contractions could be used to increase trunk flexion with rotation in the client who has difficulty reaching to put on a pair of shoes from the sitting position. The client bends forward as far as possible. At the point where active motion weakens, the client is asked to hold with an isometric contraction. This action is followed by isotonic contractions, facilitated by stretch, as the client is asked to “reach toward your feet.” This sequence is repeated either until fatigue is evident or until the client is able to reach the feet. The pattern can be reinforced further by asking the client to hold with another isometric contraction at the end of the sequence.

The use of PNF with older adults residing in assisted-living settings has been investigated.[48] Residents were provided with a 10-week training period using PNF to improve sit-to-stand, shoulder, and ankle range of motion and strength. Using repeated measures analysis of variance (ANOVA), statistically significant improvements were noted in all mentioned areas. The skills allowed individuals to engage in instrumental activities of daily living (IADLs) with improved postural control.

Elderly clients who had sustained falls were provided with training using PNF.[85] When compared to older adults who were provided only with general exercise, the older adults who had PNF training had statistically significant improvements in various measures related to fall prevention. Authors concluded that PNF training was beneficial in enhancing physical conditioning of older adults who had experienced falls.

Rhythmic initiation is used to improve the ability to initiate movement, which may be a problem with clients who have Parkinson's disease or apraxia. This technique involves voluntary relaxation, passive movement of the extremity by the therapist, and repeated isotonic contractions of the agonistic pattern. The verbal command is, "Relax and let me move you." As relaxation is felt, the command is, "Now you do it with me." After several repetitions of active movement, resistance may be given to reinforce the movement. Rhythmic initiation allows the client to feel the pattern before beginning active movement. Thus the proprioceptive and kinesthetic senses are enhanced. This rhythmic initiation was used with clients who had chronic strokes to enhance controlled movements.[98] When compared to healthy adults, the use of PNF effectively reduced the muscle stiffness noted in individuals who have chronic stroke. The muscle stiffness contributes to increased effort when attempting to move and compromises functional skills.

Reversal of Antagonist Techniques

Reversal of antagonist techniques employ a characteristic of normal development—namely, that movement is reversing and changes direction. These techniques are based on Sherrington's principle of successive induction, according to which the stronger antagonist facilitates the weaker agonist.[84] The agonist is facilitated through resistance to the antagonist. The contraction of the antagonist can be isotonic, isometric, or a combination of the two. The most common approach is the contract-relax-antagonist-contract (CRAC) method.[36] The contract-relax is the same as previously described, but then the method includes contracting the antagonist against a stable resistance. These techniques may be contraindicated for clients in whom resistance of antagonists increases symptoms such as pain and spasticity. For example, the facilitation of finger extension (agonist) would not be achieved effectively through resistance applied to spastic finger flexors (antagonist). In this situation, finger extension may be better facilitated through the use of repeated contractions, in which the emphasis is only on the extensor surface.

Slow reversal is an isotonic contraction (against resistance) of the antagonist followed by an isotonic contraction (against resistance) of the agonist. Slow reversal-hold is the same sequence, with an isometric contraction at the end of the range. For the client who has difficulty reaching his or her mouth for oral hygiene because of weakness in the D_1 flexion pattern, the slow reversal procedure is as follows: an isotonic contraction against resistance in D_1 extension with the verbal command "Push down and out," followed by an isotonic contraction of D_1 flexion against resistance with the verbal command "Pull up and across." An increase or buildup of power in the agonist should be felt with each successive isotonic contraction. Slow reversal used in conjunction with repeated contractions could be applied to trunk movement patterns to help Leticia overcome her rigidity and improve the balance of antagonists. This sequence of techniques could also be used to increase Leticia's wrist range of motion and strength once her fracture is stable.

Stabilizing reversals are characterized by alternating isotonic contractions opposed by enough resistance to prevent motion. In practice, the therapist gives resistance to the client in one direction while asking the client to oppose the force, allowing no motion. Once the client is fully resisting the force, the therapist gradually moves the resistance in another direction. Each time the client is able to respond to the new resistance, the therapist moves the hand to resist a new direction, reversing directions as often as needed to achieve the client's stability. This technique is used to increase stability, balance, and muscle strength.

Rhythmic stabilization is used to increase stability by eliciting simultaneous isometric contractions of antagonistic muscle groups. **Co-contraction** results if the client is not allowed to relax. This technique requires repeated isometric contractions, leading to increased circulation or the tendency for the client to hold his or her breath, or both. Therefore rhythmic stabilization may be contraindicated for clients with cardiac involvement, and no more than three or four repetitions should be done at a time on any clients.

In rhythmic stabilization, manual contacts are applied on both agonist and antagonist muscles, with resistance given simultaneously. The client is asked to hold the contraction against graded resistance. Without allowing the client to relax, manual contacts are switched to opposite surfaces.

Rhythmic stabilization is useful with clients lacking postural control because of ataxia or proximal weakness. Used intermittently during an activity requiring postural stability, such as meal preparation in standing posture, this technique enhances muscle balance, endurance, and control of movement. Rhythmic stabilization techniques were found to be effective in improving postural control and reducing pain for individuals who had chronic low back pain.[49]

Because these two stabilizing techniques can be superimposed on activity-based movements, they could be used to facilitate Leticia's ability to perform numerous daily activities. For example, rhythmic stabilization could be used to improve trunk endurance and stability when Leticia experiences fatigue while standing at the sink to do the dishes.

Relaxation Techniques

Relaxation techniques are an effective means of increasing ROM, particularly in the presence of pain or spasticity, which may be increased by passive stretch.

Contract-relax involves passive motion to the point of limitation in movement patterns. This is followed by an isotonic contraction of the antagonist pattern against maximal resistance, with only the rotational component of the diagonal movement allowed. This action is followed by relaxation, then by further passive movement into the agonistic pattern (eg, contract-relax could involve passive motion to the point of limitation in D_2 flexion, which would be followed by an isotonic contraction of D_2 extension, then by further passive movement into D_2 flexion). This procedure is repeated at each point in the ROM in which limitation is felt to occur.[97] Contract-relax is used when no active range in the agonistic pattern is present. However, the ultimate goal is active movement through the full range. Therefore once relaxation and increased ROM occur, active movement should be facilitated. The contract-relax (CR) technique has been demonstrated as an effective means to gain ROM when compared to passive stretch but the mechanism underlying this technique is not clear.[65]

Hold-relax is performed in the same sequence as contract-relax but involves an isometric contraction (no movement allowed) of the antagonist, followed by relaxation and then active movement into the agonistic pattern. It has been recommended that the static contraction be held for 3 seconds to achieve the greatest improvement in ROM.[82] Because this technique involves an isometric contraction against resistance, it is particularly beneficial in the presence of pain or acute orthopedic conditions. For the client with reflex sympathetic dystrophy (RSD) who has pain with shoulder flexion, abduction, and external rotation, the therapist asks the client to hold against resistance in the D_2 extension pattern, then to initiate active movement into the D_2 flexion pattern. This technique is beneficial for the client with RSD during self-care activities such as shampooing hair and zipping a shirt in back.

Slow reversal-hold-relax begins with an isotonic contraction, followed by an isometric contraction, relaxation of the antagonistic pattern, and then by active movement of the agonistic pattern. When the client has the ability to move the agonist actively, this technique is preferred. For example, to increase active elbow extension in the presence of tight elbow flexors, the therapist asks the client to perform D_1 flexion with elbow flexion as resistance is applied. When the ROM is complete, the client is asked to hold with an isometric contraction, followed immediately by relaxation. When the client relaxes, he or she moves actively into D_1 extension with elbow extension. This technique helps increase elbow extension for such activities as reaching to lock the wheelchair brakes or picking up an object off the floor.

Rhythmic rotation is effective in decreasing spasticity and increasing ROM. The therapist passively moves the body part in the desired pattern. When the client feels tightness or restriction of movement, the therapist rotates the body part slowly and rhythmically in both directions. After the client relaxes, the therapist continues to move the body part into the newly available range. This technique prepares the paraplegic client with LE spasticity or clonus to put on a pair of pants. The technique is also effective in preparing for splint fabrication on a spastic extremity.

Threaded Case Study

Leticia, Part 2

To respond to the initial three questions at the beginning of this section, we need to review our assessment of Leticia. To determine the most effective movement patterns, we need to observe Leticia in her daily tasks, in addition to her performance of specific diagonal patterns and total patterns of movement. Techniques and procedures that best address Leticia's key deficits in motor control and rigidity should be selected. In addition to a focus on these key areas, special attention should be given to whether more mobility or stability is needed. Trunk ataxia would respond best to stabilizing techniques such as rhythmic stabilization, stabilizing reversals, and approximation. Rigidity would need mobilizing techniques such as slow reversal, slow reversal–hold, and repeated contractions. These techniques can be applied to clients during occupation-based activity.

The progression of intervention begins at the time of evaluation and considers the client's abilities as well as deficiencies. In Leticia's case, intervention will need to follow PNF principles. Intervention should initially address proximal control and start in lower developmental positions where she has the ability to perform coordinated movement. Once she has achieved more proximal stability, intervention can progress to work in higher developmental postures such as standing. Integrated into this progression of movement patterns and techniques are selected procedures that facilitate the desired motor response or activity performance.

Section 2 Summary

The PNF approach emphasizes the client's abilities and potential so that strengths assist weaker components. Strengths and deficiencies are assessed and addressed in intervention within total patterns of movement and posture. Carefully selected techniques are superimposed on these total patterns to enhance motor response and facilitate motor learning.

PNF uses multisensory input. The coordination and timing of sensory input are important in eliciting the desired response from the client. The client's performance should be monitored, and sensory input should be adjusted accordingly.

To use PNF effectively, the therapist must understand the developmental sequence and the components of normal movement. The therapist must learn the diagonal patterns and how they are used in ADL, must know when and how to use the techniques of facilitation and relaxation, and must be able to apply patterns and techniques of facilitation to OT evaluation and intervention. Attaining these skills requires observation and practice under the supervision of a therapist experienced in the PNF approach.

Case Study

Sophia

Sophia, a 50-year-old woman, was referred for occupational therapy services after a right CVA resulting in left hemiplegia. Before the CVA she had a history of hypertension but otherwise good health. Referral to occupational therapy was made 10 days after onset of the CVA for evaluation and intervention in ADLs, visual perceptual skills, and left UE function.

Assessment

Initial assessment revealed intact vital and related functions, such as the oral and facial musculature and swallowing. Voice production was good. Sophia had a tendency to hold her breath during activities, and subsequent decreased endurance was noted. Visual tracking was impaired, with an inability to scan past midline and apparent left-sided neglect.

Her head and neck were observed to be frequently rotated to the right and slightly flexed because of weak extensors. Her trunk was noted to be asymmetric in a sitting posture, with most of the weight supported on her right side. Sophia's posture was flexed because of weak extensors. Static sitting balance was fair and dynamic sitting balance was poor, with Sophia listing forward and to the left.

Sophia's right arm was normal in sensation and strength, although motor planning was impaired. Her left arm was essentially flaccid, with impaired light touch, pain, and proprioceptive sensation. Sophia complained of mild glenohumeral pain during passive movement at the end ranges of shoulder abduction and flexion. Scapular instability was noted. No active movement could be elicited in her left arm.

Perceptual testing showed apraxia (especially during activities requiring crossing of the midline) and left-sided neglect. Sophia was alert and oriented, with good attention span and memory. Carryover in tasks was adequate.

Sophia needed moderate assistance in ADLs and moderate to maximum assistance in transfers. Impaired balance and apraxia were the most limiting factors in performance of ADLs. She stated her immediate goal as being able to get herself ready in the morning with less time and effort.

Intervention Implementation

Following the cervicocaudal direction of development, alignment of her head and neck was the appropriate starting point for intervention. Left-sided awareness, sitting posture, and trunk balance were directly influenced by the position of her head and neck. Before the start of self-care activities, Sophia performed head and neck patterns of flexion and extension with rotation. To reinforce rotation to left, the therapist was positioned to the left of Sophia. Clothing and hygiene articles were also placed to her left.

Lack of trunk control was another problem. During bending activities while seated, Sophia reported a fear of falling and was unsure of her ability to return to the upright position. Consequently, she had difficulty leaning forward to transfer from the wheelchair. The slow reversal–hold technique was used to reinforce trunk patterns during ADLs. For example, as a preparatory method to facilitate the trunk control needed for donning pants over legs, the therapist was positioned in front and to the left of Sophia. Manual contact was on the anterior aspect of either scapula. The therapist moved with Sophia and applied resistance as she leaned forward. At the end of the range, Sophia was instructed to hold with isometric contraction. Manual contact was then switched to the posterior surface of either scapula. Resistance was applied as Sophia returned to the upright position. The verbal command was, “Look up and over your right shoulder.” When she was upright, she was again instructed to hold with isometric contraction. In addition to reinforcing trunk control, this technique alleviated Sophia's fear of leaning forward because the therapist was in continual contact with her.

An indirect benefit of the flexion and extension patterns of the head, neck, and trunk was the reinforcement of respiration. Sophia was encouraged to inhale during extension and exhale during flexion. This approach eliminated Sophia's tendency to hold her breath.

Intervention consisted of total patterns and techniques to facilitate proximal stability in the left UE and to provide proprioceptive input. Weight-bearing activities were selected because no active movement was available in her left arm. Sophia used her right UE in diagonal patterns to perform repetitive perceptual tasks, such as a mosaic tile design, paper-and-pencil activities, and board games. These activities were performed to include the side-lying posture on the left elbow, the prone posture on elbows, the side-sitting posture with weight on the left arm, and posture on all fours. To reinforce stability at the shoulder girdle, approximation and rhythmic stabilization were used with manual contact at both shoulders and then at the shoulder and pelvis. The performance of perceptual tasks in diagonals improved Sophia's motor planning, left-sided awareness, and trunk rotation.

Sophia was instructed in bilateral asymmetric chopping and lifting patterns to support her scapula and left UE in rolling and other activities. These patterns also enhanced left-sided awareness and trunk rotation. To facilitate scapular movement during chop and lift patterns, the therapist applied stretch to initiate movement, followed by the slow-reversal technique. In preparation for the lift pattern, manual contact was placed on the posterior surface of the scapula. Stretch was applied in a lengthened range. As Sophia initiated the lifting pattern, resistance was provided and maintained throughout the ROM. This procedure was repeated for the antagonistic or reverse-of-lift pattern, with manual contact switching to the anterior surface of the scapula.

About 3 to 4 weeks after the injury Sophia was able to initiate left UE movement in synergy with a predominance of flexor tone. Weight-bearing activities and rhythmic rotation were helpful in normalizing tone, and both techniques were used with ADLs such as dressing and bathing. Wrist and finger extensions were facilitated in the D_1 extension and D_2 flexion patterns by using repeated contractions.

Outcomes

Reevaluation after 5 weeks of occupational therapy revealed increased endurance and ability to coordinate breathing with activity and consistency in crossing the midline during visual scanning activities. Sophia was able to turn her head and neck to the left without cues from the therapist. The fear of falling forward with bending had diminished, and she automatically turned her head to look up and over her shoulder to reinforce assumption of the upright position. As trunk strength continued to improve, reinforcement with head and neck rotation was no longer necessary. Visual tracking alone, in the direction of movement, was sufficient to reinforce assumption of the upright position. Eventually, Sophia was able to achieve an upright position without apparent visual or head and neck reinforcement. Sitting balance improved with bilateral weight bearing through both hips. Shoulder pain decreased and scapular stability improved during weight-bearing activities. Sophia initiated left UE movement out of a flexor synergy pattern. Right UE motor planning was within functional limits for ADLs. Transfers and self-care required only minimal assistance, and cues were no longer needed for left UE awareness.

Section 3 Neurodevelopmental Treatment Approach*

Case Study

Charlotte

Charlotte is a 69-year-old woman who sustained a left CVA with resultant right hemiplegia 4 months ago. She is able to move her right arm in a synergistic manner but does not have smooth coordinated movements. When she attempts to use her right arm as an assist for functional tasks, the movement of her arm is dominated by hypertonicity in flexor muscles and it is difficult for her to extend her elbow or open her hand to grasp objects. She is able to stand and walk but tends to maintain more weight on her left lower extremity and take small steps with her right. She is right hand dominant and is having difficulties completing both ADL and IADL tasks that require the use of both hands. In particular she reports that it is difficult for her to cook meals and dress herself. Although she was instructed in one-hand dressing techniques, she reports that it is very time consuming and tiring to use these strategies. Charlotte reports that she misses not being able to paint, play the piano, or garden. She would like to improve the control of her right arm and hand.

Critical Thinking Questions

1. What additional information would be useful in designing an intervention plan to foster improved right hand function?
2. Which assessments would be useful to evaluate Charlotte's upper extremity function in relation to her occupational goals? How would the occupational therapist best evaluate Charlotte's upper extremity function in relation to her occupational goals?
3. What intervention would support the best outcomes to meet the client's goals?
4. Through skilled analysis of client factors and performance skills, what client abilities can be fostered during intervention and used to support the client's engagement in occupations?

Historical Context of the Neurodevelopmental Treatment Approach

Neurodevelopmental treatment (NDT), as it is currently referred to in the United States, originally began as the "Bobath concept," a treatment approach developed by Berta and Karel Bobath in the 1940s. Berta Bobath received her early training as a remedial gymnast at the Anna Herrmann School of gymnastics in Germany, where she stayed on as an instructor of gymnastics upon graduation.[81] She described the focus of her educational program at Anna Herrmann:

We were taught about the analysis of normal movements and various ways of relaxation. We learned to feel and evaluate degrees of relaxation not only on tight muscles but its effect on the strength and activity of their antagonists. This was done by a special way of handling a person, inducing movements in response to being moved.

In the 1930s, when the Nazis came to power in Germany, Berta Bobath lost her job as a gymnastics instructor; the school would not retain a Jewish teacher. She subsequently moved to London, eventually working at the Princess Louise Hospital.

Based on her background and skills in analyzing normal movement, Berta Bobath was repeatedly asked to see special cases of both children with cerebral palsy and adults with hemiplegia. At the time, it was assumed that individuals with upper motor neuron (UMN) lesions could not recover from their motor deficits. Because of her background in dance, her training in posture and the analysis of movement, and likely also her "heretical or eccentric"[88] views, Berta Bobath did not ascribe to this belief. She began by using her hands and body to reposition these clients into neutral and symmetric alignment. She examined the impact of her positioning and handling on their muscle tone and ability to move. Berta described the basis of her approach as "the inhibition of released and exaggerated abnormal reflex action, the counteraction of abnormal patterns, and the facilitation of more normal automatic voluntary movements."[81]

After much experience and success with her techniques, Berta ultimately studied to become a physiotherapist and passed the examination in 1950. Dr. Karel Bobath, Berta's husband and a psychiatrist, became interested in the approach and spent much of his career studying and explaining the neurophysiology behind Berta's observations. Together, Berta and Karel Bobath are credited with the development of the Bobath concept and the neurodevelopmental treatment approach. They established the first Bobath Centre in London in 1951 and soon began training other physiotherapists on her approach to the treatment of children with cerebral palsy and adults with hemiplegia. Today, courses on this approach are taught both nationally and internationally to occupational and physical therapists, speech-language pathologists, and, in some countries, nurses, physicians, and teachers.[38] Information regarding continuing education courses in the United States (for occupational therapists) can be found at the Neuro-Developmental Treatment Association (NDTA) website: www.ndta.org.

Based on the time period in which it was established, several contemporary authors described NDT as a treatment approach that is based on a hierarchical view of the nervous system. Although the accepted view of the nervous system at the start of the NDT approach reflected a hierarchical model, it does not appear true, or consistent with the writings of the Bobaths and other historians. The NDT approach was *not originally based on* a hierarchical perspective. The approach was based on Berta Bobath's experiences—her skilled observations of alignment, posture, and movement—and she achieved remarkable results in helping clients to improve functional movement. The results were then interpreted using the reflex-hierarchical model, which, at that time, was the proposed explanation of how the CNS was organized.[72,81] This inductive sequence, from observations to theory development, is discussed in many historical accounts of the approach. Although dynamic models of central nervous system function and specifically motor control did not exist at the time, contemporary dynamic perspectives support Berta Bobath's original observations and experiences more accurately than reflex-hierarchical models. Her handling resulted in changes in tone and movement capacity that were unlikely (or could not have resulted) if the client's tone and movement patterns were exclusively reflexive in nature. Her handling tapped into the dynamic system influencing motor output that is reflected in contemporary models of motor control.[84]

Whether the original NDT approach was founded upon a reflex-hierarchical perspective or simply explained in terms of that model, it was clearly suggested as a "living concept" from its inception[38]; theoretical and intervention concepts were intended as "working hypotheses." Dr. Bobath used this terminology to stress the need for the approach to change over time with new information. Because the approach was grounded in an understanding of and appreciation for normal movement rather than pathology, he emphasized that NDT would continue to evolve as the understanding of normal movement advances through new discoveries and theory development.

Berta Bobath's Developing Theory: Original Concepts and Changes Over Time

Philosophy of Neurodevelopmental Treatment

Deeply engrained in an NDT-trained therapist's methods are the philosophical underpinnings of the approach stemming from its opposition to prevailing perspectives in the 1950s. When Berta Bobath began working with people with UMN lesions, most people believed that these individuals would not recover, and practices reflected this perspective. Individuals were either not provided rehabilitation services or were provided a compensatory approach exclusively. Any remedial intervention was from an orthopedic frame of reference—primarily stretching and strengthening—and therefore did not address the neurologic basis underlying the movement problems.[38,72] Contrary to these views and practices, and related to her clinical observations and experiences, Berta Bobath believed these individuals could regain control of movement, given the right opportunities.

Part of the NDT philosophy is *a belief in recovery*, in the client's potential. This belief was coupled with a belief in the influence that normal movement could have on a person's quality of life. In the foreword to Bobath's first book[6], Dr. P.W. Nathan (1970) eloquently exposed some of the philosophical underpinnings of the approach, the essence of which remain today:

Whether the doctor knows he is doing so or not, he chooses either a policy of persuading the client to use the hemiplegic limbs and re-train his affected side, or else a policy of encouraging the client to neglect the hemiplegic side and to use the unaffected side for all tasks previously done by the limbs of both sides. The choice affects only the upper limb and the general posture of the client. There is no choice about the lower limb; the client has to learn to use it. That being so, it is best for him to learn to use it properly. If the client gives in to this neurological disorder, he will become an invalid. If he learns to retrain his hemiplegic side, he returns to life.

Key Principles of Neurodevelopmental Treatment

The NDT approach is now widely described as a problem-solving method for restoring movement and participation for individuals with UMN lesions, specifically cerebral palsy and hemiplegia.[38] The approach is aimed at restoration of function through identifying and correcting underlying impairments that interfere with movement and participation in everyday activities. The emphasis is on regaining normal movement and postural control, and quality of movement in general. Compensations are discouraged.[30] Clinicians studying the approach are instructed in Berta Bobath's belief in the potential of the hemiplegic side to recover movement and her emphasis on addressing the whole body and the whole person. According to Tallis,[88] the "fundamental ethos of Bobath [remains today as]…the client as partner, rehabilitation tailored to the client's current situation, and rehabilitation as a 24/7 activity."

Although the basic principles of intervention remain the same, ideas regarding the nature of the client's movement deficits and how movement is controlled and learned have evolved over time in response to scientific advances. Primary changes to the approach can be tied to discoveries in neuroscience and motor learning research, specifically a dynamic and interactive understanding of the way in which movement is controlled and executed, and feedback is utilized. In the most recent edition of her book on adult hemiplegia, Bobath[8] outlined the major problems of the client as abnormal coordination of movement and abnormal postural tone and control. Current findings suggest that motor performance deficits result from the combined "neurological dysfunction due to damage of the CNS, musculoskeletal changes, and learned movement strategies."[30] Intervention is no longer directed at reducing spasticity; merely reducing spasticity will not foster improvements in the client's motor control. However, there appear to be other aspects of hypertonicity that are non-neural in nature, such as changes in muscle length (shortening), joint alignment, and recruitment patterns, that tend to be amenable to handling strategies. Motor output is organized around task goals, and therefore motor skills are practiced in function as much as possible. Errors are required for motor learning, as is active participation on the part of the client; therefore passive movement of the client is minimized and handling is graded to assure increasing autonomy on the part of the client (Fig. 31.16).

Using Neurodevelopmental Treatment to Restore Participation in Occupation

There has been a fair amount of controversy in the literature not only about the efficacy of NDT, which is addressed in the next section, but also about the approach itself.[22,60,61] Given the changes in the NDT approach over time, questions arise as to which aspects of the approach have remained constant. What are the current NDT strategies used to promote recovery of functional movement and therefore participation in occupation? What makes something NDT versus an entirely new approach to intervention? Because NDT has changed over time, other approaches have evolved from NDT, and NDT is used in combination with other approaches, it can be challenging to specify exactly which specific strategies are NDT. Physiotherapists who use the Bobath concept were surveyed and agreed that the following interventions are definitely or probably part of the approach: facilitation, mobilization, practicing motor skills of certain activities, practicing activities themselves, and teaching caregivers how to position the client.[93] Based on a review of the literature and the content of NDTA-approved courses (ndta.org), the next section represents a distillation of contemporary evaluation and intervention using the NDT approach.

It should also be mentioned that the NDT approach is incorporated into occupational therapy evaluation and intervention to address problems of motor control and functional movement. The approach alone does not provide a thorough lens with which to view the dynamics of occupational problems in context. NDT should be used in concert with other theoretical models in order to provide a comprehensive occupational therapy program. It should also be combined, as appropriate, with other interventions supported by the best available contemporary research, to effectively manage the client's needs and responses.

Evaluation

Based on a top-down approach to intervention, an occupational therapist using the NDT approach begins with an occupational history interview. Grounded in the occupational profile and the client's goals, the therapist would then observe the client's performance in various occupations. Based on NDT, this observation would include assessment not only of the client's level of assistance and the amount of movement present, but also of the *quality* of his or her movement and postural control.

Specifically, the clinician would assess the following:

1. The client's ability to maintain postural alignment required for the occupation. Consider Charlotte and her alignment when standing where the majority of her weight is shifted to her left leg and her right arm is predominantly flexed.

2. The “normal” or typical motor performance skills required for the tasks or activities that will be addressed. NDT-trained therapists analyze movement in terms of the whole body and the stability-mobility relationships between body segments in a task.

3. The client's alignment and movement while performing basic motor skills necessary in everyday activity such as reaching, sit-to-stand, and transferring, as well as while performing occupational goals.

4. Underlying impairments that are contributing to movement dysfunction. Ryerson and Levit[78] outlined the four primary impairments resulting from CNS lesions as “changes in muscle strength, muscle tone, and muscle activation, and changes in sensory processing.” It is these impairments that result in compensatory movements observed following CNS lesion and also, without intervention, often result in secondary impairments such as “changes in orthopedic alignment and mobility, changes in muscle and tissue length, edema, and pain.” Impairments are typically assessed in upright postures and during functional activity, through observation, handling, and the patient's subjective report. A common method for assessing tone is *placing,* in which the therapist guides the limb and asks the client to hold against gravity. If tone is too low, the client cannot hold the limb against gravity; if it is too high, the therapist will feel resistance during placing.[7]

Intervention

Because Bobath[7] believed that you cannot “superimpose normal patterns on abnormal ones” and because there is a desire to minimize abnormal patterns of movement from the beginning, therapists are encouraged to overlap evaluation and intervention.[44] Although “normal” movement has been emphasized since the inception of the approach, more recent descriptions emphasize efficient and functional movement, minimizing compensations.[63] Intervention typically includes facilitation of the normal motor performance skills involved in a task as well as practice of tasks themselves—or occupations—with manual guidance or handling.[51] An occupational therapist will also use the NDT framework when providing compensatory strategies to promote modified independence in necessary and valued occupations while remediating motor skills. Compensations based on an NDT approach stress incorporating the hemiplegic side as much as possible; avoiding repetition of abnormal movement patterns with the hemiplegic side, many of which lead to orthopedic impairments over time; and neutral/symmetric alignment during activities, which reinforces the other two.[78] After analyzing the client's movement problems and tendencies, both outside of and within the occupational goal, intervention is structured according to the following sequence: preparation → movement → function. These steps overlap within an intervention session as well as structure the series of sessions overall. Preparation encompasses all of the activities that are necessary for the client to actively work on motor skills required for the task and the task itself. Preparation might include the following:

1. The therapist's careful analysis of the movement components required for the task or occupational goal. A helpful way to organize this analysis is using segments of the body and analyzing the flow of movement that occurs within body segments and between body segments.

2. Set-up of the environment to promote active participation on the part of the client as well as attention to the client's starting alignment for activity. Consider the task of preparing vegetables for a meal. Although compensatory strategies may be used, incorporating the use of both hands while preparing vegetables provides a more functional approach (Fig. 31.17).

FIG. 31.17 Preparing for a meal using both hands to chop (**A**) and peel (**B**) vegetables.

3. Mobilization to give the client access to the range of motion required for the task.

Following preparation, the therapist will structure the session to work on specific motor skills required for the task. Often these are partially addressed outside of the occupation itself, in preparation for practice of the whole task, which is congruent with motor learning guidelines regarding part and whole-task practice.[28] Along with verbal cues, demonstration, and structure of the environment, facilitation of motor skills is done with *handling*. In handling, the therapist uses his or her body in contact with the client's to promote more efficient movement and avoid unwanted motor responses or alignments. Specifically, therapists use handling to add to the sensorimotor information that the client experiences during the performance of task, to make the client more aware of his or her body and incorporate the hemiplegic side, and to assist with the coordination and timing of movement patterns.[63] Continuing education courses and textbooks based on the NDT approach instruct clinicians on precise choices for hand placement that result in desired movement outcomes. These choices are referred to as *key points of control* (Fig. 31.18). Although the therapist uses manual handling and guiding, the client should be active in the process. Handling and guiding should be graded to provide just enough assistance and input to give the client a feel for a more efficient movement pattern, and gradually withdrawn as the client progresses and is able to do more of the movement pattern and task independently.[30]

FIG. 31.18 Key points of control. Trunk extension.

Intervention for limb movements is also graded from closed-chain patterns of movement to open-chain patterns. A closed-chain movement is one in which the distal part of a joint, or "chain" of joints, is fixed, and the proximal part is moving.[71] An example of a closed-chain pattern for the upper extremity (UE) would be incorporating the arm in a weight-bearing alignment for postural support and to assist with balance during an activity such as standing at a counter weight bearing on one hand for support while reaching overhead into a cupboard for an item (Fig. 31.19). Muscles in the weight-bearing arm must be active. Clinicians using an NDT approach include the UE in weight bearing as part of the base of support to assist with postural control and also to promote sensory input and isometric and eccentric control in the limb. Use of the weight-bearing or closed-chain strategy requires muscle activity in the arm; it is not passive positioning. Closed-chain weight-bearing positions are often combined with movement over the base of support to encourage activation of the UE to maintain balance.

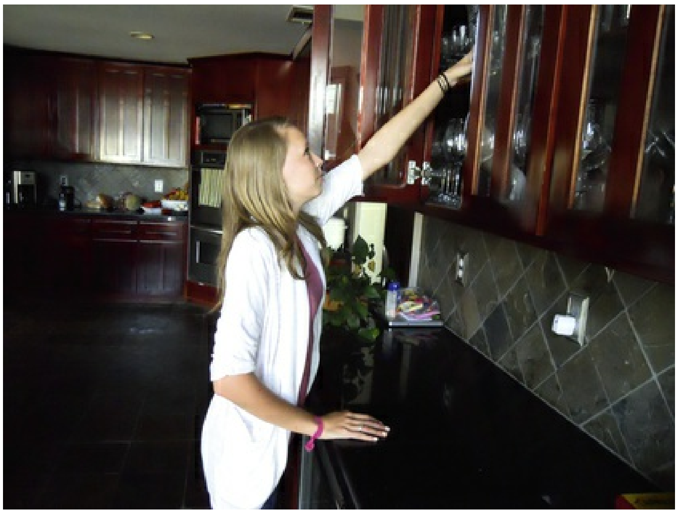

FIG. 31.19 Closed chain with weight bearing on upper extremity to support postural control.

Positioning the UE with the hand in contact with a stable surface can also be a useful position for mobilization and stretching the distal UE and to grade facilitation of isolated movement patterns in the arm. During mobilization and stretching, particularly of the wrist and hand, moving the arm on a fixed hand allows the therapist to stretch the extrinsic finger, thumb, and wrist flexors (Fig. 31.20). Muscle lengthening may lead to decreases in hypertonicity. In addition, when promoting isolated movement of the UE—for example, in reaching patterns of shoulder flexion with elbow extension—the distal contact offers the limb support and decreases the resistance or demand on proximal musculature required for the task. Similar to handling and other forms of sensory input and feedback, this support must be gradually withdrawn in order for muscle strengthening and motor learning to occur. The sequence of facilitation should proceed to incorporation of the learned movement patterns into an occupation or functional task. Handling is gradually decreased as the patient is able to complete efficient movement patterns.

FIG. 31.20 Weight bearing on the hand to mobilize and stretch wrist and finger flexors while supporting postural control.

Neurodevelopmental Treatment and Evidence-Based Practice

Evidence-based practice is a clinical reasoning process that combines the best available research, a clinician's expertise, and the client's preferences and values in order to make decisions about intervention with individual cases to provide the most effective and efficient care.[79] The best available research for clinical decision making regarding the effectiveness of specific interventions is a systematic review of randomized clinical trials or a randomized clinical trial.[27,82] Few studies exist that have addressed the effect of NDT on client outcomes. At the present time, a great majority of the evidence for the effectiveness of NDT is at a lower level on the evidence scale—expert opinion. The experts include many practitioners as well as clients and caregivers—who could be considered experts on their own lived experiences with the condition—who report positive outcomes as a result of incorporating NDT principles and management strategies into intervention.

The limited number of systematic reviews and clinical trials addressing the effectiveness of the NDT approach has yielded mixed results. One systematic review of the literature by Kollen et al.[50] examined 16 studies encompassing 813 clients and concluded that "there was no evidence of superiority of Bobath on sensorimotor control of upper and lower limb, dexterity, mobility, activities of daily living, health-related quality of life, and cost-effectiveness." Intervention studies have reported positive effects of NDT on gross motor skills in children and gait patterns in adults with CP.[47,92] Findings by Luke, Dodd, and Brock[56] indicated that although the Bobath concept was found to have slightly better results than other approaches or no intervention at all in reducing shoulder pain and tone, the Bobath concept was one approach among several that did not demonstrate "superiority of one approach over the other at improving upper limb impairment, activity or participation." Similarly, Paci,[69] in his review of 15 trials, found no evidence to support NDT as an optimal type of treatment, but also no conclusive support for the idea that the approach is not effective. Researchers agree that additional higher-level research, with more rigorous methodologies that define and detail NDT methods, is needed to provide evidence-based guidelines for practice. To systematize such research, Tyson, Connell, Busse, and Lennon[93] outlined a "typical treatment package" for future clinical trials based on their study of physiotherapists using the Bobath concept. The focus of the intervention package would be "facilitation, mobilization, practicing the components of movement, practicing a few whole activities, and teaching clients and caregivers on how to position the client." It has also been suggested that researchers study specific intervention techniques, rather than the NDT concept or approach as a whole.[93]

Neurodevelopmental treatment is not alone in lacking evidence. As Mayston stated,[62] "the reality is that there is only partial evidence to support current modalities such as task-specific training, constraint-induced movement therapy, treadmill training and muscle strengthening." The present evidence for use of the NDT approach consists of widespread clinical observations and expertise along with limited clinical trials and systematic reviews. In spite of a lack of high-level evidence supporting its efficacy, according to authors of one systematic literature review, “in the Western world, the Bobath Concept or neuro-developmental treatment is the most popular treatment approach used in stroke rehabilitation.”[50] This evidence, although useful and substantial, is not enough to warrant continued and isolated use of this approach as research demonstrating more effective or efficient methods at higher levels of evidence becomes available. Based on dynamic models integrating multiple systems within and outside the person that contribute to the control of movement, as well as occupational performance, contemporary clinical reasoning and intervention planning for individuals with UMN lesions must consider the complex web of factors contributing to function and integrate all available resources and intervention methods, supported by evidence, that contribute to effectively restoring participation in desired occupations (Fig. 31.21).

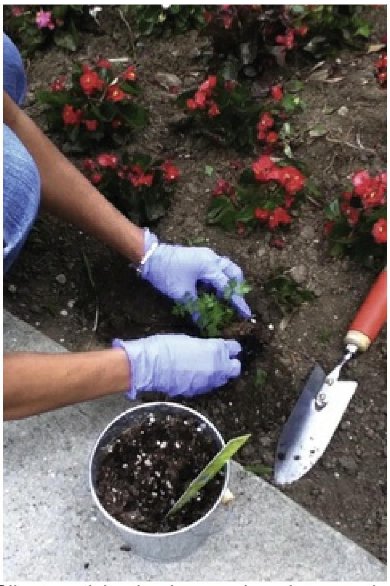

FIG. 31.21 Client participating in an enjoyed occupation, gardening.

Review Questions

1. What are the four general processes of information flow related to control of movement?
2. Define motivational urge and name the locus of this function in the brain.
3. Trace the flow of information in the central and peripheral nervous systems that leads to purposeful movement.
4. What is the sensorimotor system?
5. List the areas of the sensorimotor cortex.
6. List the structures that constitute the higher, middle, and lower levels of the CNS components for movement.
7. Name the four traditional sensorimotor approaches to treatment and the theorist responsible for each.
8. Which two models of motor control form the basis for the sensorimotor approaches to treatment?
9. Briefly describe each of the four traditional sensorimotor approaches to treatment. Compare and contrast their similarities and differences.
10. List some techniques used by therapists to influence or modify motor responses in each of the traditional sensorimotor approaches.
11. How are the sensorimotor approaches used in current clinical practice?
12. In clients with pain, what tone of voice should be used when giving verbal commands?
13. Discuss the significance of auditory, visual, and tactile input in motor learning.
14. Which UE diagonal pattern is used for the hand-to-mouth phase of eating? For zipping front-opening pants?
15. Discuss the advantages of using the chop and lift patterns.
16. Which trunk pattern is used when donning a left sock?
17. List three advantages of using the diagonal patterns.
18. What is the developmental sequence of total patterns?
19. If a client needs more stability, which of the following total patterns should be chosen: side lying or prone posture on elbows?
20. Which PNF technique facilitates postural control and cocontraction?
21. Discuss the neurophysiologic principles of Sherrington on which the PNF techniques of facilitation are based.
22. What is an effective technique to prepare a client with UE flexor spasticity to don a shirt?
23. Define maximal resistance.
24. Name two PNF techniques that facilitate initiation of movement.
25. What are the key principles of the NDT approach?
26. What is the difference between a closed and open kinetic chain?
27. Identify a task in which you would use a closed kinetic chain and a task in which you would use an open kinetic chain.

Motor Learning

Shawn Phipps, Pamela Roberts

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, the student or practitioner will be able to do the following:

1. Describe how motor control affects occupational performance.
2. Describe the dynamic systems theory and how it explains motor control.
3. Describe the task-oriented approach to motor learning.
4. Describe constraint-induced movement therapy as an intervention targeting functional use of a hemiparetic upper extremity following a neurological insult to the brain.
5. Describe the use of robotics in the use of upper extremity motor control.
6. Describe the use of virtual reality technology in the use of upper extremity motor control.
7. Describe the use of bilateral training techniques for improving upper extremity motor control.
8. Develop client-centered and occupation-based treatment programs to facilitate motor learning.

KEY TERMS

Bilateral training techniques
Brain plasticity
Constraint-induced movement therapy (CIMT)
Dynamic systems theory
Feedback
Heterarchical model
Hierarchical model
Knowledge of results
Learned nonuse
Motor control
Motor learning

Robotics
Shaping
Task-oriented approach
Virtual reality technology

Threaded Case Study

Richard, Part 1

Richard, a 66-year-old African American man, was admitted to a rehabilitation hospital on January 21, 2011, because of the onset of a left cerebrovascular accident (CVA) with resulting right-sided hemiparesis.

Before admission, the client lived with his wife in an apartment with four steps at the entrance. They have four grown children who do not live in the area. They also have three grandchildren. Richard is a retired electrician. He was independent in all activities of daily living (ADLs) before admission. He was responsible for meal preparation, household maintenance, and finances. He enjoys gardening, playing cards, and cooking. His social participation consisted of doing the weekly grocery shopping, attending church every Sunday, and going to the theater with his wife and family.

Richard's symptoms include right-sided hemiparesis. He has selective motion at the shoulder, elbow, wrist, and hand. He is able to lift his affected arm above his head and to grasp and release objects of all sizes; however, he has difficulty manipulating smaller objects.

Richard's daily routine consisted of getting up each morning at 6:00 am and walking the dog for about a mile. He then cooked breakfast for himself and his wife. After breakfast he was responsible for cleaning the kitchen and doing basic household maintenance.

Using the Canadian Occupational Performance Measure (COPM),[31] Richard identified the following occupational performance problems:

- Inability to perform cooking tasks with bilateral upper extremities
- Difficulty with fasteners and with the manipulation of objects of different textures and sizes smaller than 1 inch
- Inability to turn the pages of a prayer book while in church
- Difficulty performing the transitional movements of sitting to standing to kneeling and kneeling to standing to sitting while in church
- Inability to perform transitional movements during gardening activities
- Inability to manipulate cards with the affected upper extremity

Critical Thinking Questions

1. How has Richard's motor control affected his ability to engage in meaningful occupation?
2. What motor control intervention strategies would enable Richard to more effectively engage in his daily occupations?

Theoretical Foundations of Motor Learning

Motor learning is the acquisition and modification of learned movement patterns over time.[65] It involves cognitive and perceptual processes to code various motor programs. Motor learning requires practice and experience, which leads to permanent changes in the person's ability to produce movement sufficient to meet the demands of occupational performance. **Motor control** is the outcome of motor learning and involves the ability to produce purposeful movements of the extremities and postural adjustments in response to activity and environmental demands.[9]

The process of motor learning after a CVA, traumatic brain injury, cerebral palsy, and other neurological insults to the brain has received an enormous amount of attention in research and occupational therapy (OT) practice. Researchers have found that 5 years after the onset of a stroke, approximately 56% of clients continue to have severe hemiparesis.[17] The initial degree of motor impairment is a predictor of motor recovery, especially during the first few weeks after a stroke.[4,8] Dominkus et al.[15] assessed motor recovery in the upper extremity with the Motricity Index[14] and found that a client with initial paresis was 4.58 times more likely to achieve motor recovery than a client with initial paralysis. Furthermore, nearly 400,000 people survive with some level of neurological impairment and disability.[26] The explosion of new research on **brain plasticity**, or the ability of the brain to reorganize and develop new pathways, has paved the way for evolving approaches that target the ability of the individual to regain movement that enhances occupational performance, participation, and quality of life.[65] Recent studies support the theory that a form of brain plasticity known as cortical map reorganization plays a major role in regaining functional use of a hemiparetic upper extremity after a CVA.[12,33,63]

Dynamic Systems Theory

Modern motor control approaches are based on the **dynamic systems theory**, which views motor behavior as a dynamic interaction between client factors (eg, sensorimotor, cognitive, perceptual, and psychosocial), the context (eg, physical, cultural, spiritual, social, temporal, personal, and virtual), and the occupations that must be performed to enact the client's roles.[39,40] The dynamic systems theory is based on a **heterarchical model** in which each component (eg, client, environment, and occupational performance) is viewed as being critical in a dynamic interaction to support the client's ability to engage in occupation.[9,65] Thus, movement and motor control are the result of a dynamic interaction between each of the subsystems. In addition, any change in the system has an effect on all the subsystems. For example, a CVA can lead to changes in the client's sensorimotor, cognitive, and perceptual skills, which affects motor control, engagement in occupation, and the person's ability to master the environment.[88]

The heterarchical model is contrasted to the **hierarchical model**, which views higher centers in the central nervous system as having control over the subordinate lower centers.[40] The traditional sensorimotor approaches, such as neurodevelopmental treatment, proprioceptive neuromuscular facilitation, and the theories developed by Rood and Brunnstrom, are based on a hierarchical model. Recent research supports a dynamic systems theory approach in which motor learning plus the development of motor control is a dynamic process that involves interaction of the person, environment, and occupations that the client needs to perform or wants to perform.[2]

Task-Oriented Approach

The **task-oriented approach** to motor recovery is based on dynamic systems principles in which occupational performance and motor recovery are achieved by a dynamic interaction of the person, the environment, and the occupations that the person is performing.[39,40] In OT, this approach is occupation based and client centered and focuses on enabling the client to achieve motor recovery through occupational performance using real objects, environments, and meaningful occupations.[57,60] Research shows that the use of real objects from the environment versus simulated objects produces better functional movement.[86] The client must also have the opportunity to attempt to solve motor problems in the context of multiple environments by using a variety of strategies.[6,23] For example, Richard (refer to case study) would need to be able to turn the pages in the prayer book in the spiritual context of his place of worship, in addition to using motor strategies that allow him to move from sitting to standing to kneeling. Research has shown that the environmental context plays a key role in the transfer of motor skill acquisition.[19,38]

Occupations that the client has identified as being important through the COPM[31] can be used to motivate the client to problem-solve various motor strategies. An intervention plan that is developed collaboratively between the client and the therapist can aid the client in taking a more proactive role in making progress toward his or her outcomes and can facilitate more effective follow-through. Research has shown that a client-centered and occupation-based approach can assist clients in attaining their personal goals.[76,77] Emerging research is also demonstrating that an occupation-based approach is more effective than rote exercise in remediating motor control impairments.[a] In addition, engaging in an occupation or activity from start to finish has been shown to elicit a more efficient, forceful, and coordinated motor response than has performing only small portions of an activity.[37]

Activity analysis must be used to analyze the necessary movements that the client must perform to complete the task successfully.[51] Effective upgrading and downgrading of the activity must be incorporated for clients to feel that they are successfully moving toward their goals based on their cognitive ability.[58] Motor learning can take place only if the client has multiple practice opportunities across several real environmental contexts.[19,32] Further, the use of a self-administered graded repetitive arm supplementary program (GRASP) has been shown to improve arm function and provides an effective delivery model for improving upper limb recovery.[22]

Qualitative (eg, verbal encouragement) and quantitative (eg, concrete measures of success or failure during a motor task) analyses have been shown to produce knowledge of results, which enables the client to cognitively reflect on the strengths and weaknesses of a particular motor strategy and implement a more effective strategy for completing an activity.[27,80,82] Through this dialog, the client can learn to transfer various motor skills across multiple contexts.[68]

OT Practice Notes

Feedback and analysis of factors that promote success or failure in a particular motor strategy must be a central problem-solving dialog between the OT practitioner and the client.[24,25,41]

Constraint-Induced Movement Therapy

Constraint-induced movement therapy (CIMT), or forced use, is a therapeutic strategy designed to promote functional use of a hemiparetic upper extremity and has been credited with speeding up the cortical map reorganization process in nonhuman primates[72] and in humans.[30] CIMT is also based on the principles of dynamic systems theory and a task-oriented approach to the acquisition of motor control. In other methods of stroke rehabilitation, clients learn to use the more functional or less involved upper extremity for daily activities. This treatment approach may foster learned nonuse of the more involved upper extremity. **Learned nonuse** is a phenomenon in which the individual neglects to use the affected or more involved extremity because of the extreme difficulty coordinating movement after the onset of a stroke, brain injury, or other neurological condition.[30]

As a person or an animal moves through its environment and manipulates objects, it receives sensory feedback from various sources simultaneously. Vision, audition, proprioception, and kinesthesia provide important sensory information for skilled movement. The importance of sensory information to motor action was demonstrated in the classic experiment carried out by Mott and Sherrington.[48] The afferent (sensory) input enters the spinal cord through the dorsal roots of the spinal nerves. By selectively severing the dorsal roots, sensory input was effectively eliminated while leaving motor innervation basically intact. Experiments conducted before 1955 demonstrated that deafferentation of a single forelimb in rhesus monkeys resulted in an unused extremity when the animal was unrestricted.

Animal research has led to the discovery that cortical reorganization occurs after injury to the nervous system.[33] Research on somatosensory deafferentation in monkeys has shown that if a single monkey forelimb is deafferented, the monkey will not use that extremity.[28] In other words, the procedure left the monkeys with intact motor nerves but no sensation in the affected upper extremity. The initial shock to the nervous system prevented movement. Even after the nervous system recovered, the monkeys failed to use their affected limb. Taub[69] theorized that use of the deafferented extremity could be retrained if the intact extremity is restrained and the monkey is forced to use the affected extremity. If the restraint was used for a specific time, between 1 and 2 weeks, the functional improvement could be permanent. These studies have shown that certain training procedures can be used to enable monkeys to regain use of their deafferented extremity.[28,29,70,71] Experimental evidence indicates that the persistent loss of motor function caused by deafferentation was due to learned behavioral suppression, a phenomenon called learned nonuse.[69] Conditioned response techniques did not show promise in restoring use of the extremity for daily activities.

Another therapeutic strategy, **shaping**, did result in significant improvements in motor function during ADLs. Shaping procedures are behavioral techniques that approach a desired motor outcome in small, successive increments.[45,54,73] Shaping strategies allow subjects to experience successful gains in performance with relatively small amounts of motor improvement. Explanations from several studies have led to the development of a hypothesis that explains why the constraint and training procedures improve motor recovery after deafferentation.

The theory of learned nonuse was first described by Taub and is thought to extend to humans after central nervous system damage (Fig. 32.1).[69-71,83] Animal research has demonstrated that when the forelimb is not functional, the animal no longer uses the affected upper extremity for everyday tasks. This tendency has led to reinforcement and persistence of nonuse of the affected limb. Constraining the unaffected limb of the monkeys provided the early evidence for reversing learned nonuse.

FIG 32.1 Client with a left cerebrovascular accident and right hemiparesis before initiation of the constraint-induced movement therapy (CIMT) program. The client demonstrates learned nonuse by using her stronger, uninvolved left upper extremity during self-feeding. (Courtesy Remy Chu, OTR/L.)

To date, rehabilitation methods for those who have sustained a CVA or other neurological insult to the brain have included, but are not limited to, biofeedback, neuromuscular facilitation, and operant conditioning. These various forms of rehabilitation are often used in conjunction with methods that teach clients to compensate by using their intact upper extremity to perform their day-to-day functional activities. Compensatory rehabilitation strategies may improve the efficiency of the intact upper extremity, but at the same time they encourage learned nonuse of the affected upper extremity. At present there is minimal experimental evidence demonstrating the positive benefits of these forms of therapy.

An alternative therapeutic approach, CIMT, has been used extensively for rehabilitation. Unlike more traditional rehabilitation therapies, CIMT forces the client to use the more involved upper extremity by immobilizing the less involved or unaffected upper extremity in a sling, mitt, or a combination of both (Fig. 32.2). Clients then practice using their affected upper extremity on an intensive basis for several consecutive weeks by using shaping movements with the affected upper extremity. The improvements noted in the more involved extremity after this program were attributed to the learned nonuse phenomenon described by Taub[69]; thus, part of the theoretic framework of CIMT is taken from the neurophysiological and behavioral studies of the learned nonuse of the more affected limb seen in animal experiments. Constraining the intact forelimb of these monkeys provided the first evidence of the ability to overcome the learned nonuse phenomenon. This success led to further studies involving humans with hemiparesis that developed after a stroke, brain injury, and other neurological conditions.

FIG 32.2 Constraint-induced movement therapy (CIMT) forces the individual to use the affected upper extremity by immobilizing the unaffected upper extremity in a mitt. (Courtesy Posey Company, Arcadia, CA.)

Wolf[83,84] and Miltner et al.[44] demonstrated the positive effects of using CIMT in individuals with stroke. Liepert et al.[33] demonstrated cortical reorganization in humans undergoing CIMT. In 1993 Taub et al.[74] found significant results when using CIMT in a randomized clinical trial of nine individuals after stroke. These subjects had experienced strokes from 1 to 18 years before participation in CIMT and were required to meet inclusion criteria similar to those used by Wolf et al.[84] (eg, possessing some wrist and finger extension while still demonstrating significant disability). Additionally, the subjects had to demonstrate good balance because they would be wearing a sling and would therefore be unable to use their less affected or unaffected upper extremity to protect themselves in the event of a fall. The subjects were randomly assigned to either an experimental group or a control group. The subjects assigned to the experimental group wore a sling on the less involved upper extremity for a period of 12 days. During the 12 days the sling was worn throughout all waking hours except when specific activities were being carried out, such as when it was unsafe or extremely difficult to use the more affected arm exclusively. The study also used a behavioral contract that included an agreement from the subjects to wear the restraint device for at least 90% of their waking hours during the 12-day intervention period. The behavioral contract specifically identified activities during which the subject was to use the more involved arm exclusively, to use both arms, and/or to use the less involved arm (for safety reasons). Participants in the control group were instructed to focus attention on the more involved upper extremity and were encouraged to attempt to use the more involved upper extremity for as many new functional activities as possible at home. Activities were recorded throughout the 2-week period. Those in the control group also received two sessions involving activities requiring active movement of the more involved extremity and were provided an individualized range-of-motion exercise program. The effectiveness of treatment was measured with the Wolf Motor Function Test (WMFT) and the Motor Activity Log (MAL), a structured interview exploring functional use in the life setting. Speed, quality of movement, and functional use of the affected upper extremity were significantly improved in the research group in comparison to the control group, and functional movement was maintained over a 2-year period.

In 1999 Kunkel et al.[30] also demonstrated a greater than 100% increase in the amount of use of the affected upper extremity in real-world environments. The effective factor in all forms of CIMT appears to be intensive practice and functional use of the affected upper extremity repeatedly across multiple contexts for many hours a day for a period of consecutive days.[85]

Over the past 30 years, numerous studies have further confirmed the effectiveness of CIMT versus traditional rehabilitation therapy in improving the client's functional motor control after stroke.[64] More recently, however, research involving CIMT has used various populations, altered the inclusion criteria, and modified the intensity of treatment and the length of the therapy program from the original research protocol. For example, Pierce et al.[56] found that the forced-use component of CIMT in conjunction with a home program may be effectively incorporated into the traditional outpatient setting. Furthermore, Page et al.[53] found that repeated task-specific practice is more critical than intensity in improving upper extremity function.

In the Very Early Constraint-Induced Movement during Stroke Rehabilitation (VECTORS) study,[16] 52 subjects were randomized to one of three groups an average of 9.7 days after stroke. The three groups included the following: (1) standard CIMT, in which subjects received 2 hours of shaping therapy and wore a mitt for 6 hours per day; (2) high-intensity CIMT, in which clients underwent 3 hours of shaping exercise per day and wore a mitt for 90% of waking hours; and (3) the control treatment, consisting of 1 hour of ADL training and 1 hour of upper extremity bilateral training exercises. All treatment was provided for 2 weeks. The primary end-point measure was the total Action Research Arm Test (ARAT) score on the more affected side at 90 days after stroke onset. In all groups the total ARAT score improved with time. Subjects in the standard CIMT and control treatment groups achieved similar gains in total ARAT score (24.2 and 25.7, respectively), whereas subjects in the high-intensity CIMT group exhibited an average gain of just 12.6 points.

Overall, there is conflicting evidence of the benefit of CIMT over traditional therapies in the acute stage of stroke; however, there is strong evidence of the benefit of CIMT and modified CIMT over traditional therapies in the chronic stage of stroke. The benefits appear to be confined to stroke patients with some active wrist and hand movements, particularly those with sensory loss and neglect. These findings have broadened the scope and applicability of CIMT to various populations.

Although recent CIMT research has expanded the scope to include different diagnostic criteria, different treatment regimens, and different inclusion criteria, little of the current CIMT research has addressed the participant's self-reported satisfaction in life roles after completing a CIMT program. After individuals have a stroke or other neurological condition, they experience a disruption in their life roles. This disruption can lead to feelings of ineffectiveness, incompetence, and helplessness. To restore health and quality of life, one must identify and alter one's lifestyle to improve the fit between oneself and the environment. CIMT has been proved to be effective in improving motor control in individuals who have experienced a stroke or other neurological condition. Functional carryover of CIMT from the clinic to the natural environment has been demonstrated. Research has shown significant improvement in daily use of the affected upper extremity and an increase in the speed at which the individual carries out activities after participating in a CIMT program. Increased life satisfaction resulting from an increased ability to use the affected upper extremity has been noted in individuals who reported satisfaction in performance of meaningful daily activities and life roles.[52,59]

To determine whether a subject meets the inclusion criteria for CIMT, a telephone screening protocol is often administered.[46] Many research studies use a CIMT protocol that contains typical inclusion criteria for use of this therapeutic strategy. These criteria can include (1) a first-time CVA that occurred more than 1 year earlier; (2) not currently receiving any therapeutic intervention; (3) a score of higher than 44 on the Berg Balance Test[3] or limited balance problems requiring an assistive device for mobility in clients who had a full-time caregiver to assist in any balance issues; (4) ability to move the affected arm in 45 degrees of shoulder flexion and abduction, 90 degrees of elbow flexion and extension, 20 degrees of wrist extension, and 10 degrees of extension at the metacarpal phalanges and interphalanges as determined by the client's available active range of motion (Fig. 32.3); (5) no significant cognitive impairments as demonstrated by a Mini-Mental State Examination score of at least 22[21] or other type of cognitive test; (6) no preexisting comorbid conditions that might interfere with mobility or function; (7) limited spasticity (score of 0 or 1) as measured by the Modified Ashworth Scale[5]; and (8) the ability to identify an individual or a caregiver who could assist in the home program.[46,59] In summary, potential reasons for a person to be excluded may include motor ability that is too high or too low, cognitive deficits that prevent adequate participation, and an existing high degree of functional use of the affected upper extremity.

FIG 32.3 The client is asked to demonstrate active wrist and finger extension in her dominant right hand. The client is able to achieve 20 degrees of wrist extension and 10 degrees of finger extension (at the metacarpal phalanges) from a flexed position. (Courtesy Remy Chu, OTR/L.)

A battery of assessments is typically administered to all clients included in a CIMT treatment program.[46] Results from these assessments are used to test certain research hypotheses, whereas other assessments are used for diagnostic purposes or to generate new hypotheses. Some typical assessments include the WMFT and MAL.

The WMFT consists of 15 motor items that examine contributions from the distal and proximal muscles of the arm. The tasks in this assessment are sequenced from proximal to distal and gross to fine motor. The majority of tasks are completed with the subject seated in a chair. Standard tasks, such as lifting the forearm to the table, reaching for an object, or lifting a pencil, are rated on a scale from 0 (does not attempt with the weaker arm) to 5 (movement appears normal), and the time to complete the task is measured (Fig. 32.4). The WMFT uses a grid or template that is taped to the desk to specify standardized measurements. The WMFT is administered before the intervention, immediately after the intervention, and at a designated follow-up time.

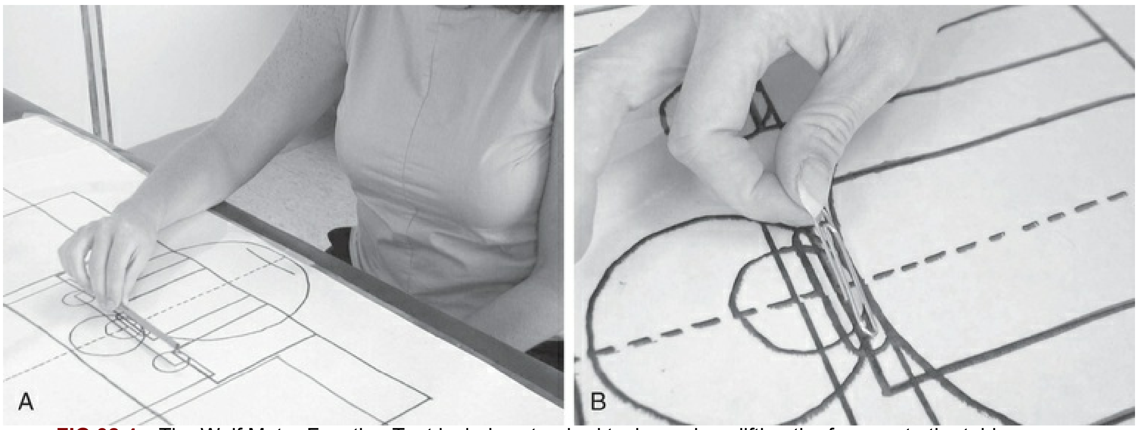

FIG 32.4 The Wolf Motor Function Test includes standard tasks such as lifting the forearm to the table and reaching for an object.

The MAL was developed for the purpose of assessing activities attempted outside the clinical setting. The MAL is a self-reported, 30-item instrument administered in an interview format. Subjects are asked to rate their performance on each activity reported, and emphasis is placed on clients' functional use of the hemiparetic upper extremity in their home environment. The assessment is administered approximately 10 times throughout the course of CIMT intervention. The instrument consists of specific functional activities, such as turning on a light switch or opening a drawer. The amount of functional use of the more involved upper extremity is rated by the participant from 0 (never used) to 5 (involved arm used the same as it was before the stroke).

Quality of movement (how well) is also self-rated from 0 (not used) to 5 (normal movement).

Therapeutic procedures using CIMT in the clinic are performed under the supervision of an OT practitioner (Fig. 32.5). The procedures are effective only if use of the affected upper extremity is carried over to the client's home and community environment. Clients are asked about their compliance in incorporating their affected upper extremity into functional activities as noted in a log or personal diary. The home diary is used to outline the clients' activities from the time at which they are discharged from the clinic until they return for their CIMT sessions. A typical daily schedule is often used. The schedule includes the time and length of rest periods.

FIG 32.5 A, Initiation of the constraint-induced movement therapy (CIMT) program during a self-feeding activity. The client requires minimal hand-over-hand physical assistance to take her first bite with her weaker right hand. Hand-over-hand physical assistance focuses on eliminating gravity as the client brings the spoon to her mouth. B and C, After 10 CIMT trials, the client is attempting to feed herself without physical assistance from the occupational therapist. (Courtesy Remy Chu, OTR/L.)

Specific shaping task practice is also listed on the daily schedule. A desired motor or behavioral objective is approached in small steps with an individualized shaping plan. During shaping, explicit feedback is provided to identify small improvements in motor or functional performance. The shaping task selected depends on the specific joint movements exhibiting impairment that have the greatest chance of improving and the client's preference among tasks that have a similar potential for producing specific improvements. Applying CIMT and shaping requires repetitive, supervised, constant practice. CIMT study protocols call for 6 hours of continuous task practice per day (Figs. 32.6 and 32.7).

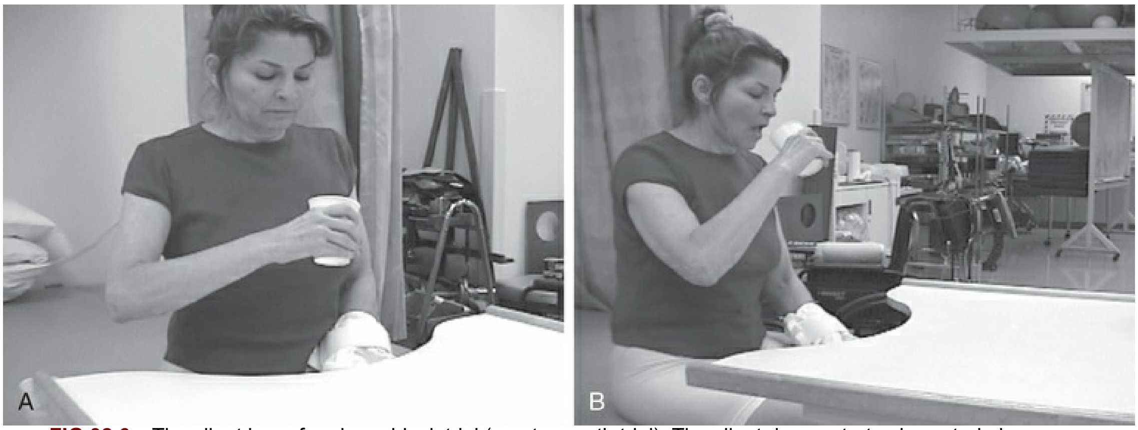

FIG 32.6 The client is performing a block trial (cup-to-mouth trial). The client demonstrates less strain in her neck and shoulder while bringing the cup to her mouth. (Courtesy Remy Chu, OTR/L.)

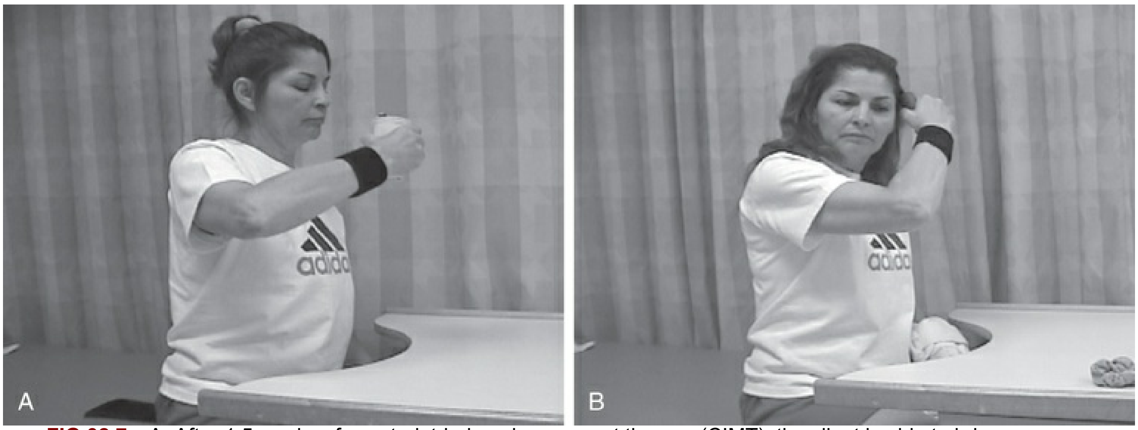

FIG 32.7 A, After 1.5 weeks of constraint-induced movement therapy (CIMT), the client is able to bring a cup to her mouth independently with the weaker right upper extremity. B, She is also able to bring her right hand to her head to brush her hair. (Courtesy Remy Chu, OTR/L.)

An important component of interventions designed to enhance motor learning is the feedback received by the client while attempting a movement strategy and the results of the movement action.[51] **Feedback** refers to the sensory experiences intrinsic to the client and the external information provided by the environment, which includes verbal comments from the OT practitioner. This combined type of feedback can be seen when a client attempts to place a hemiparetic arm into the wrong sleeve of a button-front shirt and receives the visual information that something does not "look correct," along with verbal directions by the OT practitioner that placing the arm in the other sleeve will make the task easier. **Knowledge of the results** is a form of external feedback in which the client assesses whether the correct results were achieved after completion of the motor action. The OT practitioner assists the client by providing feedback during performance of the motor task and on completion of the motor task to assess the results. These strategies are combined with shaping to foster a higher frequency of successful motor practice for functional tasks.

A more recent study that evaluated the immediate and long-term effects of upper extremity rehabilitation approaches for stroke compared functional task practice and strength training with standard care and found that task specificity and stroke severity are important factors in rehabilitation of arm use after an acute stroke.[81] Another recent approach that involves repetitive training of the paretic upper extremity on task-oriented activities has provided evidence of efficacy in stroke survivors. The Extremity Constraint Induced Therapy Evaluation (EXCITE) trial of individuals 3 to 9 months after stroke found that CIMT produced statistically and clinically relevant improvements in arm motor function that persisted for at least 1 year.[84] In summary, the initial *Cochrane Review* found a moderate significant effect on disability and a large significant effect on arm motor function with CIMT, its modified forms (mCIMT), and forced use (FU). The update to the *Cochrane Review* found that the majority of studies were underpowered and imprecise, making the overall evidence inconsistent.[11]

Robotics

Robotics, or robot-assisted therapies, involve the use of a robot to assist in initiation of movement, guidance, and resistance to movement and to provide feedback. Mirror-image motion enabler (MIME) robotic devices were developed to enable unrestricted unilateral or bilateral shoulder or elbow movement. The robotic unit applies force to the more affected forearm during goal-directed movements. A randomized study involving the use of a robotic device and a control group found that there were no significant differences between the groups on either of the ADL assessments but that the clients in the robotic group exhibited a trend toward greater improvement in Fugl-Meyer scores. These differences achieved statistical significance only if the shoulder and elbow portions of the Fugl-Meyer test were considered.[7] Another study examined robot-assisted movement therapy versus conventional therapy in individuals with chronic hemiparesis. This study found that after the first and second months of treatment, the group using robot-assisted therapy had significantly greater improvements in the proximal movement portion of the Fugl-Meyer test. The clients using the robots also had larger gains in strength and larger increases in reach extent after 2 months of treatment. At 6 months no significant differences were seen between the two groups on the Fugl-Meyer test, although the robot group did have significantly greater improvements on the Functional Independence Measure.[35]

In two other studies using robotic therapy, one found that significantly greater gains were attained after treatment in the robot-combined group than in the control group; however, the gains were not maintained at 6 months' follow-up.[36] The other study examined 19 clients following stroke with resultant hemiplegia who underwent a standardized passive exercise program using a robotic arm targeting the upper extremity. This study found no significant changes in preexercise and postexercise responses.[55] A study that examined robot-assisted therapy for long-term upper limb impairment after stroke found that robot-assisted therapy did not significantly improve motor function at 12 weeks as compared with usual therapy; however, outcomes improved over 36 weeks as compared to usual care.[34]

The conclusions regarding the use of robotics for rehabilitation of the upper extremity show that sensorimotor training with robotic devices improves upper extremity functional outcomes and motor outcomes of the shoulder and elbow. Overall, robot-assisted upper extremity therapy may assist in improving motor function during the inpatient period after a stroke.[1,18,79]

Virtual Reality Technology

Virtual reality technology allows individuals to experience and interact with three-dimensional environments. Merians and colleagues[41-43] found that computerized virtual environments have opened the doors to an "exercise environment where the intensity of practice and positive feedback can be consistently and systematically manipulated and enhanced to create the most appropriate, individualized motor learning approach."[43] Virtual reality, such as Wii gaming technology, has been studied and shown to represent a safe and provides an effective alternative to facilitate rehabilitation therapy and promote motor recovery.[61,62] "Adding computerized virtual reality to computerized motor learning activities provides a three-dimensional spatial correspondence between the amount of movement seen on the computer screen. This exact representation allows for visual feedback and guidance for the patient."[43]

Virtual reality is an innovative treatment approach that is in its infancy, but it has shown promise in improving motor function in clients who have had a stroke and are experiencing chronic hemiparesis.

Bilateral Training Techniques

As new theories of neural plasticity have developed, the use of **bilateral training techniques** for the upper limb following stroke have been discussed. Bilateral upper limb training is a technique in which clients practice the same activities with both upper limbs simultaneously. Theoretically, use of the intact limb assists in promoting functional recovery of the impaired limb through facilitative coupling effects between the upper limbs. Practicing bilateral movements allows activation of the intact hemisphere to facilitate activation of the damaged hemisphere through neural networks linked via the corpus callosum.[47,67] In a systematic review that examined 11 clinical trials, Stewart et al.[66] found that bilateral movement training alone, or in combination with sensory feedback, is an effective stroke rehabilitation protocol during the subacute and chronic phases of motor recovery. Further, the cumulative effect of bilateral arm training on motor capabilities in poststroke patients has been found to have strong evidence that supports bilateral arm training.[10]

Summary

The dynamic systems theory supports a heterarchical model of motor control in which motor acquisition is influenced by the client, the environment, and the occupations the client needs to perform or wants to perform. A task-oriented approach supports the use of occupation-based and client-centered interventions to assist clients in problem solving (eg, learning how they will perform their desired occupations in a variety of contexts to support transfer of motor learning).

CIMT is a task-oriented approach that focuses on constraining use of the unaffected upper extremity to facilitate motor recovery in the affected upper extremity during occupational performance. More research is needed in OT to support the use of a task-oriented CIMT approach to motor recovery to improve participation in occupation. Sensorimotor training with the use of robotic devices improves functional and motor outcomes of the shoulder and elbow; however, it does not improve functional and motor outcomes of the wrist and hand. In virtual reality technology, preliminary evidence has shown that this form of intervention may improve motor outcomes. Finally, bilateral arm training uses the intact extremity to assist the impaired extremity through facilitative coupling effects between both upper extremities.

Threaded Case Study

Richard, Part 2

At screening, Richard was eligible to participate in a CIMT program because his stroke had occurred more than 1 year earlier. He had residual right hemiparesis with selective motion in all joints. He was able to touch the top of his head with his weaker arm, bend his wrist, and grasp or release with slow movements. He had completed an inpatient and outpatient rehabilitation program. Richard had not had any major medical complications, had not suffered any falls in the past 6 months, and was able to walk without an assistive device. After screening, an upper extremity ROM assessment, tone assessment using the Modified Ashworth Scale, the Berg Balance Test, and the Folstein Mini-Mental State Examination were completed. Richard met all the criteria and was therefore a good candidate for CIMT.

Richard participated in the MAL interview throughout the intervention. Each task was modeled twice before the participant's performance, and the task was videotaped for scoring purposes. Specific tasks to determine grip strength and the amount of weight added to the task of lifting a box with shoulder flexion were also scored separately. He also completed the WMFT. After completion of the pretraining assessment, Richard and his wife were taught how to don and doff the mitt and use the home diary, and they both signed a behavioral contract. Richard was then scheduled for 14 days of consecutive intervention in which his less involved left arm was constrained by a mitt so that he was required to complete his daily activities with his more affected right arm. The behavioral contract stipulated that Richard would wear the mitt for 90% of waking hours. There was also a home program contract that included exceptions to wearing the mitt, such as while bathing and sleeping. Richard also kept a diary to record which upper extremity was used and the amount of time used during various daily activities, in addition to the amount of time the mitt was worn. Richard recorded all activities completed from the time he left the clinic until his return the following day.

In addition to the activity-based home program, Richard's intervention involved both a group setting and individual sessions. Each of the sessions lasted 6 hours. Tasks during the 6-hour sessions included shaping activities to ensure success in performance. Each small improvement in motor performance was reinforced with positive feedback. Tasks were progressively increased in difficulty as Richard's motor performance improved. To ensure that the activities were occupation based and client centered, they were developed according to the information provided and identified by the COPM.

After Richard arrived at the clinic, the therapist reviewed his diary and performed the MAL. The CIMT activities were identified through information obtained from the COPM. For example, Richard participated in group activities, such as playing cards, which required him to use his more affected hand to manipulate the cards while his less affected hand was constrained in the mitt. He further participated in activities such as cooking. He was responsible for set-up, preparation, and cleanup of the meal with his right upper extremity. His left upper extremity was constrained in the mitt, which necessitated use of his more affected right hand to chop vegetables. Richard would often attempt to use his less affected hand in the mitt and would require prompting from the therapist. To focus on activities that were meaningful for Richard, all activities during the 6-hour intervention session were based on his goals from the COPM. His CIMT activities became progressively more challenging, with repetitions of task practice requiring ROM, strength, endurance, and coordination. Verbal acknowledgment of daily achievements was provided.

After the 2-week intervention program, Richard learned to incorporate his more affected upper extremity into meaningful daily occupations. It became routine for Richard to initiate activities with his right upper extremity, although he primarily used his left upper extremity before the intervention. Richard's level of participation grew to include gardening, attending church, and turning the pages of the prayer book with his right hand. He also resumed his roles in cooking and performing household maintenance.

Critical Thinking Questions

1. How has Richard's motor control affected his ability to engage in meaningful occupation?

Because of impairments in motor control in his right upper extremity, Richard was unable to perform cooking tasks with both upper extremities. He also had difficulty with fasteners and manipulation of objects of different textures and sizes smaller than 1 inch. Richard was unable to turn the pages of his prayer book while in church and had difficulty with the transitional movements of sitting to standing and standing to sitting while in church. He was also unable to perform transition movements during gardening activities and was not able to manipulate cards with the affected upper extremity.

2. What motor control treatment strategies would enable Richard to engage more effectively in his daily occupations?

Richard's CIMT program consisted of restricting movement of the unaffected upper extremity by placing it in a splint, sling, or mitt for greater than 90% of his waking hours. He complied with this protocol for a period of 14 days and participated in training of the affected upper extremity through shaping for approximately 7 hours per day during the 10 weekdays of that period. This approach enabled Richard to regain functional use of his right dominant upper extremity for occupations such as preparing meals, dressing, and opening the pages of a prayer book.

Review Questions

1. How does motor control affect occupational performance?
2. What is the task-oriented approach to motor learning?
3. What is the dynamic systems theory and how does it explain motor control?
4. What is constraint-induced movement therapy and how does this approach increase functional use of a hemiparetic upper extremity after a neurological insult to the brain?
5. What is robot-assisted therapy and how does this approach improve motor control of the upper extremity?
6. What is virtual reality technology and how is this used to improve upper extremity motor control?
7. How are bilateral training techniques used to improve upper extremity motor control?
8. How would you develop a client-centered and occupation-based treatment program to facilitate motor learning?

PART VI
Intervention Applications

OUTLINE

33

Cerebrovascular Accident (Stroke)

Glen Gillen

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, the student or practitioner will be able to do the following:

1. List and describe evaluation procedures for survivors of a stroke.
2. Discuss the neuropathology of a stroke.
3. Identify risk factors associated with a stroke.
4. Identify multiple factors (e.g., impaired client factors, performance skills) that impede performance in areas of occupation after a stroke.
5. Describe evaluation procedures for impaired body functions related to neurobehavioral deficits.
6. Identify balance strategies (a body function) that support performance of areas of occupation.
7. Describe the motor control dysfunction (impaired body function) associated with stroke.
8. Identify standardized stroke assessments for multiple areas of dysfunction.
9. Apply a client-centered approach to stroke rehabilitation.

). Develop comprehensive, occupation-based treatment plans to remediate or compensate for underlying deficits.

KEY TERMS

Aphasia

Client-centered practice

Dysarthria

Ischemia

Motor control

Neurobehavioral deficit

Postural strategies

Shoulder pain

Subluxation

Task-oriented approach

Top-down approach to assessment

Transient ischemic attack

Weight bearing

This chapter focuses on occupational therapy (OT) assessment and intervention for individuals who have sustained a stroke. Specifically, it focuses on improving participation in chosen areas of occupation. After a person has a stroke, multiple client factors and performance skills are affected and potentially limit participation and engagement in occupation.[5] These multiple problems are addressed throughout this chapter.

Threaded Case Study

Jasmine, Part 1

Jasmine is a 39-year-old single mother of a 2-year-old boy. They live in a two-bedroom rented apartment. She has converted her dining area into a home office, where she works at her home-based business in desktop publishing. Jasmine drives her son to preschool each morning and shops on the way home before working for the rest of the day from home. While working on her computer, Jasmine experienced tingling and “clumsiness” in her left hand. She attributed this to long work hours. Still feeling “not quite right,” she attempted to stand to go to the bathroom and collapsed on the floor. She was able to crawl to the phone to call 911.

Jasmine next remembers waking up in the emergency department, where she was told that she had just experienced a stroke. Her neuroimaging studies eventually documented the presence of a right frontal-parietal infarct. Jasmine is unable to move or feel the left side of her body, has a left visual field cut, and tends to not respond to sensory stimuli on the left side of her body. The nursing staff are lifting Jasmine out of bed and providing full assistance for self-care and mobility. Jasmine was told that by the end of the week she will be transferred to the local rehabilitation hospital and will require “aggressive” occupational and physical therapy. Her son is under the care of his aunt and uncle. Jasmine has been crying often and is concerned that she will not be able to work or take care of her son. She is also concerned about losing her apartment; she explains that she has been “just getting by” recently. Jasmine is most concerned about returning home, being able to care for herself and her son, and returning to work.

Critical Thinking Questions

1. How will Jasmine's impaired body functions and body structures (e.g., loss of motor control, sensory loss, visual dysfunction, and neglect) affect her ability to return to her previous life style and engage in chosen areas of occupation?

2. What three assessments are most critical to administer? Why?

3. Which interventions should be considered to address Jasmine's inability to participate in activities of daily living such as self-care (e.g., toileting, dressing), mobility (e.g., bed mobility, transfers), instrumental activities of daily living (e.g., meal preparation, child care), and work throughout her rehabilitation stay?

Cerebrovascular accidents (CVAs), or strokes, continue to be a national health problem despite recent advances in medical technology. The American Heart Association[4] publishes stroke statistics that demonstrate the severity of this problem. Selected statistics include the following[4]:

- Stroke is a leading cause of long-term disability.
- On average, a U.S. citizen suffers a stroke every 40 seconds.
- Each year 795,000 people suffer a new or recurrent stroke. Approximately 610,000 strokes are first attacks, and 185,000 are recurrent.
- An estimated 6.6 million Americans over age 20 have had a stroke.
- Women have a higher lifetime risk of stroke than men.
- Of people who suffer a stroke, 28% are younger than 65 years. For people older than 55, the incidence of stroke more than doubles with each successive decade.
- The estimated overall annual incidence of stroke in U.S. children is 6.4 per 100,000 children (0 to 15 years).
- The incidence of stroke is about 1.25 times higher in men than in women.
- The aftermath of a stroke is a substantial public health and economic problem; stroke is a leading cause of serious, long-term disability in the United States.
- Stroke accounts for more than half of all clients hospitalized for acute neurological disease.
- Among long-term clients who sustained a stroke, 50% have hemiparesis, 30% cannot walk, 26% are found to be dependent in activity of daily living (ADL) scales, 19% are aphasic, 35% are clinically depressed, and 26% require home nursing care.

Obviously stroke rehabilitation as a practice area for occupational therapists is a specialization that crosses multiple settings, from the intensive care unit to community-based programs.

Definition of Stroke

A CVA, or stroke, is a complex dysfunction caused by a lesion in the brain. The World Health Organization (WHO) defines stroke as an "acute neurological dysfunction of vascular origin with symptoms and signs corresponding to the involvement of focal areas of the brain."[104] Stroke results in upper motor neuron dysfunction that produces hemiplegia, or paralysis of one side of the body, including the limbs and trunk and sometimes the face and oral structures that are contralateral to the hemisphere of the brain with the lesion. Thus, a lesion in the left cerebral hemisphere (left CVA) produces right hemiplegia. Conversely, a lesion in the right cerebral hemisphere (right CVA) produces left hemiplegia. When reference is made to the client's disability as right or left hemiplegia, the reference is to the paralyzed side of the body and not to the locus of the lesion.

Accompanying the motor paralysis may be a variety of dysfunctions other than the motor paralysis. Some of these dysfunctions include sensory disturbances, cognitive and perceptual dysfunction, visual disturbances, personality and intellectual changes, and a complex range of speech and associated language disorders. The neurological deficits must persist longer than 24 hours to be labeled a CVA.

Causes of Stroke

Bartels[10] describes a stroke as "essentially a disease of the cerebral vasculature in which failure to supply oxygen to the brain cells, which are the most susceptible to ischemic damage, leads to their death. The syndromes that lead to stroke comprise two broad categories: ischemic and hemorrhagic stroke." Ischemic strokes account for the majority of strokes.

Ischemia

Ischemia refers to insufficient blood flow to meet metabolic demand. Ischemic strokes may be the result of embolism to the brain from cardiac or arterial sources. Cardiac sources include atrial fibrillation (pooling of blood in the dysfunctional atrium leads to the production of emboli), sinoatrial disorders, acute myocardial infarction, endocarditis, cardiac tumors, and valvular (both native and artificial) disorders. Cerebral ischemia caused by perfusion failure occurs with severe stenosis of the carotid and basilar arteries, and with microstenosis of the small deep arteries.[4,10]

Age, gender, race, ethnicity, and heredity are considered nonmodifiable risk factors for ischemic strokes. In contrast, a major focus of stroke prevention and education programs is the potentially modifiable risk factors discussed in the following list.[4,51]

1. Hypertension is considered the single most important modifiable risk factor for ischemic stroke. Those with a blood pressure lower than 120/80 mm Hg have about half the lifetime risk for stroke as those with high blood pressure.[4]

2. Management of cardiac diseases, particularly atrial fibrillation, mitral stenosis, and structural abnormalities (patent foramen ovale and atrial septal aneurysm), can reduce the risk for stroke.

3. Management of diabetes and glucose metabolism can also reduce the risk for stroke.

4. Cigarette smoking increases the relative risk for ischemic stroke nearly two times.

5. Although excessive use of alcohol is a risk factor for many other diseases, moderate consumption of alcohol may reduce the incidence of cardiovascular disease, including stroke.

6. Use of illegal drugs, particularly cocaine, is commonly associated with stroke. Other drugs linked to stroke include heroin, amphetamines, lysergic acid diethylamide (LSD), phencyclidine (PCP), and marijuana.

7. Lifestyle factors (e.g., obesity, physical inactivity, diet, and emotional stress) are associated with a risk for stroke.

The responsibility for stroke prevention education (including prevention of recurrence) falls on each member of the stroke rehabilitation team.

Hemorrhage

Hemorrhagic strokes include subarachnoid and intracerebral hemorrhages, which account for only 13% of the total number of strokes.[4] This type of stroke has numerous causes. The four most common are deep hypertensive intracerebral hemorrhages, ruptured saccular aneurysms, bleeding from arteriovenous malformations, and spontaneous lobar hemorrhages.[60]

Related Syndromes

Cerebral anoxia and aneurysm can also result in hemiplegia. Some of the treatment approaches outlined in this chapter may be applicable to hemiplegia resulting from causes other than CVA or stroke, such as head injuries, neoplasms, and infectious diseases of the brain.

Transient Ischemic Attacks

Vascular disease of the brain can result in a completed stroke or in **transient ischemic attacks** (TIAs). A TIA is characterized by mild, isolated, or repetitive neurological symptoms that develop suddenly, last from a few minutes to several hours but not longer than 24 hours, and clear completely. A TIA is seen as a sign of an impending stroke.[4] Most TIAs occur in people with atherosclerotic disease. Of those who experience TIAs and do not seek treatment, an estimated one-third will sustain a completed stroke; another one-third will continue to have TIAs without a stroke; and one-third will experience no further attacks.[81] If the TIA is caused by extracranial vascular disease, surgical intervention to restore vascular flow (carotid endarterectomy) may be effective in preventing the stroke and resultant disability.

Effects of Stroke

The outcome of a stroke depends on which artery supplying the brain was involved (Fig. 33.1). Stroke diagnostic workups help localize the lesion and find a cause of the stroke. Techniques include cerebrovascular imaging such as computed tomography (CT), magnetic resonance imaging (MRI), and more recently, positron emission tomography (PET) and single-photon emission computed tomography (SPECT).[10] The information collected with these techniques (e.g., the extent of damage and location of the lesion) may help the occupational therapist identify neurological deficits that affect function. The information may also help the therapist develop hypotheses regarding recovery and plan appropriate treatment. Initial information may be collected during a medical record review that focuses on the chief complaint of the client on admission, previous medical and surgical history, results of diagnostic tests, and current pharmacologic management. The following section and Tables 33.1 and 33.2 explain patterns of impairment resulting from stroke in both the cortical and subcortical areas.

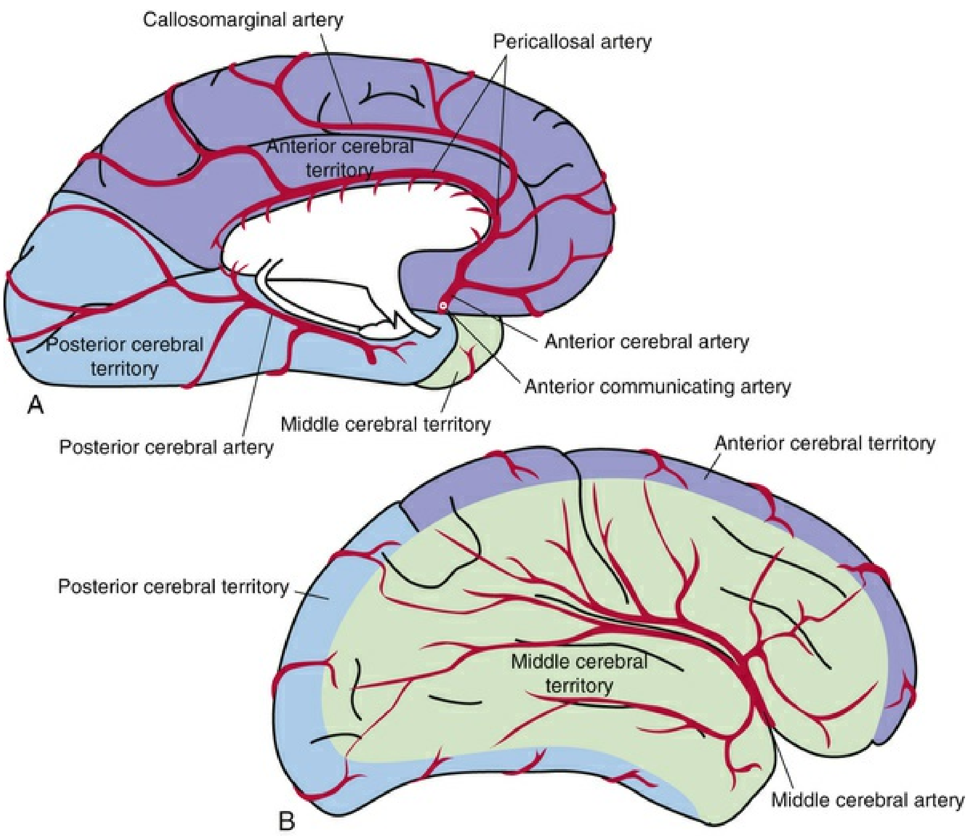

FIG 33.1 Blood supply to the brain. The middle cerebral, anterior cerebral, and posterior cerebral arteries supply blood to the cerebral hemispheres. A, Medial surface. B, Lateral surface. (Modified from Mettler FA: *Neuroanatomy,* ed 2, St Louis, 1948, Mosby. In Vanderah T, Gould D, editors: *Nolte's the human brain: an introduction to its functional anatomy,* ed 7, Philadelphia, 2016, Elsevier.)

TABLE 33.1

Cerebral Artery Dysfunction: Cortical Involvement and Patterns of Impairment

Artery	Location	Possible Impairments
Middle cerebral artery: upper trunk	Lateral aspect of the frontal and parietal lobe	• Dysfunction of either hemisphere: • Contralateral hemiplegia, especially of the face and upper extremity • Contralateral hemisensory loss • Visual field impairment • Poor contralateral conjugate gaze • Ideational apraxia • Lack of judgment • Perseveration

		• Field dependency • Impaired organization of behavior • Depression • Lability • Apathy • Right hemisphere dysfunction: • Left unilateral body neglect • Left unilateral visual neglect • Anosognosia • Visuospatial impairment • Left unilateral motor apraxia • Left hemisphere dysfunction: • Bilateral motor apraxia • Broca's aphasia • Frustration
Middle cerebral artery: lower trunk 	Lateral aspect of the right temporal and occipital lobes	• Dysfunction of either hemisphere: • Contralateral visual field defect • Behavioral abnormalities • Right hemisphere dysfunction: • Visuospatial dysfunction • Left hemisphere dysfunction: • Wernicke's aphasia
Middle cerebral artery: both upper and lower trunks 	Lateral aspect of the involved hemisphere	• Impairments related to both upper and lower trunk dysfunction, as listed in previous two sections
Anterior cerebral artery 	Medial and superior aspect of the frontal and parietal lobes	• Contralateral hemiparesis, greatest in the foot • Contralateral hemisensory loss, greatest in the foot • Left unilateral apraxia • Inertia of speech or mutism • Behavioral disturbances
Internal carotid artery	Combination of the middle cerebral artery distribution and anterior cerebral artery	• Impairments related to dysfunction of the middle and anterior cerebral arteries, as listed in previous sections
Anterior choroidal artery (a branch of the internal carotid artery)	Globus pallidus, lateral geniculate body, posterior limb of the internal capsule, medial temporal lobe	• Hemiparesis of the face, arm, and leg • Hemisensory loss • Hemianopia
Posterior cerebral artery 	Medial and inferior aspects of the right temporal and occipital lobes, posterior corpus callosum, and penetrating arteries to the midbrain and thalamus	• Dysfunction of either side: • Homonymous hemianopia • Visual agnosia (visual object agnosia, prosopagnosia, color agnosia) • Memory impairment • Occasional contralateral numbness • Right-sided dysfunction: • Cortical blindness • Visuospatial impairment • Impaired left-right discrimination • Left-sided dysfunction: • Finger agnosia • Anomia • Agraphia • Acalculia • Alexia
Basilar artery, proximal	Pons	• Quadriparesis • Bilateral asymmetric weakness • Bulbar or pseudobulbar paralysis (bilateral paralysis of the face, palate, pharynx, neck, or tongue) • Paralysis of the eye abductors • Nystagmus • Ptosis • Cranial nerve abnormalities • Diplopia • Dizziness • Occipital headache • Coma
Basilar artery, distal	Midbrain, thalamus, and caudate nucleus	• Papillary abnormalities • Abnormal eye movements • Altered level of alertness

		• Coma • Memory loss • Agitation • Hallucination
Vertebral artery	Lateral medulla and cerebellum	• Dizziness • Vomiting • Nystagmus • Pain in ipsilateral eye and face • Numbness in face • Clumsiness of ipsilateral limbs • Hypotonia of ipsilateral limbs • Tachycardia • Gait ataxia
Systemic hypoperfusion 	Watershed region on the lateral side of the hemisphere, hippocampus, and surrounding structures in the medial temporal lobe	• Coma • Dizziness • Confusion • Decreased concentration • Agitation • Memory impairment • Visual abnormalities caused by disconnection from the frontal eye fields • Simultanagnosia • Impaired eye movements • Weakness of shoulder and arm • Gait ataxia

From Gillen G, editor: *Stroke rehabilitation: a function-based approach,* ed 3, St Louis, 2011, Mosby.

TABLE 33.2

Cerebrovascular Dysfunction in Noncortical Areas: Patterns of Impairment

Location	Possible Impairments
Anterolateral thalamus	• Either side: • Minor contralateral motor abnormalities • Long latency period • Slowness • Right side: • Visual neglect • Left side: • Aphasia
Lateral thalamus	• Contralateral hemisensory symptoms • Contralateral limb ataxia
Bilateral thalamus	• Memory impairment • Behavioral abnormalities • Hypersomnolence
Internal capsule or basis pontis	• Pure motor stroke
Posterior thalamus	• Numbness or decreased sensibility of the face and arm • Choreic movements • Impaired eye movements • Hypersomnolence • Decreased consciousness • Decreased alertness • Right side: • Visual neglect • Anosognosia • Visuospatial abnormalities • Left side: • Aphasia • Jargon aphasia • Good comprehension of speech • Paraphasia • Anomia
Caudate	• Dysarthria • Apathy • Restlessness • Agitation • Confusion • Delirium • Lack of initiative • Poor memory • Contralateral hemiparesis • Ipsilateral conjugate deviation of the eyes
Putamen	• Contralateral hemiparesis • Contralateral hemisensory loss • Decreased consciousness • Ipsilateral conjugate gaze • Motor impersistence • Right side: • Visuospatial impairment • Left side: • Aphasia
Pons	• Quadriplegia • Coma • Impaired eye movement
Cerebellum	• Ipsilateral limb ataxia • Gait ataxia • Vomiting • Impaired eye movements

From Gillen G, editor: *Stroke rehabilitation: a function-based approach,* ed 3, St Louis, 2011, Mosby.

Internal Carotid Artery

In the absence of adequate collateral circulation, occlusion of the internal carotid artery results in contralateral hemiplegia, hemianesthesia, and homonymous hemianopia.[6,10] Additionally, involvement of the dominant hemisphere (i.e., the cerebral hemisphere containing the representation of speech/language and controlling the arm and leg used preferentially in skilled movements, usually the left hemisphere) is associated with aphasia, agraphia or dysgraphia, acalculia or dyscalculia, right-left confusion, and finger agnosia. Involvement of the nondominant hemisphere is associated with visual perceptual dysfunction, unilateral neglect, anosognosia, constructional or dressing apraxia, attention deficits, and loss of topographic memory.

Middle Cerebral Artery

Involvement of the middle cerebral artery (MCA) is the most common cause of stroke.[7,10,21] Ischemia in the area supplied by the MCA results in contralateral hemiplegia with greater involvement of the arm, face, and tongue; sensory deficits; contralateral homonymous hemianopia; and aphasia if the lesion is in the language-dominant hemisphere. There is pronounced deviation of the head and neck toward the side on which the lesion is located during the initial phase of the stroke.[22,31] Perceptual deficits, such as anosognosia, unilateral neglect, impaired vertical perception, visual spatial deficits, and perseveration, are seen if the lesion is in the nondominant hemisphere.[6]

Anterior Cerebral Artery

Occlusion of the anterior cerebral artery (ACA) produces contralateral lower extremity weakness that is more severe than that of the arm. Apraxia, mental changes, primitive reflexes, and bowel and bladder incontinence may be present. Total occlusion of the ACA results in contralateral hemiplegia with severe weakness of the face, tongue, and proximal arm muscles and marked spastic paralysis of the distal end of the lower extremity. Cortical sensory loss is present in the lower extremity. Intellectual changes, such as confusion, disorientation, abulia, whispering, slowness, distractibility, limited verbal output, perseveration, and amnesia, may be seen.[6,10]

Posterior Cerebral Artery

The scope of posterior cerebral artery (PCA) symptoms is potentially broad and varied because this artery supplies the upper brainstem region and the temporal and occipital lobes. Possible results of PCA involvement depend on the arterial branches affected and the extent and area of cerebral compromise. Some possible outcomes are sensory and motor deficits, involuntary movement disorders (e.g., hemiballism, postural tremor, hemichorea, hemiataxia, and intention tremor), memory loss, alexia, astereognosis, dysesthesia, akinesthesia, contralateral homonymous hemianopia or quadrantanopia, anomia, topographic disorientation, and visual agnosia.[6,10,31]

Cerebellar Artery System

Occlusion of the cerebellar artery results in ipsilateral ataxia, contralateral loss of pain and temperature sensitivity, ipsilateral facial analgesia, dysphagia and dysarthria caused by weakness of the ipsilateral muscles of the palate, nystagmus, and contralateral hemiparesis.[6,10,22,31]

Vertebrobasilar Artery System

A stroke in the vertebrobasilar artery system affects brainstem functions. The outcome of the stroke is some combination of bilateral or crossed sensory and motor abnormalities, such as cerebellar dysfunction, loss of proprioception, hemiplegia, quadriplegia, and sensory disturbances, along with unilateral or bilateral involvement of cranial nerves III to XII.

Medical Management

Specific treatment of stroke depends on the type and location of the vascular lesion, the severity of the clinical deficit, concomitant medical and neurological problems, the availability of technology and personnel to administer special types of treatment, and the cooperation and reliability of the client.

Early medical treatment involves maintenance of an open airway, hydration with intravenous fluids, and treatment of hypertension. Appropriate steps should be taken to evaluate and treat coexisting cardiac or other systemic diseases. Measures should be taken to prevent the development of deep venous thrombosis (DVT). DVT is the formation of a blood clot (thrombus) in a deep vein, usually in the lower extremity, a common risk in clients who have prolonged periods of bed rest and immobility. The incidence of DVT in individuals with stroke ranges from 22% to 73%. Emboli that are released from deep veins and subsequently lodge in the lungs are referred to as pulmonary emboli. Pulmonary embolism is the most common cause of death in the first 30 days after a stroke.[10,20]

The physician oversees routine surveillance for thrombosis, which includes daily evaluation of leg temperature, color, circumference, tenderness, and appearance. Preventive treatments for DVT may involve medication, the use of elastic stockings, the use of reciprocal compression devices, and early mobilization of the client.

Respiratory problems and pneumonia may complicate the early post-stroke course. The National Survey of Stroke reported that one-third of clients who had sustained strokes also had respiratory infections.[80]

Symptoms are a low-grade fever and increased lethargy. Medical management involves the administration of fluids and antibiotics, aggressive pulmonary hygiene, and mobilization of the client. Ventilatory insufficiency is a major factor contributing to the high frequency of pneumonia. The hemiparesis associated with stroke involves the muscles of respiration. Exercise programs that involve strengthening and endurance training of both the inspiratory and expiratory muscles help improve breathing and cough effectiveness and reduce the frequency of pneumonia.[20]

Cardiac disease is another frequently occurring condition that complicates the post-stroke course. The stroke itself may cause the cardiac abnormality, or the client may have had a preexisting cardiac condition. The former is treated in the same manner as any new cardiac diagnosis. A preexisting cardiac condition is reevaluated and the treatment regimen modified as appropriate. Monitoring of the heart rate and blood pressure, in addition to an electrocardiogram (ECG) during self-care evaluations, is frequently indicated to determine the cardiac response to activity.

During the acute phase, bowel and bladder dysfunction is common. The physician is responsible for ordering a specific bowel program that includes a time schedule, adequate fluid intake, stool softeners, suppositories, oral laxatives, and medications or procedures to treat fecal impaction. A timed or scheduled toilet program is essential in treating urinary incontinence. Catheterization may be necessary during stroke rehabilitation.

Evaluation and Intervention Procedures for Clients Who Sustained a Stroke

Tables 33.1 and 33.2 provide information related to patterns of impairments that are typically observed and that vary depending on the area of the brain that has been damaged. The location of the stroke is determined by CT or MRI and is generally documented in the medical record. Understanding this information is the first step of the evaluation process; it should take place before the OT practitioner meets the client because it helps the therapist focus his or her evaluation procedures and begin to understand which client factors are impaired and affecting performance in areas of occupation.

For example, Jasmine has documented damage in her right frontal and parietal lobes (most likely secondary to MCA occlusion). Patterns of impairment that are typically observed with this type of stroke include contralateral motor loss, contralateral sensory loss, difficulty interpreting spatial relationships (e.g., depth/distance, foreground from background), decreased attention or neglect of left-sided information (personal and extrapersonal), and left limb motor-planning deficits. These impairments may in turn affect Jasmine's ability to engage in meaningful areas of occupation. Her sensory-motor loss may prevent her from fulfilling her role as a mother (e.g., assisting her child in the bath, lifting her son into the crib, preparing meals) and as a worker (e.g., typing, filing). Simultaneously, her attention deficits (left-sided neglect) will make driving unsafe, interfere with self-care and care of her child, affect her computer use (e.g., finding information on the left side of the screen), and impede her ability to manage her household (e.g., read and write bills and checks, prepare meals.)

Typically, a client's clinical findings immediately after a stroke (the acute stage) represent the worst-case scenario. In other words, once the stroke is complete and the client who sustained the stroke has been medically stabilized, the lesion is considered static or not progressive. At this point, a client who sustained a stroke may exhibit little or no contralateral motor function (hemiparesis or hemiplegia) because of severe weakness, no response to contralateral sensory stimuli, and a severe attention deficit; the client may also require assistance performing his or her job. Fortunately, barring another neurological insult, the client is usually expected to improve from both a neurological and functional perspective. Unfortunately, predicting the amount of improvement and the length of time necessary for improvement to take place is difficult. Clinicians generally agree that the first 3 to 6 months after a stroke is the most crucial time and that the greatest improvement takes place during this period. This time frame remains controversial and should be used only as a guideline. For example, more studies[87] have documented improvements in upper extremity (UE) function in clients who sustained a stroke many years earlier. It is important to note that some clients may recover only slightly and slowly, whereas others may recover fully.

Given this information, it is important to understand that neurological recovery and functional recovery are different aspects to consider. An example of **motor control** (i.e., the process that must be performed to achieve movement) will be used to illustrate this point. Clients A and B may share similar findings (no motor function on the left side of the body) immediately after experiencing a stroke. Client A may recover substantial motor function and resume engagement in previous occupations, such as shopping and dressing, with few residual impairments (perhaps a "limp" or mild clumsiness) resulting from the stroke. Client B may not benefit from the same level of neurological motor recovery and yet still be able to resume engagement in previous occupations by using adaptive methods. Dressing may require learning new one-handed techniques, wearing clothing with a looser fit, and using equipment such as a reacher. Shopping may be accomplished with the use of powered mobility (e.g., scooter or wheelchair), an ankle-foot orthotic and a cane, or the Internet. Despite these differences, both client A and client B are able to participate in meaningful occupations.

Client-Centered Assessments

Law et al[68], involved with the development of the Canadian Occupational Performance Measure (COPM), stated:

Client-centered practice *is an approach to providing occupational therapy which embraces a philosophy of respect for, and partnership with, people receiving services. Client-centered practice recognizes the autonomy of individuals, the need for client choice in making decisions about occupational needs, the strengths clients bring to a therapy encounter, the benefits of client-therapist partnership, and the need to ensure that services are accessible and fit the context in which a client lives.*

Both Law et al.[64] and Pollack[76] suggest that therapists implementing this approach to evaluation include the following concepts:

1. Recognize that recipients of OT are uniquely qualified to make decisions about their occupational functioning

2. Offer the client a more active role in defining goals and desired outcomes

3. Make the client-therapist relationship an interdependent one to enable the solution of performance dysfunction

4. Shift to a model in which occupational therapists work with clients to enable them to meet their own goals

5. Focus the evaluation (and intervention) on the contexts in which clients live, their roles and interests, and their culture

6. Allow the client to be the "problem definer" so that he or she will in turn become the "problem solver"

7. Allow the client to evaluate his or her own performance and set personal goals

Through the use of these strategies, the evaluation process becomes more focused and defined, clients become immediately empowered, the goals of therapy are understood and agreed on, and a client-tailored treatment plan may be established. The COPM[65] is a standardized tool that uses a client-centered approach to allow the recipient of treatment to identify areas of difficulty, rate the importance of each area, and rate his or her satisfaction with current performance. It is a particularly useful tool to use with clients who sustained a stroke because of the multiple and extensive problems that this population experiences in performance of areas of occupation.

The COPM would be a good assessment to use with Jasmine. It would give the occupational therapist insight into the occupations that should be prioritized, assist in goal writing, and facilitate treatment planning. In addition, use of the COPM would empower Jasmine as an active participant in the rehabilitation process. Jasmine completed the COPM, and the results identified toilet transfers, computer use, grooming, feeding, and child care as the occupations that she wanted to pursue first; in other words, these occupations would be the focus of her initial OT. Jasmine indicated that gaining mastery in the occupations would make her feel better about herself ("boost my self-esteem") and give her hope that she could return to work ("and provide for my child").

Top-Down Approach to Assessment

A **top-down approach to assessment** has been described in the literature[95] and is applicable to the evaluation of clients who sustained a stroke. Principles of this approach include the following:

1. Inquiry into role competency and meaningfulness is the starting point for evaluation.

2. Inquiry is focused on the roles that are important to the client who sustained a stroke, particularly those in which the client was engaged before the stroke.

3. Any discrepancy of roles in the past, present, or future is identified to help determine a treatment plan.

4. The tasks that define the person are identified, in addition to whether those tasks can be performed and the reasons that the tasks are problematic.

5. A connection is determined between the components of function and occupational performance.

A top-down approach to evaluation is in contrast to a bottom-up approach, which first focuses on dysfunction of client factors.[95]

Effects of Neurological Deficits on Performance in Areas of Occupation

Using activity analysis and keen observation allows therapists to identify errors during task performance and to analyze the errors and determine the underlying deficits blocking independent functioning. Árnadóttir states that:

> *Therapists can benefit from detecting errors in occupational performance while observing ADL and thereby gain an understanding of the impairments affecting the patient's activity limitation. Therapists can use the information based on observed task performance in a systematic way as a structure for clinical reasoning to help them assess functional independence related to the performance and to subsequently detect impaired neurological body functions. Such information can be important when intervention methods are aimed at addressing occupational errors[6] (Fig. 33.2).*

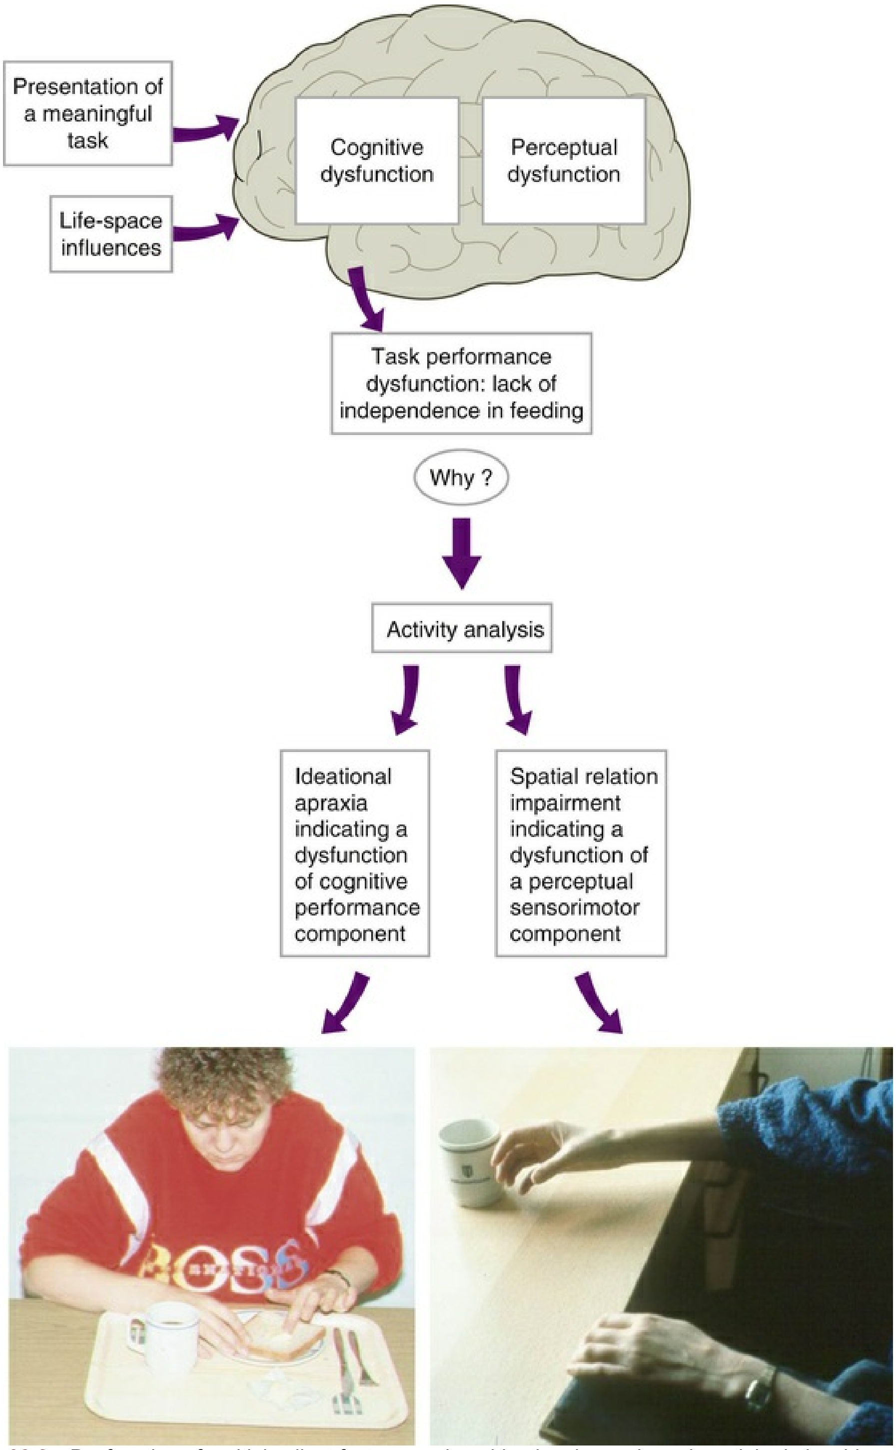

FIG 33.2 Dysfunction of multiple client factors, such as ideational apraxia and spatial relationships, can be revealed by activity and error analysis during functional tasks such as feeding. (Modified from Árnadóttir G: *The brain and behavior: assessing cortical dysfunction through activities of daily living,* St Louis, 1990, Mosby.)

Because performance of a single functional task (e.g., donning a shirt) requires the use of multiple underlying client factors and performance skills that may have been affected by a stroke, multiple variables may be evaluated in the context of one client-chosen activity (Fig. 33.3).[6,7]

Possible behavioral deficits interfering with function

Premotor perseveration: pulling up sleeve

Spatial-relation difficulties: differentiating front from back on shirt

Spatial-relation difficulties: getting an arm into the right armhole

Unilateral spatial neglect: not seeing shirt located on neglected side (or a part of the shirt)

Unilateral body neglect: not dressing the neglected side or not completing the dressing on that side

Comprehension problem: not understanding verbal information related to performance

Ideational apraxia: not knowing what to do to get shirt on or not knowing what the shirt is for

Ideomotor apraxia: having problems with the planning of finger movements in order to perform

Tactile agnosia (astereognosis): having trouble buttoning shirt without watching the performance

Organization and sequencing: dressing the unaffected arm first getting into trouble with dressing the affected arm; inability to continue the activity without being reminded

Lack of motivation to perform

Distraction: becomes interrupted by other things

Attention deficit: difficulty attending to task and quality of performance

Irritated or frustrated when having trouble performing or when not getting the desired assistance

Aggressive when therapist touches patient in order to assist her (tactile defensiveness)

Difficulties recognizing foreground from background or a sleeve of a unicolor shirt from the rest of the shirt

FIG 33.3 Possible behavioral deficits interfering with function while donning a shirt. (From Árnadóttir G: *The brain and behavior: assessing cortical dysfunction through activities of daily living*, St Louis, 1990, Mosby.)

Standardized Tools

Occupational therapists use assessment tools that are reliable, valid, and sensitive to change. In addition, assessment tools focused on task performance should be used. Tools that are focused on evaluation of client factors in isolation from performance of occupations, that use novel nonfunctional tasks, and that do not consider the effect of environmental context should be interpreted with caution. Tools are available to the occupational therapist that directly relate performance dysfunction observed during ADLs to the effect of underlying skills necessary for independent performance of activities.

The Arnadottir Occupational Therapy Neurobehavioral Evaluation[6,7] (A-ONE) objectively documents the way that dysfunction of client factors (e.g., left-sided neglect, apraxia, and spatial dysfunction) affects self-care and mobility tasks. The A-ONE has more recently been referred to as the ADL-focused Occupation-Based Neurobehavioral Evaluation.[8,9] The Assessment of Motor and Process Skills[40] (AMPS) uses predominantly instrumental activities of daily living (IADLs) to evaluate underlying performance skills related to the completion of various IADLs (e.g., reaching, grasping, and posture) and process skill dysfunction (e.g., using items and searching and locating). Table 33.3 provides a summary of standardized assessments used with clients who have sustained a stroke.

TABLE 33.3

Sample Assessments Used With Clients Who Sustained a Stroke

Instrument	Description and Use
Activity Card Sort (ACS)[12]	Uses a Q-sort methodology to assess participation in 80 instrumental, social, and high and low physical demand leisure activities. The cards have pictures of tasks people do every day, and clients sort the cards into different piles to identify activities they did before the stroke, activities they now do less often, and those they have given up since the stroke.
Arm Motor Ability Test (AMAT)[62]	Arm function evaluated by functional ability and quality of movement; test involves performance of 28 tasks (e.g., eating with a spoon, opening a jar, tying a shoelace, using the telephone)
Arnadottir Occupational Therapy Neurobehavioral Evaluation (A-ONE)[7]	Evaluates apraxias, neglect syndromes, body scheme disorders, organization/sequencing dysfunction, agnosias, and spatial dysfunction via basic activities of daily living (BADLs) and mobility tasks; directly correlates impairment and disability levels of dysfunction
Assessment of Motor and Process Skills[40]	Assessment tool covering 16 motor skills (e.g., reach, manipulation, calibration, coordination, posture, mobility) and 20 process skills (e.g., attends, organizes, searches and locates, initiates, sequences) that are evaluated within the context of client-chosen instrumental activities of daily living (IADLs) skills; clients choose familiar and culturally relevant tasks from a list of 50 standardized activities of various difficulties

Barthel Index[68]	Measure of disability in performing BADLs that ranges from 0 to 20 or 0 to 100 (by multiplying each item by 5); includes 10 items: bowels, bladder, feeding, grooming, dressing, transfer, toileting, mobility, stairs, and bathing
Beck Depression Inventory[13]	Self-rating scale of 21 items that has attitudinal, somatic, and behavioral components
Berg Balance Scale[14]	Balance assessment of 14 items scored on a 0- to 4-point ordinal scale
Boston Diagnostic Aphasia Examination[49]	Assesses sample speech and language behavior, including fluency, naming, word finding, repetition, serial speech, auditory comprehension, reading, and writing
Canadian Neurological Scale[30]	Stroke deficit scale that scores 8 items (e.g., consciousness, orientation, speech, motor function, facial weakness)
Canadian Occupational Performance Measure (COPM)[65]	Client-centered assessment tool based on clients' identification of problems in performance in areas of occupation (clients rate importance of self-care, productivity, and leisure skills and also their perception of performance and satisfaction with performance) Used as an outcome measure and a client satisfaction survey
Family Assessment Device[38]	Family assessment of problem solving, communication, roles, affective responsiveness, affective involvement, behavioral control, and general functioning
Frenchay Activities Index[54]	A 15-item scale for IADLs that evaluates domestic, leisure, work, and outdoor activities
Fugl-Meyer Test[43]	Motor function assessment that uses a 3-point scale to score the domains of pain, range of motion, sensation, volitional movement, and balance
Functional Independence Measure (FIM)[57]	Measure of disability in performing BADLs that includes 18 items scored on a 7-point scale; includes subscores for motor and cognitive function; performance areas include self-care, sphincter control, mobility, locomotion, cognition, and socialization
Functional Reach Test[37]	Balance evaluation; objectively measures length of forward reach in the standing posture
Functional Test for the Hemiparetic Upper Extremity[102]	Assessment of arm and hand function via 17 hierarchic functional tasks based on Brunnstrom's view of motor recovery; sample tasks are folding a sheet, screwing in a light bulb, stabilizing a jar, and zipping a zipper
Geriatric Depression Scale[106]	Self-rating depression scale of 30 items in a yes/no format
Glasgow Coma Scale[91]	Level of consciousness scale that includes 3 sections scoring eye opening, motor, and verbal responses to voice commands or pain
Jebsen Test of Hand Function[56]	Hand function evaluation; includes 7 test activities: writing a short sentence, turning over index cards, simulated eating, picking up small objects, moving empty and weighted cans, and stacking checkers during timed trials
Kohlman Evaluation of Living Skills (KELS)[92]	Living skills evaluation that includes ratings of 17 tasks (e.g., safety awareness, money management, phone book use, money and bill management)
Medical Outcomes Study/Short-Form Health Survey (SF-36)[101]	Quality of life measure that includes the domains of physical functioning, physical and emotional problems, social function, pain, mental health, vitality, and health perception
Mini-Mental State Examination[41]	Mental status screening test for orientation to time and place, registration of words, attention, calculation, recall, language, and visual construction
Motor Assessment Scale[25]	Motor function evaluation; includes disability and impairment measures, arm and hand movements, tone, and mobility (bed, upright, and ambulation)
Motricity Index[33]	Measures impairments in limb strength with a weighted ordinal scale
Neurobehavioral Cognitive Status Examination[59]	Mental status screening test that includes the domains of orientation, attention, comprehension, naming, construction, memory, calculation, similarities, judgment, and repetition
NIH Stroke Scale[23]	Stroke deficit scale that scores 15 items (e.g., consciousness, vision, extraocular movement, facial control, limb strength, ataxia, sensation, speech and language)
PCG Instrumental Activities of Daily Living[66]	IADL evaluation of telephone use, walking, shopping, food preparation, housekeeping, laundry, public transportation, and medication management
Rankin Scale[19]	Global disability scale with 6 grades indicating degrees of disability
Rivermead Mobility Index[29]	Uses a “pass” or “fail” scale to measure bed mobility, sitting, standing, transfers, and walking
Sickness Impact Profile[15]	Quality of life measure in the format of a 136-item scale with 12 subscales that measure ambulation, mobility, body care, emotion, communication, alertness, sleep, eating, home management, recreation, social interactions, and employment
Stroke Impact Scale[63]	A stroke-specific measure that incorporates function and quality of life into one measure. It is a self-report measure with 59 items and 8 subgroups, including strength, hand function, BADLs and IADLs, mobility, communication, emotion, memory and thinking, and participation.
TEMPA[34,35]	Upper extremity performance test composed of 9 standardized tasks (bilateral and unilateral) measured by 3 criteria: length of execution, functional rating, and task analysis; sample tasks are handling coins, picking up a pitcher and pouring water, writing and stamping an envelope, and unlocking a lock
Tinetti Test[93]	Evaluates balance and gait in the older adult population
Trunk Control Test[42]	Trunk control evaluated on a 0- to 100-point scale; tasks used include rolling, supine to sitting, and balanced sitting
Western Aphasia Battery[58]	Includes an “Aphasia Quotient” and a “Cortical Quotient,” scored on a 100-point scale; assesses spontaneous speech, repetition, comprehension, naming, reading, and writing

The A-ONE was used to objectively document the ways that Jasmine's various impairments (e.g., neglect, spatial relationship dysfunction, loss of motor control, and topographical disorientation) affected her ability to perform basic activities of daily living (BADLs) and mobility (e.g., bed mobility, transfers, wheelchair mobility, and walking when applicable). Errors observed and documented included not dressing the left side of her body, inability to locate grooming items on the left side of the sink, and difficulty dressing the lower part of her body and getting out of bed secondary to loss of motor control in her left limbs and trunk.

Adopting a Framework for Intervention

Therapists should consider overarching themes when deciding which interventions to use to address a client's inability to resume meaningful roles and successfully participate in chosen occupations. Evidence-based practice should serve as the foundation for all OT interventions. To be successful in this endeavor, practitioners must remain abreast of new and emerging research in the OT literature and in related fields. Review papers[a] and evidence-based libraries and search engines (e.g., the Cochrane Library) are sources of up-to-date information.

Over the past several years there has been a paradigm shift related to the intervention philosophies typically used with clients who sustained a stroke. In the past, sensorimotor approaches were used to treat individuals who sustained a stroke (see Chapter 31). These sensorimotor approaches were developed based on the understanding of the central nervous system (CNS) dysfunction at the time these clinicians were doing their research (mid-1900s). Although these interventions are commonly used, their effectiveness has been challenged as occupational therapists move toward models of evidence-based practice.[78] At present there is limited to no research to support these neurofacilitation approaches. Indeed, the Bobath approach (neurodevelopmental treatment [NDT]), although commonly used in the clinic, has not been shown to be superior to other treatment approaches and in fact is inferior to more current models of practice. For example, a large, nonrandomized, parallel-group study[52] ($N = 324$) compared the NDT approach with conventional treatment. Subjects were monitored for 12 months. The authors concluded that "the NDT approach was not found effective in the care of stroke patients in the hospital setting. Health care professionals need to reconsider the use of this approach."[52] Similarly, a systematic review of 16 studies involving 813 patients with stroke concluded that "there was no evidence of superiority of Bobath on sensorimotor control of upper and lower limb, dexterity, mobility, activities of daily living, health-related quality of life, and cost-effectiveness. Only limited evidence was found for balance control in favor of Bobath. This systematic review confirms that overall the Bobath concept is not superior to other approaches."[61]

In contrast, approaches that focus on the use of functional activities as the therapeutic change agent (e.g., **task-oriented approaches**) show promise from both a research and a clinical perspective.[69,70] A recent systematic review of task-oriented approaches concluded that "studies of task-related training showed benefits for functional outcome compared with traditional therapies. Active use of task-oriented training with stroke survivors will lead to improvements in functional outcomes and overall health-related quality of life."[79] The authors recommended "creating opportunities to practice meaningful functional tasks outside of regular therapy sessions."[79] A more recent evidence review concluded that "task-oriented training may be considered the foundation of interventions focused on improving occupational performance for those with motor impairment after stroke."[75] The authors further summarized that "commonalities among several of the effective interventions include the use of goal-directed, individualized tasks that promote frequent repetitions of task-related or task-specific movements."[75] One final note on the subject is that approaches focused on the use of functional tasks are more consistent with traditional and current principles of OT.[5]

Mathiowetz[69,70] outlined a series of intervention principles based on use of the OT task-oriented approach. These principles include the following:

- Help clients adjust to role and task performance limitations by exploring new roles and tasks.
- Create an environment that includes the common challenges of everyday life.
- Practice functional tasks or close simulations that have been identified as important by participants to find effective and efficient strategies for performance.
- Provide opportunities for practice outside therapy time (e.g., homework assignments).
- Minimize ineffective and inefficient movement patterns.

Functional Limitations Commonly Observed After Stroke

Multiple factors can impede effective and efficient performance of various tasks on which the client desires to focus during OT. The following sections review problem areas that are typically observed during work with clients who have sustained a stroke.

Inability to Perform Chosen Occupations While Seated

A commonly observed deficit after stroke is loss of trunk and postural control. Trunk and postural control may be considered a foundation for occupational performance. We require postural control to roll and get out of bed the first thing in the morning, feed a baby, sit at a desk to type, propel a wheelchair, eat, and so on. Impairment of trunk control may lead to the following problems[45]:

1. Dysfunction of limb control

2. Increased risk for falls

3. Impaired ability to interact with the environment

4. Visual dysfunction secondary to resultant head and neck malalignment

5. Symptoms of dysphagia secondary to proximal malalignment

6. Decreased independence in ADLs

Loss of trunk and postural control (i.e., "controlling the body's position in space for the dual purposes of stability and orientation"[82]) after a stroke may be manifested as an inability to sit in proper alignment, loss of righting and equilibrium reactions, inability to reach beyond the arm span because of lack of postural adjustments, and falling during attempts to function.

Clients who sustained a stroke and lose trunk control need to use the more functional UE for postural support to remain upright and prevent falls. In these cases the client effectively eliminates the ability to engage in ADLs and mobility tasks because lifting the more functional arm from the supporting surface can result in a fall. As Franchignoni et al.[42] noted, "Trunk control appears to be an obvious prerequisite for the control of more complex limb activities that in turn constitute a prerequisite to complex behavioral skills." Studies have found trunk control to be a predictor of gait recovery, sitting balance,[17] Functional Independence Measure (FIM) scores,[42] and scores on the Barthel Index[84] after a stroke.

Specific effects of a stroke on the trunk include the following:

1. Inability to perceive the midline as a result of spatial relationship dysfunction, leading to sitting postures that are misaligned from the vertical

2. Assumption of static postures that do not support engagement in functional activities (e.g., posterior pelvic tilt, kyphosis, lateral flexion)

3. Multidirectional trunk weakness[18]

4. Spinal contracture secondary to soft tissue shortening

5. Inability to move the trunk segmentally (i.e., the trunk moves as unit; examples of this phenomenon are clients using "logrolling" patterns during bed mobility and an inability to rotate the trunk while reaching for an item across the midline)

6. Inability to shift weight through the pelvis anteriorly, posteriorly, and laterally

Specific deficits in trunk control are evaluated during observation of task performance (Box 33.1). Observing tasks allows the therapist to evaluate trunk control in many directions (i.e., isometric, eccentric, and concentric control of the trunk muscle groups [extensors, abdominal muscles, and lateral flexors]) and the client's limits of stability. The phrase "limits of stability" refers to "boundaries of an area of space in which the body can maintain its position without changing the base of support"[87] or "an area about which the center of mass may be moved over any given base of support without disrupting equilibrium."[38] The therapist must differentiate between the client's perceived limits of stability and the actual limits of stability. After a stroke it is common to experience a disparity between the two because of body scheme disorder, fear of falling, or lack of insight into or awareness of disability. If the client's perceived limits are greater than his or her actual limits, there is a risk for falls. In other cases the client's perceived limits are less than the actual limits. In such instances the client will not attempt more dynamic activities or will rely too greatly on adaptive equipment.

Box 33.1

Trunk Control Evaluation During Task Performance: Examples of Postural Adjustments That Support Participation in Chosen Activities

Feeding

Anterior weight shift occurs to bring the upper part of the body toward the table, to prevent spillage of food from utensils, and to support a hand-to-mouth pattern.

Dressing

Lateral weight shift to one side of the pelvis occurs so that pants and underwear can be donned over the hips.

Oral Care

Anterior weight shift occurs so that saliva and toothpaste may be expectorated.

Transfer

The trunk extends with concurrent hip flexion to initiate a sit-to-stand transition.

Meal Preparation

The trunk flexes into gravity in a controlled fashion to support a reach pattern to the lower shelf of the refrigerator.

Treatment interventions aimed at increasing the client's ability to perform chosen tasks in seated postures include the following[45]:

1. Establishing a neutral yet active starting alignment (i.e., a position of readiness to function). This starting alignment (similar to a typist's posture) is a prerequisite to engaging the limbs in an activity. The desirable posture is as follows:

- Feet flat on the floor and bearing weight
- Equal weight bearing through both ischial tuberosities
- Neutral to slight anterior pelvic tilt
- Erect spine
- Head over the shoulders and shoulders over the hips

2. The client should attempt reaching activities from the previously described posture (Fig. 33.4).

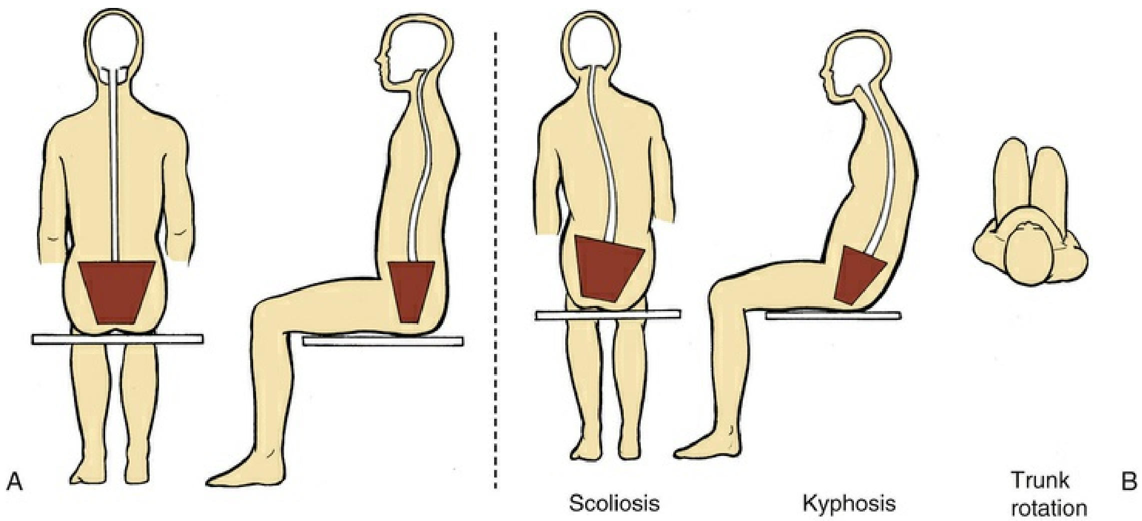

FIG 33.4 Normal (A) and post-stroke (B) sitting alignment. (From Donato SM, Pulaski KH: Overview of balance impairments: functional implications. In Gillen G, editor: *Stroke rehabilitation: a function-based approach,* ed 4, St Louis, 2016, Mosby.)

3. Establishing the ability to maintain the trunk in the midline by using external cues. Many clients have difficulty assuming and maintaining the correct posture. The therapist can provide verbal feedback (e.g., "Sit up nice and tall"). Visual feedback (e.g., using a mirror or the therapist assuming the same postural misalignment as the client) may be helpful. Environmental cues may be used to correct the posture. For example, the client may be instructed to maintain contact between the shoulder and an external target such as a bolster or wall, positioned so that the trunk is in the correct posture.

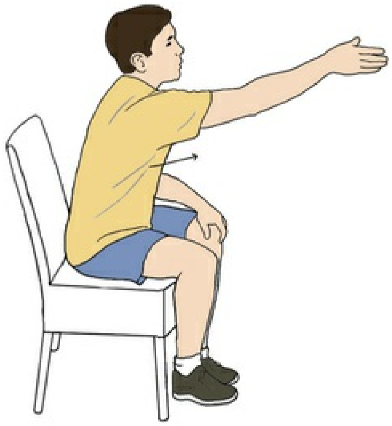
4. Maintaining trunk range of motion (ROM) by wheelchair and armchair positioning that maintains the trunk in proper alignment. The therapist can provide an exercise program focused on trunk ROM and flexibility. Activities that elicit the desired movement patterns can be chosen, and hands-on mobilization of the trunk can be used if needed. Types of trunk ROM that should be addressed include flexion, extension, lateral flexion, and rotation.

5. Prescribing dynamic weight-shifting activities to allow practice of weight shifts through the pelvis. The most effective way to train the client in weight shifts is to coordinate the trunk and limbs. Randomized controlled trials have confirmed that sitting training protocols that involve practice in reaching tasks beyond arm's length significantly improve function.[32] Successfully engaging in meaningful occupations that require reach beyond the span of either arm requires clients to adjust their posture. The client is encouraged to reach beyond arm span in all directions while seated (preferably while reaching for an object) and to analyze the corresponding postural adjustment of the pelvis and trunk. The position and goal of the task will dictate the required weight shift (Table 33.4).

TABLE 33.4

Effects of Object Positioning on Trunk Movements and Weight Shifts During Reaching Activities*

Position of Object	Trunk Response/Weight Shift
Straight ahead at the forehead level, past arm's length	• Trunk extension, anterior pelvic tilt • Anterior weight shift

On the floor, between the feet 	• Trunk flexion • Anterior weight shift
To the side at the shoulder level, past arm's length 	• Left trunk shortening, right trunk elongation, left hip hiking • Weight shift to the right
On the floor, below the right hip 	• Right trunk shortening, left trunk elongation

Behind the right shoulder, at arm's length 	• Trunk extension and rotation (right side posteriorly) • Weight shift to the right
At shoulder level, to the left of the left shoulder 	• Trunk extension and rotation (left side posteriorly) • Weight shift to the left
On floor, to left of left foot 	• Trunk flexion and rotation (left side posteriorly) • Weight shift to the left
Above the head, directly behind	• Trunk extension, shoulders move behind the hips • Posterior weight shift

*These examples are for a patient with left hemiplegia. The left-hand column indicates where to position objects during a reaching task (with the right upper extremity). The right-hand column indicates the resultant trunk position and weight shift.

From Gillen G, editor: *Stroke rehabilitation: a function-based approach,* ed 4, St Louis, 2016, Mosby.

6. Strengthening the trunk, best achieved by tasks that require the client to control the trunk against gravity. Some examples are bridging the hips in the supine position to strengthen the back extensors and initiating a roll with the arm and upper part of the trunk to strengthen the abdominal muscles. Strengthening occurs within the context of an activity.

7. Using compensatory strategies and environmental adaptations when trunk control does not improve to a sufficient level and the client is at risk for injury. Examples of interventions include wheelchair seating systems (e.g., lateral supports, lumbar rolls, chest straps, tilt-in-space frames with head supports) and adaptive ADL equipment (e.g., reachers, long-handled equipment) to decrease the amount of required trunk displacement (see Chapter 10).

For Jasmine, therapy first focused on her ability to keep her trunk stable (i.e., not moving) while using her limbs to engage in occupations. Occupations that do not require substantial weight shifting while sitting (e.g., hair care, upper body washing, feeding, card playing) were chosen first, followed by those that required progressively more weight shifting in all directions (e.g., wiping after use of the toilet, lower body dressing, scooting, reaching to the floor to pick up shoes, washing her feet). As needed, the therapist provided external support at Jasmine's shoulders during these activities to increase her confidence, prevent falls, and provide necessary support to compensate for Jasmine's weakness. As Jasmine improved, more challenging seated activities were chosen and external support was diminished.

Inability to Engage in Chosen Occupations While Standing

An inability to assume and maintain a standing posture has a significant effect on the type of activities in which a person may engage; it may also play a significant role in the eventual discharge destination for a hospitalized client recovering from a stroke. Impaired upright control has been correlated with an increased risk for falls[105] and with less than optimal functional outcomes[69] on the Barthel Index. Because many BADLs and IADLs, work, and leisure skills require control of standing postures, early training in upright control is a necessary component of stroke rehabilitation programs. **Postural strategies** (e.g., ankle, hip, and stepping strategies) are typically impaired after a stroke.

Similar to the deficits seen while sitting, upright standing postures are characterized by asymmetric weight distribution; unlike deficits occurring while sitting, the weight distribution while standing is seen through the lower extremities,[105] in addition to the trunk. Clients who sustained a stroke often experience an inability to bear weight through the affected leg. Reasons for this disability include fear of falling or buckling of the knee, patterns of weakness that will not support the weight of the body, spasticity impeding proper alignment (i.e., plantar flexion spasticity that effectively blocks **weight bearing** through the sole of the foot),[44] and perceptual dysfunction.

In addition to asymmetry and an inability to bear weight or shift weight through the affected leg, many clients who have sustained a stroke lose upright postural control and balance strategies.

Effective upright control depends on the following automatic postural reactions.[36,87,88]

1. Ankle strategies are used to maintain the center of mass over the base of support when movement is centered on the ankles. These strategies control small, slow, swaying motions, such as standing in a movie line, engaging in conversations while standing, and stirring a pot on a stovetop. They are most effective when the support surface (e.g., floor) is firm and longer than the foot. Ankle weakness, loss of ankle ROM, and proprioceptive deficits may all contribute to ineffective ankle strategies and balance.

2. Hip strategies are used to maintain or restore equilibrium. These strategies are used specifically in response to larger, faster perturbations, when the support surface is compliant, or when the surface is smaller than the feet (e.g., walking on a beam).[55]

3. A stepping strategy is used when ankle and hip strategies are ineffective or are perceived to be ineffective. This strategy results in movement of the base of support toward the center of mass movement. A step is taken to widen the base of support. Tripping over an uneven sidewalk or standing on a bus that unexpectedly stops elicits this strategy.

Both loss of postural reactions and an inability to bear and shift weight onto the affected leg will result in such functional limitations as gait deviations or dysfunction; an inability to climb stairs, transfer, and perform upright BADLs and IADLs; and an increased risk for falls. The assessment process provides the therapist with more specific information regarding the cause of the dysfunction. As Donato et al.[36] noted:

Specifically, therapists should observe what happens when patients have to move their center of mass over their base of support, move their head, stand on uneven surfaces, function in lower lighting, move from one type of surface to another, or function on a narrower base of support. Therapists should also observe patients' postural alignment, whether a bias in posture exists and in which direction that bias occurs, patients' limits of stability, the width between their feet during functional tasks, and what patients do after losing their balance.

Treatment strategies aimed at improving the patient's ability to perform chosen tasks in standing postures include the following[36,87,105]:

1. Establishing a symmetric base of support and proper alignment to prepare to engage in occupations. This starting alignment is assumed to provide ample proximal stability and to support engagement in functional tasks. The therapist may use hands-on support or visual or verbal feedback to establish proper alignment as follows:

- Feet approximately hip width apart
- Equal weight bearing through the feet
- Neutral pelvis
- Both knees slightly flexed
- Aligned and symmetric trunk

2. Establishing the ability to bear and shift weight through the more affected lower extremity.[36] The ability to bear weight may be graded at first. For example, if a client cannot assume a standing position because of postural insecurity or imbalance, sitting on a high surface (e.g., stool or raised therapy mat) allows the client to begin to bear weight but does not require bearing full body weight. As the client improves, full standing is encouraged, followed by graded weight shifts and progression to full weight bearing on the affected leg. For example, a modified soccer activity

requires the client to fully shift weight to kick the ball. The environment (e.g., work surface height and placement of objects) is manipulated in conjunction with the client's positioning to elicit the required weight shift.

3. Encouraging dynamic reaching activities in multiple environments to develop task-specific weight-shifting abilities. For example, kitchen activities that necessitate retrieval of cleaning supplies under the sink, in a broom closet, and in overhead cabinets require mastery of multiple postural adjustments and balance strategies.

4. Using the environment to grade task difficulty and provide external support. Proper use of the environment can decrease the client's fear of falling and simultaneously improve confidence and challenge underlying balance skills. Examples include working in front of a high countertop, using one hand for bearing weight as a postural support, and using a walker for support. The client must not rely too much on external supports because balance strategies may not be fully challenged to reach optimal recovery.

5. Training upright control within the context of the functional tasks that are graded. Tasks are graded in relation to the length of required reach, speed, and progressively more challenging bases of support. Examples include making a bed, changing a pet's food bowl, setting a table, stepping up on a curb, cleaning a wall mirror, playing horseshoes or shuffleboard, and doffing slippers in a standing posture. All these activities require shifting of body weight, balance strategies, and the ability to bear weight through both lower extremities. The choice of activity is driven by the client's desires, and the therapist designs positioning and setup of the activity to elicit the desired postural strategies (Fig. 33.5).

FIG 33.5 Activity is positioned to elicit the desired postural strategies. (From Donato SM, Pulaski KH: Overview of balance impairments: functional implications. In Gillen G, editor: *Stroke rehabilitation: a function-based approach,* ed 4, St Louis, 2016, Mosby.)

Jasmine was quickly engaged in activities that required standing despite persistent issues related to sitting balance. Standing was first attempted in front of stable work surfaces (e.g., kitchen counter, sink) to provide a balance point, increase Jasmine's feeling of security and safety, and highlight the functional relevance of standing. As needed, the therapist stabilized the weak joints (e.g., hip and knee) with manual support, and Jasmine wore an ankle-foot orthotic to protect the integrity of her ankle. As Jasmine improved, she was asked to begin to use the upper part of her body for function while controlling her standing. Examples include wiping the counter, organizing a shelf, and grooming while standing. Progressively more demanding occupations from a standing balance perspective were chosen (e.g., modified games, such as volleyball and Wii tennis;

vacuuming; emptying a dishwasher; and stand-pivot transfers), and external manual and environmental support was decreased as Jasmine improved. All occupations were chosen to improve Jasmine's ability to accept and shift weight through her left lower extremity.

Inability to Communicate Secondary to Language Dysfunction

Stroke may result in a wide variety of speech or language disorders, ranging from mild to severe. These deficits occur most frequently with stroke resulting from damage to the left hemisphere of the brain. They can also occur less frequently after damage to the right hemisphere. All persons with stroke should be evaluated by a speech-language pathologist for the presence of speech and language disorders. The speech-language pathologist can provide valuable information to other members of the rehabilitation team and to the family regarding the best techniques for communicating with a particular client. The occupational therapist should continue the work of the speech therapist in the treatment sessions, as appropriate. Carryover may occur in reinforcing communication techniques that the client is learning and in presenting instruction in ways that the client is able to understand and integrate.[89]

The specific speech and language dysfunctions described in the following sections can exist in mild to severe forms and in combination with one another.

Aphasia

Aphasia is an acquired communication disorder caused by brain damage that is characterized by impairment of language modalities (i.e., speaking, listening, reading, and writing); it is not the result of a sensory or motor deficit, a general intellectual deficit, confusion, or a psychiatric disorder.[50]

Global aphasia.

Global aphasia is characterized by loss of all language skills. Oral expression is lost, except for some persistent or recurrent utterance. Global aphasia is usually the result of involvement of the MCA of the dominant cerebral hemisphere. A client with global aphasia may be sensitive to gestures, vocal inflections, and facial expression. Consequently, the client may appear to understand more than he or she actually does.

Broca's aphasia.

Poor speech production and agrammatism characterize Broca's aphasia. This aphasia is manifested as slow, labored speech with frequent misarticulations. Syntactic structure is simplified because of the agrammatism, sometimes referred to as telegraphic speech. A client with this form of aphasia demonstrates good auditory comprehension except when speech is rapid, grammatically complex, or lengthy. Reading comprehension and writing may be severely affected, and a client with Broca's aphasia usually has deficits in monetary concepts and the ability to perform calculations.[89]

Wernicke's aphasia.

Wernicke's aphasia is characterized by impaired auditory comprehension and feedback, along with fluent, well-articulated paraphasic speech. Paraphasic speech consists of word substitution errors. Speech may occur at an excessive rate and may be hyperfluent. The client uses few substantive words and many function words. The client produces running speech composed of English words in a meaningless sequence. English-speaking clients produce neologisms (non-English nonsense words) interspersed with real words. Reading and writing comprehension is often limited, and mathematical skills may be impaired.[89]

Anomic aphasia.

Persons with anomic aphasia have difficulty in word retrieval. Anomia, or word-finding difficulty, occurs in all types of aphasia. However, clients in whom word-finding difficulty is the primary or only symptom may be said to have anomic aphasia. The speech of these clients is fluent, grammatically correct, and well articulated but accompanied by significant difficulty in word finding. This problem can result in hesitant or slow speech and the substitution of descriptive phrases for the actual names of things. Mild to severe deficits in reading comprehension and written expression occur, and mild deficits in mathematical skills may be present.[2,89]

Dysarthria

Clients with dysarthria have an articulation disorder, in the absence of aphasia, because of dysfunction of the CNS mechanisms that control the speech musculature. **Dysarthria** results in paralysis and incoordination of the organs of speech, which causes the speech to sound thick, slurred, and sluggish.

Communication With Clients Who Have Aphasia

Although the speech-language pathologist is responsible for the treatment of speech and language disorders, the occupational therapist can facilitate communication and meaningful interaction with clients who have aphasia. The use of gestures for communication should be encouraged. Having the client demonstrate through performance is the best way to ensure that the instructions are understood.

The occupational therapist can use routine ADLs as opportunities to encourage speech. The client should be reassured that the language disorder is part of the disability, not a manifestation of mental illness. Additional strategies for the occupational therapist to use with clients and their caregivers include the following:

- Understanding is facilitated when one person talks at a time. Extra noise creates confusion.
- Give the client time to respond.
- Carefully phrase questions to make it easier for the client to respond; for example, use "yes/no" and "either/or" questions.
- Use visual cues or gestures with speech to help the client understand.
- Never force a response.
- Use concise sentences.
- Do not rush communication because this may increase frustration and decrease the effectiveness of communication.[89]

Given that Jasmine sustained a right hemispheric stroke, aphasia would not typically be expected. Jasmine did exhibit severe sensory motor loss related to her left oral structures. She had moderate dysarthria, occasional drooling, and difficulty managing food in the left side of her mouth. Jasmine was encouraged to speak slowly and overenunciate. In addition, her occupational therapist taught her safe feeding strategies, including eating slowly, alternating solids and liquids, shifting food to the right side of her mouth, tilting her head to the right at a 45-degree angle, using her finger to sweep her mouth and clear out food pocketing on the left, and performing supervised oral care after each meal.

Inability to Perform Chosen Occupations Secondary to Neurobehavioral/Cognitive-Perceptual Impairments

A **neurobehavioral deficit** is defined as "a functional impairment of an individual manifested as defective skill performance resulting from a neurological processing dysfunction that affects performance components such as affect, body scheme, cognition, emotion, gnosis, language, memory, motor movement, perception, personality, sensory awareness, spatial relations, and visuospatial skills."[6] A major responsibility of the occupational therapist treating a client who has sustained a stroke is evaluating which neurobehavioral deficits are blocking independent performance of chosen occupations.

Árnadóttir[6] proposed a relationship among the ability to perform daily activities, neurobehavioral impairments, and the CNS origin of the neurobehavioral dysfunction (a stroke, for the purposes of this chapter). She supported this theory with the following relational statements:

1. Behaviors required for task performance are related to neuronal processing at the CNS level. Therefore, a relationship also exists between the defective behavioral responses of an individual with CNS damage during performance of ADLs and the dysfunction of neuronal processing and performance components resulting from the CNS damage.

2. Performance of daily activities requires adequate function of specific parts of the nervous system. Consequently, CNS impairment may result in dysfunction of specific aspects of ADLs. For example, a stroke caused by a lesion of the posteroinferior parietal lobe of the left hemisphere commonly results in bilateral motor apraxia. "This neurobehavioral impairment may make manipulation of objects difficult during functional activities such as combing hair, brushing teeth, or holding a spoon while eating."[6]

3. Neurological impairment can be observed through the client's engagement in daily activities. Thus, by analysis of ADLs, the integrity of the CNS can be evaluated (Box 33.2).

Box 33.2

Toothbrushing Task: Treatment of Neurobehavioral Impairments

Spatial Relationships and Spatial Positioning

- Positioning of the toothbrush and toothpaste while applying paste to the brush
- Placement of the toothbrush in the mouth
- Positioning of bristles in the mouth
- Placement of the brush under the faucet

Spatial Neglect

- Visual search for and use of the brush, paste, and cup in the affected hemisphere
- Visual search for and use of the faucet handle in the affected hemisphere

Body Neglect

- Brushing of the affected side of the mouth

Motor Apraxia

- Manipulation of the toothbrush during task performance

- Manipulation of the cap from the toothpaste
- Squeezing of toothpaste onto the brush

Ideational Apraxia

- Appropriate use of objects (e.g., brush, paste, cup) during a task

Organization and Sequencing

- Sequencing of the task (e.g., removal of the cap, application of paste to the brush, turning on the water, putting the brush in the mouth)
- Continuation of task to completion

Attention

- Attention to the task (to increase difficulty, distractions such as conversation, flushing the toilet, or running water may be added)
- Refocusing on the task after the distraction

Figure-Ground

- Distinguishing a white toothbrush and toothpaste from the sink

Initiation and Perseverance

- Initiation of the task on command
- Cleaning parts of the mouth for an appropriate period, then moving the bristles to another part of the mouth
- Discontinuation of the task when complete

Visual Agnosia

- Use of touch to identify objects

Problem Solving

- Search for alternatives if the toothpaste or toothbrush is missing

From Gillen G, editor: *Stroke rehabilitation: a function-based approach*, ed 4, St Louis, 2016, Mosby.

To properly evaluate the effect of neurobehavioral deficits on task performance, the therapist must develop activity analysis skills with the goal of analyzing which components of performance are necessary to achieve an outcome that is satisfactory to the client. Even the simplest of BADL tasks challenges multiple underlying skills (Boxes 33.3 and 33.4; also see Fig. 33.3).[6,82]

Box 33.3

Examples of Environmental and Task Manipulation to Challenge Component Skills During Meal Preparation

Spatial Neglect

- Place ingredients in both visual fields.
- Choose a task that requires use of the right and left burners.

Figure-Ground

- Place necessary utensils in a cluttered drawer.
- Use utensils that match the color of the counter.

Spatial Dysfunction

- Prepare items that require the client to pour ingredients from one container to another (e.g., pour pasta into a bowl or fill a pot with water).

Motor Apraxia

- Choose recipes that require manipulation of food items.
- Choose recipes that require control of distal extremity adjustments (e.g., using a ladle, whisking, and stirring).

Box 33.4

Sample Compensatory Strategies for Neurobehavioral Deficits Affecting Dressing Skills

Spatial Neglect

- Place necessary clothing on the right side of the closet and drawers.
- Move the dresser to the right side of the room.

Motor Apraxia

- Use loose-fitting clothing without fasteners.
- Use Velcro closures.

Spatial Dysfunction

- Use shirts with a front emblem to identify proper orientation.
- Lay out clothing in the proper orientation.

Árnadóttir[6,7] proposed a system of observing clients engaged in functional activities in which errors are allowed to occur (as long as they are safe), the errors are analyzed, and finally, impairments that are interfering with performance of tasks are detected so that an appropriate treatment plan can be developed. She cautioned that when the therapist analyzes errors and observed behavior, knowledge of neurobehavior, cortical function, activity analysis, and clinical reasoning must be considered in the results of the evaluation (Table 33.5).

TABLE 33.5

Evaluating the Effect of Neurobehavioral Dysfunction on Task Performance

Performance Area	Observed Behavior	Possible Impairment
Grooming	Difficulty adjusting grasp on razor or toothbrush	Motor apraxia
	Using a comb to brush teeth	Ideational apraxia
	Repetitive brushing of one side of mouth	Premotor perseveration
Feeding	Not eating food on left side of plate	Spatial neglect
	Overestimating or underestimating distance to glass, resulting in knocking over glass	Spatial relationship dysfunction
	"Forgetting" that a glass of orange juice is in hand, resulting in spillage as client attends to another aspect of meal	Body neglect
	Placing hand in cereal bowl	
Dressing	Client attempting to put socks on after sneakers	Organization and sequencing dysfunction
	Client unable to locate armholes in undershirt	Spatial relationship dysfunction
	Dressing only right side of body	Body neglect
	Client attempting to dress therapist's arms instead of his or her own	Somatognosia
Mobility	Client unable to locate bathroom in his or her hospital room	Topographic disorientation

	Client neglecting to lock brakes or remove wheelchair footrests before attempting to transfer	Organization and sequencing dysfunction
	After a transfer, only intact buttock is in contact with seat of chair	Body neglect

From Árnadóttir G: *The brain and behavior: assessing cortical dysfunction through activities of daily living*, St Louis, 1990, Mosby; and Gillen G, editor: *Stroke rehabilitation: a function-based approach*, ed 4, St Louis, 2016, Mosby.

Treatment aimed at counteracting the effects of neurobehavioral dysfunction may be based on an adaptive and compensatory approach or on a restorative and remedial approach.[47,72,74,82] A combination of approaches has also been suggested (Table 33.6).[1]

TABLE 33.6

Treatment Approaches for Neurobehavioral Deficits After Stroke

Compensatory and Adaptive Approach	Restorative and Remedial Approach	Combination Approach
• Repetitive practice of tasks • Top-down approach • Emphasizes intact skill training • Emphasizes modification • Uses environmental or task modifications to support optimal performance • Choice of activity driven by performance challenges, not by component deficits • Treats symptoms, not the cause • Client-driven compensatory strategies • Caregiver-therapist environmental adaptations • Task specific and not generalizable	• Restoration of component skills • Bottom-up approach • Deficit specific • Targets cause of symptoms and emphasizes components • Assumes that transfer of training will occur • Assumes that improved component performance will result in increased skill • Choice of activity driven by component deficits • Research demonstrates short-term results with skills generalizable to very similar tasks	• Rejects dichotomy between compensatory and restorative approaches • Uses optimally relevant occupations and environments as the treatment modality to challenge components • Choice of treatment driven by tasks relevant to client needs; tasks presented so that the underlying deficits are challenged via the task • Rejects use of contrived activities

Decisions regarding the selection of a particular treatment approach may be difficult. Neistadt[73,74] suggested evaluating a client's learning potential in the context of ADL evaluation and training, with a focus on such issues as the number of repetitions needed to learn new approaches to tasks and the type of transfer of learning that is demonstrated.

Toglia[94] has suggested that transfer of learning from one context to another (e.g., transferring skills learned from making a cup of tea in the OT clinic to meal preparation at home) may be facilitated by the therapist through the following methods:

1. Varying treatment environments

2. Varying the nature of the task

3. Helping clients become aware of how they process information

4. Teaching processing strategies

5. Relating new learning to previously learned skills

Toglia[94] has identified degrees of transfer of learning. The degree of transfer is defined by the number of task characteristics that differ from those of the original task. Examples of these characteristics are spatial orientation, mode of presentation (e.g., auditory or visual), movement requirements, and environmental context.

A near transfer of learning involves transfer between two tasks that have one or two differing characteristics. Intermediate transfer involves transfer of learning to a task that varies by three to six characteristics. A far transfer involves a task that is conceptually similar but has one or no characteristics in common. Finally, a very far transfer involves the "spontaneous application of what has been learned in treatment to everyday living."[94]

From her review of the literature, Neistadt[72] reached the following conclusions:

1. Near transfer from remedial tasks to similar tasks is possible for all clients with brain injury.

2. Intermediate, far, and very far transfer from remedial to functional tasks will occur only in clients with localized brain lesions and good cognitive skills and after training with a variety of treatment tasks.

3. Far and very far transfer from remedial to functional tasks will not occur in clients with diffuse injury and severe cognitive deficits.

Using a functional and meaningful task as a treatment modality promotes the acquisition of a desired skill, and the therapist may use this task to challenge multiple underlying impairments.[1,47,82]

It is up to the therapist to present the task by manipulating the environment in a way that challenges the underlying skills (see Box 33.3). If a compensatory approach is chosen, adaptive techniques are used to counteract the effects of the underlying neurobehavioral deficits (see Box 33.4).

Jasmine's left-sided neglect had a substantial impact on her ability to perform relevant occupations independently and safely. A variety of strategies was used to improve her ability to attend to the left side. Organized visual scanning was taught during daily activities such as feeding and grooming.[48] Occupations were chosen that required scanning to both the left and the right to be successful (e.g., finding ingredients in the refrigerator, locating the toothbrush on the left side of the sink and toothpaste on the right, reading, and describing a room). Vanishing physical and verbal cues were used as Jasmine progressed. Another strategy that was helpful for Jasmine was the use of a left-sided anchor. A red strip of tape was placed on the left side (e.g., the left side of the computer monitor, placemat, sink, book), and Jasmine focused on scanning to the anchor to ensure that she was attending to all of the information required to be successful at performing each occupation. Because Jasmine's neglect persisted, driving was not an option. Other modes of transportation were considered, including supervised use of public transportation, assistance with transport by friends and neighbors, and local Access-A-Ride companies. (See Chapter 11.)

Inability to Perform Chosen Tasks Secondary to Upper Extremity Dysfunction

Loss of UE control is common after a stroke; 88% of clients who sustain a stroke have some level of UE dysfunction.[77] The client's ability to integrate the affected arm into chosen tasks may be limited by multiple factors, including the following[46]:

1. Pain

2. Contracture and deformity

3. Loss of selective motor control

4. Weakness[21]

5. Superimposed orthopedic limitations

6. Loss of postural control to support UE control

7. Learned nonuse[90]

8. Loss of biomechanical alignment[24]

9. Inefficient and ineffective movement patterns

Integration Into Function

UE evaluation procedures should focus primarily on assessing the client's ability to integrate the UE into the performance of functional tasks—in other words, to use the affected UE to support performance in areas of occupation. Standardized evaluations, such as the Test d'Evaluation des Membres Supérieurs de Personnes Agées (TEMPA),[34,35] Arm Motor Ability Test (AMAT),[62] Jebsen Test of Hand Function,[56] and AMPS[40] (see Table 33.3) are available to objectively measure the client's ability to use the affected extremity during performance of tasks. In addition, self-reported measures of UE function are recommended. Examples include the following:

1. The Motor Activity Log is a self-reported questionnaire (reported by the patient or family) related to actual use of the involved UE outside structured therapy time. It uses a semistructured interview format. Quality of movement ("how well" scale) and the amount of use ("how much" scale) are graded on a 6-point scale. At present there are 30-, 28-, and 14-item versions of the tool. Sample items include holding a book, using a towel, picking up a glass, writing/typing, and steadying oneself.[99,100]

2. The 36-item Manual Ability Measure (MAM-36) is a new Rasch-developed, self-reported disability outcome measure.[27,28] It contains 36 gender-neutral, commonly performed everyday hand tasks. The patient is asked to report the ease or difficulty of performing such tasks. It uses a 4-point rating scale, with 1 indicating "unable" (I am unable to do the task all by myself); 2 indicating "very hard" (It is very hard for me to do the task, and I usually ask others to do it for me unless no one is around); 3 indicating "a little hard" (I usually do the task myself, although it takes longer or more effort now than before); and 4 indicating "easy" (I can do the task without any problem). The MAM-36 has been validated and is psychometrically sound reflecting the use of occupation-based tasks to determine hand function.[27a]

The UE may be used during functional performance in different ways (Table 33.7), including, but not limited to, the following[42]:

1. Weight bearing or accepting partial body weight through a limb. Weight bearing through the hand and forearm with an extended elbow is a pattern used during ADLs and mobility tasks. Establishment of weight bearing is a goal of UE rehabilitation.[16] Effective control of weight bearing

depends on the presence of sufficient trunk and scapula stability to accept partial body weight, control of active elbow extension, and ability of the hand to bear weight without losing the palmar arches. Once weight bearing has been established, the client can effectively use the arm as a postural support (e.g., by supporting upper body weight with the affected arm while wiping crumbs from the table with the more functional arm), as an aid during transitional movements (e.g., while pushing up from lying on the side to sitting), and for preventing falls (increased postural support is provided).[46]

2. Moving objects across a work surface with a static grasp (supported reach). Activities such as ironing clothes, opening or closing a drawer, polishing furniture, and sliding a paper across the table are all examples of UE control of movement that does not occur with the arm in space. The hand is in contact with the objects involved in the task or is supported on the work surface; therefore, these types of tasks do not require the same control as (and may require less effort than) activities performed while the client is reaching in space, such as removing dishes from a cabinet or reaching for food in the refrigerator. This movement pattern can be used for multiple tasks and at the same time strengthens the various muscle groups used to eventually support reach in space.[46]

3. Reach and manipulation. Reviews of research on UE motor control[2,46] have identified two components of function during reaching activities. The first is the transportation component, which is defined as the trajectory of the arm between the starting position and the object. The second is the manipulation component, which is the formation of grip by combined movements of the thumb and index finger during arm movement. Finger posturing anticipates the real grasp and occurs during transportation of the hand toward the object.[2] Shaping of the hand is independent of the manipulation itself. Trombly's reaching studies of clients with left hemiparesis documented that the ability to reach smoothly and with coordination was significantly less on the affected than on the unaffected side.[97] The continuous movement strategy was lost, movement time was longer, peak velocity occurred earlier, and weakness indicators were present.

TABLE 33.7

Suggestions for Categorizing Upper Extremity Tasks

Category	Tasks
No functional use of the arm	• Teach shoulder protection • Self range of motion • Positioning
Postural support/weight bearing (forearm or extended arm)	• Bed mobility assistance • Support upright function (e.g., work, leisure, activities of daily living [ADLs]) • Support during reach with the opposite hand • Stabilize objects
Support reach (hand on a work surface)	• Wiping a table • Ironing • Polishing • Sanding • Smoothing out laundry • Applying body lotion • Washing body parts • Vacuuming • Locking wheelchair brakes
Reach	• Multiple possibilities to engage the upper extremity in ADLs, leisure, and mobility; grade tasks by height/distance reached, weight of object, speed, and accuracy

From Gillen G, editor: *Stroke rehabilitation: a function-based approach*, ed 4, St Louis, 2016, Mosby.

Trombly[96] demonstrated that although muscular activity did not improve in the clients in her study, the discontinuity improved over time. She stated that the “level and pattern of muscle activity of these subjects depended on the biomechanical demands of the task rather than any stereotypical neurological linkages between the muscles.”

Clients are commonly observed demonstrating the use of stereotypical movement patterns of the UE. These patterns are characterized by scapula elevation and fixation, humeral abduction, elbow flexion, and wrist flexion. Mathiowetz and Bass Haugen[70] suggested that the use of these movement patterns is evidence of attempts to use the remaining systems to complete tasks. They gave an example of a client with weak shoulder flexors trying to lift an arm. The client flexes the elbow when trying to raise the arm because this movement strategy shortens the lever arm and eases shoulder flexion.

A recent evidence-based review[75]documented that the following interventions resulted in improved occupational performance for those with motor control limitations:

- Repetitive task practice: This term was used to describe training approaches that included performance of goal-directed, individualized tasks with frequent repetitions of task-related or task-specific movements.

- Constraint-induced movement therapy (CIMT) or modified constraint-induced movement therapy (mCIMT): A method of training that involves restraint of the unaffected limb for ~ 90% of waking hours, forcing use of the affected limb during daily activities. The other components of CIMT include shaping and intensive and repetitive task training using the affected limb for 6 hours per day for 2 weeks. Modified CIMT is a shortened version of the original CIMT. During mCIMT, the amount of time for intensive training of the affected limb, the restraint time of the nonaffected limb, or both are decreased and/or distributed over a longer period of time (Box 33.5).

Box 33.5

Main Points of Constraint-Induced Movement Therapy

1. Counteracts learned nonuse.

Hypothesized causes of learned nonuse include therapeutic interventions implemented during the acute period of neurological suppression after a stroke, an early focus on adaptations to meet functional goals, negative reinforcement experienced by patients as they unsuccessfully attempt to use the affected limb, and positive reinforcement experienced by using the less involved hand and/or successful adaptations.

2. Motor inclusion criteria.

Control of the wrist and digits is necessary to engage in this type of intervention. Current and past protocols have used the following inclusion criteria: 20 degrees of extension of the wrist and 10 degrees of extension of each finger; 10 degrees of extension of the wrist, 10 degrees of abduction of the thumb, and 10 degrees of extension of any two other digits; or the ability to lift a washrag from a table using any type of prehension and then release it.

3. Main therapeutic factor.

Massed practice and shaping of the affected limb during repetitive functional activities appear to be the therapeutic change agents. "There is thus nothing talismanic about use of a sling or other constraining device on the less-affected limb."[46]

4. Choices of activity and the therapist's interventions.

Select tasks that address the motor deficits of the individual client, assist clients in carrying out parts of a movement sequence if they are incapable of completing the movement on their own at first, provide explicit verbal feedback and verbal reward for small improvements in task performance, use modeling and prompting of task performance, use tasks that are of interest and motivational to the patient, ignore regression of function, and use tasks that can be quantified related to improvements.

5. Outcome measures.

The Motor Activity Log (actual use outside of structured therapy, or "real-world" use), Arm Motor Ability Test, Wolf Motor Function Test, and Action Research Arm Test have been used to document outcomes.

6. Cortical reorganization.

Constraint-induced movement therapy is the first rehabilitation intervention that has been demonstrated to induce changes in the cortical representation of the affected upper limb.

7. Research validity.

The rigorous research that has been and continues to be carried out to demonstrate the effectiveness or efficacy of constraint-induced movement therapy should be used as a gold standard for other rehabilitation interventions that are used traditionally (e.g., neurodevelopmental therapy) but have little or no research support.

8. Evidence-based support.

On the basis of available evidence, constraint-induced movement therapy appears to be an effective intervention for those living with stroke who have learned nonuse and fit the motor inclusion criteria.

From Gillen G: Upper extremity function and management. In Gillen G, editor: *Stroke rehabilitation: a function-based approach*, ed 4, St Louis, 2016, Mosby.

- Strengthening and exercise: All forms of strengthening and exercise, including yoga and tai chi, were combined into the intervention category of strengthening and exercise in this review.
- Mental practice: A training method during which a person cognitively rehearses a physical skill in the absence of actual movements. Most often this type of training is coupled with traditional task-oriented practice.
- Virtual reality: Participants take part in various goal-directed activities in a computer-based, interactive, multisensory-simulated environment designed to replicate real-world experiences.
- Mirror therapy: During mirror therapy, a mirror or mirror box is placed in the midsagittal position between the extremities of interest. The individual is then encouraged to concentrate on the mirror reflection of the uninvolved extremity performing movements or receiving sensory stimulation while the involved extremity remains hidden out of sight behind the mirror. This procedure creates a visual illusion whereby the activities of the uninvolved extremity are attributed to the involved extremity.

• Action observation: Participants watch another person performing common functional actions (most often by watching a prerecorded video) with the intention of imitating the observed actions. Accordingly, action observation is followed by actual task performance.

The following are examples of using treatment activities to improve the client's ability to integrate the UE into tasks.[a]

1. Using objects of different sizes and shapes to encourage control of the hand during reach and manipulation

2. Choosing activities that are appropriate to the client's level of available motor control

3. Using CIMT techniques (see Box 33.5): techniques in which the less affected UE is constrained (e.g., with a sling and splint or similar device) to compel use of the affected extremity, thereby providing massed practice of graded activities for the affected side to increase functional use[86]

4. Specifically training the arm to be used in weight bearing, reach, and manipulation situations within the context of ADLs and mobility

5. Presenting the client with graded tasks related to the number of degrees of freedom, the level of antigravity control required, and the resistance involved in the task (Fig. 33.6).

FIG 33.6 The task is designed to elicit the desired motor pattern; the purpose of the task drives the motor output. (From Gillen G: Upper extremity function and management. In Gillen G, editor: *Stroke rehabilitation: a function-based*

approach, ed 4, St Louis, 2016, Mosby.)

Jasmine had very little motor activity throughout her left UE. Therapy focused on having Jasmine position her arm correctly (on the work surface and within her sight lines) during activities to prevent it from dangling all day and to use her arm as a stabilizer (e.g., using the weight of her arm to stabilize a paper while writing or holding a book open). As Jasmine improved, she was encouraged to use her arm in weight bearing as a postural support (e.g., pushing up when transitioning from the supine position to a seated position, pushing up to stand, reaching back to sit, and using the arm as support when standing at a sink or counter). Occupations were chosen that matched her available motor control and challenged her current level.

Upper Extremity Complications After Stroke

Subluxation.

Subluxation, or malalignment caused by instability of the glenohumeral joint, is a common occurrence after stroke. The subluxation may be inferior (head of the humerus below the glenoid fossa), anterior (head of the humerus anterior to the fossa), or superior (head of the humerus lodged under the acromion-coracoid).[83] Cailliet[24] and Basmajian[11] described the mechanism of inferior subluxation, in which the humeral head drifts inferior to the glenoid fossa. This common subluxation occurs as a result of malalignment of the scapula and the trunk. The normal position of the scapula is one of upward rotation, an orientation that cradles the head of the humerus and stabilizes it in alignment. The weight of the arm combined with instability and malalignment contributes to subluxation.

A common misunderstanding about subluxation is that it is associated with pain. The literature does not support this relationship.[107] Because the shoulder is unstable after a stroke, care must be taken to support the flail shoulder in bed (e.g., using pillows to maintain alignment), in a wheelchair (e.g., with lap boards or pillows), and in the upright position (e.g., putting the hands in a pocket or taping the shoulder). Treatment to reduce subluxation should focus on achieving trunk alignment and scapula stability in a position of upward rotation.[83]

Abnormal skeletal muscle activity.

A change in the resting state of the limb and postural muscles is common after stroke.[16] Immediately after a stroke, a change in available, or resting, skeletal muscle activity occurs. Most commonly, the acute state is characterized by low tone (“low-tone stage”). During this low-tone stage, the limbs and trunk become increasingly influenced by the pull of gravity. Little or no muscle activity is available at this stage, which results in deviations from the normal resting alignment of the musculoskeletal system.

An inability to recruit and maintain muscle activity is generally the greatest limiting factor at this stage. Because of the generalized lack of muscle activity and the dependent nature of the trunk and limbs, secondary problems can occur,[44] including the following:

1. Edema affecting the dorsal surface of the hand and pooling of fluids under the extensor tendons, thereby effectively blocking active or passive digit flexion

2. Overstretching of the joint capsule of the glenohumeral joint

3. Eventual shortening of muscles that are passively positioned in an effort to support a weak limb (Commonly, flaccid UEs are positioned in the client's lap, on a pillow, on a lap tray, or in a sling. Although these support the arm, the static positions result in prolonged positioning of certain muscle groups [internal rotators, elbow flexors, and wrist flexors] in a shortened position, which places them at risk for mechanical shortening. Interestingly, these are the muscle groups that tend to become spastic as time progresses.)

4. Overstretching of the antagonists to the previously mentioned muscles

5. Risk of joint and soft tissue injury during ADLs and mobility tasks (Because of the lack of control associated with a low-tone stage, the arm dangles and is not positioned appropriately during dynamic activities. Common examples include an arm being caught in the wheel during wheelchair

mobility, pinning of the arm during bed mobility or rest, sitting on the arm after a transfer, or weight bearing through a flexed wrist during engagement in self-care activities.)

Progression to a state of increased or excessive skeletal muscle activity (increased tone), such as clonus, stereotypic posturing of the trunk and limbs, hyperactive stretch reflexes, and increased resistance to passive limb movements that are dependent on velocity, may occur within several days or months of the stroke.[44]

As spasticity increases, the risk for soft tissue shortening is heightened. This factor may lead to a vicious circle of spasticity to soft tissue shortening to overrecruitment of shortened muscles to increased stretch reflexes. Secondary problems that may occur if the spasticity is not managed in a therapy program include the following[44]:

1. Deformity of the limbs, specifically the distal end of the upper limb (elbow to digits)

2. Maceration of palm tissue

3. Possible masking of underlying selective motor control

4. Pain syndromes resulting from loss of normal joint kinematics (These syndromes are usually related to soft tissue contracture that blocks full joint excursion. A typical example is loss of full passive external rotation of the glenohumeral joint. Attempts at forced abduction in these cases will result in a painful impingement syndrome of the tissues in the subacromial space.)

5. Impaired ability to manage BADL tasks, specifically UE dressing and bathing of the affected hand and axilla when flexor posturing is present

6. Loss of reciprocal arm swing during gait activities

Prevention of pain syndromes and contracture

Protection of unstable joints.

During the low-tone stage, joints tend to become malaligned secondary to loss of muscular stabilization. In these cases clients are at risk for injury to unstable joints (e.g., traction injuries and joint trauma) because of the joint instability. The glenohumeral and wrist joints are particularly at risk. The glenohumeral joint (usually already inferiorly subluxated at this stage) is at risk for a superimposed orthopedic injury if another individual unknowingly pulls on the affected arm during self-care and mobility or during unskilled passive range of motion (PROM) of the joint. The unstable glenohumeral joint is in a malaligned state, which puts the client at risk for an impingement syndrome during PROM if normal joint mechanics is not addressed. Key joint motions of concern are upward rotation of the scapula and external (lateral) rotation of the shoulder. If these motions are not present and ROM is forced, the client is at risk for the development of an impingement and pain syndrome.[44]

Clients with low tone also have an unstable wrist. Care should be taken to protect the wrist if the client is not controlling the joint during ADL and mobility tasks. Clients commonly practice a bed mobility or lower extremity dressing sequence and then complete the task while bearing weight through a malaligned flexed wrist. These clients are at risk for orthopedic injury (traumatic synovitis) and may be considered candidates for splinting to protect the wrist.[46]

Maintaining soft tissue length.

Clients who have both increased and decreased skeletal muscle activity are at risk for soft tissue contracture secondary to the immobilization that occurs during both low-tone and increased-tone stages. Maintenance of tissue length is a 24-hour regimen. It involves frequent variations in resting postures during waking hours, teaching the client and significant others appropriate ROM procedures, daytime and nighttime positioning programs, and staff and family education so that positioning and exercise programs may be carried out in the home environment.[44]

Prolonged static positioning (e.g., prolonged use of a sling) must be avoided. Teaching clients to adjust their resting postures during the day will help prevent soft tissue tightness.

Positioning programs.

The same wheelchair and bed positioning programs should not be applied to every client. Instead, positioning should be individualized and should focus on (1) promoting normal resting alignment of the trunk and limbs in an effort to maintain tissue length on both sides of the joints; (2) providing stretch to muscle groups that have been identified as being prone to contracture or already shortened; and (3) placing particular focus on maintaining passive external rotation of the shoulder.[3]

Soft tissue elongation.

If soft tissue shortening and length-associated changes have already developed, the treatment of choice is low-load/prolonged stretch (LLPS). LLPS involves placing the soft tissues in question on submaximal stretch for prolonged periods. This technique is quite different from the common PROM with terminal stretch (high-load/brief stretch) programs commonly used to treat this population.[71]

LLPS can be implemented in various ways, including splinting, casting, and positioning programs. For example, during a UE assessment a client is noted to have tightness in the internal rotators, overactive internal rotation during attempts to move, and weakened external rotators. An effective LLPS program would involve having the client rest in a supine position with the arm abducted to 45 degrees and in external rotation. This position has been shown to decrease the potential for contracture.[3]

LLPS can also be achieved through splinting programs. A common example is the use of a splint designed to elongate the long flexors of the hand during sleeping hours.

Orthotics.

Commonly a controversial subject in the management of stroke, orthotics should be considered on a case-by-case basis and may be quite effective for many clients.[71] The most common uses for orthotics during the low-tone stage are for maintaining joint alignment, protecting the tissues from shortening or overstretching, preventing injury to the extremity, and serving as an adjunctive treatment to control edema.[71] Specifically, orthotic support may be needed to provide palmar arch support and maintain neutral wrist deviation and a neutral position of the wrist between flexion and extension. In most cases the fingers do not require splinting in this stage of recovery.[71]

Orthotics may also be effective for clients in whom spasticity is developing. In these cases the splints may be used to maintain soft tissue length, provide LLPS, place muscles at their resting lengths on both sides of the joints, and attempt distal relaxation by promoting proximal alignment.[71]

Client management.

In addition to the interventions already described, it is helpful to train the client to manage his or her UE. For a client with low tone, the most important information to share with the client and significant others is the method for protecting the unstable joints and maintaining full ROM. In the spastic stage, the treatment of choice is to teach positioning that will provide prolonged elongation of the overactive muscles and prevent contracture. Examples of positions that may be prescribed during leisure or self-care activities include the following[44]:

1. Weight bearing on the extended arm (elongates the commonly shortened UE musculature)

2. In the supine position, hands behind the head while allowing the elbows to drop toward the bed (provides stretch of the internal rotators)

3. In the supine position, a pillow protracting the scapula and under the elbow to promote glenohumeral joint alignment

4. Lying on a protracted scapula to maintain stretch of the retractors and scapulothoracic mobility

5. Supporting the involved wrist with the more functional hand and reaching down toward the floor with both hands (This pattern will elongate muscles that tend to contract during difficult activities, which is particularly helpful after gait activities or difficult self-care activities.)

6. Cradling the affected arm with the stronger arm, lifting it to chest level, and gently raising and lowering (staying below 90 degrees) and gently abducting or adducting the arm (Fig. 33.7).

Cautionary note: Clasping the hands and lifting the affected arm overhead should be discouraged because of the risk for increasing pain, causing an impingement syndrome, and stressing the carpal ligaments (Fig. 33.8). Similarly, overhead pulleys should be avoided.

FIG 33.7 "Rock the baby." The client lifts the right upper extremity to chest level (A), adducts (B), and abducts (C) horizontally to allow trunk rotation.

FIG 33.8 Because of multiple biomechanical concerns (e.g., impingement), self–overhead range of motion is discouraged.

The keys to prescribing a proper resting posture are (1) to identify muscle groups in the trunk and upper limb that are shortening, overactive, or at risk for the development of shortening and (2) to select a comfortable posture that elongates the muscle group for a prolonged period.

Jasmine and her family were taught appropriate positioning when Jasmine is in bed and on chairs and during upright activities. In addition, Jasmine learned how to safely perform self-ROM exercises and was provided with a resting hand orthotic at night.

Nonfunctional Upper Extremity

Although restoration of UE control is a realistic goal for some clients, many clients will not regain enough control to integrate the affected UE into ADL and mobility tasks. Clients who will not regain sufficient control require extensive retraining in BADLs and IADLs (see Chapter 10) with one-handed techniques and prescription of appropriate assistive devices (Box 33.6). Persons in this population are also candidates for dominance retraining. Control of deformity to prevent body image issues is paramount for these clients.

Inability to Perform Chosen Tasks Secondary to Visual Impairment

Processing of visual information is a complex act that requires intact functioning of multiple peripheral nervous system and CNS structures to support functional independence. The site of the lesion determines the visual dysfunction and the effect on performance of tasks (Fig. 33.9).[7]

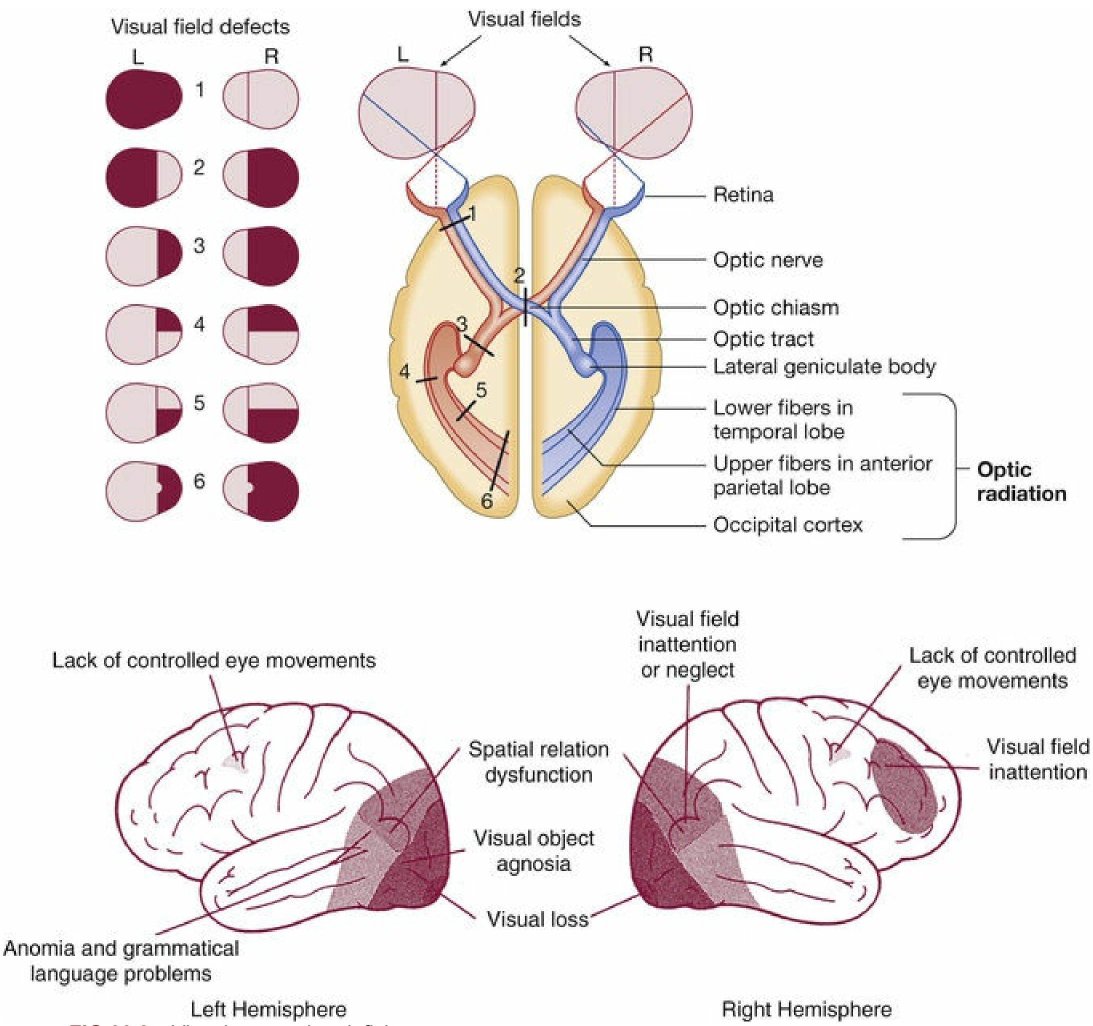

FIG 33.9 Visual processing deficits. (*Top* from Walker BR, et al: *Davidson's principles and practice of medicine,* ed 22, Edinburgh, 2014, Churchill Livingstone; *Bottom* from Árnadóttir G: *The brain and behavior: assessing cortical dysfunction through activities of daily living,* St Louis, 1990, Mosby.)

Visual dysfunction and its treatment are detailed in Chapter 24. In general, treatment approaches may focus on remediation, such as eye calisthenics, fixations, scanning, visual motor techniques, and bilateral integration. Adaptive techniques are also used, including a change in working distance, the use of prisms, adaptations for driving and reading, changes in lighting, and enlarged print.[85]

Psychosocial Adjustment

The psychological consequences of a stroke are substantial. The incidence of depression in this population is 35%, according to statistics collected by the American Heart Association.[4] The highest reported incidence is found in clients in acute and rehabilitation hospitals, and the lowest is in samples of those living in the community after stroke. Other psychological manifestations that have been documented in survivors of stroke include anxiety, agoraphobia, substance abuse, sleep disorders, mania, aprosody (difficulty expressing or recognizing emotion), behavioral problems (e.g., sexual inappropriateness, verbal outbursts, aggressiveness), lability (alteration between pathological laughing and crying), and personality changes (e.g., apathy, irritability, social withdrawal).[39]

A critical role of the occupational therapist is to help the client adjust to hospitalization and, more important, to disability. Much patience and a supportive approach by the therapist are essential. The therapist must be sensitive to the fact that the client has experienced a devastating and life-threatening illness that has caused sudden and dramatic changes in his or her life roles and performance. The therapist must be cognizant of the normal adjustment process and must gear the approach and expectations of performance to the client's level of adjustment. Frequently, the client is not ready to engage in rehabilitation measures with wholehearted effort until several months after the onset of the disability.

Family education is extremely important throughout the treatment program. Family members are better equipped to assist their loved one in adjusting to disability when they are knowledgeable about the disability and its implications.

Many clients dwell on the possibility of full recovery of function; they should gradually be made aware that some residual dysfunction is likely. The therapist may approach this probability by discussing in objective terms what is known about the prognosis for functional recovery after stroke. It may be necessary to review this information many times before the client begins to apply it to his or her recovery. This education should be done in a way that is honest and yet does not destroy all hope.

Falk-Kessler[39] has provided occupational therapists with guidelines related to interventions for the psychological manifestations of stroke, including the following:

- Fostering an internal locus of control related to recovery
- Using therapeutic activities to improve self-efficacy or confidence in the performance of specific activities
- Promoting the use of adaptive coping strategies, such as seeking social support, information seeking, positive reframing, and acceptance
- Promoting success in chosen occupations to improve self-esteem
- Encouraging social support networks, such as families, friends, or support groups
- Using occupations to promote social participation

In addition to the aforementioned interventions, it is important to remember that pharmacologic interventions have been shown to be effective in this population and should not be overlooked[39] as part of a team approach. Such interventions include, but are not limited to, antidepressants for depression or for individuals with a pathologic affect, benzodiazepines for generalized anxiety disorder, and neuroleptic medications for those with post-stroke psychosis.[26]

The OT program should focus on the skills and abilities of the client. The client's attention should be focused, through the performance of activity, on his or her remaining and newly learned skills. The OT program can also include therapeutic group activities for socialization and sharing of common problems and their solutions. The discovery that there are residual abilities and perhaps new abilities and success at performing many daily living skills and activities that were initially thought to be impossible can improve the client's mental health and outlook.

Summary

Stroke is a complex disability that challenges the skills of professional healthcare workers. Although the number and effectiveness of approaches for the remediation of affected motor, sensory, perceptual, cognitive, and performance dysfunctions have increased considerably (Box 33.7), many limitations in treatment remain. The occupational therapist must bear in mind that the degree to which the patient achieves treatment goals depends on the CNS damage and recovery, neurological impairment residuals, psychosocial adjustment, and the skilled application of appropriate treatment by all concerned health professionals.

Box 33.7

Summary of Recent Reviews of Evidence-Based Interventions to Improve Occupational Performance After Stroke

- *Motor impairments limiting occupational performance:* Evidence suggests that repetitive task practice, constraint-induced or modified constraint-induced movement therapy, strengthening and exercise, mental practice, virtual reality, mirror therapy, and action observation can improve upper extremity function, balance and mobility, and/or activity and participation. Commonalities among several of the effective interventions include the use of goal-directed, individualized tasks that promote frequent repetitions of task-related or task-specific movements.[75]

- *Cognitive impairments affecting occupational performance:* Evidence is available from a variety of clinical trials to guide interventions regarding general cognition, apraxia, and neglect. The evidence regarding interventions for executive dysfunction and memory loss is limited. There is insufficient evidence regarding impairments of attention and mixed evidence regarding interventions for visual field deficits. The effective interventions have some commonalities, including being performance focused, involving strategy training, and using a compensatory as opposed to a remediation approach.[75]

- *Psychological/emotional impairments affecting occupational performance:* Evidence from well-conducted research supports the use of problem-solving or motivational interviewing behavioral techniques to address depression. The evidence is inconclusive for using multicomponent exercise programs to combat depression after stroke and for the use of stroke education and care support and coordination interventions to address post-stroke anxiety. One study provided support for an intensive multidisciplinary home program in improving depression, anxiety, and health-related quality of life.[53]

- *Improving performance in areas of occupation and participation:* Most of the literature targeted interventions based on activities of daily living (ADLs) and collectively provided strong evidence for the use of occupation-based interventions to improve ADL performance. The evidence related to instrumental activities of daily living (IADLs) was much more disparate, with limited evidence to support the use of virtual reality interventions and emerging evidence to support driver education programs to improve occupational performance post stroke. Only six studies addressed leisure, social participation, or rest and sleep, and evidence was sufficient to support only leisure-based interventions.[103]

Some patients remain severely disabled despite the noblest efforts of rehabilitation workers, whereas others recover quite spontaneously with minimal help in a short period. Most patients benefit from the professional skills of occupational therapists and other rehabilitation specialists and achieve improvement of performance skills and resumption of meaningful occupational roles.

Jasmine demonstrated a clear relationship between her impaired body functions (e.g., loss of motor control, sensory loss, visual dysfunction, and neglect) and her ability to return to her previous life style and engage in chosen areas of occupation. Through the development of an occupational profile, standardized assessments and skilled observation made while Jasmine was performing her chosen occupations of feeding, grooming, toilet transfers, computer use, and child care, it was determined that several impairments were affecting Jasmine's ability to perform independently:

- Feeding: Jasmine was unable to cut or open containers secondary to unilateral UE weakness on the left; she had a tendency to eat only the food on the right side of her plate; and she was unable to locate utensils on the left side of the plate. In addition, food remained between her left gums and cheek ("pocketing") after meals, resulting in oral hygiene issues and putting Jasmine at risk for aspiration.
- Grooming: Jasmine had difficulty opening and applying toothpaste with one hand. She attended only to the right side of her body while grooming, with the left side of her mouth and hair not being cared for during oral and hair care.
- Toilet transfers: Jasmine required moderate physical assistance to transfer to the toilet secondary to an inability to bear weight on her left leg and an inability to control her trunk (she falls laterally when sitting on the toilet). The occupational therapist also noted that when Jasmine "completed" the transfer to the toilet, only the right side of her body was sitting on the toilet. She neglected to include the left side of her body in the transfer and left it in the wheelchair.
- Computer use: During attempts to use the computer, Jasmine became easily frustrated and made comments such as, "I feel like a failure" and "I can't even provide for my child anymore." Jasmine agreed to attempt to write a letter to her friend on the computer. Multiple mistakes were noted because Jasmine seemed to "not see" the left-sided keys, could not control the shift keys, and generally appeared disorganized in her approach to the task.
- Simulated child care: A weighted doll was used to observe Jasmine's ability to care for her child. It was quickly decided that this area of occupation would be deferred until Jasmine's status improved. Jasmine and her occupational therapist made this decision collaboratively on the basis of safety concerns and Jasmine's emotional status. Jasmine was gravely concerned about her ability to care for her child. The occupational therapist wanted to focus on occupations that Jasmine could master, build her confidence, and upgrade her occupations systematically according to Jasmine's abilities.

These findings were determined based on the initial assessment choices. The first assessment administered was the COPM.[64,65] Because multiple areas of occupation are limited after a stroke, it is imperative to use a tool such as this to determine the client's priorities for intervention. These priorities, in turn, become the client's initial goals. In addition, the FIM[57] and the A-ONE[6,9] were used to objectify limitations in daily function and to determine limiting factors. The FIM is typically used in inpatient rehabilitation settings and documents the level of caregiver burden related to BADLs and mobility. The A-ONE is complementary to the FIM and determines the reasons for lack of independence by evaluating client factors that result in errors in occupational performance by skilled observations of tasks performed in natural contexts.

Several interventions were considered to address Jasmine's inability to participate in chosen occupations (toilet transfers, computer use, grooming, feeding, and child care). Task-specific training of grooming, feeding, and toileting served as the basis for her initial OT. A system of vanishing physical and verbal cues was used as Jasmine relearned the tasks at hand. Jasmine had substantial motor loss in her left limbs, thus making training with adaptive equipment imperative. Examples included a rocker knife and Dycem for feeding and a grab bar and raised toilet seat. To ensure continued integration of her affected upper limb, Jasmine was taught to use her left limb as a stabilizer during tasks. She was also taught to keep her arm positioned on a surface and in her line of sight. A strategy that was used to help Jasmine overcome her neglect was use of a perceptual anchor. In addition to her left arm being positioned on the left side of a surface, a strip of red tape was placed on the left edge of work surfaces (e.g., on the table to the left of her place setting and on the left side of the sink). As Jasmine gained mastery of these tasks, task-specific training of work tasks via similar strategies was introduced.

Review Questions

1. Define stroke and list two of its causes.
2. Name three modifiable risk factors associated with stroke.
3. Define TIA.
4. Name three functional deficits that occur as a result of loss of trunk control.
5. Name two components of a client-centered approach to evaluation.
6. What are two frames of reference used to treat neurobehavioral impairments after stroke?
7. Name three postural reactions that support standing activities.
8. How does aphasia differ from dysarthria?

Traumatic Brain Injury

Michelle Tipton-Burton [a]

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, the student or practitioner will be able to do the following:

1. Describe the pathology underlying traumatic brain injury (TBI).
2. State current medical, surgical, and pharmaceutical interventions for acute TBI.
3. Identify levels of consciousness in individuals with TBI by using standard scales.
4. Describe the clinical picture of individuals with TBI, including common physical, cognitive, and psychosocial sequelae.
5. Identify occupational therapy (OT) evaluation methods for lower, intermediate, and higher functioning individuals with TBI.
6. Identify several standard OT assessments for physical, cognitive, and psychosocial impairment after TBI.
7. Describe OT intervention methods for lower, intermediate, and higher functioning individuals with TBI.
8. Describe the continuum of care services available for an individual with TBI in the acute, subacute, and post-acute stages of rehabilitation.

KEY TERMS

Compensatory model
Decerebrate rigidity
Decorticate rigidity
Diffuse axonal injuries (DAIs)
Environmental interventions
Impaired initiation
Interactive interventions
Neuromuscular reeducation
Neuroplasticity
Pelvic alignment
Post-traumatic amnesia (PTA)
Postural deficits
Rehabilitative model
Sensory regulation
Tone normalization
Traumatic brain injury (TBI)
Unilateral neglect syndrome

Case Study

Marisol

Marisol, an 18-year-old Hispanic woman, was an unrestrained passenger in a sport utility vehicle involved in an accident. Marisol sustained a severe brain injury in the crash. She is a high school graduate who lives with her boyfriend and works as a waitress. A computed tomography (CT) scan showed a basilar skull fracture and diffuse subdural hematoma. Approximately 2 weeks after she had been injured, she was transferred to an acute rehabilitation unit to participate in a journey to recovery program, which is designed for clients whose progress is expected to be slower than that of typical acute care clients. This is determined by the extent of the injury; typically these clients are at level II or III on the Rancho Los Amigos (RLA) Scale.

The results of the occupational therapy (OT) evaluation indicated that Marisol was dependent for all mobility and daily activities of living as a result of deficits in motor and process skills. She also displayed significant deficits in various client factors. Her right upper extremity had full active and passive range of motion with minimal ataxia in all joints. Her left upper extremity had decreased range of motion at her shoulder, elbow, and wrist. Severe spasticity was noted throughout her left upper extremity. Marisol was alert and able to visually attend and track. She was nonverbal and being fed through a gastrointestinal (GI) tube. When positioned at the edge of the bed, she required total assistance to maintain a sitting position, including support of her head and trunk. She did not display sitting balance.

Occupational therapy was begun to foster Marisol's ability to engage in self-care and some instrumental activities of daily living (IADLs) by accomplishing the following: (1) improving her left upper extremity range of motion, (2) reducing spasticity in her left upper extremity, (3) improving functional use of her right upper extremity to facilitate participation in self-care tasks, (4) improving head and trunk control so that she could sit upright in a wheelchair, (5) participating in bed mobility and transfers, and (6) improving cognition such that she could participate in a self-care and self-feeding program and communicate with others.

Critical Thinking Questions

1. How should Marisol's injury be characterized?

2. What is her cognitive state?

3. How might Marisol's progress be measured?

4. How will her various problems be treated?

Epidemiology

Traumatic brain injury (TBI) is defined as an alteration in brain function, or other evidence of brain pathology caused by an external force. There may be a resultant loss of consciousness, **post-traumatic amnesia (PTA)**, skull fracture, or objective neurological findings that can be attributed to the traumatic event on the basis of radiologic findings or a physical or mental status examination.[26,73,78]

TBI is the most common cause of death and disability in young people.[26] More than 52,000 Americans die; 235,000 are hospitalized; and 2.2 million are treated and released from an emergency department (ED). Among children up to age 14, TBI results in an estimated 2,685 deaths, 37,000 hospitalizations, and 435,000 ED visits. The number of people with TBI who are not seen in an ED or who receive no care is unknown. The direct and indirect costs of TBI in the United States have been estimated to be in excess of $60 billion annually.[11] Survivor costs account for more than $31 billion, and fatal brain injuries cost another $16.6 billion.[59,79] The Centers for Disease Control and Prevention (CDC) estimates that at least 5.3 million Americans currently have a long-term or lifelong need for help to perform activities of daily living (ADLs) as a result of TBI.[10]

According to the CDC, the leading causes of TBI are falls (40.5%), struck by against (15.5%), motor vehicle accidents (14.3%), assaults (10.7%), and other (19%).[10] Men are three times more likely to die as a result of TBI than are women. The highest rate of TBI is among those age 65 or older, and the leading cause of TBI varies by age group: age 65 or older—falls; ages 5 to 24—motor vehicle accidents; and newborn to 4 years—assault.[10]

The etiology of TBI is closely associated with age and gender. Children younger than age 5 tend to be injured in falls and motor vehicle crashes and by adults inflicting violence. Those ages 5 to 15 are also injured on bicycles, skateboards, and horses; as pedestrians; and during sports activities. From age 15 to 40, high-speed motor vehicle and motorcycle crashes are the most common causes of TBI. After age 40, the incidence of violence-related injury approaches that of motor vehicles, particularly in metropolitan areas. Young and middle-aged males are 1.5 times more likely to be injured than their female counterparts. The two age groups at highest risk for TBI are newborns to age 4 and teens from age 15 to 19.[10] Elderly individuals are injured just as often (80%) by a fall or during a pedestrian mishap as they are in motor vehicle accidents.[22,50] Blasts are a leading cause of TBI in active duty military personnel in war zones.[10]

Nontraumatic or acquired brain injuries include toxicity from drug overdose, chronic substance abuse, carbon monoxide poisoning, and environmental exposure; anoxia from cardiopulmonary arrest or near-drowning; brain abscess or tumors, meningitis, and encephalitis from bacteria, viruses, acquired immunodeficiency syndrome (AIDS), fungi, or parasites; nutritional deficiencies; genetic and congenital disorders; chronic epilepsy; and degenerative diseases, such as dementia.[53]

Concussions

A concussion is an injury to the brain that occurs because of a blow to the head, or because a fall or blow to another part of the body causes rapid back-and-forth movement of the head. When a concussion occurs, the individual may experience symptoms such as headache, dizziness, blurred vision, memory lapses or loss, alterations in judgment or decision making, or changes in coordination. It is important to know that loss of consciousness frequently does not accompany a concussion. Concussions can be difficult to identify because the symptoms can be vague, and often individuals minimize or fail to report symptoms. Concussions are difficult to treat. Rest is usually the best intervention, although a physician may recommend that the individual refrain from contact sports and avoid strenuous or challenging cognitive activities, such as exercise and driving. The symptoms of a concussion can last several days or even weeks or months. Repeated concussions can have greater effects on the trauma to the brain and require even longer recovery times. Long-term effects of concussions can include attention deficits and symptoms of other types of nerve and brain damage.

Chronic Traumatic Encephalopathy

Chronic traumatic encephalopathy (CTE) is a progressive **degenerative disease** seen in people with a history of repetitive brain trauma, including symptomatic concussions and subconcussive hits to the head that do not cause symptoms.[42]

Individuals with CTE may show symptoms of dementia (eg, memory loss, aggression, confusion and **depression)**, which generally appear years or many decades after the trauma. Baseline tests, such as the imPACT test (Immediate Post-Concussion Assessment and Cognitive Testing[41]), have been created to assess potential cognitive impairment in athletes in contact sports. However, as yet no test is available to detect CTE in a living person; the condition can be determined only by autopsy.

Although the aforementioned conditions often have characteristics similar to those resulting from TBI (particularly with regard to rehabilitation approaches), this chapter's primary focus is assessment of and intervention for individuals with traumatic brain injury.

Substance abuse is strongly linked to TBI. At least 20% of adolescents and adults who are hospitalized and at least 30% of those requiring rehabilitation are intoxicated at the time of their injury.[45] An even greater number of individuals have a previous history of alcohol or other substance abuse in the year preceding the injury. The American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition: DSM-5* defines substance abuse as (1) failure to fulfill major role obligations at work, school, or home; (2) use of a substance in situations in which it is physically hazardous; (3) substance-related legal problems; or (4) continued use despite persistent or recurrent social or interpersonal problems related to use.[3,18,45,51] Therefore, knowledge of the acute and chronic sequelae of substance abuse disorders is crucial when assessing and treating individuals with brain injuries. Unsurprisingly, individuals who use alcohol or other drugs after sustaining a brain injury do not recover as well as those who don't use alcohol or other drugs.

Recovery from any type of brain injury depends on the client's age and preinjury capabilities, the severity of the injuries incurred, and the quality of intervention and support available during recovery. Unfortunately, recurrent brain injury is all too common and occurs in those who have previously sustained trauma, have developmental disabilities, or have acquired disabilities associated with other causes.

Prevention of secondary complications is critical throughout all stages of the recovery process—at the time the person is resuscitated (ie, at the site of injury), in acute medical care settings, during acute and post-acute rehabilitation programs, and when the individual is trying to reintegrate into his or her family and community. Many of the available medical and therapeutic interventions target these secondary complications. A well-coordinated team of knowledgeable professionals, family members, and supportive community caregivers can optimize the outcome for a given individual.[13]

Pathophysiology

Neuropathologists and neurosurgeons currently categorize the early stages of TBI as primary (occurring at the moment of impact) and secondary (occurring in days to several weeks after the injury). Prevention of primary injury includes never driving under the influence; reducing distractions while driving (eg, texting, phone calls); using safety belts and air bags; and wearing protective helmets during sports such as bicycling, snowboarding, roller blading, and skiing; all these measures can minimize the impact of the initial cause of injury. Prevention also includes making living areas safer for older adults, such as removing fall hazards and installing grab bars.

Prevention of secondary injury typically begins at the point of contact, with those providing first aid at the scene of the trauma. It continues with emergency medical services (EMS), resuscitation and transport, and acute medical and surgical management; it then carries over to rehabilitation settings. (The section on medical interventions, later in the chapter, particularly discusses secondary interventions to prevent further disability.)

An individual with TBI will typically have some combination of primary focal and diffuse brain injury, depending on the cause and mechanism of the initial injury. In best case scenarios, a minimal amount of secondary brain damage and functional disability occurs as a result of brain swelling, hypotension, hypoxia, and systemic injury; prompt recognition of these complications and appropriate intervention improve survival and the functional outcome.[26]

Focal Brain Injury

Focal brain injury is caused by a direct blow to the head after collision with an external object or a fall, a penetrating injury resulting from a weapon, or collision of the brain with the inner tables of the skull. The bones of the face or skull may or may not be fractured. Common findings in individuals with a focal injury resulting from falls include intracerebral and brain surface contusions, particularly in the inferior and dorsolateral frontal lobes, the anterior and medial temporal lobes, and less commonly, the inferior cerebellum. Assault and missile wounds can occur anywhere in the brain, depending on the direction of force. Other surface areas of the brain, including those not directly below the blow to the head, can also suffer contusions as a result of collision of the brain with the inner tables of the skull. The directly injured area is referred to as the *coup*, and the site of the indirect injury is known as the *contrecoup*.[31,32]

If there are injuries to the coverings of the brain, especially the dura, pia, and arachnoid, other focal hemorrhages occur. Epidural hematomas (EDHs) are associated with skull fractures in adults with disruption of the integrity of the meningeal arteries; children may have arterial disruption with or without a skull fracture. Individuals with an EDH may initially be alert after the blow to the skull; as the hematoma develops between the skull and the dura, it can cause pressure on underlying brain tissue (secondary injury) with rapid deterioration in mental and physical status. Prompt recognition and neurosurgical treatment can save lives and limit morbidity.[38]

Subdural hematomas (SDHs) occur between the dura and the brain surface through tearing of bridging veins. The rate of hemorrhage is often slower than that of an EDH because venous bleeding is more gradual than arterial. An SDH may occur just as frequently on the side of the head opposite the direct blow; therefore, an EDH can occur on one side of the brain adjacent to the trauma and an SDH on the other. SDHs tend to spread around the entire surface of one hemisphere or, less commonly, in the posterior fossa. Acute SDH is diagnosed within 48 hours of injury, subacute SDH within 2 to 14 days after injury, and chronic SDH after 2 weeks. The fall or blow to the head in individuals with subacute or chronic SDH may have occurred days before the person arrives at the hospital with symptoms typical of changes in mental status. The urgency of treatment for SDH depends on the clinical condition of the individual and the extent of adjacent brain tissue affected, as observed radiologically.[72]

Multifocal and Diffuse Brain Injury

In multifocal and diffuse brain injuries, there may be sudden deceleration of the body and head, with variable forces transmitted to the surface and deeper portions of the brain. Motor vehicle, bicycle, and skateboard crashes are typical etiologic factors, but falls from a high surface or off a horse or bull can also result in multifocal and diffuse injuries.

Intracerebral hemorrhage (ICH) is nearly always a focal injury with missile wounds and is common after falls and assaults. Within the first week after TBI, particularly in clients with blood-clotting abnormalities, ICH may appear on follow-up CT scans. With a high-speed deceleration injury, multiple small, deep ICHs occur throughout the neuraxis; on high-resolution CT or magnetic resonance imaging (MRI), they are typically visible at the junction between gray and white matter and in the basal ganglia, corpus callosum, midbrain, and/or cerebellum.

Subarachnoid hemorrhage (SAH) and intraventricular hemorrhage (IVH) occur when the pia or arachnoid is torn. SAH caused by trauma is less frequently associated with vasospasms than is SAH caused by rupture of an aneurysm. A large IVH can block the flow of cerebrospinal fluid (CSF) and result in acute hydrocephalus. Thus, clinical evaluation for a possible ruptured aneurysm causing brain dysfunction, which may result from a fall or motor vehicle crash, is important with either of these entities.

Diffuse axonal injuries (DAIs) are prototypical lesions caused by rapid deceleration. The degree of injury may vary from primary axonotomy, with complete disruption of the nerve, to axonal dysfunction, in which the structural integrity of the nerve remains intact but there is loss of ability to transmit normally along neuronal pathways. The clinical severity of DAI is measured by the depth and length of coma (ie, the time from the onset of injury until the individual performs purposeful activity) and associated signs, such as pupillary abnormalities.[51]

Prevention of Secondary Brain Injuries

The brain, like any body tissue, reacts to injury with swelling or edema, neurochemical injury cascades, changes in blood flow, and inflammation. Unlike other tissues, however, the brain is confined in a closed container, the skull; this protects it from outside injury, but also restricts the amount of swelling or blood accumulation that can occur. The brain is also the organ least able to tolerate loss of blood flow or oxygen. Secondary injury occurs as a result of the effects of brain swelling in a closed space, loss of perfusion, and decreased delivery of oxygen to healthy and damaged tissue. Recovery is related to the extent of the initial pathology and secondary injury.[25] Improved outcomes result when secondary, delayed insults are prevented or respond to treatment.

Guidelines for the management of severe TBI to minimize the impact of secondary injury have been developed over the past 10 years by the American Association of Neurological Surgeons (AANS) and the Brain Trauma Foundation. Some of the areas addressed include resuscitation of blood pressure and oxygenation, management of elevated intracranial pressure (ICP) or hypertension, nutrition after acute trauma, and seizure prophylaxis. These care recommendations are based on a critical review of the available literature on the management of individuals with TBI, and they are categorized into three groups: *standards*, which represent a high degree of clinical certainty; *guidelines*, which represent a moderate degree of clinical certainty; and *options*, which represent a low degree of clinical certainty.[12] Each of these terms (standards, guidelines, and options) is used as a label for forms of intervention for individuals who have sustained a TBI.

Areas of intervention that are considered standards are relatively few and relate to interventions that may be more harmful than helpful. They include the following:

- In the absence of increased ICP, chronic prolonged hyperventilation should be avoided.
- Steroids are not recommended to reduce ICP.
- Prophylactic anticonvulsants are not recommended for preventing late (ie, after the first week) post-traumatic seizures (PTSs).

Guidelines, which have a moderate degree of certainty regarding efficacy, include the following for individuals with severe TBI: (1) all geographic regions should have an organized trauma care system to provide emergency care; (2) hypotension (systolic blood pressure [SBP] below 90 mm Hg) or hypoxia (apnea, cyanosis, oxygen saturation below 90% in the field, or a partial arterial oxygen pressure [PaO_2] of 60 mm Hg) must be corrected immediately and the condition monitored; (3) ICP monitoring is appropriate for injuries in individuals younger than age 40 with an SBP pressure below 90 mm Hg, with a Glasgow Coma Scale (GCS) score between 3 and 8, or when CT scans show hematomas, contusions, edema, or compressed basal cisterns; (4) intervention should be initiated to lower the ICP if it exceeds 20 to 25 mm Hg; (5) effective ICP treatments include mannitol, high-dose barbiturate therapy, ventriculostomy for drainage of CSF, and craniectomy (ie, removal of portions of the skull to allow external brain swelling [bone flap]); and (6) enteral or parenteral nutritional support at 140% of the basal rate in nonparalyzed and 100% in paralyzed individuals, with 15% of calories provided as protein within 7 days of TBI.

PTSs are classified as *immediate* when they occur during the first 24 hours after injury, *early* when they occur during the first 7 days, and *late* after the first 7 days. Prophylactic treatment with phenytoin or carbamazepine during the first week after TBI is an intervention option recognized by both the AANS and the American Academy of Physical Medicine and Rehabilitation (AAPM&R). Both organizations recognize that the efficacy of prophylactic treatment diminishes greatly after the first week and therefore recommend discontinuation of anticonvulsant medication as standard treatment after the first week.[11,12] If late PTSs develop, treatment is warranted because the reoccurrence rate is greater than 80%.[35] All clients and caregivers should learn recognition of and first aid for seizures, in addition to risk modification. Avoidance of alcohol, street drugs, and prescribed medications that lower the seizure threshold is important for clients recovering from TBI. The groups at highest risk of developing PTS are those with penetration of metal and bone into the brain substance, biparietal contusions, multiple intracranial operations, and any injury that causes more than a 5-mm lateral shift on CT scans.[21]

Implementation of the aforementioned standards and guidelines more typically takes place in designated trauma centers, where physicians, nurses, and allied health providers are accustomed to treating large numbers of individuals with TBI. Studies in both academic and community hospital settings have shown that morbidity and mortality can be reduced appreciably by following the AANS guidelines.[64]

Ongoing optimal medical and health management can facilitate an individual's recovery and ability to participate in his or her own rehabilitation. Early detection and prompt management of sleep and mood disorders, pain, hydrocephalus, heterotopic ossification, and endocrinopathies, all common sequelae of TBI, must be addressed. Medical therapeutic interventions should be based on behavioral, cognitive, and functional performance factors that are observable and measurable by members of a rehabilitation team.

Case Study

Dewayne

Dewayne, an 18-year-old with multiple cerebral contusions, has right arm and leg tremors with intentional movement and severe rigidity. He also has increased tone in his left arm and leg. He is dependent for all self-care and mobility.

After a baseline evaluation conducted over 2 days, both occupational and physical therapists note that the tremors increase with any voluntary movement. Medication is introduced to reduce the tremors, and feedback is provided to the prescribing physician about Dewayne's performance of self-care activities and bed mobility. Over the next 2 weeks, Dewayne developed the ability to use his right hand to wipe his face with minimal assistance, which takes 10 seconds, and his medication dose is tapered, with no worsening of the tremor.

Meanwhile, the flexor tone on his left side is increasing, especially at the elbow; this prevents progress in upper body dressing. A temporary musculocutaneous nerve block with bupivacaine results in increased ability to extend his left arm so that dressing now requires only moderate assistance; the next day, a phenol nerve block is performed, at the therapist's suggestion, for longer term relief of the elbow flexion tone. This intervention is directed toward a focal area of difficulty for the client, which is his ability to use his left arm for upper body self-care. Alternative interventions include systemic tone-reducing medications, which may have adverse side effects, and inhibitive casting of the elbow, which may help but makes the limb less useful while casted.

Coma and Levels of Consciousness

A TBI typically results in an altered level of consciousness. The continuum of consciousness ranges from coma to conscious awareness. After a brain injury, an individual's progression along this continuum of consciousness depends on the client's age and previous health status, the severity of the injury, and the methods of medical, therapeutic, and environmental management.

Consciousness is a state of environmental awareness and self-awareness. Coma is the absence of awareness of self and the environment despite maximal external stimuli. No periods of wakefulness occur in the coma state.[65] When sedating and hypnotic medications are discontinued, the coma rarely lasts longer than 4 weeks. When the coma resolves, the person becomes either partially aware of self and the environment (minimally conscious) or, if no awareness is present, "vegetative."

The Glasgow Coma Scale has been the traditional method used by healthcare professionals to assess levels of consciousness after TBI (Table 34.1). The GCS has been used to quantify the severity of brain injury and predict outcome. The three behavioral areas assessed in the GCS are best motor response, verbal response (talking), and eye opening. The most reliable is the motor score; when it reaches 5, which signifies a purposeful response to pain (eg, pushing away noxious stimuli), or 6, which represents an ability to follow simple commands, the injured individual is no longer in a coma or vegetative state. This is an important landmark in recovery from TBI.[79]

TABLE 34.1

Glasgow Coma Scale

Examiner's Test		Individual's Response	Assigned Score
Eye opening	Spontaneous	Opens eyes on own	4
	Speech	Opens eyes when asked to in a loud voice	3
	Pain	Opens eyes when pinched	2
	Pain	Does not open eyes	1
Best motor response	Commands	Follows simple commands	6
	Pain	Pulls examiner's hand away when pinched	5
	Pain	Pulls a part of the body away when pinched by examiner	4
	Pain	Flexes body inappropriately to pain (decorticate posturing)	3
	Pain	Body becomes rigid in an extended position when examiner pinches (decerebrate posturing)	2
	Pain	Has no motor response to pinch	1
Verbal response (talking)	Speech	Carries on a conversation correctly and tells examiner where and who he or she is and the month and year	5
	Speech	Seems confused or disoriented	4
	Speech	Talks so examiner can understand but makes no sense	3
	Speech	Makes sounds that examiner can't understand	2
	Speech	Makes no noise	1

Adapted from Rosenthal M: *Rehabilitation of the head-injured adult*, Philadelphia, 1984, FA Davis.

The vegetative state is most succinctly described as wakefulness without awareness. A person in a vegetative state has the following characteristics: (1) no awareness of self or the environment, and inability to interact with others; (2) no sustained, reproducible, or voluntary behavioral responses to sensory stimuli; (3) no language comprehension or expression; (4) sleep/wake cycles of variable length; (5) ability to regulate temperature, breathing, and circulation to permit survival with routine medical and nursing care; (6) incontinence of bowel and bladder; and (7) variably preserved cranial nerve and spinal reflexes. A persistent vegetative state refers to a condition of past and continuing disability with an uncertain future; the typical onset is within 1 month of a TBI or nontraumatic brain injury or after a month-long metabolic or degenerative condition. The condition may improve and the client may achieve a minimally conscious state (MCS) over time. If the client does not improve, the term permanent vegetative state is appropriate and signifies that the chance of regaining consciousness before death is exceedingly small.[71] Recovery of consciousness is rare for individuals in a persistent vegetative state 12 months after a TBI or 3 months after a nontraumatic brain injury.[77]

Practice parameters for the care of individuals in a persistent vegetative state indicate that appropriate diagnosis of the condition is crucial; a physician with experience in this area should participate in the determination. Once the diagnosis has been established, the prognosis should be explained in detail to the family, surrogates, and caregivers. Appropriate care respects the individual's comfort, hygiene, and dignity. Careful observation of any signs of emergence to MCS is important in determining the intensity of therapeutic interventions. Positioning and other interventions to manage tone and prevent contractures should be included. The amount of extraordinary care is guided by the advance directives or presumed directives supplied by the client's surrogate.[67]

Many individuals emerge from a persistent vegetative state to MCS in which there is definite behavioral evidence of awareness of self, environment, or both. Clearly discernible, reproducible behavior in one or more of the following areas must be demonstrated: (1) ability to follow commands, (2) gestural or verbal yes/no responses (regardless of accuracy), (3) intelligible verbalizations, and (4) purposeful movements or affective responses that are appropriate reactions to environmental stimuli. Examples include reaching for objects; touching or holding objects and accommodating for their size and shape; engaging in eye pursuit movements or sustained fixation in direct response to stimuli; and smiling, crying, vocalizing, or gesturing in response to relevant stimuli. Convenient ways to assess for MCS are testing an individual with situational orientation questions ("Are you standing?" "Are you in a chair?") and giving the individual an object of common use (eg, washcloth or comb) to see whether he or she tries to use it appropriately. Testing for MCS should be done in a quiet environment when the client is alert (ie, not under sedating medication or in a physical position that encourages inattention). Requested commands should not exceed the client's physical capabilities and should not involve reflexive movements.[27] Serial assessment tools that can be useful for measuring the cognitive progress of individuals in MCS include the JFK Coma Recovery Scale–Revised (JFK-Revised), Wessex Head Injury Matrix (WHIM), Coma–Near Coma Scale, Sensory Stimulation Assessment Measure, and the Western Neuro Sensory Stimulation Profile.[15,28,62]

Another important landmark in recovery is post-traumatic amnesia, which is probably the single best measurable predictor of functional outcome in the research literature (Table 34.2). PTA is the length of time from the injury to the moment when the individual regains ongoing memory of daily events. Some evidence suggests that the duration of PTA is highly correlated with individual outcomes. A longer PTA is associated with poorer long-term cognitive and motor abilities and a decreased ability to return to work and school. PTA that lasts 4 weeks or longer is correlated with significant long-term disability.[57] PTA is measured with the Galveston Orientation and Amnesia Test (GOAT) or the Orientation Log.[52] The latter test is easier to administer to individuals with moderate to severe TBI in which the examiner may not know the details of circumstances immediately before the injury and in which the injured individual has begun to remember events.[43,52]

TABLE 34.2

Relationship of Severity of Injury to Duration of Post-Traumatic Amnesia (PTA)

Severity of Injury	Duration of PTA
Very mild	<5 min
Mild	5–60 min
Moderate	1–24 hr
Severe	1–7 days
Very severe	1–4 weeks
Extremely severe	>4 weeks

From Rosenthal M: *Rehabilitation of the head-injured adult*, Philadelphia, 1984, FA Davis.

The Rancho Los Amigos Scale of Cognitive Functioning is a descriptive measurement of eight (and sometimes 10) levels of awareness and cognitive function.[68] Progression through the levels occurs most typically with traumatic injuries. However, in some very severely injured individuals, the recovery curve may actually skip a level (typically level IV, an agitated confused state). Other clients may never be as low as level I or II, but they may be agitated and confused for several weeks (level IV). These individuals may experience periods during which they also function at level V or VI. Thus, this scale can be helpful to staff and family members in designing specific behavioral interventions for a given. Box 34.1 presents a complete description of the RLA scale.

Box 34.1

Rancho Los Amigos Levels of Cognitive Functioning

Level I No response	The individual appears to be in a deep sleep and is completely unresponsive to any stimuli presented.
Level II Generalized response	The individual reacts inconsistently and nonpurposefully to stimuli in a nonspecific manner. Responses are limited in nature and are often the same, regardless of the stimulus presented. Responses may be physiologic changes, gross body movements, or vocalization. Often the earliest response is to deep pain. Responses are likely to be delayed.
Level III Localized response	The individual reacts specifically but inconsistently to stimuli. Responses are directly related to the type of stimulus presented, as in turning the head toward a sound or focusing on an object presented. The individual may withdraw an extremity or vocalize when presented with a painful stimulus. He or she may follow simple commands in an inconsistent, delayed manner, such as closing the eyes, squeezing, or extending an extremity. After the external stimulus has been removed, the individual may lie quietly. He or she may also show a vague awareness of self and body by responding to discomfort by pulling at a nasogastric tube or catheter or resisting restraints. The individual may show bias by responding to some people (especially family and friends) but not to others.
Level IV	The individual is in a heightened state of activity with a severely decreased ability to process information. He or she is detached from the present and responds primarily

Confused, agitated	to his or her own internal confusion. Behavior is frequently bizarre and nonpurposeful relative to the immediate environment. The individual may cry out or scream out of proportion to the stimuli even after removal and may exhibit aggressive behavior, attempt to remove restraints or tubes, or crawl out of bed in a purposeful manner. However, the individual does not discriminate among people or objects and is unable to cooperate directly with treatment effort. Verbalization is frequently incoherent and inappropriate to the environment. Confabulation may be present; the individual may be euphoric or hostile. Thus, gross attention is very short, and selective attention is often nonexistent. Being unaware of present events, the individual lacks short-term recall and may be reacting to past events. He or she is unable to perform self-care (eg, feeding and dressing) without maximal assistance. If not disabled physically, the individual may perform motor activities (eg, sitting, reaching, and ambulating), but as part of the agitated state and not as a purposeful act or on request.
Level V Confused, inappropriate, nonagitated	The individual appears alert and is able to respond to simple commands fairly consistently. However, with increased complexity of commands or lack of any external structure, responses are nonpurposeful, random, or at best fragmented toward any desired goal. The individual may exhibit agitated behavior, not on an internal basis (as in level IV), but rather as a result of external stimuli and usually out of proportion to the stimuli. He or she has gross attention to the environment but is highly distractible and lacks the ability to focus attention on a specific task without frequent redirection back to it. With structure, the individual may be able to converse on a social, automatic level for short periods. Verbalization is often inappropriate; confabulation may be triggered by present events. Memory is severely impaired, with confusion of past and present in the reaction to ongoing activity. The individual lacks initiation with regard to functional tasks and often shows inappropriate use of objects without external direction. He or she may be able to perform previously learned tasks when they are structured for him or her, but the individual is unable to learn new information. He or she responds best to self, body, comfort, and often family members. The individual can usually perform self-care activities with assistance and may accomplish feeding with maximal supervision. Management on the unit is often a problem if the individual is physically mobile because he or she may wander off either randomly or with the vague intention of going home.
Level VI Confused, appropriate	The individual shows goal-directed behavior but is dependent on external input for direction. The response to discomfort is appropriate, and the individual is able to tolerate unpleasant stimuli (eg, nasogastric tube) when the need is explained. The individual follows simple directions consistently and shows carryover for tasks that have been relearned (eg, self-care). He or she is at least supervised with old learning but is unable to maximally assist in new learning with little or no carryover. Responses may be incorrect because of memory problems, but they are appropriate to the situation. Responses may be delayed, and the individual shows a decreased ability to process information with little or no anticipation or prediction of events. Past memories have more depth and detail than recent memory. The individual may show beginning awareness of his or her situation by realizing that he or she doesn't know an answer. The individual no longer wanders and is inconsistently oriented to time and place. Selective attention to tasks may be impaired, especially with difficult tasks and in unstructured settings, but the individual is now functional for common daily activities (30 minutes with structure). He or she shows at least vague recognition of some staff members and has increased awareness of self, family, and basic needs (eg, food), again in an appropriate manner, in contrast to level V.
Level VII Automatic, appropriate	The individual appears appropriate and oriented in the hospital and home settings and goes through the daily routine automatically but is frequently robot-like. The individual exhibits minimal to absent confusion but has shallow recall of what he or she has been doing. He or she shows increased awareness of self, body, family, foods, people, and interaction in the environment. The individual has superficial awareness of, but lacks insight into, his or her condition, demonstrates decreased judgment and problem solving, and lacks realistic planning for the future. He or she shows carryover for new learning, but at a decreased rate. He or she requires at least minimal supervision for learning and for safety purposes and is independent in self-care activities and supervised in home and community skills for safety. With structure the individual is able to initiate tasks in social and recreational activities in which he or she now has an interest. Judgment remains impaired, such that the individual is unable to drive a car. Prevocational or avocational evaluation and counseling may be indicated.
Level VIII Purposeful and appropriate	The individual is alert and oriented, is able to recall and integrate past and recent events, and is aware of and responsive to his or her culture. He or she shows carryover for new learning if it is acceptable to him or her and his or her life role. The individual needs no supervision after activities are learned within his or her physical capabilities. He or she is independent in home and community skills, including driving. Vocational rehabilitation is indicated, to determine ability to return as a contributor to society (perhaps in a new capacity). The individual may continue to show decreased ability, relative to premorbid abilities, in reasoning, tolerance for stress, judgment in emergencies, or unusual circumstances. His or her social, emotional, and intellectual capacities may continue to be at a decreased level but are functional for society.
Levels IX and X are used at some out-client facilities to identify higher functioning individuals.	
Level IX Purposeful, appropriate: stand-by assistance on request	• Independently shifts back and forth between tasks and completes them accurately for at least 2 consecutive hours. • Uses assistive memory devices to recall daily schedule and to-do lists and to record critical information for later use with assistance when requested. • Initiates and carries out steps to complete familiar personal, household, work, and leisure tasks independently and unfamiliar personal, household, work, and leisure tasks with assistance when requested. • Aware of and acknowledges impairments and disabilities when they interfere with task completion and takes appropriate corrective action, but requires stand-by assistance to anticipate a problem before it occurs and take action to prevent it. • Able to think about the consequences of decisions or actions with assistance when requested. • Accurately estimates abilities but requires stand-by assistance to adjust to task demands. • Acknowledges others' needs and feelings and responds appropriately with stand-by assistance. • Depression may continue. • May be easily irritable. • May have low tolerance for frustration. • Able to self-monitor appropriateness of social interaction with stand-by assistance.
Level X Purposeful, appropriate: modified independent	• Able to handle multiple tasks simultaneously in all environments, but may require periodic breaks. • Able to independently procure, create, and maintain own assistive memory devices. • Independently initiates and carries out steps to complete familiar and unfamiliar personal, household, community, work, and leisure tasks, but may require more than the usual amount of time and/or compensatory strategies to complete them. • Anticipates impact of impairments and disabilities on ability to complete daily living tasks and takes action to prevent problems before they occur, but may require more than the usual amount of time and/or compensatory strategies. • Able to independently think about the consequences of decisions or actions, but may require more than the usual amount of time and/or compensatory strategies to select the appropriate decision or action. • Accurately estimates abilities and independently adjusts to task demands. • Able to recognize the needs and feelings of others and automatically respond in appropriate manner. • Periods of depression may occur. • May show irritability and low tolerance for frustration when sick, fatigued, and/or under emotional stress. • Social interaction behavior is consistently appropriate.

Adapted from the Adult Brain Injury Service: *Original scale, levels of cognitive functioning*, Downey, CA, 1980, Rancho Los Amigos Medical Center.

Many studies have analyzed factors such as the client's age, the severity and cause of the injury, substance abuse, and the client's psychosocial status in predicting outcomes after TBI; however, these factors have definite limitations in predicting the recovery of an individual.[a] Individuals with TBI improve over a period of months to years, especially once the individual becomes aware of his or her altered capabilities.[66] Monitoring an individual's personal rate of recovery is probably more predictive of future recovery than any other factor.

Clinical Picture

Physical Status

An individual with TBI may exhibit a variety of symptoms, depending on the type, severity, and location of the injury. Individuals may have limitations in most of the areas discussed in the following sections, or they may have subtle deficits evident only during more complex activities. Table 34.3 shows some of the most common clinically diagnosed physical signs and symptoms of a client who has sustained a TBI.

TABLE 34.3

Clinical Signs and Symptoms Commonly Seen in a Client With a Traumatic Brain Injury

Sign	Lesion Location	Clinical Characteristics	Interventions
Decerebrate rigidity	Midbrain, pons, diencephalon	Extended internally rotated shoulders; extended elbows; flexed wrists, fingers; extended internally rotated hips, extended knees, ankle plantar flexion, inversion; increased rigidity when awake	Positioning, range of motion (ROM), neuromuscular blocks, early casting
Decorticate rigidity	Cortical white matter, internal capsule, thalamus, cerebral peduncle, basal ganglia	Internally rotated shoulder; flexed elbow, wrists, fingers; extended, internally rotated hips; knee flexion; ankle plantar flexion, inversion; increased rigidity when awake	Positioning, ROM, neuromuscular blocks, early casting
Bruxism	—	Persistent jaw clenching, grinding of teeth with or without temporomandibular dislocation or subluxation	Neuromuscular blocks, oral orthotics
Spasticity	Upper motor neuron syndrome; corticospinal pathways	Velocity-dependent resistance, hyperreflexia/clonus, muscle shortening; present in face, neck, trunk, limbs; worse when awake and with effort	Bed/chair positioning, ROM, weight bearing, neuromuscular blocks, inhibitive casting, enteral and intrathecal medications, tendon releases, relaxation techniques
Rigidity and bradykinesia; parkinsonism	Substantia nigra, extrapyramidal pathways; also with medications that block dopamine	Velocity-independent resistance; lead pipe, cogwheel types of rigidity; worse when awake	Positioning, ROM, functional activities, medications
Torticollis		Dystonic posture of the neck; spasticity and/or contracture of the sternocleidomastoid, splenius muscles	Positioning, modalities and ROM, medications, neuromuscular blocks
Myoclonus	Variable	Abrupt, shocklike involuntary jerks in large (limb) or small muscles when sleep or awake	Medications, neuromuscular blocks
Tremor	Variable	Involuntary rhythmic oscillations while awake	Weighted devices, weight bearing, medications, neuromuscular blocks, appropriate assistive devices
Dystonia	Variable	Dynamic contraction/relaxation of muscles with slow, writhing or repetitive twisting movements or sustained contortions; usually distal limb(s)	Positioning, ROM, neuromuscular blocks, medications, appropriate assistive devices
Athetosis	Basal ganglia, medications with effect on dopamine	Slow, sinuous movements of the face, tongue, or limbs	Relaxation techniques, taper offending medications
Chorea	Contralateral neostriatum, thalamus	Involuntary dancelike or jerky movements without rhythmic pattern; distal	Medications
Hemiballismus/ballismus	Contralateral subthalamic nucleus, thalamus, cerebellum	Sudden irregular flinging movements starting in the hip or shoulder, occasionally facial or oral with or without rotator component; worse with arousal/excitement, absent in sleep	Medications
Tics	Variable	Sudden stereotypic coordinated automatic movements or vocalizations while awake	Medications, behavioral management, relaxation techniques
Pseudobulbar athetoid syndrome	Bilateral pyramidal tract	Postural dystonia with fragmentary athetosis, with or without bradykinesia; often preserved intellect/personality	Positioning, appropriate assistive devices

Data from Mayer NH, Keenan MAE, Esquenzi A: Limbs with restricted or excessive motion after traumatic brain injury. In Rosenthal M, Griffith ER, Kreutzer JS, Pentland B, editors: *Rehabilitation of the adult and child with traumatic brain injury*, ed 3, Philadelphia, 1999, FA Davis; Mayer NH: Choosing upper limb muscles for focal intervention after traumatic brain injury, *J Head Trauma Rehabil* 19:119, 2004; Zafonte R, Elovic E, Lombard L: Acute care management of post-TBI spasticity, *J Head Trauma Rehabil* 19:89, 2004.

Decorticate, Decerebrate, and Motor Rigidity

Rigidity is the presence of increased resistance to passive movement throughout most of the range that is independent of stretch velocity.[51] Comatose individuals often display one of two common positions, decorticate rigidity or decerebrate rigidity. In **decorticate rigidity**, the upper extremities (UEs) are in a spastic flexed position with internal rotation and adduction. The lower extremities (LEs) are in a spastic extended position but also internally rotated and adducted. Decorticate rigidity results from damage to the cerebral hemispheres, particularly the internal capsules, which causes an interruption in the corticospinal tracts (which emerge from the cortex and send voluntary motor messages to all extremities).

In **decerebrate rigidity**, both the UEs and LEs are in a position of spastic extension, adduction, and internal rotation. The wrists and fingers flex, the ankles are in plantar flexion with the feet inverted, the trunk extends, and the head retracts. Decerebrate rigidity occurs as a result of damage to the brainstem and extrapyramidal tracts (which send involuntary motor messages from the brainstem to the extremities). Individuals with decerebrate rigidity have a poorer prognosis than do those exhibiting decorticate rigidity.[16,31]

Cogwheel or lead pipe rigidity resembling Parkinson's disease can occur, typically in individuals with severe TBI. It may respond to dopamine agonists, such as levodopa/carbidopa or amantadine. Dystonia of the neck (torticollis), jaw, or distal ends of the limbs can also occur and may require treatment with motor point blocks.[55]

Abnormal Muscle Tone and Spasticity

Although decorticate rigidity and decerebrate rigidity are associated with the most severe types of abnormal muscle tone and tend to occur in comatose individuals, hypertonicity may range from minimal to severe in any muscle group. Individuals functioning at a higher cognitive level than coma generally display a combination of hypotonicity (ie, decreased tone, or flaccidity) and hypertonicity (ie, increased tone, or spasticity). Flaccidity (hypotonicity) is a decrease in normal muscle tone. It is usually attributed to peripheral nerve injury resulting in soft muscle feel, in which the muscles offer no resistance to passive movement. Spasticity (hypertonicity or hypertonia) is an involuntary increase in muscle resistance that is dependent on velocity.[51] The **Modified Ashworth Scale**, a widely used assessment of muscle tone, scores muscle tone on a scale of 0 to 4[8]:

0	No increase in muscle tone
1	Slight increase in muscle tone, manifested by a catch and release or by minimal resistance at the end of the range of motion (ROM) when the affected part or parts is moved in flexion or extension
1+	Slight increase in muscle tone, manifested by a catch, followed by minimal resistance throughout the remainder (less than half) of the ROM
2	More marked increase in muscle tone through most of the ROM, but the affected part or parts are easily moved
3	Considerable increase in muscle tone, passive movement difficult
4	Affected part or parts rigid in flexion or extension

Because individuals with spasticity cannot voluntarily relax their limbs, voluntary movement of an affected limb may be impossible. Spasticity can be seen as early as a few days after brain injury, or it may take 3 to 6 months to develop. In as little as 2 weeks, spasticity may cause muscles to shorten permanently, which in turn can cause joints to lose motion. The condition of permanent shortening is called a *muscle contracture.*

OT Practice Notes

It is important to instruct all staff members involved in the client's care that tone can fluctuate as a result of changes in position, volitional movement, medication, infection, menstruation, illness, pain, environmental factors (ie, ambient temperature), and emotional state.[7]

Primitive Reflexes

If damage to the midbrain has occurred, impaired righting reactions are commonly observed. Similarly, damage to the basal ganglia can result in the absence of equilibrium reactions and protective extension. The absence of righting reactions, equilibrium reactions, and protective extension places the individual at significant risk for further injury from falls during such activities as transfers, getting out of bed, toileting, bathing, and dressing.

Muscle Weakness

A decrease in muscle strength without the presence of spasticity can occur as a result of peripheral nerve or plexus injuries and lack of physical activity caused by secondary factors associated with TBI (eg, compromised respiration, fractures, and infection). A functional muscle and sensory test may be indicated when an individual exhibits decreased strength in the limbs. Additionally, impaired gross and fine motor coordination will be evident and should be assessed.

Decreased Functional Endurance

Decreased endurance and vital capacity usually accompany reduced muscle strength as a result of medical complications such as infections, poor nutrition, or prolonged bed rest. Increasing the individual's muscle strength and endurance is a primary goal in the acute stage and in the initial stages of rehabilitation.

Ataxia

Ataxia results from impairment of the cerebellum itself or the motor pathways leading to and from the cerebellum; it can also occur with impaired proprioception. Ataxia is a movement abnormality characterized by incoordination, impaired sitting and standing balance, or both.[7] Ataxia can occur in the entire body, in the trunk, or in the UEs and LEs; it presents as jerkiness during movement. An individual with ataxia has lost the ability to perform the small adjustments in the distal and proximal ends of extremities that are necessary for smooth, coordinated movement.

The degree of ataxia ranges from mild to severe. An individual with ataxia in the trunk displays impaired postural stability when sitting and standing. He or she has difficulty maintaining the trunk in a stable position to free the UEs or LEs for activities. The individual may compensate for this deficit by grasping a stable surface, such as a tabletop. Ataxia in the UEs causes dysfunction in activities in which the individual attempts to perform a combination of gross and fine motor movements, such as bringing a glass of water to the mouth. The UE oscillates back and forth, causing the water to spill. Ataxia in the LEs results in an impaired ability to ambulate while maintaining balance; falls can easily occur with this condition.

Postural Deficits

Postural deficits develop as a result of an imbalance in muscle tone throughout the body. An individual may inadvertently accentuate the postural deficits by using ineffective strategies to compensate for impaired motor control; delayed or absent righting reactions; or impaired vision, cognition, or perception. Therapists must have a thorough knowledge of the postural deficits of their clients to position them properly in a wheelchair with the appropriate seating system, which is necessary to obtain an upright posture, maintain good postural alignment, and prevent further postural deformities. Frequently exhibited abnormal postures include the following:

1. *Pelvis.* Posterior pelvic tilt is often due to prolonged bed rest in the supine position, which causes loss of ROM in the lower part of the back. Posterior pelvic tilt results in sacral sitting and facilitates kyphosis. Pelvic obliquity is observed when one side of the pelvis sits lower than the other side as a result of hypertonicity of the quadratus lumborum on the involved side.

2. *Trunk.* Kyphosis, scoliosis, and lordosis may all be present as a result of weak or spastic trunk muscles (eg, pectoralis, abdominal, spinal, and paraspinal). It is also common to observe lateral flexion toward the involved side (trunk shortening) with elongation of muscle on the opposite side.

3. *Head and neck.* Forward flexion or hyperextension of the neck and lateral flexion of the head often accompany lateral flexion of the trunk.

4. *Scapula.* The scapula may be depressed, protracted or retracted, downwardly rotated, or all of these at once. This results from an imbalance in scapular muscle tone; some muscles are hypertonic, whereas others are hypotonic.

5. *Upper extremities.* UEs may be bilaterally or unilaterally involved. In unilateral involvement, it is common to see variations in ROM, tone, and strength in each muscle group and joint of the arm, forearm, wrist, and hand.

6. *Lower extremities.* Severe extension patterns are often observed in both LEs, which can pose a problem with wheelchair positioning; this is evident when the individual thrusts forward and slides out of the seating system. Hip adduction, internal rotation, knee flexion, plantar flexion, and inversion of the feet can all be observed.

Limitations of Joint Motion

Loss of ROM in the joints is a common problem. It is often difficult to distinguish between several possible causes of decreased ROM, such as increased muscle tone, volitional resistance, contractures, heterotopic ossification, fractures or dislocations, and pain. Because the intervention addressing decreased ROM depends on the cause, the therapist should consult a physician to determine the cause of the decreased ROM before initiating intervention. Distal limb fractures are often overlooked in acute trauma settings when clients are unable to communicate because of cognitive deficits. Therapists are typically the first to detect the hard end feeling of joints with limited ROM typical of heterotopic ossification, the formation of lamellar bone in soft tissue.[36]

Sensation

Clients with TBI may exhibit signs of absent or diminished sensation, including problems with light touch, differentiation between sharp and dull sensations, proprioception, temperature, pain, and kinesthesia. Additionally, impaired senses of taste and smell, caused by cranial nerve injury, may be observed.[7] Lost or diminished stereognosis, two-point discrimination, and graphesthesia (ie, the ability to interpret letters written on the hand without visual input) may be present. Hypersensitivity, which can often interfere with postural alignment, may also occur.

Integration of Total Body Movements

Total body movements involve the integration of head, neck, and trunk control with dynamic sitting and standing balance while reaching, bending, stooping, and ambulating. To perform total body movements, the individual must coordinate and modulate gross and fine motor movements of the trunk, head, neck, and limbs while performing ADLs. An individual with severe physical involvement often displays poor sitting and standing balance and is unable to maintain an upright position to free the UEs for activities. Individuals functioning at a more advanced level may exhibit subtle deficits in total body movements that make it difficult to bend down, reach overhead to retrieve items in a cabinet, or stoop to retrieve an item that has fallen to the floor. Integrated total body movements are necessary for the performance of all ADLs.

Dysphagia

Dysphagia, or difficulty completing the four stages of chewing and swallowing, is caused by damage to the cranial nerve or brainstem (see Chapter 27). There is a higher incidence of oral preparatory–, oral-, and pharyngeal-stage dysphagia than esophageal-stage dysphagia for individuals with TBI. Typically, more than one stage of chewing and swallowing is impaired.[5,6]

An individual may display oral muscular hypotonicity or hypertonicity, instability of the jaw, and abnormal oral reflexes such as rooting, biting, sucking, gagging, and coughing, which prevent or impair the activity of speaking or eating. As a result of cognitive deficits, the individual may experience difficulty sequencing chewing, swallowing, and breathing.

Self-Feeding

Clients with TBI may be unable to sustain attention long enough to feed themselves. If impulsivity is apparent, these clients will have difficulty monitoring the amount and rate of food brought to the mouth, thus causing coughing and possibly aspiration. Oral apraxia, an inability to perform an intended action or execute an act on command with the mouth or lips, may occur. If clients have ideational apraxia, they will have difficulty understanding the demands required of the self-feeding activity and will be unable to recognize utensils as tools for eating. Because they may also have lost the motor plan for self-feeding (ideomotor apraxia), they may be unable to gain access to the neurological motor pattern for bringing food to the mouth. Hemianopia (visual field cut) or visual neglect may prevent them from seeing half of the plate of food.

Cognitive Status

Cognitive deficits are always evident to varying degrees and can affect many aspects of the individual's quality of life, as mentioned in previous sections. The most common cognitive deficits include decreased attention and concentration, impaired memory, impaired initiation and termination of activities, decreased safety awareness and poor judgment, impulsivity, and difficulty with executive functions and abstract thinking (eg, problem solving, planning, integration of new learning, and generalization).

Attention and Concentration

Reduced attention and concentration impair the ability to maintain focus on an activity without becoming distracted and the ability to resume an activity when interrupted. Clients with TBI often lose the ability to concentrate for a length of time and the ability to filter out distractions from the surrounding environment. The inability to attend to and concentrate on activities severely impedes the ability to function at work and school and complete ADLs. Although deficits in attention and concentration can diminish as neurological recovery progresses, such deficits can remain to varying degrees throughout an individual's life. Even clients who experience mild TBI can demonstrate subtle deficits in attention and concentration that often linger for years after the injury and can affect everyday functioning.

Memory

Impaired memory, the most frequently observed cognitive deficit in clients with TBI, can remain a lifelong problem. Memory impairment ranges from forgetting several words just heard (immediate memory), to forgetting which family members visited the night before (short-term memory), to forgetting events that occurred years before the injury (long-term memory). Despite neurological recovery, most of these clients continue to demonstrate difficulty learning new information. Safety concerns include getting lost, leaving doors unlocked, and leaving a stove on; clients with impaired memory typically require supervision if compensatory methods cannot be used. This loss of independence can be emotionally devastating because clients with TBI often have insight into both who they were before the injury and their accomplishments, goals, and plans for the future, many of which are severely disrupted and perhaps lost as a result of TBI.

Memory losses are also labeled in relation to the time of the injury or brain damage. Loss of memories for events before the time of the specific injury is referred to as retrograde amnesia. The client may forget events that occurred just before the accident or forget events that happened several days, weeks, and even months before the accident. After TBI the client is often unable to form new memories, and this is referred to as anterograde amnesia; this period can last for days, weeks, or even months after the injury.

Initiation and Termination of Activities

Impaired initiation and termination of activities affect the ability to start and end activities. An inability to initiate activities without assistance affects the individual's ability to live independently. In general, clients who exhibit deficits in initiation demonstrate the greatest progress in a rehabilitation setting that provides assistance and structure. After returning home, these individuals may regress and have difficulty completing basic daily activities if the necessary structure has not been set up. Similarly, clients may exhibit difficulty terminating an activity once it has been started, which is a type of perseveration. For example, a client may begin brushing the teeth but may be unable to end the task because he or she feels compelled to continue. Perseveration sometimes involves a thought process. Clients may be unable to concentrate on one activity because they are perseverating on the idea that another activity (eg, the laundry) must be completed.

Safety Awareness and Judgment

Frontal lobe damage often results in an impairment in insight about a person's limitations and in impulsivity, or the inability to consider consequences before acting. Such individuals demonstrate poor safety awareness and judgment. For example, the client may attempt to rise out of a wheelchair without locking the brakes or moving the footrests. A more mobile client who has been reintegrated into the community may attempt to cross streets without observing traffic signals or remove pots from the stove or oven without using protective oven mitts or pot holders. It is important for the OT to structure the client's environment to reduce accidents and increase the client's awareness of his or her limitations through repeated opportunities to practice and relearn safe and appropriate behavior.

Processing of Information

Most people with TBI experience some degree of difficulty processing external information from the environment. A delay in response time is often noted and can range from a few seconds to several minutes. It is important for the therapist to recognize the presence of delayed processing and distinguish the delay from the absence of function. For example, during sensory evaluation a client may exhibit a delay in response to a dull stimulus. The therapist may mistakenly interpret the individual's delayed processing time as an absence seizure or impairment of sensory awareness. A delay in the processing of external information from the environment can involve visual, auditory, sensory, and perceptual processing.

Executive Functions and Abstract Thought

Executive function skills include the ability to plan, organize, set goals, understand the consequences of one's actions, and modify behavior in accordance with environmental responses. Abstract thinking is the ability to hold and manipulate a concept in one's mind by using critical reasoning and analytic skills. Many clients with TBI exhibit concrete thinking, in which they are able to interpret information only at the most literal level. For example, individuals with impaired executive and abstract functions may be able to complete a meal preparation activity accurately and safely only if step-by-step directions are provided. If the directions do not specifically direct the reader to modify the cooking temperature, these individuals may burn the food because they are unable to foresee the consequences of maintaining the stove on a high setting.

Generalization

Generalization of new learning is the ability to learn a specific task and transfer the skills needed for that task to a similar activity. Deficits in executive function skills, abstract thinking, and short-term memory significantly impair the generalization of new learning. For example, an individual who has learned in a day treatment setting the skills for completing a laundry task may be unable to transfer the skills at home or at a different laundromat. Such deficits often occur as a result of concrete thinking and the inability to form abstractions. Although the cognitive pattern for completing laundry tasks with the laundry machine in the clinical setting is established, the individual cannot transfer that cognitive pattern to a similar but unfamiliar laundry machine in a different environment. Impaired generalization of new learning is one of the most significant problems impeding the individual's ability to resume independent functioning in a community setting.

Visual Status

Visual skills involve the ability to accurately see stimuli from the external environment (see Chapter 24). Visual skills do not involve the identification of objects, which is a function of perception. Among the many deficits in visual skills that may result from TBI are accommodative dysfunction (causing blurred vision), convergence insufficiency (the inability to maintain a single vision while fixating on an object), lateral or medial strabismus, nystagmus, hemianopia, and impairment of scanning and pursuits. Saccades (fast, jerky movements of the eyes as they change from one position of gaze to another, as is needed to read a book) may also be compromised by TBI. Reduced blink rate, ptosis (drooping of the eyelid), and lagophthalmos (incomplete eyelid closure) are also common visual deficits resulting from damage to the oculomotor nerve.[7]

Dysfunction in any of these visual elements can profoundly affect daily life function. Individuals rely on vision indirectly in social and interpersonal interactions. Vision is used as a cueing and feedback system for motor skills such as ambulation and for eye-hand coordination activities. Deficits in vision can affect all daily life activities, including the areas of hygiene and grooming, meal preparation and eating, wheelchair mobility, reading and writing, and driving.

Perceptual Skills

Perception is the ability to interpret stimuli from the external environment (see Chapter 25). Perception is a function of the secondary cortical areas of the right hemisphere, including the secondary visual area, the secondary somatosensory area, the secondary auditory area, and the multimodal parietal-occipital-temporal area. Perceptual deficits are more often a result of right hemisphere damage but may also occur with lesions in the left hemisphere. Perception can be grouped into the following categories: visual perception, body schema perception, motor perception, and speech and language perception. An individual with impairments in visual perceptual may exhibit difficulty in right-left discrimination, figure-ground discrimination, form constancy, position in space, and topographic orientation. Visual perceptual deficits also include visual agnosia, in which the individual displays difficulty recognizing familiar objects and people. For example, prosopagnosia is the inability to connect faces with names. Prosopagnosia results from damage to the multimodal association area.[7]

Body schema perception is awareness of the spatial characteristics of a person's own body. This awareness is derived from the neural synthesis of tactile, proprioceptive, and pressure sensory associations about the body and its individual parts. A common problem in people with TBI is anosognosia, a failure to recognize deficits or limitations. This may lead to the body schema perceptual dysfunction of **unilateral neglect syndrome**, in which the individual has lost the ability to integrate perceptions from one side of the body or environment (usually the left). Unilateral neglect is commonly caused by a lesion in the right parietal lobe but can also occur as a result of frontal and occipital lobe damage. Clients with left unilateral neglect may disown their left extremities and treat them as though they belong to someone else. For example, these individuals may shave only the right side of their face or dress only the right side of their body.[7]

Aphasia is a disturbance in the comprehension or formulation of language (or both) caused by dysfunction in specific brain regions, typically the left hemisphere.[20] A few left-handed individuals have language dominance in the right hemisphere. Establishing reliable communication is crucial in treating a person with aphasia. If auditory comprehension is compromised, gestural demonstration of instructions or activities is more reliable. Common types of aphasia involving disorders of comprehension include the Wernicke and transcortical sensory types. Affected individuals have longer periods of PTA because they do not understand orientation questions, and although their spoken language is fluent, it includes verbal paraphasias, or word substitutions. Clients with aphasia may also misinterpret speech and become suspicious and agitated. Insight into their communication deficit may be limited.

The nonfluent aphasias (Broca's aphasia and transcortical motor aphasia) are characterized by relatively preserved comprehension but effortful or explosive speech with phonemic paraphasias (eg, “bork” for “fork”). Conduction aphasia (ie, intact comprehension, fluent speech, impaired repetition) and anomic aphasia are characterized by circumlocution and frequently paraphasias. Individuals with these types of aphasia are typically aware of their problems and are often frustrated by their limitations. They should be encouraged to use gestures to express their immediate desires and needs.

Dyslexia (disturbance in reading), agraphia (disorder of writing), and dyscalculia (disturbance in calculation) frequently accompany the aphasias. However, with traumatic aphasias, these capabilities may be better preserved than with stroke; treating therapists should always attempt alternative modes of communication.

Dysprosody or aprosody is impaired production or comprehension of the tonal inflections or emotional tone of speech. Executive dysprosody is an inability to inflect one's voice to convey emotion. It can occur with cerebellar, basal ganglia, or right frontal lobe injury. Receptive dysprosody is an inability to perceive the emotional content of other people's spoken language. It occurs with right temporal or parietal injury and less often with left hemisphere injury. Individuals with this disorder may miss the point of a joke or story because they cannot comprehend the subtle innuendoes and implicit meanings conveyed through tonal qualities and inflections.[80] Even more disabling is the inability to interpret anger, humor, or sarcasm during communication with others.[19] Perceptual motor dysfunction is impairment in motor planning, or an apraxia. It is a disorder of learned movement that cannot be explained by weakness, lack of sensation, inattention, or comprehension of the requested task.[19]

The apraxias are usually a result of impairment of the premotor cortex, corpus callosum, or connections between the temporal and parietal lobes and frontal motor cortex.[39] It is in these cortical areas that established motor patterns for specific activities are stored and accessed for the execution of common movement patterns. **Ideational apraxia** is an inability to understand the demands of a task or use of the wrong motor plan for a specific task. For example, individuals suffering from ideational apraxia may not understand that a shirt is an item of clothing to be placed on the torso and UEs. Not understanding the demands of the task, they may be unable to activate the motor plan for UE dressing or may activate the wrong plan and attempt to place their legs through the sleeve holes. This deficit is sometimes referred to as a dressing apraxia. **Ideomotor apraxia** is loss of the kinetic memory of a movement pattern for a specific activity. Individuals with this disorder may understand that a shirt is an item of clothing to be placed on the torso and UEs, but they may be unable to execute the appropriate movement plan because it is no longer accessible. Constructional apraxia is an inability to accurately assemble pieces of an object to form a three-dimensional whole. For example, a former carpenter who suffers from constructional apraxia may be unable to put together the wooden pieces of a basic birdhouse kit.

Psychosocial Factors

Researchers have found that the greatest concerns of clients 1 or more years after TBI are the psychosocial deficits that prevent them from rebuilding a satisfactory quality of life. As the time after injury increases, clients and family members view such psychosocial factors as more detrimental than both the physical and cognitive sequelae of TBI.

In Marisol's case, it was initially difficult to assess her psychosocial status because she was nonvocal. The team was able to assess her mood on the basis of her level of participation and affect during therapy. Marisol would laugh appropriately and become visibly more interactive, with brighter affect, when her boyfriend arrived to visit.

Marisol continued to engage in positive interactions throughout her 4-month in-client and day treatment stay. Her discharge plan involved moving to Georgia with her mother. When the move was discussed with Marisol, it was evident that she was quite saddened by the knowledge that she would no longer be able to see her boyfriend. The team observed her closely to assess whether her sadness would eventually culminate in depressive symptoms.

Self-Concept

One of the most difficult psychosocial sequelae of TBI is alteration of the individual's self-concept. Self-concept is the internal image a person holds about personal human identity, sexual and gender identity, body image, personal strengths and limitations, and position in the family, peer group, and community systems. An individual's self-concept changes drastically after TBI. One of the most difficult characteristics of TBI is that although short-term memory is often impaired, long-term memory commonly remains intact. Individuals with TBI often have a clear memory of who they were before their injury and must now resolve the emotional conflict of having to replace their preinjury self-concept with a post-injury self-concept that is both meaningful and satisfying. Affected individuals sometimes describe this process as an unwanted death and rebirth. They say that the person who lived before the injury is now gone, replaced by someone who is very different from the person they remember themselves to have been.[63]

Social Roles

Self-concept is derived largely from the social roles the person attains in the family, peer group, and larger community systems. Frequently, an individual with TBI loses most preinjury roles and the activities that supported those roles. Family and peer group roles change. Family members and friends are often readily visible during the acute and subacute stages of TBI rehabilitation. However, as the time after injury increases, family and friends become progressively less involved with the individual, which frequently leads to feelings of isolation and abandonment. Many individuals with TBI report that the feeling of isolation and the inability to form and maintain social relationships are their most troubling post-injury concerns. Loss of the role of dating partner or spouse commonly leaves clients with TBI with a deep sense of loss and failure if they cannot rebuild a post-injury life that includes intimacy with another human being, partnership in a committed relationship, and parenting of children. Loss of the work role and inability to support oneself are intimately tied to feelings of dependence and lack of personal control.[48]

Independent Living Status

As a result of the physical, cognitive, and psychosocial sequelae of TBI, many affected individuals find they require supportive living arrangements or must live with their parents. Loss of the ability to live independently in the community further reinforces feelings of dependence and decreased personal control. As a result of these role losses, adults who sustain TBI commonly experience role strain and feel that they cannot reenter their communities. The TBI, particularly if it occurred between the ages of 18 and 30, disrupts the developmental transition from adolescence to adulthood and leaves individuals feeling inadequate and unable to attain a post-injury adult status. Depression, withdrawal, and apathy are common psychosocial sequelae of the alterations in self-concept discussed earlier and of the loss of desired social roles.[56]

Dealing With Loss

People with TBI and their family members often go through a process that resembles the stages of death and dying experienced by the terminally ill.[49] These stages begin with denial, in which affected individuals deny that they are experiencing physical, cognitive, or psychosocial deficits. Denial can impede therapy because these clients may refuse to participate, in the belief that it is unnecessary. Denial gradually subsides as they continually confront their limitations in ADLs. Anger follows denial. Clients grow increasingly aware of their deficits and become frustrated and angry because recovery is slower than desired. Bargaining is the next stage. Clients strike a deal with the Creator or fate and offer to work as diligently as possible in therapy if only their preinjury lifestyle could be restored. The bargaining stage is often marked by increased motivation and optimism. Depression tends to emerge next. Eventually, clients begin to realize the severity of the injury and its effect on the rest of their lives. Acceptance of the injury and its resultant limitations, the next stage in the process, is necessary for clients to become sufficiently motivated to attempt to build a post-injury life that although drastically different from their preinjury goals and expectations, is nevertheless meaningful and personally valuable. These stages may require years of transition. Frequently, denial, anger, and bargaining occur in the first few months to a year after the injury. Depression sets in as the individual is able to let go of some of the denial and becomes aware of the effect that the injury will have on the future. It may take years before he or she can truly accept the injury and alterations in personality, skill, and lifestyle and move on to rebuild a new life.

The process of denial, anger, depression, and acceptance does not generally proceed in a linear fashion. Clients with TBI commonly experience repeated periods of denial, anger, and depression throughout their years of rehabilitation. Renewed denial, anger, and depression may occur in response to a new environmental demand, such as a change in life condition (eg, a need to move from the parental home to a community group home) or the development of further physical, cognitive, or psychosocial deterioration over time (eg, the need for increased ambulatory assistance because of deterioration in visual skills).

Affective Changes

Depression, increased emotional lability, involuntary emotional displays of mood that are overly frequent and excessive, and decreased affect can result from the neurological damage itself. Individuals with left hemisphere damage tend to exhibit increased depression and emotional lability. Lesions of the left orbitofrontal lobe often cause severe depression and heightened affect (including excitement, agitation, and tearfulness). Lesions of the left dorsolateral frontal lobe commonly result in a decreased or flat affect. Individuals with these lesions may appear depressed even though they feel fine. Neurological damage to the right hemisphere frequently causes a strange sense of euphoria or lack of emotional response to the severity of injury.[63]

People with brain injury often have difficulty recognizing others' emotions. Because this ability is essential for guiding appropriate emotional and behavioral responses toward others, this type of impairment poses various psychosocial and emotional problems.[59]

Behavioral Status

Behavioral impairments are a natural part of the recovery process. The Rancho Los Amigos cognitive level IV is typically described by the rehabilitation team as the “agitated, confused” level.[68] During this stage of recovery, affected individuals can be described as restless and combative. They may be responding to internal body experiences, or some external environmental stimuli may be provoking the agitation. Commonly observed behavior includes yelling, swearing, grabbing, and biting. Behavioral problems can be disturbing to both the individual's family and the intervention team; therefore, behavioral management is an essential component of TBI rehabilitation.

Ethical Considerations

Working with clients who have behavior problems can be frustrating and sometimes frightening. Untrained staff members can be injured, and they often reinforce the client's negative behavior through their own actions and responses.

A comprehensive behavior management program should be established for anyone who exhibits behavior that interferes with active participation in therapy and achievement of goals. The goals and objectives of a comprehensive program include maintaining a safe environment for individuals and staff members at all times, developing and consistently implementing behavior management techniques, minimizing the use of all restrictive modalities, and providing an environment that facilitates participation and appropriate behavior in the hospital setting and after discharge.[70]

Interventions used in an effective behavior management program include one-on-one coaching, intervention with psychotropic medications, and individually designed behavior management guidelines and interventions. One-on-one coaching, usually performed by a trained nursing assistant or rehabilitation technician, is especially necessary for clients who are at risk of harming themselves or others. In many cases, implementation of a behavior management program is necessary 24 hours a day, 7 days a week. A coach helps reinforce the client's behavior plan and redirects inappropriate or maladaptive behavior. Medications are required to regulate sleep and minimize agitation and combative behavior until clients can control the behavior on their own. Because pain may often provoke agitation, assessing a client's level of pain and providing appropriate medication may resolve the restlessness, agitation, and/or inability to sleep. Medications must be chosen carefully to prevent side effects such as clouding of awareness and psychomotor slowing. Clients should have specific behavioral end points, such as establishing adequate sleep at night, facilitating attention during functional activities, and reducing the frequency of verbal or physical outbursts.

Environmental modifications are a proactive approach to prevent and minimize undesirable behavior. Such modifications may include use of a cubicle or net bed, an alarm system, a helmet, and walkie-talkies. A drug and alcohol policy is frequently necessary; it is well documented that many individuals with TBI have preexisting alcohol or drug problems (or both).[71]

The first step in becoming more comfortable when working with clients who have behavior problems is to understand why the problems occur and how they manifest themselves.

Clients exhibiting agitation, combativeness, disinhibition, and refusal to cooperate and participate in activities typically have difficulty filtering distractions and can become agitated in noisy environments. Providing a quiet room during interventions and use of a cubicle bed may help minimize noise and reduce outbursts.

A disinhibited individual may lack awareness of the external environment and may make indiscriminate sexual remarks or gestures to others. Ignoring comments, redirecting inappropriate behavior, and modeling acceptable behavior are typical therapeutic interventions.

Clients who refuse to cooperate and participate in intervention can be the most challenging because this behavior may affect their ability to remain in an acute rehabilitation program. The lack of participation is typically organically based and due to cognitive deficits such as impaired initiation and lack of insight into the disability. It is important to document such behavior throughout the course of care; however, when clients refuse to participate, documenting progress can be challenging. Interventions include providing consistent structure through daily schedules and goal sheets that provide visual cues for expectations, and also visual and physical guidance through activities until clients are capable of completing tasks without assistance.

OT Practice Notes

Behavior management is essential in all TBI rehabilitation programs. It is important to develop and implement a behavioral program, whether the behavior is passive (decreased initiation), active (agitation), or somewhere along the continuum. An effective program includes comprehensive staff training, tools that track and monitor behavior and techniques, and consistent multidisciplinary communication (behavior management meetings) to ensure that the individualized behavior plan is effective and goal oriented.[71]

Evaluation of the Individual at a Lower RLA Level

Clients emerging from coma and at the beginning stages of the injury (RLA levels I through III) may exhibit minimal arousal and limited purposeful movements. It may be necessary to evaluate such individuals in short sessions and at different times of the day. A quiet environment with minimal distractions will enhance the client's ability to attend to and follow commands. Evaluation includes assessment of the following:

1. *Level of arousal and cognition:* Can the client visually attend to the speaker and follow commands such as "Open your mouth" and "Squeeze your eyes closed"? Can he or she communicate through verbalizations, gestures, or eye movements? Does he or she demonstrate purposeful movements, such as pulling at vital tubes? How easy or difficult is it to wake the client, and how long can the client stay awake?

2. *Vision:* Is the client able to visually scan or attend to a person, object, or activity? Can the client maintain eye contact?

3. *Sensation:* Does the client respond to external stimulation, such as pain, temperature, and movement of the joints?

4. *Joint ROM:* Has the client lost ROM in certain joints as a result of decorticate or decerebrate posturing, increased tone or spasticity, contractures, or heterotopic ossification?

5. *Motor control:* Does the client exhibit decorticate or decerebrate posturing? Is there an increase in tone and spasticity? Is there decreased tone and hypotonicity? Are deep tendon responses present, diminished, or absent? Does the client exhibit the presence of primitive reflexes? Does the client engage in spontaneous motor movements, such as scratching the face?

6. *Dysphagia:* Does the client handle his or her own secretions, drool, or swallow spontaneously? Does the client demonstrate poor oral motor control? Answers to these questions provide valuable information on whether a swallowing evaluation is indicated.

7. *Emotional and behavioral factors:* Is the client's affect flat or expressive? Are responses such as crying or laughing observed in response to interactions with the rehabilitation team or family members?

Evaluation of lower level individuals with TBI is generally accomplished with tools such as a goniometer, clinical muscle and tone testing, traditional neurological screening, and clinical observations. Many acute TBI rehabilitation facilities have developed their own initial evaluation forms. A variety of scales can be used to establish a baseline and predict recovery. The GCS and RLA scale are common; however, newer cognitive scales are also being used (eg, the JFK-Revised and WHIM).[67] Some clients tend to emerge quickly and move expeditiously through the RLA levels, whereas others (eg, those with anoxia) may demonstrate limited or slow recovery. A subacute program or a rehabilitation center that specializes in slow to recover clients may be necessary. In either case, a rehabilitation program with active therapeutic intervention is necessary to prevent contractures, encourage activity, and facilitate the client's progress through the rehabilitative process.

In the case of Marisol, the team decided to address her spasticity and joint contractures first by providing appropriate medical interventions, including blockade of her musculocutaneous nerve to decrease her left UE spasticity. This was followed by casting to reduce her elbow contracture. The team also gave Marisol a comprehensive activity schedule in a multistimulus environment. This schedule involved transferring her out of bed and into a customized wheelchair, in which she would remain 6 to 8 hours a day, getting up into a standing frame daily, and requiring active participation in all therapies 4 hours per day. Her cognitive level was assessed weekly with the JFK-Revised scale, and her ability to follow through with basic mobility and self-care tasks also was assessed.

Intervention for the Individual at a Lower RLA Level

The general aim of intervention for those at RLA levels I through III is to increase the individual's level of response and overall awareness of self and environment. All stimulation should be well structured and broken down into simple steps and commands. Allotting sufficient time for an individual's response is necessary because cognitive processing is often significantly delayed during this phase of recovery. Intervention at this stage can be grouped into six areas: sensory stimulation, bed positioning, casting or splinting, wheelchair positioning, management of dysphasia, and emotional and behavioral management; family and caregiver education also begins. Interventions may occur simultaneously to optimize progress. Each intervention affects and enhances the next. Because clients often respond more to the familiar and routine, it is important to involve close family members and friends in the sessions.

Sensory Stimulation

Intervention for clients emerging from coma should start as soon as they are medically stable. Intervention generally begins in the intensive care unit. At this stage, clients frequently lack responsiveness to pain, touch, sound, or sight. They may exhibit a generalized response to pain that appears reflexive (eg, attempting to pull away from painful stimuli). The goal of intervention is to increase the client's level of awareness by trying to increase arousal with controlled sensory input. **Sensory regulation** increases neurological signals to the reticular activation system, the structure of the brainstem that alerts the brain to important sensory input from the external environment.

Sensory stimulation can be introduced in a variety of ways and methods. Introducing isolated visual, auditory, tactile, olfactory, and gustatory stimulants to the individual may heighten arousal. For example, a flashlight may be used to elicit eye opening and visual tracking. Playing familiar music may facilitate autonomic responses, such as a change in the respiratory rate or changes in blood pressure. Introducing olfactory stimulation through a variety of scents may elicit eye opening or head turning. Gustatory stimulation involves the controlled presentation of taste to the client's lips and tongue using a cotton swab. Such stimulants may include salty, sweet, bitter, and sour tastes. Any response from the client is noted.

OT Practice Notes

The most effective types of sensory stimulants are those that have personal meaning to the client, such as favorite songs or stories. Family members often bring in familiar objects and pictures that can facilitate responses from the client. It is helpful to learn about the client's preinjury history to incorporate familiar items and routines into his or her intervention plan.

Kinesthetic input is incorporated early in the intervention. One of the most effective ways to facilitate volitional movement is by actively guiding movements in a normalized fashion while performing functional activities. The therapist actively helps the client perform simple movements (eg, rolling from side to side) and simple functional activities (eg, wiping the mouth with a washcloth, combing the hair, and applying lotion to the skin). The theoretical aim of functional sensory stimulation is to reactivate highly processed neural pathways that had been established before the injury. Other activities related to functional sensory stimulation include sitting the individual up at the edge of the bed and having the client stand by using a tilt table or a hydraulic standing frame. During all these activities, the therapist observes the client for any changes, such as visual tracking, turning of the head, physical responses, vocalizations, and ability to follow verbal commands.

Wheelchair Positioning

Seating and positioning are important components of treatment in clients at lower RLA levels. Proper positioning in a wheelchair allows these clients to interact with their immediate environment in an upright, midline posture. Proper positioning facilitates head and trunk control so that clients can see and interact with people and objects in the environment. A proper wheelchair seating position helps prevent skin breakdown and joint contractures, facilitate normal muscle tone, inhibit primitive reflexes, increase sitting tolerance, enhance respiration and swallowing function, and promote function (Fig. 34.1).

FIG 34.1 Proper wheelchair seating position.

Effective seating and positioning require a stable base of support at the pelvis, maintenance of the trunk in the midline, and facilitation of the head in an upright, midline position. This position frees the UEs for use and allows the client to visually scan the environment. Once the client has a seating system that encourages and promotes function, therapy sessions can be more effective and beneficial. For example, clients generally find it easier to handle their secretions in this position, so swallowing trials may be safer and more effective.

Marisol required a wheelchair and specific positioning devices when she entered the acute rehabilitation program. Given her motor abilities and deficits, what type of wheelchair setup would you prescribe?

Pelvis

Wheelchair positioning should begin at the pelvis. Poor hip placement adversely alters trunk and head alignment and influences tone in the extremities. Because sling-seat wheelchairs contribute to internal rotation and adduction of the hips, it is important to insert a firm, solid seat (padded with foam and covered by vinyl) to facilitate a neutral to slightly anterior pelvic tilt. A lumbar support may also help maintain the natural curve in the lumbar spine. A wedged seat insert (with the downward slope pointing toward the back of the chair) can be used to facilitate hip flexion and inhibit extensor tone in the hips and LEs. The individual's buttocks should bear weight evenly, with both ischial tuberosities firmly resting on the wheelchair seat. A seat belt angled across the pelvis helps maintain this desired position. Because these clients have spent a significant amount of time in bed, loss of anterior pelvic tilt is present. Before clients are positioned in a wheelchair, significant stretching of the pelvis and trunk often is necessary to achieve neutral **pelvic alignment** and upper trunk extension. These stretches often facilitate upright, symmetric trunk alignment, which may have occurred secondarily to prolonged bed rest and abnormal tone, reflexes, and patterns.

Trunk

The trunk should be positioned after the pelvis because it is the next most proximal body structure. A solid back insert or firm contoured back should be placed behind the client's back to maintain the spine in an erect posture. A back insert contoured to the curves in the spine will maintain the lumbar and thoracic curves. Lateral trunk supports can be used to reduce scoliosis and lateral trunk flexion caused by imbalanced tone of the intrinsic muscles of the back. A chest strap (with easily opened Velcro fasteners) can be used to reduce kyphosis, facilitate shoulder retraction and abduction, and expand the upper part of the chest for proper diaphragmatic breathing and UE use.

Lower Extremities

An abductor wedge placed between the LEs just proximal to the knees may be used to reduce hip adduction and internal rotation. If hip abduction is present, a padded abductor wedge can be placed along the lateral aspect of the thigh to reduce LE abduction. Ideally, the knees should be positioned at 90 degrees, with the heels slightly behind the knees while sitting. Both feet should be maintained securely on the foot plates to provide proprioceptive input and facilitate weight bearing in both heels to normalize tone.

Upper Extremities

The UEs should be positioned with the scapulae in a neutral position (neither elevated nor depressed), the shoulders slightly externally rotated and abducted, the elbows in a neutral position of slight flexion with forearm pronation, and the wrists and digits in a functional position. This position is often difficult to achieve because of severe spasticity and soft tissue contractures of the UEs. A splint or cast may be applied to reduce spasticity and facilitate a functional position of the UEs. Frequently, a lap tray is used to provide support for the UEs and encourage bilateral UE weight bearing and use.

Head

Lower functioning clients with TBI often have little or no active head control. Attaining a neutral-midline head position, which allows optimal visual contact with the environment, is difficult. A dynamic head-positioning device (Fig. 34.2) can be used to maintain neutral head alignment and facilitate head control. A contoured headrest that cradles the head posteriorly and laterally may be used to support the head in a midline position. A forehead strap (fabricated from soft, padded material) may be used to prevent the head from falling forward. Slightly reclining the wheelchair also prevents the client's head from falling forward and facilitates visual interaction with the environment. The client should be reclined 10 to 15 degrees; reclining the client beyond this point reduces weight bearing through the trunk and pelvis and tends to encourage extensor tone, a posterior pelvic tilt, and sacral sitting. If the client has had a portion of the skull removed, a helmet is necessary to protect the brain during all mobility and when getting the client out of bed into a wheelchair.

FIG 34.2 A dynamic head-positioning device maintains neutral head alignment and facilitates head control.

As the client progresses in rehabilitation, wheelchair seating and positioning should be continually reevaluated to better meet his or her specific needs. Devices should be modified gradually or removed as the client begins to control his or her body actively and manipulate more items in the environment. A schedule is necessary to indicate the length of time the client can tolerate being seated in the wheelchair. Keeping the client in a wheelchair longer than can be tolerated may result in fatigue, which can subsequently interfere with active participation in therapy.

Bed Positioning

Proper bed positioning is critical in the early stages of TBI. Because the client tends to spend a lot of time in bed, proper bed positioning is crucial to prevent pressure sores, facilitate normal muscle tone, and prevent loss of pelvis and trunk ROM and mobility. It is often difficult to maintain optimal positioning because of spasticity and abnormal posturing. Other complications that may interfere with proper positioning are casts or splints, intravenous tubes, nasogastric tubes, fractures, and any medical precautions that must be followed while the client is in bed.

If the client exhibits abnormal tone or posturing, a side-lying or semiprone position is preferable. This position assists in normalizing tone and providing sensory input. A supine position may elicit a tonic labyrinthine reflex and extensor tone. A supine position with the head in a lateral position could elicit an asymmetric tonic neck reflex. Clients with TBI generally have bilateral involvement, requiring a program for side-lying on both sides. The traditional bed-positioning techniques used for clients who sustained a cerebrovascular accident may require modification, depending on the extent of bilateral involvement. Pillows, foam wedges, and splints may be incorporated into the bed-positioning program to facilitate normal positions and prevent abnormal postures, such as extreme elbow flexion, head and neck extension, and footdrop deformity.

OT Practice Notes

Because all clients have unique needs, each should be assessed and set up with an ideal positioning program. It often helps to take a photo of the client once positioned and post it to ensure that it can be easily duplicated and carried out by staff and family members.

Splinting and Casting

Splinting or casting may be indicated when (1) spasticity interferes with functional movement and independence in ADLs, (2) joint ROM limitations are present, and (3) soft tissue contractures are possible. Splints have been thought to provide elongation and inhibition by positioning the joint in a static position with the muscles and soft tissues on stretch. Splinting of the elbows, wrists, and hands is often implemented to maintain a functional position at rest and to reduce tone. Serial casting is a more aggressive intervention to increase ROM in the joints when contractures have formed or spasticity is present (or both). Splinting and casting not only reduce contractures and increase ROM, but also prevent skin breakdown. Because clients with TBI often have limited active ROM, the UE joints often assume a position of flexion (particularly when severe finger flexor spasticity has caused the fingers and nails to embed in the palmar surface of the hand), and this may cause moisture, redness, and breakdown of the skin.

A resting functional position or antispasticity splint (Fig. 34.3) is worn when the client is not involved in active movements or functional tasks. Once the splint has been fitted, a wearing schedule must be established for the rehabilitation team and caregivers to follow. A typical splint schedule during the day requires the client to wear the splint for repeated, alternating 2-hour periods (2 hours on, followed by 2 hours off). The client must be monitored frequently for any skin breakdown or tonal changes that may change the initial fit of the splint. The team and caregivers should be trained in proper application and removal of each splint.

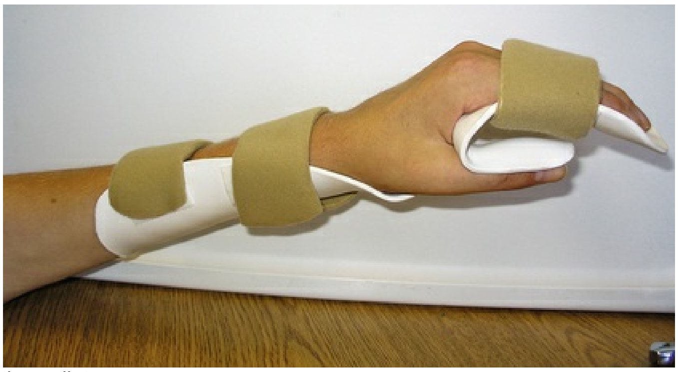

FIG 34.3 Resting splint. (From Cifu DX: *Braddom's physical medicine and rehabilitation*, ed 5, Philadelphia, 2016, Elsevier.)

Other common splints worn at this stage of recovery are cone splints, which are used in the palm of the hand to keep the fingers from digging into the palmar surface. Frequently, rolled cloths are put into the clenched hand; however, because this may facilitate increased spasticity, a hard cone splint is more appropriate. An antispasticity splint (Fig. 34.4) not only positions the hand and wrist in a functional position, but also abducts the fingers to further reduce spasticity. Splints are modified as needed and may eventually be discontinued if the individual's motor control and tone improve.

FIG 34.4 Antispasticity splint. (From Skirven TM, et al: *Rehabilitation of the hand and upper extremity,* ed 6, Philadelphia, 2011, Mosby.)

A serial casting program is indicated when moderate to severe spasticity cannot be managed by splints. The goal of casting is to increase ROM and decrease tone gradually by using a progressive succession of separately fabricated casts, each worn continuously for a period of weeks. Casts are often left on for 5 to 7 days, which places the muscle and tendons on prolonged stretch and reduces tone. Successive casts are designed to increase ROM further until a functional joint range is achieved and maintained. A common difficulty that prevents success with serial casting is skin breakdown. If skin breakdown occurs because of a cast that is worn for several days, the cast must be removed until the skin has healed. While wound healing is occurring, spasticity again increases, and any gain in joint ROM is often lost.

The most common UE casts are the elbow cast, which is used for loss of passive range of motion (PROM) in the elbow flexors, and the wrist-hand cast, which is used for loss of PROM in the wrist and finger flexors. Variations of these casts include elbow dropout, wrist, thumb, hand, and individual finger casts. However, casting of more than one joint at a time often leads to skin breakdown as a result of multiple pressure points. Therefore, casting should be applied to one joint at a time.[30]

Casting is frequently used in conjunction with motor point blocks, nerve blocks, or botulinum toxin injections. Blocks involve the injection of a chemical substance (eg, lidocaine, bupivacaine, phenol) into the nerve or motor point to temporarily inhibit the innervation of spastic muscles. Botulinum toxin is injected directly into the target muscle and works by causing presynaptic blockade of acetylcholine release.

Indications for termination of a casting program include achieving functional ROM or plateauing (eg, the individual has not gained significant improvement in ROM after two consecutive casts). When improvement in ROM has been made and the goal has been achieved, the final cast is cut in half lengthwise, the edges are finished, and the cast is used as a bivalve splint to maintain the functional position. Velcro straps or elastic wrap bandages are used to secure them in place (Fig. 34.5). A wearing schedule is then established for the bivalve splint (cast).

FIG 34.5 Spasticity splint. (From Skirven TM, et al: *Rehabilitation of the hand and upper extremity*, ed 6, Philadelphia, 2011, Mosby.)

Casting is an advanced intervention technique that carries some risk. Competent application of the technique requires knowledge and advanced clinical training.

Marisol had increased spasticity and reduced function in her UEs. What splint or cast (or both) would best suit her needs initially?

Dysphagia

Clients emerging from coma are fed through a nasogastric or gastrointestinal tube. Once the client is alert and more oriented, the physician decides when evaluation for dysphagia is indicated. Dysphagia programs usually begin when the client has moved into the intermediate or advanced levels of rehabilitation (see Chapter 27).

Behavior and Cognition

As clients emerge from coma and become more alert and aware of their surroundings, it is important to track their improvement and attempt to establish a form of communication. In acute rehabilitation, tracking the level of arousal and awareness is important because it demonstrates progress. Several scales and assessments are available, including the WHIM, JFK-Revised, and Orientation Log. These measurement tools document improvements in visual attention, visual tracking, and ability to follow commands.

Establishing a way for the client to communicate wants and needs is of the utmost importance because it helps guide intervention. It also allows the team to more accurately assess the client's cognitive level. A reliable yes/no system should typically be implemented. Examples include eye blinks, eye gaze, head nods, and motor movements, such as thumb up and thumb down. Once a system has been established, communication is possible.

Marisol gained some active movement of her right UE and with guiding was able to use large colored buttons to answer yes or no to questions. The yes and no buttons, which were positioned on the lap tray of her wheelchair, buzzed when Marisol touched them. Thus she was effectively able to answer simple questions, such as, “Do you need to use the bathroom?” and “Are you in pain?”

Family and Caregiver Education

Education of family members and caregivers starts immediately because they are an integral part of the intervention team. Family members often play an essential role in eliciting the client's responses and implementing the sensory regulation program, positioning the client in bed, and contributing to the ROM program. At the earliest stage after injury, therapy may be limited; therefore, setting up a simple intervention plan for the family to implement is important in fostering the client's recovery and maintaining passive joint motion. Family members often feel helpless, and allowing them to be actively involved helps alleviate their feelings of helplessness and focuses their array of emotions.

Later, when the individual is more alert and mobile, family members can be involved in transfers, wheelchair positioning, feeding programs, and ADL retraining. Providing several education materials is helpful for family members. Brain injury education booklets and Internet websites are effective tools in educating clients and family members.

Evaluation of the Individual at an Intermediate or Higher RLA Level

During the intermediate and advanced levels of recovery (RLA levels IV to VIII), the client is alert but often displays confused, agitated, and inappropriate responses. The client may be able to follow simple two- or three-step verbal commands but is easily distracted. Minimal or moderate cues are often necessary to assist clients at an intermediate or a higher level in the performance of ADLs. In general, they can complete most components of the OT evaluation; however, they may require several breaks during the evaluation process because of distractibility or agitation. The evaluation is similar to that for clients in the earlier recovery levels in that physical status, dysphagia, psychosocial and behavioral factors, vision, sensation, and perception are all assessed. However, clients at intermediate or higher levels require more extensive evaluation of ADLs (including driving), work readiness, and ability to reintegrate into the community.

Physical Status

The physical status evaluation includes an assessment of joint ROM, muscular strength, sensation, proprioception, kinesthesia, fine and gross motor control, and total body control (ie, dynamic sitting or standing balance). Limitations in physical status are usually the result of abnormal tone, spasticity, and muscle weakness without abnormal tone, heterotopic ossification, fractures, soft tissue contractures, and peripheral nerve compression. Tools to assess physical status include goniometers, dynamometers, manual muscle testing, and clinical observation.

Dysphagia

The dysphagia assessment may include both clinical (bedside) evaluation and videofluoroscopy. The bedside examination provides the therapist with a variety of information. For example, aspiration can be caused by impulsivity because the client may gulp large portions of food quickly. Pocketing food and drooling may be apparent and are a result of impaired oral motor control. The dysphagia examination can also provide the therapist with information about cognitive status. Does the client appear to understand what to do with the utensils and food items? Is neglect present and causing the client to leave one side of the plate untouched? Does the client know the names of the utensils and food items, or is aphasia suspected?

Performed by a speech pathologist or a trained occupational therapist, videofluoroscopy provides information about the anatomy and physiology of the oral, pharyngeal, and esophageal stages of swallowing. Videofluoroscopy is the primary dysphagia assessment tool that can provide information on the individual's ability to manage liquids and solid foods, particularly during the oral, pharyngeal, and esophageal phases of the swallow. This information is used to design a feeding program, which may require a diet of thick liquids and pureed foods. Swallowing status should be reevaluated as the individual improves in rehabilitation and can progress to thin liquids and solid foods. (See Chapter 27 for more information on dysphagia.)

Improper positioning, behavioral disorders, and cognitive-perceptual impairment have all been implicated as factors contributing to swallowing disorders. Dysphagia intervention must address seating and positioning and cognitive-perceptual distortions. Formal assessments to evaluate dysphagia include the Dysphagia Evaluation Protocol[6] and the Evaluation of Oral Function in Feeding.[74]

Cognition

Cognitive skills are assessed within functional tasks (eg, ADLs, meal preparation, money management, and community skills). Tasks that involve paper and pencil can also provide valuable information, although they are only part of the equation. Assessment of a client's cognition during preparation of a cold meal may include the following skills: (1) following two- or three-step written or spoken directions, (2) correctly sequencing the order of steps, (3) attending to the task with minimal distraction, and (4) displaying good safety and judgment. The therapist may evaluate the client's cognitive status by using any of the following: (1) counting the number of errors and correct responses, (2) assessing the amount of assistance or cueing required (minimal, moderate, or maximal), and (3) determining the percentage of the task that was completed correctly. Assessment of the complexity of the activity (simple versus multistep or basic to complex) and the conditions of the environment (isolated versus multistimulus or quiet to distracting) is also important.

When assessing an individual's cognitive skills, the therapist must consider and document other factors that may affect performance, such as language barriers (eg, the presence of aphasia, a primary language other than English), visual-perceptual deficits, the effects of medication on cognitive level, educational and cultural background, and previous experience with the task. Formal cognitive assessments that may be used with clients with a TBI include the Allen Cognitive Level Test,[2] Loewenstein Occupational Therapy Cognitive Assessment,[54] Rivermead Behavioral Memory Test,[82] Kohlman Evaluation of Living Skills,[47] and Cognitive Assessment of Minnesota.[69]

Vision

Clients with TBI should undergo vision screening. This screening should be completed as early as possible in the rehabilitation process because early detection of visual deficits allows the intervention team to obtain more reliable information about the client's overall health status. For example, diplopia (double vision) or accommodative dysfunction (inability to adjust focus for changes in distance) will probably influence the results of the neuropsychology or speech-language pathology assessments.

Vision screening is a tool that allows therapists to identify potential deficits in vision. Although therapists cannot diagnose conditions of vision dysfunction, they can determine whether an individual passes or fails a visual screening based on standard criteria. The screening is a means of determining which clients require referral to an optometrist or ophthalmologist for a complete evaluation and intervention. A comprehensive vision intervention program is designed by an optometrist and implemented by an occupational therapist or vision therapist. A visual history questionnaire also should be completed. The questionnaire should contain an ophthalmologic history, questions about the use of glasses and contact lenses, and questions about the presence of blurred vision, dizziness, headaches, eyestrain, diplopia, and visual field loss.

Common areas evaluated in a vision screening include visual attention, near and distant acuity, ocular movement (eg, pursuits and saccades), convergence, accommodation, ocular alignment, depth perception (stereopsis), and visual field function. Visual dysfunction can also be identified during clinical observation of the individual's performance in functional activities. Tilting the head as a result of a field deficit, closing or covering one eye to reduce blurred vision, and bumping into walls or objects in the environment because of a field deficit or unilateral neglect are all easily observed behaviors indicative of visual dysfunction.

Perceptual Function

Perceptual evaluation should be performed when the therapist has obtained a clear understanding of the individual's cognitive, sensory, motor, and language status because deficits in these areas may skew the client's performance on a perceptual evaluation. Evaluation of visual perception should include right-left discrimination, form constancy, position in space, topographical orientation, and naming of objects. Evaluation of perceptual speech and language function should assess for aphasia and anomia. Evaluation of perceptual motor function should include the functions of ideational praxis, ideomotor praxis, three-dimensional constructional praxis, and body schema perception (including identification of unilateral neglect). Formal perceptual assessments that can be used for adults with TBI include the Hooper Visual Organization Test,[40] Motor-Free Visual Perception Test–Revised,[17] Rivermead Perceptual Assessment Battery,[76] and Loewenstein Occupational Therapy Cognitive Assessment.[54]

Activities of Daily Living

Clients at an intermediate RLA level should be assessed in all basic ADLs (eg, grooming, oral hygiene, bathing, toileting, dressing, functional mobility, and emergency response). Clients at an advanced RLA level should also be assessed in instrumental activities of daily living (IADLs), such as hot and cold meal preparation, money management, community shopping (Fig. 34.6), household maintenance, cleaning and clothing care, safety procedures, medication routine, and work readiness. The therapist will have ample opportunity during assessment to observe cognitive skills, perceptual skills, and behavioral appropriateness.[33] Formal assessments that can be used for clients with TBI to assess ADL skills include the Arnadottir OT-ADL Neurobehavioral Evaluation (A-ONE),[4] Assessment of Motor and Process Skills (AMPS),[24] Functional Independence Measure (FIM),[37] and the Klein-Bell Activities of Daily Living Scale.[46]

FIG 34.6 Community shopping. (Courtesy iStock.com.)

Clients with a history of alcohol abuse require assessment of leisure patterns. An interest history and interest checklist may reveal healthful leisure interests that can replace alcohol use. The combination of leisure skills development and substance abuse rehabilitation will help clients manage time more effectively and thereby refrain from using alcohol after discharge.

Driving

Many states require physicians to report anyone to the Department of Motor Vehicles who has lapses of consciousness, seizure disorders, and cognitive, visual, and perceptual dysfunction caused by TBI. Regulations that apply to clients with such disorders often mandate that the driver's license be revoked until further assessment confirms that the person can drive without posing a safety risk to himself or herself or others. These laws vary from state to state.

Clients with TBI who are at an advanced RLA level and who do not have seizure disorders or severe cognitive deficits must undergo a comprehensive driving evaluation to assess their ability to resume driving. Two types of driving evaluation can be performed: a clinical assessment (evaluation of the individual's visual, cognitive, perceptual, and physical status as these relate to driving) and an on-road assessment. Both types of evaluation are necessary because the client may fail the clinical assessment but pass the on-road assessment by using compensatory strategies. Conversely, the client may perform successfully on the clinical assessment but fail the on-road assessment (see Chapter 11).

Clients with TBI frequently exhibit deficits (eg, visual processing disorders, figure-ground discrimination dysfunction, and impulsivity) that significantly affect their ability to drive safely. Individuals with delayed visual processing hesitate during driving maneuvers and stop in an unsafe manner (eg, in the middle of the road or at a corner) to allow themselves adequate time to process visual information. Those with figure-ground impairments may be unable to identify stop signs and traffic signals at intersections or locate the gearshift near the dashboard. Impulsive individuals may respond aggressively rather than defensively when driving, increasing the risk of accidents. They may use poor judgment when making driving decisions and may be unable to inhibit inappropriate responses. The Elemental Driving Simulator[29] and Driving Assessment System[29] are off-the-road clinical driving assessments that can be used with an on-road assessment to determine a client's ability to resume driving after brain injury.

Occasionally clients have a strong desire to drive but poor insight into whether they have the safety skills to resume driving. Because most rehabilitation centers and out-settings do not have an adaptive driving program and expensive driving simulators, occupational therapists need to use low-tech options to determine driving readiness and educate clients on whether they are safe to drive. There are many commercially available computerized driving assessments and training tools that are easy to download and inexpensive. One option is the Roadwise Review, distributed by the American Automotive Association (AAA).[1] This computer-based tool measures the functional abilities scientifically linked to the risk of crashing in older drivers. Because it assesses useful field of view, visual-perceptual skills, and reaction times, it is an excellent tool that can be used for adults with TBI.

Vocational Rehabilitation

Clients at an advanced RLA level may be evaluated to determine whether they are ready to return to work. It has been well documented that return to work after moderate to severe TBI is generally unsuccessful. The high unemployment rate among individuals with TBI has been attributed to the adverse emotional, behavioral, and neuropsychological changes arising from brain injury. Substance abuse in clients with TBI is another major factor inhibiting the person's ability to return to and maintain employment.[27]

Vocational assessment for clients at an advanced RLA level must involve assessment in the actual work setting because psychometric tests and job simulations in themselves do not accurately determine work potential. The client is often able to compensate in a familiar work setting for deficits that may appear to be significant impairments on a psychometric test. The therapist's vocational evaluation should summarize the individual's interests, strengths, and areas of deficit. The report should conclude with recommendations stating the modifications required, realistic job goals, and a plan for achieving these goals with professional assistance as needed.

Psychosocial Skills

Clients at an advanced RLA level who will be discharged to the home or to a community supportive living residence should also undergo a psychosocial skill evaluation. Such an evaluation should assess role loss, social conduct, interpersonal skills, self-expression, time management, and self-control. In addition, the therapist should assess the client's social support system, ability to form and maintain friendships, and resources for reducing feelings of isolation (eg, TBI support groups). The ability to form and maintain intimate and sexual relationships after TBI will be of paramount concern to single clients who sustained a TBI between the ages of 18 and 30. Childrearing and care of family members will be of concern for clients who are responsible for children and other family members.

Assessment of psychosocial skills in clients with TBI is critical. For 1 or more years after injury, clients with TBI report that their psychosocial deficits significantly diminish life satisfaction and are a greater problem than the physical and cognitive deficits combined. Psychosocial impairment is often neglected in the rehabilitation setting, which prioritizes intervention for acute physical, cognitive, and perceptual deficits. Psychosocial difficulties are more apparent after discharge, when the individual has left the structured and safe setting of the rehabilitation hospital to reenter the community. It is important to address psychosocial difficulties before the individual is discharged. Psychosocial assessment tools that can be used for these clients include the Assessment of Communication and Interaction Skills,[70] Occupational Role History,[25] and Role Checklist.[61]

Marisol received skilled OT intervention throughout a 3-month in-client rehabilitation stay, followed by 6 weeks in a day treatment program. Marisol participated in a multifaceted spasticity reduction program and **neuromuscular reeducation**, which improved ROM and functional use of her right UE. As her ROM and selective movement improved, Marisol learned how to feed, dress, and bathe herself with minimal assistance. As Marisol's head and trunk control improved, she was able to participate in all aspects of bed mobility and transfers. Daily guided self-care tasks were a critical part of her morning schedule. Performing meaningful, routine tasks allowed Marisol to work on her basic cognitive abilities. Spontaneous neurological recovery, cognitive reeducation, and memory strategies improved Marisol's ability to plan, organize, and sequence her ADLs and recall her daily therapy schedule, with occasional verbal cues. Marisol was referred to an out-client OT program after discharge from the day treatment program.

Intervention for the Individual at an Intermediate or Higher RLA Level

Intervention for individuals at an intermediate or higher RLA level (IV through VIII) involves two primary approaches: the rehabilitative model and the compensatory model. The **rehabilitative model** is supported by the theory of **neuroplasticity**, which holds that the brain can repair itself or reorganize its neural pathways to allow relearning of functions lost as a result of neural damage sustained in the accident. The **compensatory model** holds that repair of damaged brain tissue either has occurred to its fullest extent or cannot occur, with the individual being left unable to perform lost functions without external assistance. Tools used in the compensatory model are adaptive equipment, environmental modification, and compensatory strategies that allow the client to perform ADLs. It is valuable to approach intervention using both the rehabilitative and compensatory approaches by addressing neuromuscular impairment, cognitive deficits, perceptual deficits, vision dysfunction, and behavioral disorders. In general, a rehabilitative approach is used in the acute stage of TBI recovery until the client has plateaued or progress has slowed, at which time a compensatory approach is attempted.

Neuromuscular Impairments

As with clients at lower RLA levels, clients at intermediate or advanced levels can have numerous types of neuromuscular impairment. Spasticity, rigidity, soft tissue contractures, primitive reflexes, diminished or lost postural reactions, muscular weakness, and impaired sensation affect the ability to perform activities independently and with normal control (see Table 34.3). The prerequisites for normal movement include normal postural tone, balanced integration of flexor control (reciprocal innervation), normal proximal stability, and the ability to implement selective movement patterns.

The common principles of intervention for neuromuscular impairment are to facilitate control of muscle groups, progressing proximally to distally; encourage symmetric posture; facilitate integration of both sides of the body into activities; encourage bilateral weight bearing; and introduce a normal sensory experience. Effective rehabilitation techniques for such individuals include neurodevelopmental treatment (NDT), proprioceptive neuromuscular facilitation (PNF), myofascial release, and some physical agent modalities (see Chapters 29 and 31). These clinical interventions require education beyond the entry level and must be either incorporated into or followed by a meaningful functional activity that requires the same movement. The following brief overview of principles is merely an introduction and cannot substitute for training in the specific techniques.

Intervention for impaired neuromuscular control should begin at the pelvis because positioning of the pelvis affects the motor control of all other body parts. A variety of approaches may be used to normalize pelvic positioning. For example, clients with TBI commonly have a posterior pelvic tilt. To move the client to a more functional erect pelvic position, a therapist trained in NDT might use anterior pelvic tilt mobilization. A therapist with a different approach might use a bed sheet behind the pelvis to lift and rotate the pelvis forward over the heads of the femurs. In either case, the client would be directed to raise the head and sit up tall.

The trunk is positioned after the pelvis. Proper positioning of the trunk frees the UEs for functional activities. Major principles include (1) facilitating trunk alignment, (2) stimulating reciprocal trunk muscle activity, (3) encouraging the individual to shift weight out of a stable posture into all directions (bending forward, bending backward, reaching to each side while laterally flexing the trunk), and (4) helping the individual move the lower part of the trunk on a stable upper trunk or move the upper trunk on a stable lower trunk. Once trunk control improves, intervention should progress to the UEs.

Competent practitioners may apply rehabilitative techniques in a variety of ways. A client with soft tissue contractures or spasticity in a particular muscle group may benefit from NDT mobilization and inhibitory techniques for the agonistic muscle group. A client with low tone or weak muscles (without spasticity) may benefit from NDT, PNF, and physical agent modalities. Kinesiotaping can assist in providing stability to weak muscle groups. Neuromuscular electrical stimulation can effectively stimulate UE muscle groups, including the triceps, pronators, supinators, and wrist and finger extensors, to enhance muscle strength, increase sensory awareness, and assist in motor learning and coordination.[14]

Many clients at an advanced RLA level have fairly intact motor control and are able to ambulate independently and use both UEs in functional activities. However, close observation reveals subtle trunk and extremity deficits related to coordination and speed of movement. The intervention for trunk control focuses on developing full isolated movements of the trunk and extremities, good dynamic standing balance for all activities (including reaching and bending to high and low surfaces), and the ability to shift weight naturally from one LE to the other during activities. UE intervention programs are designed to increase scapular stability and improve fine motor control. A goal of intervention is to improve the client's speed while maintaining good coordination and minimizing compensatory strategies (Fig. 34.7).

FIG 34.7 Use of both hands during meal preparation.

Ataxia

Ataxia is a common motor dysfunction that occurs primarily as a result of damage to the cerebellum or to the neural pathways leading to and from the cerebellum. Ataxia develops early in the acute stage of recovery and may remain permanently. It is a clinical problem for which rehabilitation methods are generally ineffective. More often, therapists train the client to use compensatory strategies to control the effects of ataxia. For example, weighting body parts and using resistive activities often improve control during the performance of tasks but show inconsistent carryover of muscular control when the resistance is removed.

When applying weights to clients, the therapist must identify at which joint (or joints) the tremor originates. Applying weights to clients' wrists when the tremor emerges from the trunk and shoulders is ineffective. Weighted eating utensils and cups are also used as compensatory aids to reduce the effects of ataxia on the UEs; however, these assistive devices are limited in their effectiveness.

Cognition

Intervention designed to enhance cognitive skills should be implemented through functional ADLs and IADLs. A common impairment in cognition is concrete thinking, in which the individual is likely to have difficulty with abstract concepts. Activities that require generalization of skills from one task to another are difficult for clients with TBI. It is best to engage these clients in activities they need to participate in in everyday life. For example, if the client will return to a community environment in which it is necessary to use public transportation, interpreting bus schedules is a meaningful and relevant activity that addresses many critical cognitive skills, including problem solving, planning, organization, concentration, tolerance of frustration, sequencing, money management, and categorization. Another way to address the aforementioned cognitive skills is by planning a trip to the hardware store to purchase supplies necessary to install a handheld showerhead.

Clients at an advanced level of recovery who demonstrate high-level cognitive skills often display subtle cognitive deficits in the areas of organization, planning, sequencing, and short-term memory.

OT Practice Notes

Activities such as establishing a monthly budget to live independently and negotiating the community public transportation system to pay a utility bill provide a context for cognitive retraining to address subtle cognitive deficits. Activities should be challenging, age appropriate, and relevant to the individual's real-life needs. Compensatory strategies may include the use of a schedule, memory book, electronic handheld device, monthly budget chart, and simplified maps of the client's community. For optimal results, the system chosen must take into account the client's familiarity with and motivation to use the given strategy. For example, a client may have used a high-tech cell phone as a day planner before the injury and may also prefer to use this system after the injury.

Generally, neuropsychologists and cognitive educators have implemented the use of computers in cognitive retraining. However, use of computer programs has not been shown to generalize to the cognitive skills needed to improve performance in IADLs.[60] Computers can be used in therapy if they are meaningful in the client's daily life; the therapist should address the client's specific computer needs. For example, by simplifying tool bars and menus and programming step-by-step written directions that appear on the screen, therapists may reprogram a client's home computer to make it less complicated to use. Software programs that do not represent functional activities should be avoided.

Since computers in the home are now commonplace and Americans with disabilities are likely to benefit from the use of accessible technology, it is important to introduce computer use into intervention sessions as a therapeutic modality.[53a] Not only can occupational therapists set up a computer using the built-in accessibility options and utilities, they also can provide specialty assistive technology products (eg, voice recognition, alternative keyboards, and trackballs) to allow clients to access and use a computer successfully.[32] Computer access not only facilitates cognitive retraining opportunities, but also can serve as a source of communication and can address visual, perceptual, and motor deficits.

Vision

Intervention alternatives for clients with TBI and visual dysfunction include the use of corrective lenses, occlusion (eg, patching one eye), prism lenses, vision exercises, environmental adaptations, and corrective surgery. An optometrist or ophthalmologist can evaluate the client's vision and prescribe glasses to address any accommodative dysfunction caused by brain injury. However, the glasses should not be prescribed until the client has passed the subacute phase of rehabilitation because an accommodative dysfunction that appears in the acute stage of brain injury may improve during the recovery process.

A common technique for eliminating double vision (diplopia) is patching, or occlusion. The client wears a patch over one eye to block the image seen by that eye and eliminate diplopia. Patching is a temporary compensatory strategy. An optometrist may prescribe prism glasses or binasal occluders for clients with consistent diplopia resulting from permanent oculomotor nerve damage. The prisms assist the eyes in fusing images. Prism glasses are not effective for those with significant lateral strabismus or exotropia (outward eye turn). Binasal occluders encourage the malaligned eye to fixate centrally. Prism glasses and binasal occluders are used with vision exercises. The goal of this intervention is to reduce the diplopia and eventually eliminate the need for prisms or occluders.

Vision exercises consist of a series of activities that (1) maximize residual vision, (2) enhance impaired vision skills (the rehabilitative approach), (3) increase the client's awareness of his or her visual deficits, and (4) help the client learn compensatory strategies. Intervention progresses from monocular to binocular vision and follows a developmental progression (supine to sitting to standing). Exercises initially address basic skills, such as visual attention, pursuits, and saccades, and may progress to more difficult skills, such as fusion and stereopsis. These vision exercises are based on the rehabilitative model, which holds that impaired visual skills can improve with training.

Environmental adaptations for visual deficits are based on the compensatory model. Compensatory strategies for visual deficits include using a colored border along one side of a page to facilitate reading. A colored strip of tape along one side of a plate or meal tray to promote self-feeding is one option. Use of large objects, such as a clock with bold numbers or a telephone with enlarged buttons, is another compensatory technique. Using contrasting colors to highlight controls and knobs (eg, marking TV/VCR remote control buttons with fluorescent paint) may be helpful. Increasing lighting in an environment and using textures as cues (eg, placing textured tape on a banister by the bottom step to alert the individual that the bottom step is coming and thereby reduce falls) may be used for clients with low vision. The latter compensatory strategy is also valuable for clients with vertical gaze paralysis who can look neither up nor down. Those who have lost pupil constriction should wear sunglasses whenever they are in bright light.

Corrective surgery performed by an ophthalmologist may be indicated to align the eyes and eliminate double vision; however, the individual must wait at least a year after the injury to allow any improvement that may occur naturally in the course of recovery.

Perception

Treatment of perceptual deficits involves both rehabilitative and compensatory intervention. For example, impairment of figure-ground perception might be treated using a rehabilitative approach through the repeated practice of locating objects against a similar background (eg, finding a white shirt on a bed with white sheets or finding a spoon in a drawer of similar stainless steel utensils). Using a compensatory approach, the therapist would help the client arrange the kitchen drawers so that utensils are categorized (perhaps color coded) and distinctly divided to facilitate identification.

Aphasia (a perceptual speech disorder) can also be treated by both rehabilitative and compensatory approaches. Expressive aphasia may be treated through a rehabilitation approach by using repeated conversation exercises in which clients are given feedback about their incorrect spoken words and challenged to express the words they meant to verbalize. If the client has not made significant gains in expressive speech through use of the rehabilitative approach, the compensatory approach should be used to help the client articulate his or her needs to caregivers. For example, a chart with letters, words, or pictures (or a combination of the three) of important items in the client's environment can be used to help the client identify needs such as eating, toileting, and medications. Such a chart may be used along with rehabilitative approaches.

Through a rehabilitative approach, apraxia can be treated by helping the client perform specific tasks (eg, brushing the hair) hand over hand (ie, the therapist's hands guide the client's hands during brushing). The rehabilitative approach holds that through repeated hand-over-hand exercise, the client's brain can repair the neural pathways that mediate specific motor patterns, such as those needed for brushing the hair, or can reorganize pathways so that different, undamaged areas of the brain can establish new pathways for specific motor patterns. In a compensatory approach, the client may brush the hair by following steps through the visual interpretation of sequentially depicted (pictures) or listed (words) on a poster or note card.

Neglect syndrome (a disorder of body schema) can also be addressed by using rehabilitative and compensatory strategies. Severe neglect syndromes tend to decline as a natural part of the recovery process. However, some neglect syndromes may continue into the post-acute rehabilitation stage. With a rehabilitative approach, the client is encouraged to use the neglected extremity for all ADLs. The client's room may be rearranged to encourage interaction with the neglected part of the environment (eg, placing the television or standing bed tray on the left side of the room if the client has left-sided neglect). A compensatory model is used when the client has not demonstrated significant improvement in attending to the neglected side of the body or environment. The meal tray may be placed within the client's field of vision to maximize success. A colored border may be placed on the left side of book pages to cue the individual to scan the entire line while reading.

Behavioral Management

The types of intervention strategies used to reduce or eliminate problem behavior may be divided into two categories: environmental and interactive. **Environmental interventions** alter objects or other environmental features to facilitate appropriate behavior, inhibit unwanted behavior, and maintain individual safety. Agitated clients should be placed in a quiet, isolated room without a roommate. All extraneous stimuli (eg, radios and televisions) should be removed. Similarly, therapy is provided in a private, quiet room away from other people and extraneous stimuli.

An agitated client who demonstrates severe behavioral problems may require one-to-one care. The client is assigned a rehabilitation aide who remains with the client throughout the day (including during therapy) to monitor and regulate his or her behavior. The rehabilitation aide may wear an alarm bracelet that signals staff when the client attempts to wander away from the appropriate floor or out of the building. Walkie-talkies, pagers, and wander guards may be used with those who are at risk of eloping. One walkie-talkie or pager remains in the nursing station; the other is held by the therapist or staff member who is providing one-to-one care to the client. If the client begins to act aggressively or attempts to elope, the rehabilitation aide can alert the staff that assistance is needed.

Interactive interventions are the approaches staff members and caregivers use to interact with the client. The entire team should implement these interventions in a consistent way. Consistent implementation includes speaking in a calm and concise manner and deliberately refraining from detailed explanations that will only increase the client's confusion and frustration. For safety's sake, therapists should also keep the door open when working with the client at the bedside and should always maintain awareness of the individual in relation to self.

A client in the post-acute stages of rehabilitation who continues to exhibit behavioral problems should be placed in a behavioral management program. Such a program should allow the client to experience the natural consequences of inappropriate behavior (eg, losing community recreational privileges) in an effort to encourage more appropriate responses. Drug therapy may be used for those who do not make significant improvements in their behavior and who present a safety risk to themselves and others.

Dysphagia and Self-Feeding

Intervention strategies for dysphagia follow the same guidelines as for other neurological impairments; however, intervention may be more complex for these clients because of bilateral neurological involvement, cognitive and behavioral issues, and severe neuromuscular impairments.[5,6] A self-feeding program may begin in a quiet area, such as the client's room. Eating is then advanced to more social situations, such as the hospital dining room. Common pieces of adaptive equipment, such as a rocker knife, plate guard, and nonspill mug, may be used if the client demonstrates diminished strength, coordination, or perceptual deficits. If the client displays decreased attention, introducing one piece of adaptive equipment at a time may help. Clients with heightened impulsivity may benefit from the strategy of placing the fork down after each bite to ensure that they completely chew and swallow before initiating the next bite. Depending on the client's level of dysphagia (ie, preoral, oral, pharyngeal, or esophageal), a diet of thick liquids or pureed foods may be indicated until the client makes progress toward recovery.

Functional Mobility

Mobility training can be subdivided into bed mobility, transfer training, wheelchair mobility, functional ambulation during performance of ADLs, and community mobility. The NDT principles of bilateral extremity use, equal weight bearing, and **tone normalization** are used in intervention strategies that address functional mobility. The rehabilitation model based on the principles of NDT and PNF should be used for intermediate-level clients with TBI in the acute and subacute stages of rehabilitation. Allowing a client with loss of function to use compensatory strategies, such as grabbing a bed rail with one hand and rolling or standing on one leg to transfer, may appear to enable the client to function more independently earlier. However, use of such strategies diminishes the client's ability to perform activities with a bilateral UE pattern at a later point. In time, unilateral performance of activities results in hemiplegic postures, contractures, and abnormal gait deviations. Compensatory strategies should be used only in the later stages of recovery and when the client has not been able to demonstrate significant improvement in functional mobility skills and thus must learn compensatory strategies to enhance the ability to live independently in the community.

Bed Mobility

An intermediate-level client with TBI may require training in bed mobility skills, including (1) scooting up and down in bed, (2) rolling, (3) bridging, and (4) moving from a supine position to and from sitting and standing positions.

Wheelchair Management

Wheelchair management includes the ability to manage wheelchair parts (eg, removing footrests and locking brakes) and propelling the wheelchair both indoors and outdoors on a variety of surfaces (eg, low-pile carpeting, sidewalks, and ramps). Customized wheelchairs may be ordered for a client who is in the post-acute stage of rehabilitation and continues to exhibit neuromuscular impairment that requires the use of a wheelchair for long-term mobility needs. A custom wheelchair provides a seating and positioning system that contours the client's body for comfort and skin protection, includes adaptive supports for proper pelvic and trunk alignment, and offers a seating position that enhances the client's ability to interact with the environment. Clients who cannot propel or control a manual wheelchair may require an electric wheelchair for independent home or community mobility.

Functional Ambulation

Functional ambulation refers to the ability to walk during functional activities. Physical therapists address gait training, whereas occupational therapists facilitate the carryover of ambulation skills into ADLs. Ambulation during performance of ADLs often requires the integrated use of UEs and LEs to carry and manipulate objects (eg, carrying a plate to a table, holding a book bag or purse, sweeping with a broom or vacuum cleaner, and carrying an infant). Functional ambulation also requires the ability to negotiate an ambulatory device (eg, straight or quad cane and walker) with one or both UEs during performance of ADLs. This is a high-level activity that requires eye-hand coordination and the integration of total body movements. Compensatory aids to improve the client's ability to negotiate an ambulatory device while performing ADLs include walker bags and baskets, wheeled carts (to provide balance and support during transport of items such as plates to a table), canes with built-in reachers, pouch belts (to hold keys, wallet, and memory books), and an apron during meal preparation (also see Chapter 10).

Community Travel

For clients who will be discharged to home or a community supportive living arrangement, the ability to negotiate their environment must be considered. Negotiating uneven sidewalks and curb cutouts, and correctly interpreting traffic light signals and the direction and speed of oncoming traffic, are important skills to practice for safe and independent community mobility. Functional ambulation in the community requires the client to respond and initiate actions quickly; for example, to cross the street after the light turns green and before it turns red. Clients must perceive depth and spatial relationships (to correctly judge the distance and speed of oncoming and turning traffic) and visually identify and avoid environmental hazards that could cause falls (eg, potholes and cracks in the sidewalk). Power mobile scooters or power wheelchairs are often recommended for clients who need long-distance mobility in the community but who fatigue easily or are unable to walk independently. Use of a power mobile scooter or power wheelchair requires good static sitting balance and the ability to quickly integrate UE hand control and cognitive decisions about the environment. Practicing with clients during the wheelchair evaluation is crucial to determining whether they are able to safely propel a power system in the community.

Transfers

All transfers, whether from bed to chair, from wheelchair to toilet, or from lying in bed to sitting on the edge of the bed, need to be performed in a safe manner. Individuals with TBI commonly have memory deficits and limited carryover of information; therefore, transfer training should be consistent (in technique and sequence) among all staff members treating the client. It is preferable that transfers for intermediate- and advanced-level clients be practiced while moving to both the right and the left sides of the body. Without such practice, clients who become proficient in a transfer toward the uninvolved side (in the hospital) may be dismayed to find that the home setting or public restroom requires transfers toward the opposite side. Additionally, teaching clients to transfer to both sides provides weight bearing on both LEs, the use of bilateral trunk muscles, and bilateral sensory input.

Family members and caregivers should be trained in proper transferring techniques (including proper body mechanics) by a therapist before transferring the individual alone. The decision on when to begin caregiver training depends on the client's functional level and ability to cooperate, the discharge date, and the caregiver's physical and cognitive abilities.

Home Management

As the client's skills and independence in self-care, dressing, self-feeding, and functional mobility increase, intervention is expanded to include home management skills in preparation for discharge to the community. Home management skills include meal preparation, laundry, cleaning, money management (eg, balancing a checkbook, paying bills, and budgeting), home repairs (eg, changing a washer in a leaking faucet), and community shopping (making a shopping list, locating the correct items in the store, and paying the correct amount of money at the cash register). Examples of high-level activities include planning a monthly budget, organizing a file cabinet, ordering from a catalog or the Internet, and filing income taxes. These are skills that adults need to live independently in the community and are thus relevant for most clients with TBI.

The degree to which clients participate in home management activities varies. For example, some prepare only simple meals using a microwave oven. For those who must prepare meals to live independently in the community but who are not interested in cooking, the goal is to help them safely prepare simple hot and cold meals at home. Some clients perform no household cleaning activities other than making their bed and doing the laundry. Common sense dictates that therapeutic interventions first address the activities that the client performed before the injury.

As in all other areas of intervention, home management skills are graded to accommodate the client's functional level. Beginning meal preparation tasks may involve making a cold sandwich, whereas beginning money management skills may involve learning to perform basic cash transactions. As clients progress in home management skills, the meal preparation task may be upgraded to preparing a two-item hot meal using a stovetop, oven, or microwave oven. Money management skills may be upgraded to writing checks and balancing a checkbook. As the client continues to gain skills, activities requiring higher level demands are performed until the client reaches the desired goals.

Child care, if appropriate, must not be overlooked as an area of intervention. Family involvement is critical if a mother or father is to return effectively to his or her role as a spouse and parent. Sensory overload and its resultant agitation in a parent with TBI are a commonly reported problem for families. OT sessions should gradually reintroduce parents to their role of caring for their children. Some hospitals have a family suite in which family members can practice ADLs and interpersonal skills with the client on weekends in preparation for discharge. This allows family members to gain a greater awareness of their loved one's impairments and need for assistance. It also makes the transition from hospital to home less stressful for both clients and family members.

The occupational therapist can also assist parents with TBI in the adaptation of strollers, cribs, and child care equipment to make handling of such items easier. Safely bathing or carrying a baby, preparing a meal while simultaneously caring for children, and one-handed diapering and dressing techniques are all examples of areas that could be addressed by OT services.

Community Reintegration

Clients who will be discharged from the acute rehabilitation hospital to home or to a post-acute residential supportive living arrangement should receive training to facilitate the transition from the hospital to the community. Clients who achieve a maximal level of independence in the protected and structured environment of the rehabilitation hospital may find that community reintegration holds even greater challenges. Community trips, in which an advanced-level client with TBI is accompanied by the occupational therapist (and perhaps a family member) to practice IADLs in the natural environment, should be implemented to provide the client with the opportunity to rebuild daily life skills. Depositing or withdrawing money from the bank or ATM, using the public transportation system, planning a shopping list, and purchasing items at the grocery or hardware store are activities that can facilitate initiation of the client's reentry into the community. Having the client perform ADLs in the community setting also allows the therapist to observe the client's ability to interact successfully or otherwise with the environment. The client is provided a chance to receive valuable feedback from others in the community about his or her behavior.

Some clients are discharged from the acute rehabilitation center to a transitional living center. Transitional living centers are designed to develop daily life skills by providing the client an opportunity to temporarily live in a community group setting with 24-hour staff supervision and assistance. The goal of transitional living centers is to facilitate progression from supervised living to greater independence in community living. The client is usually discharged from the transitional living center to a relative's home or to a residential supportive living facility that provides various levels of living arrangements (eg, community apartments and shared community group homes). Because long-term residential community facilities for people with TBI are expensive and not covered by most insurance companies, many are discharged home, where they receive continued intervention in out-rehabilitation or in day treatment programs that provide community, work, and school reentry training.

Psychosocial Skills

One or more years after their injury, individuals with TBI commonly report that psychosocial impairment is the greatest obstacle to rebuilding a meaningful lifestyle. Many report feeling a deep sense of isolation and loneliness. Loss of roles such as partner or spouse, worker or student, independent home maintainer, friend, and community member often leaves individuals feeling as though they have lost their identity. The goal of the occupational therapist, particularly in post-acute TBI centers (eg, day treatment programs, out-rehabilitation, transitional living sites, and long-term community supportive living arrangements), is to help rebuild desired occupational and social roles. This involves a three-step process: (1) identifying the desired roles that were lost as a result of TBI, (2) identifying activities that would support the desired roles, and (3) identifying rites of passage that were either lost or never transitioned through as a result of the TBI. Rites of passage are socially recognized events that mark the transition from one life stage to another. Common rites of passage in Western society include obtaining a driver's license, graduating from secondary school or obtaining a higher education degree, securing full-time employment, living independently in the community, dating, marrying, and parenting.

Once the desired occupational and social roles, activities, and rites of passage have been identified, the therapist facilitates the client's use of adaptation, compensatory strategies, and integration of new learning. The therapist will also help the client enhance or regain interpersonal skills, self-expression, social appropriateness, time management, and self-control. Such psychosocial skills are critical if the client is to reenter the community; that is, to live in a neighborhood setting, hold a job, perform volunteer work in the community, and participate in desired recreational opportunities along with other adult community members.

Group intervention is beneficial because it enables the client to meet others experiencing the same life concerns (thereby reducing feelings of isolation). Groups can offer exposure to peer reactions, which is particularly helpful if the client exhibits socially inappropriate behavior. Groups may also facilitate problem solving by providing the opportunity to speak with others who have successfully dealt with the same or similar problems. Participants who have been in the group longer can become peer mentors to new group members. The opportunity to help others—that is, to share one's experience of having a brain injury with others who can benefit from that knowledge—has been shown to enhance an individual's life satisfaction, feelings of competence, and sense of usefulness. Many states have state associations for brain injury that provide support groups for individuals with TBI.

Substance Use

If the client's preinjury history includes substance use, he or she should receive drug and rehabilitation services specifically designed for individuals with TBI. Clients with a history of substance use may not display any signs of a desire to return to substance use while in the structured and protective environment of the subacute rehabilitation facility. Substance use may become a problem only after the client is discharged to the home, a community-supported living arrangement, or any residential situation in which long periods may be spent alone and unsupervised. Drug rehabilitation services are critical for clients with a substance abuse history because return to substance use after brain injury has been closely implicated in the occurrence of a second TBI.

Discharge Planning

Planning for discharge from OT services begins at the initial evaluation and continues until the last day of intervention. Components of discharge planning include a home safety evaluation (if the client will be discharged home), equipment evaluation and ordering, family and caregiver education, recommendations for a driver's training program (if indicated), and recommendations for a successful return to school or vocational retraining and work skills.

Home Safety

If the client is to be discharged home, the therapist should visit the home (or transitional living setting) to recommend modifications for increased safety. For example, clients with balance difficulties should have grab bars in the shower stall. Increased lighting should be provided as necessary for clients with visual deficits because low lighting has been linked to falls. Recommendations should also be made regarding the client's ability to handle sharp items (eg, knives or glass items that could shatter easily), use the stove, and remember to turn off the faucet and other appliances. The temperature for the hot water system should be set at 120°F or lower to prevent scalding.

Anything the client could trip over (eg, throw rugs, appliance cords, furniture legs, objects placed on steps) should be removed. If feasible, nonslip flooring should be added to slippery surfaces (eg, bathroom and kitchen tiles). If a wheelchair is indicated, the therapist should recommend modifications to doorways and bathroom spaces and should suggest replacement of high-pile carpeting with tile, wood, or other surfaces that can be easily traversed by a wheelchair.

Additionally, family members and caregivers should be educated in the appropriate steps to follow during a seizure, should understand how to evacuate the individual in case of emergency, and should practice methods by which to transfer the individual safely. Caregivers should be able to identify unsafe activities in which their loved one should not participate, and they should know the length of time the person can be safely left alone, if that is possible at all.

Equipment Evaluation and Ordering

If a client will be discharged from the acute rehabilitation facility, an evaluation of the equipment needed in the next setting is required. This may necessitate reevaluation of the client's equipment needs because many of the adaptive devices that were valuable in the beginning and intermediate stages of rehabilitation may be discarded as the client improves. For example, a tub bench or shower chair may have been needed initially because of dynamic standing balance difficulties. The client may have progressed sufficiently during the course of rehabilitation to stand in the shower while using only a grab bar. Because clients with TBI may demonstrate improvements over the course of many months, a rental wheelchair may be considered.

Family and Caregiver Education

Family members and caregivers should be involved in the client's rehabilitation from the beginning of treatment and should be considered members of the intervention team. Education of caregivers in such activities as transfers, wheelchair mobility, ADLs, bed positioning, splint schedules, use of equipment, ROM exercises, and self-feeding techniques facilitates follow-through with the skills the client has learned in the rehabilitation hospital. Individual safety is of primary importance for caregiver education. The caregiver should be trained in implementation of the home program (in either written or videotape form). Home programs may include the areas listed previously, in addition to specific activities for the improvement of cognition, vision, perception, and motor control.

Recommendations for Driver's Training

If the client passes the clinical driver's evaluation, the OT may recommend a specific number of hours of driver's training. An occupational therapist or a driving instructor who has experience working with individuals with TBI (see Chapter 11) should implement the driver's training.

Recommendations for Vocational Training and Work Skills

If indicated, an OT may make recommendations for vocational training if the client is discharged to a day treatment program, an out-rehabilitation center, or a transitional living site. Vocational training is an extended process that requires the involvement of an occupational therapist and possibly a vocational counselor. The client's eventual return to work may require the assistance of a job coach. The success of a client's return to work depends highly on the environment to which he or she is returning and the supportiveness of the environment. These are all aspects that must be considered when a client's potential is evaluated.

Summary

Treatment of adults with TBI is challenging and requires flexibility, stamina, and creativity. Behavioral and psychosocial deficits greatly influence recovery. Substance abuse, a possible contributing factor, must be assessed and addressed. Most clients have a multitude of problems requiring intervention. Coordination of evaluation and goal setting with the interdisciplinary team (including the client and family) is assumed. Intervention should be individualized and oriented toward functional outcomes that are meaningful to the client. An effective transition from acute care to intermediate care and then to the community requires the therapist to plan thoughtfully and communicate clearly. For some people with TBI, recovery and adjustment are lifelong challenges; for this reason, and because the needs of these individuals continue to evolve, providing resources throughout the continuum is essential for an ongoing productive outcome.

Review Questions

1. What are two important measurable landmarks of recovery from TBI?
2. Name five types of neuromuscular impairment that may be present in a client with TBI.
3. Describe the types of care settings available for clients with TBI in the acute, subacute, and post-acute stages of rehabilitation.
4. Describe the psychosocial deficits that may be present in a client with TBI.
5. List two components of a behavioral management program.
6. Name three standard assessments for individuals with TBI and describe the performance components and areas they assess.
7. List four visual skills that are evaluated in a vision screening.
8. Why is it important for a client with TBI to complete an on-road driving assessment?
9. What are the goals of a proper wheelchair positioning program?

Degenerative Diseases of the Central Nervous System

Winifred Schultz-Krohn, Diane Foti, Carolyn Glogoski

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, the student or practitioner will be able to do the following:

1. Describe the course of amyotrophic lateral sclerosis (ALS).
2. Describe the differences between familial ALS (FALS) and sporadic ALS (SALS).
3. Describe the role of the occupational therapist for a client with ALS.
4. Describe the three subtypes of ALS.
5. Identify the symptoms and incidence of Alzheimer's disease.
6. Describe the pathophysiology of Alzheimer's disease.
7. Describe the overall model of medical management used by primary care providers and other health care professionals.
8. Describe an approach to evaluation used by occupational therapists.
9. Identify stages of disease progression and general treatment interventions associated with stages of dementia.
10. Describe the course and stages of Huntington's disease (HD).
11. Identify current research regarding the etiology of the disease.
12. Describe the medical management of HD.
13. Describe the purpose of occupational therapy for a client with HD.
14. Describe the three typical forms of multiple sclerosis.
15. Describe current research regarding the etiology of the disease.
16. Describe the symptoms of multiple sclerosis.
17. Describe complications that may occur as a result of the disease.
18. Describe the role of the occupational therapist for the person with multiple sclerosis.
19. Describe the course and stages of Parkinson's disease (PD).
20. Identify current research regarding the etiology of the disease.
21. Describe the medical management of PD.
22. Describe the role of the occupational therapist for a client with PD.

KEY TERMS

Alzheimer's disease
Amyotrophic lateral sclerosis
Bradykinesia
Chorea
Emotional lability
Exacerbation
Fasciculations
Festinating gait
Huntington's disease
Motor neuron disease
Multiple sclerosis
Parkinson's disease
Relapse
Remission
Rigidity
Stereotactic surgery

Case Study

Marguerite

Marguerite is a 35-year-old woman who was diagnosed with multiple sclerosis (MS) when she was 26. Although Marguerite was initially identified as having the relapsing-remitting form of MS, her neurologist recently diagnosed her with the secondary progressive form of MS and referred Marguerite to occupational therapy. Marguerite now uses an ankle-foot orthosis (AFO) on her right lower extremity when walking and has diminished sensation and dexterity in her nondominant left hand.

An occupational profile revealed the following background information about Marguerite. She is married and has two boys, ages 8 and 6. Both children participate in soccer and swimming on a weekly basis. Her husband travels every month for his job as a sales manager at an insurance company. Marguerite is a special education teacher in an elementary school and works full time, although she was unable to work during relapses. She cares for her 69-year-old mother, who has been diagnosed with Alzheimer's disease. Her mother lives alone in her own apartment in the same city. Although Marguerite has two sisters, neither lives within driving distance; Marguerite has the primary responsibility of caring for her mother and her children.

Marguerite was asked to identify what areas of occupational performance were problematic or successful. She quickly replied that being a chauffeur for her children, a manager of her mother's medical care, and a housekeeper for her family were problematic. She felt as though she was constantly juggling schedules; recently, her children's swimming class changed to a different day, causing a big change in the schedule. Although she wants her children to have the opportunity to pursue sports, Marguerite finds it difficult to supply snacks every month for these extracurricular activities, an obligation that each participant's mother is expected to fulfill. Her husband does try to help with household chores when he is home, but he works long hours and does not have time to shop for the family's groceries. Marguerite is also responsible for arranging all of her mother's medical appointments; shopping for her mother, who no longer drives; and visiting her mother daily. Marguerite reports that she often feels so tired after teaching all day and running all of her errands that she has trouble making dinner when she returns home.

Marguerite was most comfortable with her work situation and reported that many of her colleagues had offered to help with various tasks such as playground duty or monitoring the students during lunchtime. This allowed Marguerite to have a brief break during the day to rest.

Critical Thinking Questions

1. What evaluations would you perform to collect additional data to develop an intervention plan?
2. Where would you start your intervention plan, considering Marguerite's report of her occupational profile?
3. How would the change in Marguerite's diagnosis from the relapsing-remitting form to the secondary progressive form of MS affect her current occupational roles?
4. How would the strategies you select for Marguerite be applied to other clients who have degenerative neurologic disorders?

Introduction

This chapter addresses the impact of degenerative neurologic disorders on a person's occupational performance and outlines the role of occupational therapy (OT) in providing services to clients with these disorders. The specific disorders discussed in this chapter are amyotrophic lateral sclerosis (ALS), Alzheimer's disease (AD), Huntington's disease (HD), multiple sclerosis (MS), and Parkinson's disease (PD).

In degenerative neurologic disorders, the disease progresses and an individual's occupational performance is often increasingly compromised. Occupational therapy aims to help the client compensate and adapt as function declines secondary to the disease process. Environmental adaptations and modifications are often necessary to maintain functional skills for as long as possible.

Degenerative neurologic diseases may occur because of structural or neurochemical changes within the central nervous system (CNS).[70] In the disorders discussed in this section, the client's CNS usually functions normally during childhood and adolescence. After these years, the client experiences signs and symptoms indicating that CNS functions are deteriorating. The progressive nature of the disorder varies from person to person. Some clients have a rapid decline in function, whereas others maintain functional skills for many years.

The decline in function may compromise the individual's sense of self-efficacy in performing various tasks.[190] No longer is the individual able to perform personal or instrumental activities of daily life at the same level of independence. Dependence on others can alter the client's concept of self-worth and self-control. The OT practitioner serves an important role in reframing the client's sense of self even though functional independence may be deteriorating. A man with PD who is unable to dress independently may now direct a personal care attendant (PCA) or home health aide (HHA) to perform these tasks. A woman with MS who was previously responsible for household finances may need to instruct a member of the family to complete these activities.

The disorders discussed in this chapter are most often diagnosed during adult or later adult life, after habits, routines, and patterns of independent behavior are well established. A client may encounter a significant change in social relationships and interactions secondary to a decline in functional abilities. The OT practitioner must consider the ways in which progressive loss of function affects the client's social and occupational roles, whether those roles are as husband, wife, parent, adult child, worker, sibling, or friend. OT must address the needs of the client within the context of his or her social, physical, and cultural environment.

OT intervention aims to support the client's ability to function within his or her environment. The rate at which the client's symptoms progress influences the intervention plan. A client who displays a progressive loss of fine motor skills over 20 years has a much different profile than a client who loses all upper extremity function within 2 years. Use of adaptive equipment must be carefully weighed against the rate of deteriorating skills.

The OT practitioner must be knowledgeable about support services and respite care available to clients with a degenerative neurologic disorder. A PD support group may provide the necessary social support for both the person with this disorder and the individual's family. MS support groups may offer clients information regarding new intervention methods available, along with the opportunity to share life experiences.

An OT intervention plan should address not only the physical limitations associated with various disorders but also their cognitive, social, and emotional implications. Many individuals with neurodegenerative disorders have concomitant depression. Depression can be a reaction to the loss of function associated with some disorders or the primary symptom of other disorders. Occupational therapists should regularly screen for depressive features. An instrument such as the Beck Depression Inventory can effectively evaluate this component.[23,24] In addition to the evaluation of depression in clients with neurodegenerative disorders, cognitive abilities should be evaluated. Clients may have concomitant cognitive problems because of the destruction of neurologic structures, and these deficits can have a dramatic effect on intervention. Brief assessments such as the Mini Mental State Examination (MMSE)[66] or the Cognistat[146] can be used to determine cognitive abilities and establish a baseline of performance.

In most cases, the occupational therapist is a member of a team providing services to the individual with a degenerative neurologic disorder.[93] As a team member, the occupational therapist must consider the roles other professionals and family members play in the client's life and incorporate this knowledge into the intervention plan. OT practitioners provide a unique and needed service to individuals with degenerative neurologic disorders. A client who is able to engage in meaningful occupations despite deteriorating skills reflects the significant contribution of OT.

Three case studies are presented to illustrate the similarities and differences among clients faced with degenerative neurologic disorders. The first case concerns a woman, Marguerite, who has MS. That case is presented at the beginning of the chapter. The second case concerns a man, Marcus, who has ALS, and is presented at the beginning of Section 1 on ALS to serve as a frame of reference for the chapter content. The third case concerns a man, Carl, with PD and is presented at the end of the chapter to serve as a review. The cases should prompt clinical reasoning and decision making as you read this chapter.

Section 1 Amyotrophic Lateral Sclerosis

Diane Foti

Case Study

Marcus

Marcus is a 61-year-old man diagnosed with ALS. He is married and has two grown adult children. He works as the supervisor at an automotive parts outlet store that is a small local family business. He was planning to retire in 6 months when he turns 62. He shares all of the household chores with his wife, Sandy, who also works full time. He loves to garden, goes to church, reads, and plays harmonica.

About 6 months prior to his diagnosis he noticed that he was having difficulties sustaining his grasp on tools and was often dropping things at work. He also reported he was having a harder time lifting boxes off of shelves taller than shoulder height. He fell two times, once at work tripping on a step and once in the garden. His primary doctor noticed the fasciculations in his forearms and calves along with slight atrophy of the intrinsics of his hands. He was referred to a neurologist who made the definitive diagnosis of ALS. The neurologist referred Marcus to occupational therapy (OT) and physical therapy (PT) in the outpatient department. The OT referral was for evaluation and treatment of activities of daily living (ADLs) with a specific focus on Marcus' desire to keep working for at least 6 additional months. The PT referral was for an ankle-foot orthosis and gait evaluation.

The OT evaluation included learning which occupations were the most important and most problematic for Marcus. This allowed the OT to collaborate and prioritize goals with him. She asked Marcus to describe his understanding of his condition. Marcus said he was not sure if the neurologist's diagnosis was correct so he was seeking a second opinion. Either way, he decided it would not hurt to come to his OT and PT appointments. He stated the doctor told him he would get weaker but he thought if he just exercised enough he could improve his hand, shoulder, and leg weakness and prevent it from getting worse.

Along with a discussion of Marcus' work, family, and home environments, the OT assessed his motor and sensory skills and completed a cognitive screening. The OT presented the cognitive screening as a tool to help her determine how he best learns. The cognitive screening was within normal limits without any evidence of impaired short-term memory, spatial deficits, attention deficits, or problem-solving issues.

The OT practitioner found he had intrinsic weakness bilaterally but was right-handed. He had a weak key pinch. His gross grasp strength was 3+/5. He was able to pick up small coins but could not manipulate them in his hands. He also had 4/5 shoulder flexion strength. The therapist also noted hip and ankle dorsiflexion weakness. When he got up from a chair he used his hands to push off and at time shuffled his feet.

Marcus reported that most of his socialization beyond his family occurred at work with his buddies. He had known some of them for 20 years. He went to church regularly but did not socialize there. He stated church was a personal quiet introspective time, not a time to socialize.

Marcus and his wife live in a two-story house with a half-bath downstairs and his bedroom upstairs. There are two steps to enter and exit the house. He has lived in this house for 15 years. One of his sons and a daughter-in-law live down the street with their two children.

Marcus' daily routine includes having coffee in the garden or in the sunroom and dropping off his two grandchildren at school on his way to work. Typically he came home from work and would either take a walk with his wife and dog or work in the garden. On the weekends Marcus goes for long walks with his wife and spends time playing harmonica.

Functional deficits noted during the initial evaluation are as follows:

- Home: ADLs/ instrumental activities of daily living (IADLs)

- Difficulty fastening buttons and zippers

- Difficulty with handwriting
- Increased effort to get off of the toilet, chair, couch
- Difficulty handling tools for repairs at home

- Leisure

- Difficulty shoveling dirt
- Difficulty getting off the ground when weeding
- Fatigues rapidly when playing harmonica

- Work

- Dropping coins when ringing up a purchase
- Difficulty carrying boxes greater than 15 pounds and walking
- Extreme fatigue at the end of the day and needs to take a nap when he gets home

OT interventions during the initial evaluation included the following:

- Prioritizing goals with Marcus
- Instruction in energy-conservation principles in all occupations
- Hand splint option of using a custom-made short opponens splint to improve key pinch
- General hand strengthening with soft Theraputty with instruction not to overdue the repetitions
- Instruction in compensatory strategies for sit to stand
- Resources for bathroom equipment including a shower seat, low/small-diameter grab bars (to function as long as possible with progression of the disease), shower hose, rubber mat, and rationale for implementing equipment as energy-conservation technique and fall prevention
- Recommendations for easy-to-don clothing and instruction in use of a button hook
- Education on Americans with Disabilities Act (ADA) and work accommodations
- The future need for a home evaluation or lengthy discussion about potential access issues in his home
- Discussing frequency of follow-up appointments and alternative methods of communicating via the secure healthcare message system
- Education on the scope of OT and how the OT practitioner will work with Marcus throughout the course of the ALS to make ongoing adaptations to the activities he feels are important

The therapist continued to work with Marcus and his family throughout the course of his disease. The frequency of services depended on his current needs. Marcus and his wife frequently communicated with the OT via e-mails asking about different adaptive equipment and ideas to remain functional. He eventually was followed by an occupational therapist who worked for Home Health and Hospice. At that time Marcus used a power wheelchair full time with a chin switch, a Hoyer lift for transfers, and was dependent with all ADLs and IADLs except using an adapted phone and tablet. He had a percutaneous endoscopic gastrostomy (PEG) feeding tube. Marcus entered the hospice program approximately 2 years after initial diagnosis. His goals at that time were to be more comfortable, continue to use his tablet to e-mail friends at work, see his grandchildren's pictures on Facebook, and do online grocery shopping for the family.

Critical Thinking Questions

1. What evaluations would you perform to collect additional data for developing an intervention plan? What events would indicate a need for reevaluations?

2. Where would you start your intervention plan in light of Marcus' report of his occupational concerns?

3. The early and late stages of ALS are briefly described in the case study. What types of participation and performance skill deficits will likely arise during the middle stage of ALS?

4. When would you begin to include Marcus' family in treatment?

The role of the occupational therapist when working with an individual diagnosed with ALS (such as Marcus in the case study) is to focus on the occupations most important to the individual and on the adaptation methods he will need to apply as his performance skills decline.[7] Occupations that occupational therapists focus on are as diverse as the individuals' personal interests, goals, and priorities. The novice should not assume that basic ADLs are a priority but should listen to what motivates, drives, and frustrates the client and family. The therapist will have the opportunity to use the expanse of OT skills through the evaluation process and treatment interventions, which may include ADL/IADL adaptation; hand splinting; adaptive equipment; cognitive assessment and strategies; psychosocial assessment; environmental modifications for work, home, and leisure; and wheelchair seating and positioning. Most critical is to listen to the client and family about their needs and make those a priority. The personal context of the individual will significantly influence the choices an individual makes regarding home modification and choice of power versus manual wheelchair mobility. For example, a person with limited financial means may choose to not make significant home modifications. Diagnosis and progression of disease are described in terms of the loss of performance skills, whereas Box 35.1 describes the OT interventions in relation to both occupation and performance skills as identified in the Occupational Therapy Practice Framework.[7]

Box 35.1

People With Cognitive Dysfunction Benefit From the Following Approaches

- Use simpler tools for communication than you would use for patients who do not have cognitive deficits.

- Use simpler and more straightforward language and communicate clearly and directly.

- Supervise eating more closely. Patients with frontal lobe abnormalities and poor swallowing ability may have difficulty following medical advice to limit solid foods, or they may place too much food in their mouth.

- Assess patients' ability to make decisions by talking with them and the caretaker because patients with neurologic disorders are faced with complicated medical, financial, and sometimes legal issues.

- Even patients with subthreshold cognitive deficits who do not meet the criteria for dementia may lack the ability to make sound judgments about their care. Poor insight is common, so caregiver involvement may be appropriate.
- Supervise walking. Patients with cognitive deficits often have a loss of impulse control and may make poor decisions about where to walk, how far to walk, or when to use equipment such as a walker.
- Remind caregivers and family to avoid taking the person's behavior personally.
- Help them understand that there is a physiological cause for the behavior.
- Encourage the caregiver and the family to build an atmosphere of comfort and love with a calm and orderly environment.

Modified from ALS Association: *ALS, cognitive impairment (CI) and frontotemporal lobar dementia (FTLD): a professional's guide,* 2005, 27001 Agoura Road, Suite 250, Calabasas Hills, CA 91301-5104. Phone: (800) 782-4747. Website: alsinfo@alsa-national.org / www.alsa.org.

The term **amyotrophic lateral sclerosis** (ALS) is used to identify a group of progressive, degenerative neuromuscular diseases. The underlying neurologic process involves destruction of motor neurons within the spinal cord, brainstem, and motor cortex.[196] Affected individuals exhibit a combination of both upper motor neuron (UMN) and lower motor neuron (LMN) deficits at some point in the progression of the disease.

In the United States, ALS is also known as Lou Gehrig's disease.[25] The term **motor neuron disease** refers to a group of diseases that includes ALS, progressive bulbar palsy, progressive spinal muscular atrophy, primary lateral sclerosis, and an inherited form, spinal musculature atrophy.[102,140] Table 35.1 describes each of these distinct subtypes of ALS. The classic forms of ALS are presented in this section. The National ALS Registry identified the prevalence or number of people living with ALS at any one time to be about 4 people out of every 100,000 in the United States.[205]

TABLE 35.1

Clinical Subtypes of Amyotrophic Lateral Sclerosis

Name	Area of Destruction	Symptoms
Progressive bulbar palsy (PBP; bulbar form)	Corticobulbar tracts and brainstem motor	Dysarthria, dysphagia, facial and tongue weakness, nuclei involved and wasting
Progressive spinal muscular atrophy	Lower motor neurons in the spinal cord	Marked muscle wasting of the limbs, trunk, (PMA or PSMA) (LMN form) and sometimes the brainstem and/or the bulbar muscles
Primary lateral sclerosis (PLS; UMN form)*	Destruction of the cortical motor neurons; progressive spastic paraparesis may involve both corticospinal and corticobulbar regions.	Progressive spastic paraparesis

*The World Federation of Neurology Classification of spinal muscular atrophy and other disorders of the motor neurons does not identify primary lateral sclerosis (PLS) as a subtype of amyotrophic lateral sclerosis (ALS).[25] This author is including PLS in the list in recognition of the many other articles and books that recognize it as a subtype of ALS.

From Belsh JM, Schiffman PL, editors: *ALS diagnosis and management for the clinician*, Armonk, NY, 1996, Futura Publishing; Guberman A: *An introduction to clinical neurology, pathophysiology, diagnosis, and treatment*, Boston, 1994, Little, Brown.

ALS incidence increases after age 40, with cases peaking among those in their 60s and 70s. There is a higher incidence in males than females. Some studies have shown an increased incidence of ALS in veterans of World War II, the Korean War, the Vietnam War, and the Gulf wars. An approximate twofold risk of ALS was reported for veterans of the 1990–1991 Persian Gulf War and for all U.S. veterans.[83,218]

Two primary forms of ALS are recognized: sporadic and familial. Sporadic ALS makes up about 90% to 95% of ALS cases. Between 5% and 10% of individuals with ALS are found to have a family history of the disease. There is no difference in the symptoms or course of the disease for clients with the familial and sporadic types.

The diagnosis is primarily determined by clinical symptoms, electrophysiological exam, and ruling out other neurologic disorders. Criteria established by the World Federation of Neurology and more recently revised by Costa and colleagues state that it is critical for the diagnosis to determine both upper and lower motor neuron involvement with progressive weakness and to exclude all alternative diagnoses.[47] Definite ALS occurs when motor neurons from three or four of the following regions are involved: bulbar (jaw, face, palate, larynx, and tongue); cervical (neck, arm, hand, and diaphragm); thoracic (back and abdomen); and lumbosacral (back, abdomen, leg, and foot). The presence of upper and lower motor neuron involvement but intact bowel and bladder, the absence of sensory changes, and a normal spinal x-ray all support a positive diagnosis for ALS.[196]

Pathophysiology

The etiology of ALS has not been established. Multiple theories have been proposed as the cause of the motor neuron destruction, including gene mutation, metabolic disorders of glutamate insufficiency, metal toxicity, autoimmune factors, and viral infection.[196]

Clinical Picture

The symptoms of ALS vary, depending on the initial area of motor neuron destruction. An individual with ALS typically has a focal weakness beginning in the arm, leg, or bulbar muscles. The individual may trip or drop things as in the case of Marcus and may have slurred speech, abnormal fatigue, shortness of breath, and **emotional lability**, which is uncontrollable periods of laughing or crying. As the disease progresses, marked muscle atrophy, weight loss, spasticity, muscle cramping, and **fasciculations** (i.e., twitching of the muscle fascicles at rest) ensue (Fig. 35.1). To better understand the condition, the OT practitioner may want to research videos that show fasciculation. This will improve the OT practitioner skills when assessing function and reporting symptoms and deficits to the physician. Performance areas may be affected as the individual has greater difficulty with walking, dressing, fine motor activities, and swallowing. In the end stages the individual may elect to use complex, life-prolonging interventions such as tube feedings and a ventilator for respiration. ALS is a rapidly progressive disease, with the majority dying of respiratory failure in 2 to 5 years after the onset of symptoms if no tracheostomy and ventilation are performed. Approximately 10% of the population will live 10 to 20 years or longer.[141] As ALS progresses, the disorder does not affect a person's eye function, bowel and bladder function, or sensory function.

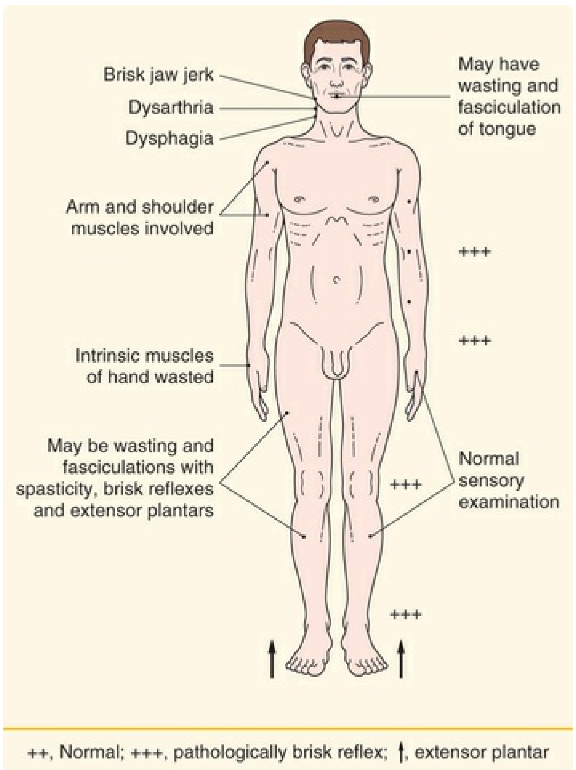

FIG 35.1 Clinical findings in a patient with classic amyotrophic lateral sclerosis with a mixture of upper and lower motor neuron signs. (From Yogarajah M: *Crash course in neurology*, ed 4 (updated), Edinburgh, 2015, Mosby.)

Research has found that mild to moderate cognitive changes occur in 50% of the population with ALS and as much as 20% of the population has dementia.[126] Specific cognitive deficits have been identified, such as frontal temporal lobe dysfunction and disorders of executive function.[183] Executive function impairment includes reasoning, judgment, sequencing, ordering, inferring, regulating emotions, planning, retrieval inefficiency, and a person's ability to have insight into his or her behaviors. A clinician or family member may observe repetition of questions, actions, or phrases; getting stuck on an idea; and an overly emotional response to a situation. Risk factors for developing cognitive problems, behavior changes, or a full-fledged dementia syndrome may include older age, bulbar onset ALS, a reduction in functional vital capacity (FVC), and a family history of dementia.[169]

The prognosis is difficult to predict. Generally, individuals with early bulbar involvement have a poorer prognosis.[196] A more positive prognosis is usually associated with the following factors: younger age at onset; onset involving LMNs located in the spinal cord; deficits in either UMNs or LMNs, not a combination of both areas; absent or slow changes in respiratory function; fewer fasciculations; and a longer time from the onset of symptoms to diagnosis.

The loss of function with ALS is more rapid, without episodes of remission or plateauing as may be seen with individuals diagnosed with multiple sclerosis (MS). A person with ALS must cope with a fatal disease, whereas a person with MS or Parkinson's must cope with a chronically disabling condition.

Medical Management

The American Academy of Neurology has established practice parameters and standards to address major management issues for persons with ALS. An OT practitioner working with this population should be familiar with the standards to better understand the approaches and rationale for intervention. The parameters cover the following topics: how to inform the client of the diagnosis, when to consider noninvasive and invasive ventilator support, evaluation of dysphagia and intervention with a feeding tube, management of saliva and pain, and use of hospice services.[127] Symptoms such as muscle cramping, excessive saliva, depression, lability, and pain are managed with medication. The client's respiratory status should be reevaluated frequently to determine when noninvasive and invasive ventilator support is necessary. Swallowing function should also be evaluated frequently to prevent aspiration and to determine when and whether a feeding tube should be placed.

The Food and Drug Administration approved the drug riluzole (Rilutek) in 1995. Riluzole, an antiglutamate, was the first drug used specifically to alter the course of the disease by prolonging survival. Researchers believe that the success of riluzole indicates that an excess of glutamate leads to the death of motor neurons.[155] Research has shown that riluzole prolongs the life of clients with ALS by at least a few months.[127] Although additional medications may be used to manage symptoms, there is no cure for ALS and no medication to reverse the course of the disease.[155]

Many clinical trials have been funded for research on extending survival, slowing the decline associated with the disease, and assessing and treating the resulting deficits. A comprehensive list of current studies can be found on the National Institutes of Health, clinicaltrials.gov, and the alsconsortium.org websites.

Occupational Therapy Evaluation and Intervention

It is essential to work with the client and family throughout progression of the disease as client factors and performance skills become impaired. The case study of Marcus presents OT intervention for a newly diagnosed individual at the end stage, but there are many more opportunities for the client to benefit from occupational therapy in the middle stage of ALS (Table 35.2). The client factors, including cultural, social, and spiritual values, must be understood because these factors will influence ongoing decisions about personal care and life support. When working with Marcus, the OT practitioner should recognize that his work site is his primary social networking opportunity and that he has a consistent role as a grandfather driving his grandchildren to school.

TABLE 35.2

Amyotrophic Lateral Sclerosis Interventions

Patient Characteristics	Interventions With Focus on Performance Areas of Occupation	Interventions With Focus on Client Factors
Phase I (Independent)		
Stage I Mild weakness Clumsiness Ambulatory Independent with ADLs	Continue normal activities or increase activities if client is sedentary to prevent disuse atrophy and prevent depression. Integrate energy conservation into daily activities, work, and leisure. Provide opportunity for individual to voice concerns (provide psychological support as needed).	Begin range-of-motion program (e.g., stretching, yoga, tai chi). Add strengthening program of gentle resistance exercise to all musculature, using caution to prevent overwork fatigue.
Stage II Moderate, selective weakness Slightly decreased independence in ADLs; for example, difficulty climbing stairs, difficulty raising arms, difficulty buttoning clothing	Assess self-care, work, and leisure skills impaired by loss of function; if patient continues to work, focus on how to adapt tasks with current deficits; assist with balance between work, home, and leisure activities; include significant others in treatment. Use adaptive equipment to facilitate ADLs (e.g., button hook, reacher, built-up utensils, shower seat, grab bar). Integrate hand orthotic use into daily activities. Perform baseline dysphagia evaluation; reevaluate throughout each stage of the disease.	Continue stretching to avoid contractures. Continue cautious strengthening of muscles with MMT grades above F+ (3+). Monitor for overwork fatigue. Consider orthotic support (e.g., AFOs, wrist or thumb splints—short opponens splint).
Stage III Severe, selective weakness in ankles, wrists, and hands Moderately decreased independence in ADLs Tendency to become easily fatigued with long-distance ambulation Slightly increased respiratory effort	Prescribe manual or power wheelchair with modifications to eventually allow recline or tilt posture with headrest, elevating leg rests, adequate trunk and arm support. Help patient prioritize activities and provide work simplification. Reassess for adaptive equipment needs (universal cuff to eat). Assess and adapt use of communication devices (e.g., regular phone to cordless or speaker phone; pen and paper to computer with adapted typing aid). Provide support if there is loss of employment or other activities; explore alternative activities. Begin discussing need for home modification, such as installing ramps or moving the bedroom to the lowest floor. Provide education regarding the types of bathroom equipment available for energy conservation and safety.	Keep patient physically independent as long as possible through pleasurable activities and walking. Encourage deep breathing exercises, chest stretching, and postural draining if needed.
Phase Ii (Partially Independent)		
Stage IV Hanging-arm syndrome with shoulder pain and sometimes edema in the hand Wheelchair dependent Severe lower extremity weakness (with or without spasticity) Able to perform some ADLs, but fatigues easily	Evaluate need for arm slings, overhead slings, mobile arm supports for eating, typing, page turning. Prescribe power wheelchair if the patient wants to be independent with mobility; controls must be adaptable from hand to other mode of control. Evaluate need for assistive technology such as environmental control systems, voice-activated computer; augmentative communication device. Help the patient prioritize activities, and consider negotiating roles with significant others. Reinforce the need for home modifications. Reinforce the need for shower seat or transfer tub bench and shower hose. Assist with patient's ability to participate in closure activities, such as writing letters or making tapes for children, completing a life history, and writing a log on household management for family.	If arm supports are not used, provide arm troughs or wheelchair lap tray for wheelchair positioning; wrist cock-up splints for full resting; hand splints may be needed for positioning. Provide pain and spasm management through the following: Heat, massage as indicated to control spasm and pain Anti-edema measures Active assisted or passive range-of-motion exercises to the weak joints; caution to support and rotate shoulder during abduction and joint accessory motions Isometric contractions of all musculature to tolerance
Stage V Severe lower extremity weakness Moderate to severe upper extremity weakness Wheelchair dependent Increasingly dependent in ADLs At risk for skin breakdown caused by poor mobility	Instruct family in methods to assist patient with self-care, especially bathing, dressing, and toileting; aim to minimize caregiver's burden and stress. Family training to learn proper transfer, positioning principles, and turning techniques. Instruct in use of mechanical lift if needed for transfers out of bed (patients in slings require head support). Adapt and select essential control devices for telephone, stereo, television, electric hospital bed controls for independent use. Adapt wheelchair for respiratory unit if needed to allow for continued community access.	Instruct family and patient in skin inspection techniques. Instruct in use of electric hospital bed and antipressure device. Adapt wheelchair for respiratory unit if needed; reassess adequacy of wheelchair cushion for pressure relief.
Phase Iii (Dependent)		
Stage VI Dependent, with all positioning in bed or wheelchair Completely dependent in ADLs Extreme fatigue	Eating: Evaluate dysphagia, and recommend appropriate diet; therapist may recommend tube feedings if patient is at high risk for aspiration; recommend suction machine for handling secretions and preventing aspiration. Augmentative speech devices may be recommended, in addition to speech therapy.	Continue with passive-range-of-motion exercises for all joints Provide sensory stimulation with massage and skin care.

Modified from Yase Y, Tsubaki T, editors: *Amyotrophic lateral sclerosis: recent advances in research and treatment*, Amsterdam, 1988, Elsevier Science. In Umphred DA, editor: *Neurological rehabilitation*, ed 3, St. Louis, 1995, Mosby.

The client and family members must regularly update decisions about care. Decisions range from when or whether a wheelchair or adaptive eating device should be used to whether the client should undergo a tracheostomy, choose tube feeding, or use of a ventilator. The entire health care team should provide psychosocial support regarding decisions about the extent of life support and medical intervention, with the physician and client having the primary responsibility. As the occupational therapist works with Marcus considering ADL adaptation and home modification, opportunities will arise for the OT practitioner to discuss how much intervention the client wants and what type. Several studies have shown that caregivers and patients have different needs and perceptions of quality of life. It may be beneficial for patients and caregivers to have time for education and support separately to meet their individual needs.[29,154]

Initial and ongoing OT assessment is essential to educate the client about ways to adapt functional activities as the disease progresses. As Marcus declines in physical function and relies more on caregivers, the emphasis is on caregiver training. Education is needed for nursing staff and physicians to understand the role of the occupational therapist in the treatment of clients with ALS.

Steady disintegration in the ability to speak, swallow, move, and perform activities of daily living (ADLs) makes it easy to overlook the presence of some common signs of cognitive or behavioral dysfunction, such as poor insight and deficits in planning.[2] Multiple cognitive domains may be affected in persons with ALS, including psychomotor speed, fluency, language, visual memory, immediate verbal memory, and executive function.[169]

With impaired executive function, a person with ALS may have difficulty handling the visual, auditory, and other sensory data required for complex decision making.[155,183] These cognitive and behavioral issues are pertinent when considering teaching strategies and the need for caregiver counseling and support.

Role of the Occupational Therapist

ALS progresses rapidly, with ongoing deterioration in physical status and possibly cognitive deficits. The intervention plan should focus on the client's participation in occupational performance because the client's functional status changes frequently and intervention focused on physical performance is limited. As the client's function declines, there is a greater need for environmental support through providing durable medical equipment, modifying the home, and providing adaptive equipment. Some studies have shown that exercise, including passive range of motion and light resistive exercise, improves an individual's function and reduces spasticity. Daily range of motion to reduce spasticity and prevent contractures is important during the middle to late stages of the disease.[11] Depending on the client's level of understanding, life support choices, and acceptance of the disease, the OT intervention may initially focus on structuring the client's environment to support independence, and in middle to later stages attention may shift to caregiver training and adaptation to ADLs with assistance. Some clients with ALS may choose to have the maximum environmental and life support available to extend life. In this case, the occupational therapist may provide periodic reevaluations to determine the client's need for adapting self-care, work, and leisure activities. Other clients may request that no extraordinary life support be used, in which case the occupational therapist would assume a supportive role, perhaps helping these clients create a memory book to give to their loved ones. Table 35.2 provides a list of the functional deficits at various stages of the disease and interventions that may be required. When referring to this table, the OT practitioner must remember that each client's clinical picture is unique and that symptoms may appear in a different sequence than the table indicates. For example, a client with early-onset bulbar signs will require earlier intervention regarding swallowing assessment and communication devices; another client may not need a wheelchair until the very late stages. The ALS Association website (www.alsa.org) provides practical solutions for ADLs and a variety of resources that address many of the problems that this population faces, and it is an invaluable resource for practitioners, patients, and families.

Individuals and their families require an interdisciplinary approach to the rapid changes in function, complex psychosocial factors, and quality-of-life issues associated with ALS. The impact of the disease on the client's quality of life has been examined frequently. One study indicated that those who were less distressed and less depressed[39] and had a more positive attitude lived longer.[86] Fatigue and depression have been associated with a poor quality of life for an individual with ALS.[118] Research has found that level of disability was not directly correlated with degree of anxiety and depression.[39] Hecht and colleagues found that social withdrawal correlated with levels of disability; based on the results of this investigation, the authors recommended that mobility be improved with power wheelchairs and public transportation to prevent social withdrawal.[86] Studies have also examined the impact of hope, spirituality, and religion as a means of coping with the disease.

OT Practice Note

Formulation of an occupational profile during the occupational therapy evaluation can promote better understanding of the client's outlook and help determine the most appropriate interventions to improve quality of life with this rapidly progressing disease.

Section 1 Summary

The Marcus case study demonstrates how ALS symptoms manifest and the impact on occupations and client factors. As ALS progresses rapidly, OT reassessment and interventions are needed throughout the process. OT aims to maximize the client's function by providing interventions and periodic reassessment to compensate for declining motor function through modification of the environment, occupations, and tasks and by helping the client and family achieve their client-centered goals.

Section 2 Alzheimer's Disease

Carolyn Glogoski With Winifred Schultz-Krohn

Dementia is the general word used for a group of symptoms caused by serious disorders of the brain. Memory loss and other related problems in language, perception, thinking, and judgment interfere with learning, communicating, relating, and even caring for self. Dementia is not just one disease but includes a number of diseases (e.g., vascular dementia, Lewy body dementia, frontotemporal dementia). The most common form of dementia is **Alzheimer's disease** (AD), especially in persons over 65 years of age.

Alzheimer's disease (AD) is considered a primary dementia as it does not result from other diseases. Secondary dementia is a word that may be used to refer to symptoms of dementia that are associated with other physical diseases (Parkinson's and Huntington's disease, amyotrophic lateral sclerosis, multiple sclerosis) and are discussed elsewhere in this chapter. AD, unlike the other neurologic disorders discussed in this chapter, is formally classified as a mental disorder by the American Psychiatric Association.[10] The exact cause of AD is still unknown, although one pathological change that has been identified is the accumulation of amyloid-beta 42 (AB42) plaques in the central nervous system.[186,202] It is not known why the plaques trigger the degenerative impact on the nervous system, and to date it is not clear what promotes the quick onset of these plaques that are one cause of AD. Because of the damage to brain cells and irreversible cognitive decline, the disease results in impaired higher mental processes, altered behavior, and disturbances in mood. The disorder progresses gradually, producing multiple cognitive deficits, a significant decline from previous levels of functioning, and noticeable impairment in social and occupational functioning is seen over the course of time. Effects on the motor and sensory systems are not apparent until later in the disease process.

Dementia is a significant healthcare problem because of the increasing number of individuals who are living longer, the higher incidence of dementia among older persons, the very high cost of supervised care, and the extensive use of medical resources.[206] Medicare spends almost three times as much money on persons with AD and other dementias than on beneficiaries without AD.[4,5] Early recognition of cognitive decline by physicians, occupational therapists, and all other healthcare professionals is critical.[58] Slower progression of the disease, greater understanding of functional decline, improved quality of life, and time to prepare for the future for older adults and their families could be an outcome of early recognition. The AD diagnosis is often overlooked or mistaken for other disorders, especially in the early stages.

OT Practice Note

Occupational therapists have an essential role in helping the client with AD enjoy life and remain as self-sufficient as possible and in supporting families and caregivers over the course of this difficult disease.

Incidence

Alzheimer's disease accounts for more than two-thirds of the cases of dementia, and the incidence increases dramatically as people age.[4,5,38,202] It is estimated that close to 13% of adults 65 years of age and older have AD. The disease affects more than 5 million people in the United States, and 4.9 million are persons over 65 years of age. Age is the strongest primary risk factor. The incidence of AD more than doubles every 5 years after age 65. It is estimated that 40% to 50% of the population of old-old (85+ years) adults have AD. Many more Americans are surviving into their 80s and 90s because of advances in medical technology. In a study of 97-year-olds 61% of the population had some form of dementia.[99] As the population of old-old adults continues to grow, the number of persons with AD is also expected to grow. Family history and genetics are other risk factors for AD.[204] Two general forms of AD are reported and primarily determined by the age of onset of the disease: early onset, which is diagnosed before the age of 65, and late onset, diagnosed after the age of 65.[35] The early-onset form is seen in only 10% of AD cases, and the far more common form of AD is the late-onset type. Early-onset, familial forms of AD are linked to genetic "mutations of the amyloid precursor protein (APP), and/or presenilin-1 and 2 (PS-1, PS-2) genes."[202] Although this genetic link has been identified, even for early-onset familial forms of AD, the genetic marker is only present in approximately 5% of individuals with early-onset AD (EOAD).[35] Late-onset AD has been linked to the apolipoprotein E-4 (APOE-4) allele on chromosome 19, but it should be noted that this allele has also been found in older persons who do not have AD.[137] It is generally agreed that although genetic factors pose some risk in late-onset AD, risk factors may be more influenced by the interactive effects of diet, lifestyle, and environment affecting each person differently.[187] Previous head trauma is a well-established risk factor for AD; other factors that increase risk include diabetes mellitus, APOE gene variation, current smoking, and depression. There is limited evidence for increased risk associated with the use of estrogens and nonsteroidal anti-inflammatory drugs. There is inconsistent evidence for risk factors associated with heart disease, high blood pressure, and obesity. Researchers are also exploring the effects of certain inhaled anesthetics, lead exposure, and timing in the use of hormone replacement therapy postmenopause.[137-139]

Although the incidence of dementia is growing rapidly, it does not occur in all older adults. Many older adults experience a normal slowing of information processing, called age-related cognitive decline. They do not develop clinically significant cognitive deficits.[112] (APA, 2013).

A portion of the older adult population will develop mild cognitive impairment (MCI), a condition that involves problems with memory, language, or other essential cognitive functions that is serious enough to be noticeable to others and to show up on tests, but this impairment is not severe enough to interfere with daily life.[138] Some, but not all, persons with MCI go on to develop AD. A study by Driscoll and colleagues found that persons with MCI showed brain atrophy, but the group who went on to develop AD showed a pattern of atrophy in the region of the sides of the brain in the temporal lobes.[57] A term sometimes used by laypersons to talk about older adults with memory loss or cognitive impairments is *senility*. Senility is not a medical term. The use of the word *senility* perpetuates stereotypical impressions that progressive cognitive decline occurs in normal aging. Such ideas prevent early recognition and accurate diagnosis of dementia.

Pathophysiology

AD is the result of degenerative changes in the CNS. Neuroanatomic (structural) and neurochemical changes occur in genetically or environmentally susceptible brains. Many neurons die, stop functioning, or lose their connections with other neurons. Disruptions of communication, metabolism, and neuron repair occur. The result of these changes is progressive and diffuse neuronal loss in the cerebral cortex and the hippocampus.[137,188] Three noticeable pathologic changes have been found through microscopic examination of brain tissue after death. These changes include accumulation of amyloid in the space between neurons, increased neuritic plaques, and neurofibrillary tangles, with loss of neurons and synapses. Early AD is associated with decreased cholinergic markers in areas of the brain where there is also increased distribution of plaques and tangles. Many of the changes in the brains of persons with AD can be seen only at autopsy, although neuroimaging techniques (e.g., computed tomography [CT], magnetic resonance imaging [MRI], and positron emission tomography [PET]) provide further diagnostic information such as enlarged ventricles (Fig. 35.2). Degenerative changes in the brain involve several processes that affect neurotransmission and result in neuronal death.[188]

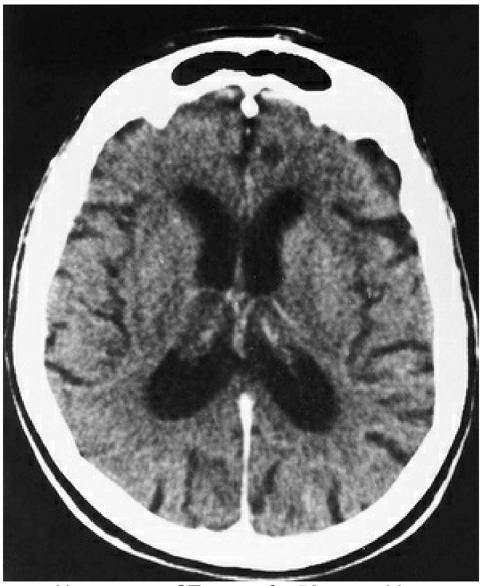

FIG 35.2 Alzheimer's disease. Noncontrast CT scan of a 56-year-old woman with progressive dementia shows generalized enlargement of ventricular system and sulci. (From Eisenberg RL: *Comprehensive radiographic pathology*, ed 6, St. Louis, 2016, Elsevier.)

Studies suggest that the sequence of disease events with AD involve amyloid deposits in the earliest stages that are not yet associated with actual cognitive impairment.[129,137,201] Then, later there is an accumulation of abnormal tau causing loss of synapses, neurons, and brain volume. An inflammatory process causes the tau proteins in the cortical and limbic neurons to undergo microtubular dysfunction, preventing the neurons from sending nutrients and hormones along the axons. The paired filaments of these intracellular proteins actually become cross-linked in an abnormal metabolic process. These filaments form neurofibrillary tangles that eventually lead to neuron death as the neuron-transport system collapses. Neurofibrillary tangles are also seen in the temporal areas and to a lesser degree in the parietal association areas. Neuritic plaques are large, extraneuronal bodies consisting of accumulated B-amyloid and neuronal debris—small axons and dendrites. Distribution of neuronal plaques predominates in the temporal and parietal areas in early AD. This material degenerates, taking up cellular space. Extracellular accumulation of too much insoluble B-amyloid into neuritic plaques contributes to neuron degeneration. When neurons lose their connections, they cannot function and eventually die. The neuron degeneration and death spreads through the brain, connections between other neurons break down, and affected regions begin to shrink in a process called brain atrophy. By the final stage of AD, damage is widespread, and brain tissue has shrunk significantly.

Clinical Picture

Initially, the presentation of Alzheimer's disease may seem puzzling, as it can affect different people in different ways.[4] The most prominent symptom is the progressive inability to remember new information. The Alzheimer's Association has compiled a checklist “Know the 10 Signs,” an Early Detection Matters education campaign that assists older adults and their families with early recognition and contact with their primary care physician.[3] Symptoms and patterns of behavior in AD are often described in terms of stages, but it is important to recognize that it can be difficult to place a person with Alzheimer's in a specific stage, as stages may overlap. The simplest description of staging, useful for caregivers and consumers, defines the progression of AD in terms of a three-point stage scale using early, middle, and late stages.[76] A more clinically and diagnostically complex scale, such as the seven-point Global Deterioration Scale (GDS),[176,177] is used in research or modified for diagnostic purposes and often used as part of an assessment battery. It is important to realize that no two people will progress at the same rate or show the same pattern of symptoms with AD despite the GDS staging framework.

The primary symptom of AD is impairment in recent memory that worsens with time and includes at least one other cognitive deficit such as apraxia, aphasia, agnosia, or impaired executive function, according to the American Psychiatric Association.[10] Memory impairment involves increased difficulty learning new information and recalling information after more than a few minutes.[137,195] Over time, the ability to learn deteriorates further and the ability to recall old memories also declines. Symptoms such as speech and language problems, impaired recognition of previously familiar objects, and impaired ability to perform planned motor movement are more variable and may not be seen in all persons with AD. The expression of symptoms depends on the areas of the brain most affected by the disease. Executive function (the ability to initiate, plan, organize, safely implement, and judge and monitor performance) inevitably deteriorates as AD progresses. Visuospatial dysfunction is common. Mood and behavioral changes are often observed in the early stages of AD, with personality shifts and the development of depression, anxiety, and increased irritability. Later in the course of the disease, troubling behavioral problems such as agitation, psychosis (i.e., delusions and hallucinations), aggression, and wandering can emerge.[4,5,137,138] Motor performance areas such as gait and balance may become impaired, and sensory changes usually arise in the middle to later stages in the course of AD (Table 35.3). Frequently, delirium and depression complicate the clinical picture. The life expectancy following the diagnosis of AD is typically from 8 to 10 years but can range from 3 to 20 years, with a variable rate of progression.

TABLE 35.3

Progression of Alzheimer's Disease and Intervention Considerations

Client Characteristics	Intervention Using Occupational Performance Patterns and Client Factors	Intervention Using Performance Patterns and Client Factors
Stage I: Very Mild to Mild Cognitive Decline		
Feels loss of control, less spontaneous; may become more anxious and hostile if confronted with losses	Listen to client concerns; collaborate with client in identifying areas that are challenging, and identify associated feelings (depression or anxiety).	Encourage physical exercise and wellness behavior.
Mild problems with memory and less initiative; difficulty with word choice, attention, and comprehension; repetition sometimes necessary; conversation more superficial; mild problems with gnosis or praxis	Begin training the caregiver to serve as a case manager.[21]	Help client and caregiver establish a daily routine, and post it in a central place.
Seems socially and physically intact except to intimates; decline in job performance	Provide educational and other resources for disease information, support and relaxation, support groups, or activities for both client and caregiver.	Use environmental aids such as calendars, appointment books, adhesive notes, and notebooks to enhance memory and reinforce engagement in occupation.
	Identify roles, activity frequency, and configuration; encourage continuation of or increase in enjoyable activities by keeping a log and planning enjoyable activity daily or weekly[203]; use activity or task as a focus in socialization.	Identify appropriate environments, or adapt for activities that are currently challenging.
	Explore meaning of occupations and occupational role changes with client and caregiver.	In teaching new tasks, use auditory, visual, and kinesthetic input, and provide supportive or positive feedback; grade activity for success to decrease anxiety.
	Identify needs, preferences, and goals of the caregiver. Discuss driving skills, and plan for future evaluation and restrictions.	During communication training, rehearse with client how to use “I” statements and assertively express self and needs in response to changed ability and the feelings aroused.
		Educate and train caregiver in how to empower client to keep active and facilitate initiation of tasks.
Stage II: Mild to Moderate Decline (Problems From Stage I Are Exacerbated)		
Use of denial, labile moods, anxious or hostile at times; excessive passivity and withdrawal in challenging situations; possible development of paranoia	Emphasize to caregiver the importance of environment in managing dementia at home.[46]	Maintain routines and design environmental support (e.g., lists, posters, and pictures) and level of assistance for cues to remember daily routine and important events
Moderate memory loss, with some gaps in personal history and recent or current events; decreased concentration; possible tendency to lose valued objects; difficulty with complex information and problem solving; difficulty learning new tasks; visuospatial deficits more apparent	Analyze and adapt meaningful leisure, home management, and other productive activities so as to allow the client to safely participate and exert initiation, independence, and control.	Avoid tasks involving new learning; help to simplify surroundings and tasks; make objects accessible, establish expectations for object use, simplify instructions, and clarify the meaning of “success.”

Need for supervision slowly increases; decreased sociability; moderate impairment in IADLs that are complicated and mild impairment in some ADLs (e.g., finances, shopping, medications, community mobility, cooking complex meals); no longer employed; complicated hobbies dropped	Identify needs, and design ways to adapt and grade activity by simplifying complex tasks; train the caregiver to provide cognitive support (verbally) with the client on IADLs and some ADLs.[21]	Help caregiver interpret behavioral problems by understanding source of frustration and the effects of memory loss on behavior.
	Encourage scrutiny of family structure and resources to respond to increasing need for supervision; consider outside resource (e.g., day care, legal planning, friendly visitor volunteer, public transportation for the disabled).	Maintain socialization, and structure opportunities in which others initiate socialization to ensure satisfying relationships in group activity and other social activities.
		Use reality orientation activities, photo albums, and pictures around the home as a reminder of the past, past competence, and opportunities for socializing.
		Encourage stretching, walking, and other balance activities.
Stage III: Moderate to Moderately Severe Decline in Cognition (Problems From Stage II Are Exacerbated—Difficulties Involving Physical Status)		
Reduced affect, increased apathy; sleep disturbances; repetitive behaviors; hostile behavior, paranoia, delusions, agitation and violence possible if client becomes overwhelmed	Maintain involvement in meaningful activity and reactivate alternative roles; identify and design tasks in home management activity; client can assist caregiver with design of productive activity related to former work role.[113,114,210]	In managing problem behaviors (e.g., assaultive behavior), teach caregivers to identify problem, understand and consider possible precipitants for the behavior (e.g., feelings; antecedent events; who, where, when; medical problem or task; environment; or communication problem), and adapt own behavior or change the environment.[40,53,225]
Progressive memory loss of well-known material; some past history retained; client unaware of most recent events; disorientation to time and place and sometimes extended family; progressively impaired concentration; deficits in communication severe; apraxia and agnosia more evident	Help caregiver problem-solve and recognize degree of need for initiation, verbal cues, physical assistance, and ADLs; provide time orientation; simplify environment.	It is essential to maintain consistent daily routines as means of facilitating participation in overlearned tasks, maintain function, and continue to define the self.[40]
Slowed response, impaired visual and functional spatial orientation	Support socialization at home and with family or in structured settings outside of the home.	Teach family that overlearned tasks are possible but require safe environment; overall, tasks take longer, need to be simplified, and require setup and grading to comprise two steps or less.
Unable to perform most IADLs; in ADLs, assistance eventually needed with toileting, hygiene, eating, and dressing; beginning signs of urinary and fecal incontinence; wandering behavior	Ensure safety in the home and other environments by making adaptations suited to level of client functioning (e.g., alarms, restricted use of heating devices and sharps, cabinet latches, ID bracelet, visual cues for item location, and visual camouflaging).[41,68,92,191]	Make further environmental adaptations to compensate for perceptual deficits and ensure safe mobility.
		Rehearse and review names of family and others, using pictures.
		Encourage standby or assisted ambulation, stretching, and exercise on a regular basis.
		In new environments, cue and assist client in navigation, and provide more light and pictorial representations to cue.
Stage IV: Severe Cognitive Decline and Moderate to Severe Physical Decline		
Memory impairment severe; may forget family member's name but still recognize familiar people; can become confused even in familiar surroundings	For ADLs (hygiene, feeding), instruct caregivers (family or nursing assistants) regarding need for simple communication, one-step commands, step-by-step verbal cues, and physical guidance.	Encourage caregiver to use respite programs and maintain recreation and leisure activity for himself or herself.
Gait and balance disturbances; difficulty negotiating environmental barriers; generalized motoric slowing	Encourage continued socialization by family; socialization depends on initiation of conversation by others and may not consistently include a response from the client.	Encourage assisted ambulation methods until client is no longer able to use them.
Often unable to communicate except by grunting or saying single word; psychomotor skills deteriorate until unable to walk; incontinent of both urine and feces; unable to eat; often becomes necessary to place client in nursing home at this time	Use dysphagia techniques to promote swallowing, prevent choking, and encourage eating.	Maintain proper positioning in bed and wheelchair; instruct family in skin inspection.
	Instruct family in transfer techniques.	Provide controlled sensory stimulation involving sound, touch, vision, and olfaction to maintain contact with reality.
		Begin program of active and assisted and passive ROM exercises.

Adapted from Baum C: Addressing the needs of the cognitively impaired elderly from a family policy perspective, *Am J Occup Ther* 45:594, 1991; Morscheck P: An overview of Alzheimer's disease and long term care, *Pride J Long-Term Health Care* 3:4, 1984; Glickstein J: *Therapeutic interventions in Alzheimer's disease*, Gaithersburg, MD, 1997, Aspen; Gwyther L, Matteson M: Care for the caregivers, *J Gerontol Nurs* 9, 1983.

Deterioration in the individual's functional performance usually occurs in a hierarchical pattern. This pattern of decline consists of initially a gradual progression from mild impairments in work and leisure performance to more moderate difficulties in performing instrumental activities of daily living (IADLs), especially with finances and driving. Eventually, there is a progressive loss of the ability to perform even basic self-care tasks in ADLs. The disability pattern is usually characterized by lower extremity ADL problems (walking) before decline in upper extremity ADL functions.[82,200] The trend in AD is for cognitive deficits to increase and executive function to become more impaired (see Table 35.3). Motivation and perception can influence functional performance but may not be routinely considered in individuals with AD.[68,112]

Medical Management

According to Larson,[106] medical management of the individual with AD in primary care settings generally includes several areas. Many aspects of what is termed medical management may also be performed by certain other members of an interdisciplinary health care team, including the nurse, social worker, physical therapist, or occupational therapist. First, there is a need for early recognition and diagnosis of AD.[106] Second, there is the issue of how to intervene on behalf of the person with AD who is living in the community, before institutionalization or more restrictive care becomes necessary. The third area concerns intervention issues as the disease progresses. Last is the role of healthcare providers in recognizing and addressing treatment of other conditions that lead to excess disability in the person with AD.

Although dementia is relatively common in persons who are more than 80 years of age, such individuals often are not diagnosed until approximately 2 to 4 years after the onset of dementia symptoms.[105,106,108,124] A comprehensive physical examination, laboratory evaluation, mental status examination, brief neurologic examination, and informant interview are essential in diagnosing AD. It is important to identify and treat medical conditions (e.g., metabolic disturbances, infections, alcohol use, vitamin deficiencies, chronic obstructive pulmonary disease, heart disease, and drug toxicity) that can contribute to comorbidity. MRI, PET, and CT scan results can be useful, but overreliance on these techniques should be avoided because their value is in identifying relatively uncommon, treatable causes of cognitive impairment. A comprehensive and skillful interview with a reliable informant is essential to the evaluation and diagnostic process in order to recognize decline by comparing current changes with past performance. Informant questionnaires, interviews, and screening measures may be performed by many health care professionals other than physicians and are important to the diagnostic process.

The goal of health care providers in the successful management of an individual with dementia, whether in the community or in a semi-institutional or institutional setting, is to "minimize behavior disturbances, maximize function and independence, and foster a safe and secure environment."[195] Increased mortality is associated with dementia.[31,195] Regular health maintenance visits in primary care settings to identify treatable illnesses such as depression, Parkinson's disease, low folate levels, arthritic conditions, urinary tract infections, and other conditions that may exacerbate dementia are important for all older adults, but especially those with AD.[110,188]

Depression and dementia easily may be mistaken for each other, or they may coexist.[195] Careful attention to whether the onset of symptoms has been gradual (dementia) or more recent (depression) is an important diagnostic issue because affective and cognitive symptoms frequently occur together.[175] Cognitive impairments and especially functional performance may improve in individuals with both dementia and depression after they are treated for depression. Delirium (i.e., impairment in attention, alertness, and perception) and dementia frequently coexist as well, especially in hospital settings.[195] Both conditions involve global cognitive impairment, but delirium is usually acute in onset, shows fluctuating symptoms, disrupts consciousness and attention, and interferes with sleep. Adverse drug reactions are more common in AD because of the vulnerable, impaired brain.[107] Often, a cause of delirium, such as drug toxicity, is treatable.

Hearing, vision, and other sensory impairments are known to make dementia worse and cause greater strain on the caregiver.[213,214] Falls with hip fractures are 5 to 10 times more common in persons with AD than in normal persons of the same age and often result in earlier institutionalization for the individual and the need for higher levels of care.[32] Unsafe mobility quickly becomes an overwhelming burden for caregivers, especially those who are aged.

According to Small and colleagues,[195] pharmacotherapy for the treatment of individuals with AD should be assessed carefully and justified at regular intervals. Although OT practitioners do not prescribe medications, knowledge of pharmacotherapy for individuals with AD is useful when providing OT intervention.[37] Cholinesterase inhibitors such as tacrine and donepezil may improve cognition and functional performance, at least in the short term. Promising research is under way in this area. Other agents that may improve cognitive function include estrogen, nonsteroidal antiinflammatory agents, ginkgo biloba, and vitamin E.[185] Evidence about the benefits of these agents is inconclusive. Antidepressant medications, especially selective serotonin reuptake inhibitors (SSRIs), are often prescribed.[195] However, some of the tricyclic antidepressants (e.g., amitriptyline, imipramine, and clomipramine) and monoamine oxidase inhibitors (MAOIs) can have troublesome side effects in older adults. Atypical antipsychotics such as clozapine, risperidone, and olanzapine may be used to reduce agitation and psychosis.[120,195] Benzodiazepines are prescribed for treating anxiety and infrequent agitation but have been found to be less effective than antipsychotics when the symptoms are severe.[195]

Role of the Occupational Therapist

Most individuals with AD live in the community, alone, or with family and friends, rather than in institutions. A predominant feature of AD is significant and progressive deterioration of function from previous levels of performance because of advancing brain atrophy and pathologic tissue changes. Families and significant others connected with persons who have AD become progressively involved as the disease itself progresses. Family and significant others provide increasing oversight and personal assistance.[37,75] Changes in the brain caused by AD result in deficits in client factors, which in turn lead to deterioration in occupational performance skills, occupational performance areas, and major changes in occupational roles. Over time, more structured, supervised living environments are needed. Increased difficulties in performing everyday functions create challenges for the individual with AD and impact the quality of life for the client, family, and caregivers as the disease progresses. Effective OT interventions must be directed at supporting occupational performance for the individual and creating as much quality of life as possible. Intervention should focus on supporting and maintaining capabilities, adapting tasks and environments, and otherwise compensating for declining function in individuals with AD while trying to help them retain as much control as possible over their lives in the least restrictive environment.[8]

Ethical Considerations

Support for the caregiver is a must. Collaboration with and training of the caregiver is essential in the management of clients with dementia. Family members should encounter an open and encouraging environment in which to discuss safety, security, and dependence issues. Legal, financial, and health concerns that require advance directives (e.g., medical and legal), trusts, activity restrictions (e.g., driving, financial matters, and medication management), and contingency and transitional care plans (e.g., day care, residential care, and long-term care) are important in preparation for the inevitable progression of the disease.[106,194]

Behavioral problems can be expected in the client with AD until the terminal or bed-bound stage. Encouragement to use respite care, in-home support services, and support groups is important. Caregivers also need effective strategies for dealing with behavioral disturbances and disruptions in mood. The use of environmental adaptations, therapeutic interpersonal approaches, referral to other disciplines, and resource sharing helps in collaborating with the client's family and handling these problems. Health professionals use education, training, counseling, and support to help caregivers deal with their feelings, manage behaviors, and maintain quality of life for themselves and for the client with AD. Awareness of the multidimensional effects of this illness on the individual, the family, and the society at large is important to promote more effective and efficient care.[170]

Evaluation

An OT screening is often performed before the evaluation. OT services are indicated for individuals who have demonstrated a recent decline in function; whose behaviors pose a safety hazard to family, staff, other residents, or self; or who may experience improved quality of life.[27]

The type of assessment and the depth of the evaluation process used are influenced by the setting, the stage of progression of AD, the reimbursement process, the presence of other medical and mental health disorders, and the cooperation and interest of the caregiver or care staff. An instrument used to detect changes in progression of the disease process is the Alzheimer's Disease Assessment Scale–Cognitive subscale (ADAS-cog).[162] This 11-item instrument has been successfully used to detect decline in cognitive function over the course of time and has good sensitivity. This tool is often part of an interdisciplinary assessment, and the psychologist or the OT practitioner may be involved in administering this instrument.

Much of the OT practitioner's time in community settings and in long-term care is spent helping families and caregivers develop strategies and environmental adaptations to cope with the overwhelming stresses of safely managing a cognitively impaired individual.[21] The consequences of caregiving and the needs of the caregiver can vary greatly, depending on gender, family relationships, culture, and ethnicity. The caregiver's understanding of dementia, reaction to dementia-related behaviors, use of problem-solving skills, use of the environment, use of formal and informal support systems, and decision-making style greatly affect the caregiver's ability to participate in the care plan and treatment of persons with dementia.[19,45,60,111,221] The Activities of Daily Living Inventory is a 23-item inventory that assesses both activities of daily living and instrumental activities of daily living using the caregiver interview.[37] This instrument does not focus on what the individual might be able to do but rather asks for specific information on what the individual with AD actually does in day-to-day life. It has been used as a primary outcome measure in research regarding the efficacy of OT services provided to individuals with AD and their respective caregivers.

Evaluations for individuals who have AD should be comprehensive despite changing reimbursement requirements. Substantial information can be gathered before an interview and intervention session by asking caregivers, family members, and staff informants to complete questionnaires and rating scales. These scales assess occupational performance, functional abilities, and skills using measures such as the Functional Behavior Profile,[22] the Activity Profile,[21] the Caregiver's Strain Questionnaire,[179] the Katz Activities of Daily Living Scale (KADL),[98] and the Instrumental Activities of Daily Living Scale (IADL).[109] Informant rating measures should routinely be followed by an interview either before or during the first visit. The use of a few brief screening instruments for mental status (e.g., the MMSE),[66] depression,[24,222] and anxiety[110] provides baseline data and a wealth of information about factors that are likely to influence performance.

The functional evaluation of an individual with AD depends on the stage of cognitive decline.[8] The American Occupational Therapy Association's statement on services for persons with AD suggests that tasks involving work, home management, driving skills, and safety should be targeted in the early stages of the disease. Driving has been specifically identified as an area where OT practitioners should provide not only ongoing assessment but also intervention.[88] Although the on-road driving assessment is considered the gold standard, standardized off-road assessments are available to determine the safety of drivers who have cognitive impairments. In the later stages, the focus shifts to self-care, mobility, communication, and leisure skills.

The concerns and observations of the caregiver are important, but the therapist's observation of task performance is also necessary. Many of the functional ADL scales developed for use with older adults have targeted physical performance in the assessment process and are not appropriate for persons experiencing cognitive decline.[71] Fortunately, several excellent, standardized measures that determine whether individuals are able to use their cognitive skills to perform tasks in ADLs and IADLs have been developed. The Kitchen Task Assessment (KTA) determines the level of cognitive support a person with AD needs to complete a cooking task successfully. Baum and colleagues created the Executive Function Test (EFT) with standardized administration and scoring.[22] The Allen Cognitive Level (ACL)[1] test determines the quality of problem solving an individual uses while engaged in perceptual motor tasks. Levy[114,115] has written at great length about the use of the ACL for clients with cognitive impairments. Consistent with the Allen theoretical approach, the Cognitive Performance Test (CPT)[2,34] was developed to identify cognitive deficits that are predictive of functional capacity using several ADL and IADL tasks. Another measure, the Assessment of Motor and Process Skills (AMPS),[63] has been used with individuals who have dementia.[63,150] The AMPS measures motor (e.g., posture, mobility, and strength) and process (e.g., attentional, organizational, and adaptive) skills by using task performance in IADLs. The Disability Assessment for Dementia (DAD)[71] uses informant ratings to determine the ability of the individual with AD to complete tasks in both ADLs and IADLs. The DAD also provides information relevant to executive functioning, such as the person's ability to initiate, plan, and execute the activity. Further information regarding the evaluation of cognitive function and ADL performance is given in Chapters 10 and 26. After obtaining through evaluation a good understanding of the disease process and the functional level of the person with AD, the therapist can begin to look at the all-important question of what aspects of the occupational performance context, especially the environment and care provider interactions, must be modified to optimize function of the person with AD.[150]

Intervention Methods

The goals of occupational therapy are to provide services to persons with dementia and their families and caregivers so as to emphasize remaining strengths, maintain physical and mental activity for as long as possible, decrease caregiver stress, and keep the person in the least restrictive setting possible.[9,14,84,96] Though AD is the primary presenting problem, the OT practitioner has to consider the complexities of developing interventions with an older adult who may be experiencing additional sensory losses and numerous medical problems such as arthritis, orthopedic issues, COPD, diabetes, and heart disease in addition to AD.[56,95] Intervention planning takes into account the physical issues associated with aging, co-occurring disorders such as depression and anxiety, the progressive nature of the disorder, the expected decline in function, and the care setting itself. OT interventions for clients with dementia are directed toward maintaining, restoring, or improving functional capacity; promoting participation in occupations that are satisfying and that optimize health and well-being; and easing the burdens of caregiving.[21] The caregivers need to be included as an important member in developing the intervention plan, and OT services may be focused on reducing the caregiver distress and enhancing caregiver coping strategies.[117] A program developed specifically for caregivers focused on the level of stress and dysfunctional coping strategies. When caregivers were supported, the burden of caring for the person with AD was reduced.[117] Gitlin and colleagues instituted a program to improve the overall pleasure of persons living at home with dementia in an effort to decrease the distress of the caregivers who are affected by the behaviors of the persons with AD for whom they were caring.[75a] A program called the Tailored Activity Program (TAP), an occupational therapy service that evaluates the interests and capabilities of persons with dementia, provides customized activities for each individual. TAP then trains their families to use those activities as part of their daily care routines. The methods therapists use in the intervention process include activity analysis, caregiver training, behavior management techniques, environmental modification, use of purposeful activity, and the provision of resources and referrals. Services are provided in many settings, such as home care, adult day care, and semi-institutional or institutional long-term care. The intervention setting and the stage of the illness help frame the focus of intervention, determine the recipients of service, and prescribe the methods used (see Table 35.3).

Section 2 Summary

AD is a neurologic condition characterized by the development of multiple cognitive impairments with a gradual onset. The effect of these impairments is a significant and progressive decline from previous levels of functioning. The course of the disorder is variable, but loss of function generally occurs in a hierarchical pattern, beginning with work and progressing to difficulties with home management, driving, and safety until even basic self-care skills such as dressing, functional mobility, toileting, communication, and feeding are affected.

OT interventions should be directed at enhancing the abilities of the client with AD by continually adapting tasks of daily living and modifying the physical and social environment as the client experiences progressive loss of function. Given many of the current limitations in treatment time imposed by third-party payment, therapists may find it useful to employ some of the self-report and informant report measures identified in this chapter as a means of gathering information more efficiently during the evaluation process. Several standardized measures also have been identified to assist with the assessment of functional performance and the establishment of a baseline of performance. Recommendations for OT treatment of AD have been identified. The focus of intervention must be flexible and depends on an understanding of the particular expression of the disease process in the client, the specific treatment setting, and the needs of the caregiver. Generally, the goals of OT services for persons with dementia are to maintain or enhance function, promote continued participation in meaningful occupation, optimize health and quality of life, and work collaboratively with the caregiver to ease the burden of caregiving.

Section 3 Huntington's Disease

Winifred Schultz-Krohn

Incidence

Huntington's disease (HD) is a fatal, degenerative neurologic disorder that affects 5 to 10 of every 100,000 individuals.[74,160,181] The disorder is transmitted in an autosomal dominant pattern. Each offspring of an affected parent has a 50% chance of having HD. Genetic studies have identified a mutation (cytosine-adenine-guanine [CAG]) on the Huntington gene (HTT) of chromosome 4 as the cause of this disease.[136,160,168,173,181,215] Presymptomatic diagnosis of HD is possible with genetic testing when the family history shows this disease.[158,160] Diagnosis is also made through clinical examination when the family history is unavailable or unknown.

Pathophysiology

The neurologic structure associated with HD is the corpus striatum (Fig. 35.3). Deterioration of the caudate nucleus is more severe and occurs earlier than atrophy of the putamen.[42,156] The corpus striatum plays an important role in motor control, and deterioration in this area contributes to the **chorea** associated with HD. The caudate nucleus is also linked to cognitive and emotional function through connections with the cerebral cortex. Thinning of the gray matter in the caudate and dorsolateral prefrontal cortex have been identified with the progression of HD.[48] A progressive loss of tissue occurs in the frontal cortex, globus pallidus, and thalamus as the disease advances.[160] The degeneration of the corpus striatum results in a decrease in the neurotransmitter gamma-aminobutyric acid (GABA). Additional deficiencies in acetylcholine and substance P, both neurotransmitters, are noted in clients with HD. The triggering mechanism for the neuronal degeneration has not been clearly identified, but it is linked to genetic coding on the HTT chromosome.[173]

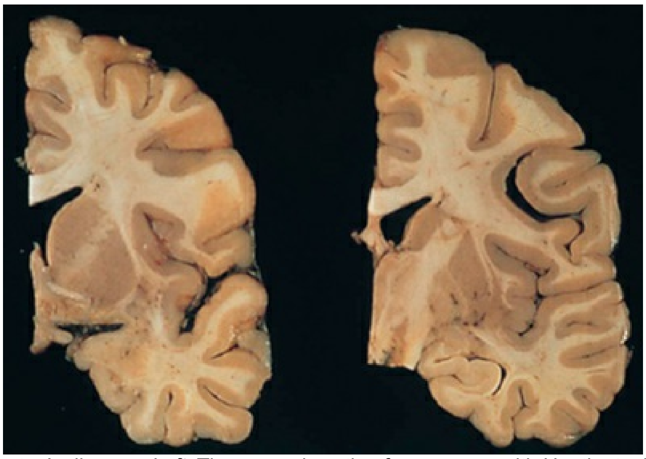

FIG 35.3 Huntington's disease. *Left*, The coronal section from person with Huntington's disease shows atrophy of the caudate, putamen, and globus pallidus. *Right*, Normal coronal section for comparison. (From Perkin GD: *Mosby's color atlas and text of neurology*, St. Louis, 2002, Mosby.)

Clinical Picture

HD is characterized as a progressive disorder involving both voluntary and involuntary movement, in addition to a significant deterioration of cognitive and behavioral abilities.[160,192] A client usually experiences an insidious onset of symptoms in the third to fourth decade of life, but cases have been reported in teenage and younger clients.[220] Clients who are positively identified by genetic testing should be carefully monitored for the first indications of HD symptoms. Not all individuals who have the potential to develop HD, because of family history, elect to undergo genetic testing, and this may negatively affect the time at which first symptoms are identified. The course of progression of HD is often divided into three stages, early, middle, and late, but with the advent of genetic testing, a presymptomatic stage has been added.[216] During the presymptomatic stage, monitoring symptoms is critical, and a decrease in the speed of finger tapping (an item on the Unified Huntington's Disease Rating Scale (UHDRS) may mark the beginning of the early stage of HD. The UHDRS has been used to divide the course of the disease into five stages.[215] The presymptomatic stage is considered stage I. The early stage of the disease process is sometimes referred to as stage II. The middle stage of the disease is stage III, and the late stages, marked by little to no functional capacity, are stages IV and V. The stages refer to specific scores obtained on the UHDRS-Functional Assessment. Regardless of the method used to indicate the stage of the disease, symptoms progress over a 15- to 20-year period, ultimately necessitating long-term care or hospitalization for the client.[160] Death is often the result of secondary causes, such as pneumonia.[158]

The initial symptoms vary but are most often reported as alterations in behavior, changes in cognitive function, and choreiform movements of the hands.[216,220] The early symptoms of cognitive disturbances are most likely related to the degeneration of the caudate nucleus. The client may appear forgetful or display difficulty concentrating. During the early stages of HD, a client may have difficulty maintaining adequate work performance. Family members often identify the initial behavioral changes in the person with HD as increased irritability or depression. Irritability and depression may be attributed inappropriately to the decline in work performance rather than to the disease process.[48] Emotional and behavioral changes are often the earliest symptoms of HD.[17,65] Chorea, seen in clients with HD, consists of rapid, involuntary, irregular movements.[159] During the early stages of HD, chorea is often limited to the hands. A client may mask the initial chorea by engaging in behaviors such as manipulating small objects within the hands. These irregular movements are exacerbated during stressful conditions and decrease during voluntary motor activities in the early stages of HD. Chorea is absent when the client is sleeping. Onset of HD in teenage years is associated more often with early symptoms of **rigidity** than with chorea.[216,220]

Cognitive and emotional abilities progressively deteriorate over the course of the disease.[220] Disturbances in memory and in decision-making skills become more apparent during the middle stages of HD. Establishing and maintaining meaningful habits and routines for the individual who has HD are important ways to support continued participation in occupational pursuits. A client may be able to complete familiar tasks at work or in the home, but if the environment is changed or if additional demands are placed on the individual, task performance is significantly compromised. Further deterioration of cognitive abilities in the person with HD may result in dismissal from employment. The cognitive deficits most frequently associated with HD are problems with mental calculations, the performance of sequential tasks, and memory.[65] Verbal comprehension is often spared until the middle or later stages of the disease, and even then, dysarthria presents as a more significant issue than difficulty in comprehension until the late stages of HD.

Over the course of HD, depression often worsens and suicide is not uncommon.[216,220] Clients with HD are often hospitalized because of various psychiatric problems, including depression, emotional lability, and behavioral outbursts. Although the loss of function may contribute to the client's level of depression, depression is clearly identified as a specific characteristic of HD.[65,135] This affective disorder frequently is treated with various antidepressants. Periods of mania have also been reported in approximately 10% of individuals diagnosed with HD.

As the disease progresses, the chorea becomes more severe and may be observed throughout the entire body, including the face (Fig. 35.4).[160] Disturbances in gait are often observed during the middle stages of the disease, and balance is frequently compromised.[65] The individual with HD may display a wide-based gait pattern and have difficulties walking on uneven terrain. This staggering gait is at times misinterpreted by others in the client's life as evidence of alcoholism.[159] The client also has progressive difficulty with voluntary movements.[160] The performance of voluntary motor tasks is slowed (**bradykinesia**), and the initiation of movement is compromised (akinesia). Although handwriting ability may be spared initially, the client displays increasing difficulties with this task as the disease progresses. Letter size is enlarged, and letter formation, such as slant and shape, is distorted. Saccadic eye movements and ocular pursuits may be slowed at this stage of HD.[158] Slight dysarthria may be noted, which compromises communication.[65] Dysphagia is seen, and the client may choke on various foods. Difficulties may be noted with the coordination of both chewing and breathing while eating.

FIG 35.4 Typical chorea movements in a patient with Huntington's disease. (From Schindelmeiser J: *Neurologie für sprachtherapeuten*, ed 2, München, 2012, Elsevier GmbH, Urban & Fischer.)

In the later stages of HD, choreiform movements may be reduced because of the further deterioration of the corpus striatum and globus pallidus.[160] Hypertonicity and rigidity often replaces the chorea as the disease progresses, and the client experiences a severe reduction in voluntary movements. Severe difficulties in eye movement are common during the final stage of the disease.[158] At this stage, the client often needs significant support from others or resides in a long-term care facility. The client is usually unable to talk, walk, or perform basic ADLs without significant assistance.[136]

Medical Management

Medical management of clients with HD can address symptoms, but no effective course of treatment has been identified to arrest the progression of this disease.[48,171,181] Intervention based on replacing the deficient neurotransmitters has not been effective in changing the course or rate of progression of HD. Tricyclic antidepressants are often used to treat the depression seen in clients with HD, but MAOIs are contraindicated because of possible exacerbation of chorea.[220] Haloperidol may be used to decrease the negative effects of chorea on the performance of functional activities.[160] Haloperidol is prescribed cautiously and only when the chorea significantly compromises a person's daily activities. Tetrabenazine has also been approved as a treatment for chorea.[181] Medical management focuses on three areas: managing symptoms and reducing the burden of the symptoms, maximizing function, and providing education to the client and significant others regarding the course of the disease progression.[135] A team of professionals, including occupational therapists, is advocated when working with a client who has HD.

Investigations have noted how active engagement in activities, through the use of a multidisciplinary team approach, improved function for the client with HD.[48] Occupational therapy services were provided, once every 2 weeks, to clients diagnosed with HD to improve cognitive skills and executive functioning. Clients also participated in home exercises designed to improve overall muscle strength and fine motor skills. Following 9 months of intervention clients had a significant increase in gray matter of the caudate and prefrontal cortex. Significant gains were also noted in learning and memory skills following the 9 months of multidisciplinary intervention services.

A team of various medical professionals is needed to support the individual who has HD and support the family members and significant others in the client's life.[87,97] The perception of the illness experience and coping strategies used by the client who has HD is an important part of the overall medical services provided.[87] Likewise, the significant others in the client's life need support and guidance in developing coping strategies as their loved one experiences progressive deterioration.[97]

Systematic evaluation of a client with HD must be performed at regular intervals to identify the rate of symptom progression and modify intervention strategies. Standardized instruments are available for determining the presence and severity of various symptoms.[91,192] The Unified Huntington's Disease Rating Scale (UHDRS) is an evaluation tool that combines aspects from several instruments into a scale that can be administered within 30 minutes. The UHDRS is often administered by a team. This tool provides an accurate means of determining a change in the areas of "motor function, cognitive function, behavioral abnormalities, and functional capacity."[91] The UHDRS has been used to assess the rate of decline, and it demonstrates good reliability.[103] The occupational therapist should complete additional assessments before an intervention plan is developed. An evaluation would address functional daily living skills; cognitive abilities such as problem solving, motor performance, and strength; and personal interests and values. The occupational therapist must consider the client's role within the family and community and incorporate these data into the intervention plan. An evaluation at both the home and work site would provide needed information that could be modified if necessary.

Role of the Occupational Therapist

The role of the OT practitioner varies depending on the stage of the disease.[93] During the early stages of HD, an occupational therapist should address the cognitive components of memory and concentration. A client may still be employed at this stage. Strategies such as establishment of a daily routine, the use of checklists, and task analysis to break down tasks into manageable steps can be very helpful. These strategies provide the external structure and support to help the person with HD maintain functional abilities at both the workplace and home. Specific OT intervention to help clients develop verbal strategies and problem-solving skills have significantly improved functional abilities for individuals who have HD.[48] A work site evaluation can identify changes that would allow the person with HD to continue working. Modifications may include the use of tools such as organizers, electronic planners, and reminders to prompt an individual to complete regularly occurring tasks in the workplace. Family members should also be instructed in the use of these techniques. Environmental modifications such as providing a quiet workplace and reducing extraneous stimuli will decrease the impact of compromised memory and concentration on performing functional tasks in the workplace. Even during the early stages, work performance may deteriorate and the client may be dismissed due to an inability to meet the job essentials. This increases the stress experienced by the client from a financial perspective and from the loss of a role as a worker.

Psychological issues during this stage of the disease often include anxiety, depression, and irritability.[65,85] A client may express guilt that any of his or her children have a 50% chance of having HD.[159] The diagnosis of HD often is not confirmed until a person is 30 to 40 years old unless genetic testing is completed and confirms HD. The client may already be married and have children by that time. Decisions as to whether to complete predictive genetic testing on children may be a significant stressor for the client with HD and for his or her family members. As mentioned previously, not all individuals elect to be genetically tested, and sporadic presentations of HD do exist where no family member has HD. During this early stage of HD, clients may use denial as a coping strategy even though choreiform movements are present in the hands.[87]

Maintaining social contacts and engaging in purposeful activities are important in designing interventions for clients with HD.[159] Changes in cognitive abilities and unpredictable or exaggerated emotional responses may result in the loss of a job and decreased income for the family, even during this early stage of the disease.[65] This additional stress should also be considered when developing an intervention plan. The OT intervention plan must include community support services for the client with HD. OT services should include providing clients with information regarding support groups, opportunities to engage in community activities, and virtual resources accessible through the Internet. During the early and middle stages of the disease, rehabilitation services focused on cognitive skills, quality of life, physical strength, and endurance have shown positive results for individuals with HD.[208] Occupational therapy services were able to support cognitive as well as physical function.

The motor disturbances during the early stages of HD are usually limited to fine motor coordination problems.[65] The characteristic chorea may be noticed only as a twitching of hands when the client is anxious. OT should provide modifications to diminish the effect of chorea and fine motor incoordination on performance of functional activities.[93] This would include modifications to clothing and selection of clothing that does not require small fasteners such as small buttons, snaps, or hooks. Shoes with Velcro closures or elastic closures are recommended to compensate for diminished fine motor skills. Home modifications should be instituted at this stage to allow the client with HD to become familiar with the changes. Developing the skills of using adaptive equipment or modifications and then converting these skills into habits are critical during the early stage of HD. Typical modifications are the use of cooking and eating utensils with built-up handles, unbreakable dishes, a shower bench or seat with tub safety bars, and sturdy chairs with high backs and armrests. Throw or scatter rugs should be eliminated wherever possible in the home, and walkways should be kept free of clutter. The occupational therapist should establish a home exercise program with the client to address the flexibility and endurance of the entire body.[101] In a randomized control pilot investigation, individuals who were in the middle stage of HD engaged in a regular home exercise program to improve balance, gait, and level of physical activity. After completing 8 weeks of home exercises, substantial improvements were noted in physical abilities, but no significant change in quality of life was seen on the Short Form-36 (SF-36) instrument. The occupational therapist should develop home exercises that can be incorporated into the client's daily routine. As the movement disorder progresses with increased chorea and difficulties with oculomotor control, the client will no longer be safe driving a car and may experience further losses of community mobility. These further losses of independent function and control must be considered within the OT intervention plan. Alternative methods of community mobility must be explored.

As HD progresses, the role of OT changes to meet the client's needs.[93] During the middle stages of HD, further deterioration of cognitive abilities often requires the person to resign from a job. Engagement in purposeful activities is greatly needed at this stage and should be a focus of the OT intervention plan.[85,159] Decision-making and arithmetic skills show further deterioration, and family members may need to arrange for others to handle the client's financial matters.[65,142] Generally, comprehension of verbal information is better preserved than ability to complete sequential tasks during this stage. The occupational therapist should encourage the family to use simple written cues or words to help the family member with HD complete self-care and simple household activities. For example, selecting clothing items for the person with HD and placing the clothes in a highly visible area can prompt the individual to change from pajamas to daytime clothes in the morning. Arranging the bathroom with visual cues, such as putting the toothpaste and toothbrush by the sink, can remind the client to brush his or her teeth in the morning and evening.

During the middle stage of HD, the client may display increasing levels of irritability and depression.[220] Clients with HD may attempt suicide. The OT intervention plan should focus on the client's engagement in purposeful activities, particularly leisure activities.

When selecting craft activities, the therapist should always consider the client's interests but should also strive to ensure that no sharp instruments are required.[85,142] Modification of craft activities allows the client with HD to successfully complete a task with minimal support.[28] Materials often require additional stabilization to compensate for the client's movement disorders, and any tools used in the leisure activity, such as a wood sander and paintbrushes, should have enlarged or built-up handles. New leisure activities can be explored during the middle stage of HD.[198] In one study, clients in the middle stage of HD were provided with the opportunity to engage in gardening activities. A multidisciplinary team designed these activities, and OT figured prominently in the assessment and design of the program. Positive results were noted following the use of this program.[198]

Motor problems become more apparent during the middle stage of HD, necessitating further modifications in daily living tasks.[93,192] The client's compromised balance may require that tasks such as dressing, brushing teeth, shaving, and combing hair be performed while the client is seated. The client may require the use of a walker or wheelchair at this stage. A rollator walker is preferred to a standard walker without wheels. The walker may need to be fitted with forearm supports to provide additional stability when the client is ambulating. When a wheelchair becomes necessary, it should have a firm back and seat; however, additional padding is often required on the armrests because of the client's chorea. Many clients with HD are better able to move the wheelchair with their feet than with their hands. The seat height of the wheelchair should be fitted to allow the client to use his or her feet to move the chair, if possible.

Fatigue is a common issue during the middle stage of HD and can be addressed by taking frequent breaks during the day. Breaks must be scheduled because the person with HD may not readily recognize fatigue. Clothing should have few or no fasteners, and shoes should be sturdy with low heels.[142] Additional adapted equipment that may prove helpful for the client with HD includes shower mitts, an electric razor or chemical hair removal method, covered mugs, and nonslip placemats.[93] The choreic movements may become so severe as to necessitate the use of a bed with railings. Padding should be used on the railings, and additional cushions should be used in the bed.

Because of excessive movements associated with chorea, the client with HD often needs to consume 3000 to 5000 calories per day to maintain weight.[142] Clients with HD display a higher energy expenditure compared to individuals without HD and consequently have issues with weight loss and difficulties maintaining appropriate weight.[211] Smaller, high-calorie meals should be provided five times a day. This schedule may require additional support from family members or a personal care attendant. Dysphagia, poor postural control, and deficient fine motor coordination compromise the client's ability to eat.[93] Positioning during feeding is crucial, and the trunk should be well supported during mealtime. The client with HD should be able to support his or her arms on the table while the feet are stabilized. Feet may be supported on the floor, or the client may wrap the feet around the legs of the chair for additional support. Problems with dysphagia can be addressed with positioning, oral motor exercises, and changes in diet consistency. Soft foods and thickened fluids are preferable to chewy foods, foods with mixed textures, and thin liquids. Nutritional support has been successfully used for clients with HD to maintain appropriate weight.[211] Appropriate body weight is important to maintain overall health for the client with HD.

During the final stages of HD, the client often depends on others for all self-care tasks because of the lack of voluntary motor control.[93,136] In some clients, the chorea may diminish, leading to rigidity. The occupational therapist provides important input on positioning and the use of splints to prevent contractures at this stage. Because of the risk of aspiration, oral feedings are provided by trained personnel; alternatively, the client may receive nutrition through a feeding tube.[142] A combination of oral feedings and tube feedings may be used during this stage.

Although cognitive abilities continue to deteriorate, the level of functional decline is difficult to assess because of dysarthria and the loss of motor control.[65] Dementia is part of the HD profile and must be considered in the development of the intervention plan. For example, a person in the late stage of HD may still recognize family members and enjoy watching television. The occupational therapist should explore the use of various environmental controls to allow the client control of and access to the immediate environment.[16] Providing a touch pad or switch for selecting television channels may prove beneficial for the client.

Behavioral outbursts have been reported in approximately one-third of clients with HD living in long-term care facilities.[136] OT can decrease the frequency of these outbursts by organizing consistent daily schedules and routines for the client with HD.

Section 3 Summary

Although HD is a progressive, degenerative process, OT has much to offer clients with this disease.[85,93,142,159] The diminishing ability to control the environment has been identified as one of the variables contributing to the deterioration of function in clients with HD. Throughout the course of the disease, OT addresses the client's ability to exercise a degree of control over the environment and engage in purposeful activity.

Section 4 Multiple Sclerosis

Diane Foti

Incidence

Multiple sclerosis (MS) is the most common progressive, inflammatory neurologic disease in young adults. Almost 70% of cases show signs and symptoms between the ages of 20 and 40 years of age; however, the disease has been identified in children as young as 3 and adults as old as 67.[174] The prevalence in the United States is approximately 350,000.[33] It is more prevalent in women than in men.[36] The highest prevalence of the disease is in Caucasians of northern European ancestry.

Typically MS has been considered a disease of the white matter, but research now shows there are also lesions in the gray matter structures. Large lesions, known as plaques, are often seen in the spinal cord (50%), optic nerves (25%), brainstem/cerebellum (20%), and periventricular white matter (Fig. 35.5). The myelin is typically damaged in discrete regions of the white matter, with relative preservation of the axons and astrocytic gliosis.[174] Disruption of the myelin sheath has differing effects on axonal conduction, depending on the amount of myelin deterioration or inflammation and the length of the damaged segment.[36] When axons are conducting impulses in a slower manner because of inflammation of the myelin sheath, a person with MS may have intermittent symptoms of sensory distortion, incoordination, visual loss, or weakness. This inflammatory process accounts for the unpredictability of the disease.

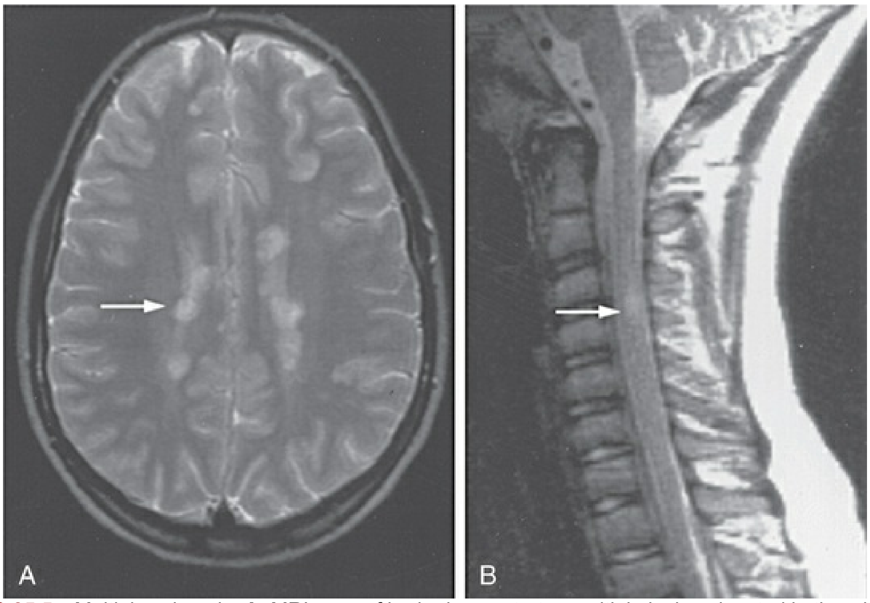

FIG 35.5 Multiple sclerosis. **A,** MRI scan of brain demonstrates multiple lesions located in the white matter characteristic of multiple sclerosis *(arrow)*. **B,** MRI scan of spine indicates a demyelinating plaque of multiple sclerosis in the midcervical region *(arrow)*. (From Kliegman RM, et al, editors: *Nelson textbook of pediatrics,* ed 18, Philadelphia, 2007, Saunders.)

In advanced cases of MS, acute and chronic plaques develop throughout the white matter including the corpus callosum. Axons may be damaged and severed in advanced cases of MS and result in extensive loss of function. MRI may show lesions and changes in brain volume.[26]

Etiology

The specific cause of MS is unknown. Current theories include environmental, immunologic, infectious, and genetic factors. Environment is considered a factor because there is a higher incidence of MS among individuals living farther north of the equator. Studies have shown that 30% to 60% of new clinical attacks of the disease occur after a cold, flu, or common viral illness.

Genetics plays an important factor, as identical twins have a 25% chance of developing the disease, whereas an average person in the United States has a 0.1% chance of developing MS.[144]

Clinical Picture

The symptoms that occur in individuals with MS are related to the area of the CNS affected. These symptoms may include the following:

- Fatigue
- Numbness or weakness in one or more limbs that typically occurs on one side of the body at a time, or the legs and trunk
- Partial or complete loss of vision, usually in one eye at a time, often with pain during eye movement
- Double vision or blurring of vision
- Tingling or pain in parts of the body
- Electric-shock sensations that occur with certain neck movements, especially bending the neck forward
- Tremor, lack of coordination, or unsteady gait
- Slurred speech
- Dizziness
- Problems with bowel and bladder function[123]

Symptoms may temporally worsen when body temperature is elevated but resolve with time. Cognitive deficits are reported to occur in 30% to 70% of persons with MS but do not necessarily correlate with a physical decline.[6,148] Cognitive deficits have been documented in individuals during early stages of the disease.[189] In advanced stages of the disease process, the individual may have varying degrees of paralysis, from total lower extremity paralysis to involvement of the upper extremities, dysarthria, dysphagia, severe visual impairment, ataxia, spasticity, nystagmus, neurogenic bladder, and impaired cognition.

The course of MS is unpredictable. It is marked by episodes of exacerbation and remission.[148] An **exacerbation** may be an episode as minor as fatigue and sensory loss or as extensive as total paralysis of all extremities and loss of bladder control. **Remission** may involve total resolution of the symptoms, slight return of some function with the symptoms remaining, or a short plateau in which no new symptoms occur but the current symptoms remain.

Four patterns seen in MS are (1) relapsing and remitting, (2) secondary progressive, (3) primary progressive, and (4) progressive relapsing.[132] The relapsing and remitting form of MS involves 85% of the MS population and leads to episodes of exacerbation and remission of symptoms that result in a slow, stepwise progression as the deficits accumulate. The secondary progressive course of the disease begins with a pattern of **relapses** and remissions but evolves into the progressive form of the disease given time. Before the introduction of disease-modifying drugs, approximately 50% of clients with relapsing and remitting MS progressed to the secondary progressive form of the disease. Marguerite was first diagnosed with the relapsing remitting form of MS and was later diagnosed with the secondary progressive course of the disease. She is now experiencing sustained diminished fine motor abilities and sensation in her left hand. She also has weakness in one lower extremity, requiring the use of an ankle-foot orthosis and a quad cane.

Though not as common as adult-onset MS, childhood MS does occur and children account for 3% to 10% of the MS population.[72,161] Ninety-five percent of children with MS initially experience a relapsing and remitting course of the disease. Over time, secondary progressive MS will develop in approximately 60% of children.[207]

The primary progressive form of MS (10% of the MS population) is distinguished by a downward course with episodes of exacerbations or remissions. Individuals with this form eventually become nonambulatory and incontinent of urine and may have dysphagia and dysarthria, severely compromised lower extremity function, and varying limitations in upper extremity function. These individuals have difficulty remaining in the workforce and require more assistance with activities of daily living.

The progressive relapsing form of MS is the least common of the four types of MS. This type of MS accounts for approximately 5% of the MS population. These individuals experience a steady worsening of symptoms but with episodes of exacerbations.[212]

Kaufman and colleagues found that individuals with MS typically live 6 years less than those without MS.[97a] Approximately 50% of individuals with MS live for at least 30 years after onset of the disease, and 50% die of complications of MS. Most people with MS will live to experience other changes related to normal aging, which can complicate the clinical picture. Typically, the course of the disease can generally be determined after 5 years of the initial symptoms (Box 35.2).

Box 35.2

Predictors of Poor or Favorable Prognosis at the Onset of Multiple Sclerosis

Predictors of a Poor Prognosis

- Progressive course
- Age at onset >40 years
- Cerebellar involvement
- Polysymptomatic onset
- Male sex

Predictors of a Favorable Prognosis

- Minimal disability 5 years after onset of the disease
- Complete, rapid remission of the initial symptoms
- Age at onset <40 years
- Only 1 symptom during the first year
- Onset with sensory symptom or mild optic neuritis

Medical Management

Medical management is dependent on the type of MS. Disease-modifying drugs are used in those with relapsing and remitting MS, and for all forms of the disease anti-inflammatories are used to treat exacerbations.[148] The anti-inflammatory medications, such as prednisone and methylprednisolone, help reduce symptoms and shorten the duration of the exacerbation.[36,132] For the relapsing and remitting form of MS, disease-modifying medications are thought to have an effect in slowing progression of the disease. These medications are available in injectable, oral, and infusible forms. Patients treated with these medications, administered by self-injection, showed a one-third reduction in frequency of exacerbations. Studies regarding the effectiveness of these medications in individuals with the progressive form of the disease are ongoing. The physician and patient determine which is the most appropriate form of treatment. It is important for the occupational therapy practitioner to understand that some individuals experience side effects from the medications, which affect function for a day or so following application.

Medical management primarily focuses on treating the symptoms of the disease. Symptom management includes treatment of spasticity, bladder management, prevention of bladder infection, and management of pain and fatigue. Symptom-specific medications may be prescribed. The OT practitioner can learn more specifically about all of the medications from the MS Society medication site.[144] Spasticity is often managed with medications; unfortunately, this may also worsen the muscle weakness. Bladder management may involve the use of incontinence pads or catheters, along with prevention of bladder infections. Fatigue should be managed with good nutrition, prevention of over-fatigue with energy-conservation methods, regular exercise, establishment of routines for rest and sleep, and control of stress; in addition, several medications are available that may help with fatigue.[133] The ADL evaluation for Marguerite should include questions about bowel and bladder management and how it affects her function at work, at home, and during sleep.

Changes in cognition and mood often occur in persons with MS. Cognitive deficits are reported to occur in 30% to 70% of the MS population but do not necessarily correlate with a physical decline.[6,80,149] The volume of lesions seen on MRI correlates with cognitive decline in the areas of complex attention, processing speed, and verbal memory.[197] One investigation evaluated overall brain atrophy and size of the ventricles in relation to cognitive abilities. The results suggested a relationship between an increase in the size of the third ventricle and a decrease in cognition.[26]

Emotional changes such as depression may also be present. Persons with MS and other chronic conditions experience a higher rate of depression than the general population does.[143] Depression may have different causes and should be assessed by the team. Depression may be caused by a physiological response to the disease process, may be a psychological response to the diagnosis, or might be a side effect of one of the disease-modifying medications. Depression may occur at any stage of the disease process. It should be addressed promptly because it may contribute to fatigue and an inability to cope with challenges and make adaptations as needed.[143] Dementia may develop in individuals who exhibit euphoria and indifference. Dementia occurs in less than 5% of the population with MS.[81]

The most widely accepted tool to measure clinical impairment in a person with MS is the Expanded Disability Status Scale (EDSS).[157] The scale should be completed by a physician because it includes a detailed neurologic examination. The EDSS combines an assessment of neurologic function and a scale to measure a client's ambulatory and functional mobility status. There are limitations with this tool; it does not allow specific assessment of all ADLs and is not sensitive to potential cognitive and sexual deficits in MS.[157] The OT practitioner should be familiar with the EDSS because it is often mentioned in the literature as a baseline for evaluating disability and has been adopted by the International Federation of MS Societies.[94,217] The MS Functional Composite was developed to measure leg function and ambulation, arm and hand function, and cognition.[43,134] It can be used for periodic baseline function and may be more sensitive for use as baseline cognitive evaluation than the EDSS.

Role of the Occupational Therapist

OT practitioners provide services for persons with MS in a number of settings. The type and degree of intervention provided will be determined by the setting, the type of reimbursement, and the client's and caregiver's responses to intervention. Preisnner provides an overview of the OT role for persons with MS. This reference is a starting point for the beginning practitioner.[166]

Evaluation includes an occupational profile to guide the evaluation process. The occupational therapist then selects the necessary instruments to assess occupational performance of ADLs, IADL education, work, play, leisure, and social participation. During the performance of various occupations, the following skills should be evaluated: motor and praxis, sensory-perceptual, emotional regulation, cognitive, and communication skills. This is generally accomplished with a combination of standardized and nonstandardized assessments, through the use of interviews with the family and client, and by observation. The MS Society recommends a number of standardized evaluations appropriate for the OT evaluation.[145] Optimally, a home evaluation should be completed. Because not all settings allow a home evaluation, the occupational therapist should interview the client and caregiver regarding the home environment and potential barriers. Because MS has an unpredictable course, the client may need referral for other resources and will benefit from periodic reevaluation by an occupational therapist.[12] If the client has a cognitive deficit, a family member or significant other should be included in the evaluation process to provide accurate information, if the client allows. It is essential that actual performance evaluations be used for persons with MS because studies have shown that self-report is frequently inaccurate.[79] Having an understanding of the client's cultural, social, and spiritual perspective will provide insight into available support systems and their impact on the client's adaptation to the disability.

Assessment of sensorimotor skills is discussed thoroughly in previous chapters. Because endurance and fatigue are such significant factors, it is important to not rely solely on the results of assessment of a specific client factor. For example, a manual muscle test is not likely to accurately reflect the degree of weakness experienced throughout the day. Observing a client performing a functional activity over a certain period or gathering information about the client's daily activity patterns will provide the clinician with a more accurate evaluation of fatigue.[90] The National Multiple Sclerosis Society recommends use of the Modified Fatigue Scale (MFS) or the Fatigue Questionnaire to understand specific problems resulting from fatigue.[133] In Marguerite's case, the MFS assessment may help determine the impact of fatigue on her daily activities.

When evaluating a client's activity patterns, the OT practitioner should also ask about sleep patterns. Disrupted sleep patterns sometimes contribute to fatigue in the MS population. The information can be shared with the client's physician so that appropriate intervention can be undertaken either medically or with counseling to address the habits and routines that may contribute to the client's disrupted sleep.[15] Marguerite's OT practitioner may ask whether toileting issues disrupt sleep also.

MS may also affect visual abilities, and compromises may be noted in visual tracking, scanning, and acuity. An objective evaluation will help determine the type of deficits, when the deficits occur, and more specifically how they affect ADLs and IADLs.

Perceptual processing and cognitive status should be reassessed periodically. The data gathered will help identify specific deficits and their potential impact on functional activities so that the OT practitioner can incorporate this information into family training.[147] Cognitive deficits vary from a slight decrease in short-term memory and attention span to poor orientation and severely impaired short-term memory. The literature is mixed on the relationship between cognitive deficits and the degree of physical deficits.[50] Assumptions should not be made regarding the presence or absence of cognitive deficits based on physical deficits or abilities or on an individual's basic social skills. A person with significant physical deficits may have fewer cognitive deficits than an ambulatory person with MS. The client's perceptual and cognitive deficits are factors that must be considered when deciding whether the client needs close, constant supervision or can stay home alone. Various standardized cognitive and perceptual assessments are included in previous chapters of this text. Basso developed a screening tool for cognitive dysfunction in individuals with MS. Basso's tool was found to be both sensitive to functional impairment and cost-effective.[20] Occupational therapists or practitioners in other disciplines can use this tool when evaluating a person with MS for cognitive deficits. ADLs may be evaluated with a check-off list, a standardized evaluation such as the Assessment of Motor and Process Skills,[54] or other standardized assessments for ADLs.[13]

Marguerite's occupational therapist should consider completing a cognitive screening or, as appropriate, a full cognitive evaluation. Compensation for mild cognitive deficits may contribute to fatigue. If the results of the cognitive screen indicate deficits, Marguerite may also benefit from a full cognitive assessment administered by a psychologist or neuropsychologist to help her better understand deficits and obtain a baseline of her current cognitive abilities. These assessments could help Marguerite receive disability benefits if her MS deficits progress to the point where she is unable to work. The OT practitioner should also teach compensatory strategies for cognitive deficits along with how fatigue may contribute to cognitive difficulties.

Evaluation of the cultural, social, and physical environment is important to consider with each client. MS is usually identified during the phase of life in which a person is raising a family and developing a career, as was seen with Marguerite. Because the disease is unpredictable and fluctuating, it leads to disruptions in normal daily activities and in family life. These disruptions create stress for the spouse or partner, children, and other family members. The occupational therapist must determine the type of support the client can expect from family members. The therapist may recommend that Marguerite begin to teach her teenage children to help prepare dinner as an energy-conservation technique.

The occupational performance assessment should include listening to the client and family members describe performance patterns to identify the activity demands, typical daily habits, routines, and roles. Assessment and treatment should also focus on the client's engagement in the occupations and the impact on his or her life, sense of self-identity, and sense of competency.[116]

Evaluating and treating the client at different times during the day will often reflect different levels of fatigue. Understanding the performance patterns of rest periods; quality and amount of sleep; exercise patterns; intensity of activity (activity demands) during various times of the day, week, or month; and the time of the day when activities are most challenging is critical in developing treatment planning strategies. Understanding the performance patterns may help the OT practitioner understand how the side effects of the disease-modifying medications affect activity and also how to encourage integrating use of the medication into daily routines while managing side effects.

Ethical Considerations

Consider the following situation: a client, with multiple sclerosis, is able to drive the car but has cognitive deficits that are exacerbated by fatigue in the afternoon. Because the client has discontinued work, the family members do not want to take away driving privileges as well. However, by continuing to drive, the client places himself and others at risk for injury. The occupational therapist may need to educate the family about the deficits by providing examples of the ways in which cognition is evaluated and by discussing the ways in which cognitive deficits affect driving and other daily activities. The occupational therapist is responsible for reporting the driving risk to the client's physician.

Emotional and behavioral issues vary depending on the premorbid personality, progression of the disease, coping skills, and social environment of the person with MS. Cognitive deficits and denial of the progressive nature of the disease may lead to behavior that places the client at risk and makes management difficult. If family members do not understand or recognize the client's behavioral problems, further complications may arise when the behavior is not restricted or modified by the family. Other emotional and cognitive issues include a client who is depressed or labile, has poor memory, refuses assistance from outside caregivers, or uses poor judgment regarding safety with medications and transfers. Each client demonstrates a unique set of behavioral issues and requires individual evaluation and an intervention approach that encompasses the client and caregivers.

Goal Setting and Intervention

For a client with a progressive disease such as MS, goal setting focuses on the client's need to adapt as the disability progresses and during the relapse phases. Goal setting should be client centered and client driven, and it should be short term with follow-up provided.[12] Families often need to negotiate role changes to accommodate the person with MS who may not be able to participate consistently in a previously established family role. For example, with Marguerite's family, her husband may consider taking over the job of grocery shopping. Marguerite and her children can add items to an electronic phone application that allows her husband to have a comprehensive grocery list**.** Hwang and colleagues found that support from family and friends helped clients adjust to the diagnosis, maintain their health, and participate in productive and social activities.[92a] The client's ability to adapt depends on the family's and client's acknowledgment of deficits and willingness to consider alternatives. OT intervention may include (1) problem-solving compensatory strategies, (2) fatigue management group treatment intervention,[62,223,224] (3) role delegation, and (4) the use of adaptive equipment to compensate for motor, sensory, endurance, cognitive, and visual deficits. The National Multiple Sclerosis Society has developed guidelines and recommendations for care at home that address many ADL issues requiring OT treatment. These guidelines are by no means all-encompassing regarding interventions for ADLs and IADLs but provide a solid starting point to problem-solve with the patient and family.[147] For specific techniques related to the individual's deficits, see Chapter 10.

Marguerite may be referred to an OT group designed for persons who have MS to learn fatigue management techniques.[122] The fatigue management group intervention may involve analyzing daily and weekly routines to identify activities that can be eliminated, modified, or delegated. Marguerite may be asked to set short-term realistic goals. She may consider grocery shopping online or delegating this task to her husband. Marguerite will need to evaluate the number of activities in which her teenagers participate and the possibility of carpooling so her teenage children can participate in various activities. She may need adaptive equipment for activities that require bilateral strength and dexterity because of the loss of sensation and dexterity in her left hand. Because Marguerite is receptive to potential home modifications she and her husband can work with the OT practitioner to determine the most important immediate changes and future changes that may be needed. Long-term changes and home modifications should be discussed in light of her MS diagnosis being changed from relapsing-remitting to secondary progressive.

The benefits of an exercise program should be discussed with clients who have MS. An individual may already have an exercise program recommended by a physical therapist, and coordination would be important so that the client is able to engage in a manageable exercise program. The OT role may involve helping clients with fatigue management issues to fit the exercise program into their usual routine. It has long been thought that exercise will exacerbate and worsen symptoms, but recent studies report benefits such as improved quality of life, reduced fatigue, and improved ambulation from a regular exercise program.[130,151,219] Fatigue management recommendations should include assessment of the client's typical exercise routine.

As a method of learning coping strategies, Marguerite may benefit from attending a cognitive behavioral therapy (CBT) support group. Evidence shows that participation in CBT may help with depression, which is common among individuals with MS.[224,225]

Section 4 Summary

Because MS affects each person in a unique way, individual evaluation is essential to determine the client's deficits and strengths. Individuals with MS may range from being ambulatory with limited symptoms, primarily fatigue and energy management issues, to partially limited in mobility and hand function, to the need for full-time wheelchair use and assistance with ADLs. Working with clients who have MS requires the practitioner to use expertise in evaluation and intervention from all areas of occupational performance. A comprehensive evaluation will include status of ADL/IADL, sensorimotor, visual-perceptual, and cognitive and depression screens. The social, cultural, and physical environment must also be considered. Because Marguerite's occupational profile indicates many areas are affected by her MS symptoms, the therapist may ask her to prioritize them. If her husband is present he may also prioritize the issues he sees as most problematic.

With a pattern of relapses and remissions over the course of the disease process, development of an OT intervention plan is particularly challenging. The OT practitioner should know the client's specific type of MS diagnosis, as this will drive the clinical interventions. If the client has relapsing and remitting and is currently experiencing an exacerbation/relapse, minimal changes to the home environment may be made, as the client is expected to improve. If an individual has progressive MS or secondary progressive MS, the OT practitioner may strongly recommend more extensive home modifications such as a roll-in shower. Because the client may expect return of function, he or she may deny deficits and refuse to adapt to a change in status; this attitude can create safety problems. The OT practitioner focuses on assessing the current level of functioning and the best methods for the client to adapt to current changes in status.[125] The occupational therapist may also assist the family in making long-range, realistic plans. For example, if the family is planning to remodel the bathroom, the therapist may encourage consideration of a roll-in shower and not just a standard shower stall with a shower seat.

As with the other progressive neurologic conditions, working with clients who have MS requires a multidisciplinary approach. In addition to the occupational therapist, a physician, physical therapist, registered nurse, social worker, and psychologist may be involved as team members. Because the social environment may create complex and difficult problems, good communication among all team members is needed to ensure that the team goals are congruous. The occupational therapist has a unique perspective to offer the team regarding the client's strengths and weaknesses when cognitive, perceptual, psychosocial, and motor abilities are assessed and treated in a functional context.

Section 5 Parkinson's Disease

Winifred Schultz-Krohn

Incidence

Parkinson's disease (PD) is one of the most common adult-onset, degenerative neurologic disorders,[55] second only to Alzheimer's disease.[193] Three classic symptoms are associated with PD: tremor, rigidity, and bradykinesia. The incidence rate for PD varies greatly, from 10 to more than 400 per 100,000.[226] Prevalence increases with age, and the disease affects 1.4% of the population over the age of 55,[52] but approximately 3% of all PD cases are initially recognized in individuals younger than 50 years of age.[193] Approximately 10% to 30% of clients with PD report first-degree relatives who also have PD. Gender differences have been noted; the prevalence of PD in men between the ages of 55 and 74 is slightly higher than in women of the same age. After the age of 74, women show a slightly greater prevalence of PD than do men. Diagnosis is most often made after the age of 60.

The etiology for PD has not been definitively established.[18,78] Previous literature referred to familial and sporadic forms of PD, but those distinctions are being revised in light of current genetic research. Although a positive family history has been established as a risk factor for PD, a single predictive genetic marker has not been absolutely identified. To date, mutations have been found in several genes that are associated with Parkinson's disease and include alpha-synuclein, parkin, ubiquitin carboxyl terminal hydrolase, SCA2, and DJ-1.[193] These mutations have been found to have a role in abnormal protein processing in cells.[18] Current genetic work has identified a gene mutation in familial PD, and this genetic mutation has also been identified in clients with sporadic PD, providing further evidence of a genetic determination for this disease process.[193]

Previously, environmental factors were considered as a possible cause of PD.[78] The possibility of an exogenous agent's producing PD gained considerable recognition when narcotic addicts began using 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP). After using MPTP, many addicts quickly exhibited parkinsonism that "strictly mimics the clinical and anatomical features of Parkinson's disease."[78] Although environmental factors have not been completely eliminated as contributing factors in the etiology of PD, these appear to play less of a role when compared to various genetic mutations.

Pathophysiology

The neurologic structure associated with PD is the substantia nigra, specifically the pars compacta portion.[153] The pars compacta receives input from other basal ganglia nuclei and appears to serve as a modulator of striatal activity.[160] The substantia nigra nuclei undergo significant deterioration as the disease progresses. The significant reduction in the dopaminergic neurons in the substantia nigra pars compacta produces a decrease in activity within the basal ganglia and an overall "reduction in spontaneous movement."[160] The substantia nigra serves as one of the major output nuclei for the basal ganglia to other structures.[156] In addition to the loss of dopaminergic neurons, intracytoplasmic inclusions are found on postmortem examination within the substantia nigra.[153] These intracytoplasmic inclusions are also known as Lewy bodies.[59] Although the greatest amount of neurodegeneration is found in the pars compacta substantia nigra, destruction of other neurologic structures has been reported.[153] Deterioration is also seen in the remainder of the substantia nigra, locus ceruleus, nucleus basalis, and hypothalamus.

Clinical Picture

PD is characterized as a slowly progressive, degenerative movement disorder.[160] The diagnosis of PD is usually made after the age of 55. Although PD is not considered fatal, the degeneration of various neurologic structures severely compromises performance of functional tasks. A person diagnosed with PD may live an additional 20 to 30 years, with a progressive loss of motor function that eventually requires specialized care.[59] A person with PD has an increased risk for developing pneumonia, which may be fatal.

PD is characterized by dysfunction in both voluntary and involuntary movements.[160] A classic triad of symptoms includes tremor, rigidity, and a voluntary movement disorder (Fig. 35.6). By the time these "motor symptoms are clinically recognized, 60% of the dopaminergic" cells of the substantia nigra have deteriorated.[193] The disturbances in voluntary movement are identified as difficulty initiating movement (akinesia) and slowness in maintaining movement (bradykinesia). The bradykinesia and akinesia are often the most disabling motor symptoms for the client with PD.[51] The delay in initiating movement patterns and the slowness in executing the motion compromise functional tasks such as driving, dressing, and eating.

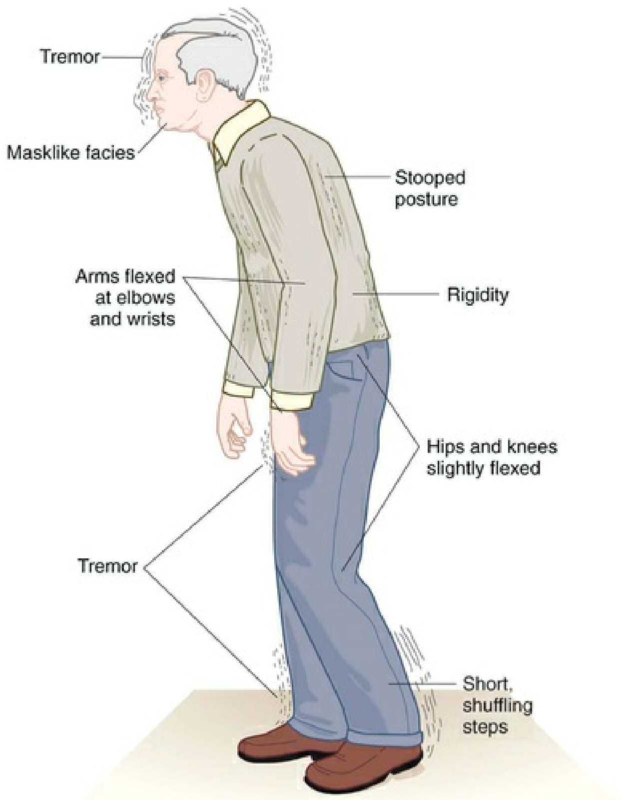

FIG 35.6 Symptoms and signs of Parkinson's disease. (From Hopper T: *Mosby's pharmacy technician: principles and practice*, ed 3, St. Louis, 2012, Saunders.)

In addition to the slowness of movement, rigidity is a characteristic of PD. Rigidity is the stiffness within a muscle that impedes smooth movement. This stiffness occurs in both directions for each plane of motion at a specific joint.[167] The characteristic resting tremor with a rate between 4 and 5 Hz is a disturbance of involuntary movement.[128] This tremor often diminishes with activity, but in some clients the tremor persists during performance of functional activities.

Additional symptoms of PD are disturbances in gait and postural reactions and masked face with decreased facial expressions, and emotional disturbances including depression and psychosis.[77,160] Deterioration in gait is seen throughout the course of the disease.[182] Initially, gait may be fairly normal, but as the disease progresses, changes in stride length and speed of gait are apparent. The characteristic **festinating gait** is often seen; as the client walks, the stride length decreases in length and the speed slightly increases, creating a shuffling effect. A reduced arm swing during ambulation is evident, and trunk rotation is markedly decreased during walking. Another motor disturbance associated with gait is the phenomenon of "freezing."[73] Freezing occurs when the person ceases to move, often after attempting to initiate, maintain, or alter a movement pattern. During gait, freezing may be seen as the client attempts to change directions or approach a narrow hallway or stairs. As the client attempts to alter the trajectory of walking to turn to enter another room, he or she may cease moving. Freezing can also be seen during other motor tasks, such as writing, brushing teeth, and speaking.

Postural abnormalities associated with PD include a flexed, stooped posture with the head positioned forward.[131] The client tends to stand with flexion at the knees and hips. In addition to the stooped posture, balance reactions are compromised.[165] Righting and equilibrium reactions are markedly reduced in effectiveness, and the person with PD may experience frequent falls.

Approximately 50% of individuals with diagnosed PD exhibit depression,[165] which is not merely reactive to the severity of symptoms or the chronic nature of the disease.[59] The depression seen in individuals with PD appears to be related to a serotonergic deficit, which is similar to that in clients without PD who have depression. Complicating the feature of depression is a decrease in facial expressiveness caused by akinesia.[165] This decrease in spontaneous facial expressions, or so-called masked face, is characteristic of clients with PD. Initially, decreased facial expressions are seen unilaterally, but as the disease progresses, spontaneous expression decreases on both sides of the face.[59] Individuals with PD may also self-limit social interaction because they are embarrassed by their decreased facial expressions and movement disorders. Psychosis is also a common complication for clients with PD, and they may experience hallucinations and delusions.[77] These disturbances compromise cognitive abilities and often limit functional skills.

Mental status is fairly normal throughout the early stages of PD, but visual-spatial perception is often compromised.[165] Higher-order cognitive disorders are common in clients with PD. Clients with PD often have difficulty shifting attention among various stimuli. Processing simultaneous information is often difficult for the individual with PD, and tasks that require a sequential process are somewhat easier to perform. Driving a car presents a particular challenge because it necessitates the processing of multiple forms of information in a simultaneous manner. Some self-care tasks, such as brushing teeth, have a clear sequence that can be followed; these activities can be performed with less demand on cognitive functioning. Although dementia is seldom seen in clients with an earlier-onset form of PD, approximately one-third of people over 70 years old who have PD display dementia.

Additional symptoms associated with PD include autonomic dysfunction, dysphagia, and dysarthria.[165] A client with PD may have bowel and bladder problems, with reduced intestinal motility producing constipation. Clients often report an increase in the frequency and urgency of urination. Clients also frequently complain of orthostatic hypotension, but syncope is rare.[59] Clients with PD occasionally report periods of sweating and abnormal tolerance of heat and cold.[165] Because speech volume is often decreased, persons with PD often seem to whisper. Articulation is imprecise, and speech is monotone. Dysphagia tends to occur in the later stages of PD, and clients may be at risk for choking and aspiration pneumonia resulting from the dysphagia.

The course of the disease varies from person to person, but the first clinical symptom identified is typically a unilateral resting tremor in the hand.[128] Hoehn and Yahr[89] established a scale identifying the progression of symptoms in PD. A client at stage I exhibits unilateral involvement, typically a hand tremor, but no impairment of functional abilities is reported. A client is able to complete personal ADLs and IADLs, but performance often requires additional effort and energy. Depending on job demands, a client with PD at stage I is often employed but may require modifications to the work site. During this stage the client's handwriting may become very small, with letters that are cramped together.[59] This change in handwriting is referred to as micrographia. The client may also complain of muscle cramping when required to write for extended periods. Slight rigidity may be seen when the client is asked to rapidly open and close the involved hand.

Stage II denotes a progression of symptoms and the development of bilateral motor disturbances.[89] Although the course of PD is variable, this stage is usually seen 1 to 2 years after initial diagnosis. Even though tremors or rigidity may be noted bilaterally, the client can still perform ADL skills. Performance of IADL skills may require modification because of motor difficulties. Work, depending on the job requirements, often requires additional modifications, and the client may require several rest breaks during the day. The client should make decisions at this point regarding the benefits of remaining employed relative to the energy expenditures. Posture becomes slightly stooped, with flexion at the knees and hips. The person with stage II PD is still able to ambulate independently.

As PD progresses to stage III, the client experiences delayed righting and equilibrium reactions. Balance is impaired; the client has difficulty performing daily tasks that require standing, such as showering and meal preparation. Employment may be difficult because of its energy demands. Safety in walking is a concern because of the client's reduced balance, and home modifications are necessary at this stage. A person with stage IV PD has significant deficits in completing daily living tasks. The client is still able to ambulate at this stage, but motor control is severely compromised and negatively affects dressing, feeding, and hygiene skills. Stage V is the final stage of PD. The client is typically confined to a wheelchair or bed and depends on others for most self-care activities. The rate of progression through these stages varies from person to person, but PD is a slowly progressive disorder.

The extent of PD symptoms in individual clients has been measured using the Unified Parkinson's Disease Rating Scale.[61] This scale evaluates a client's motor skills, functional status, and extent of disability. Motor skills are evaluated by a trained observer.[178] The functional status and extent of disability are measured through a client interview that includes items addressing ADL skills and cognitive and emotional factors.[119] This instrument has been used for research and clinical practice to measure the effectiveness of various interventions in reducing PD symptoms (Table 35.4).

TABLE 35.4

Progression of Symptoms in Parkinson's Disease

Stage	Symptoms	OT Management
1	Unilateral tremor, micrographia, poor endurance for previous occupations, fatigue	Work evaluation if client is employed; work simplification for work and home settings; develop the habit of taking frequent rest breaks; use of utensils with enlarged handles
2	Bilateral motor disturbances, mild rigidity reported, difficulties with simultaneous tasks, difficulties with executive function	Energy conservation techniques related to ADLs; develop a daily flexibility exercises focused on trunk rotation; driving assessment and alternatives for community mobility, use of task analysis to structure sequential tasks
3	Balance problems with delayed reactions, difficulties with skilled sequential tasks	Environmental modifications in the home including raised toilet seats, chairs with arm rests, removal of throw rugs; use of visual cues and supports for sequential tasks
4	Fine motor control severely compromised, oral motor deficits	Modifications to support participation in self-care tasks, changes in food textures
5	Client severely compromised in regard to motor skills, dependent with ADLs	Use of environmental controls to allow access to environment

Medical Management

The most frequently used medical management strategy for PD is the provision of a dopamine agonist to make up for the depletion of dopamine caused by the destruction of the substantia nigra.[55,184] Levodopa is the medication most commonly used in the treatment of PD.[163] This oral medication is actually a precursor to dopamine because dopamine is too large to cross the blood-brain barrier. Levodopa provides substantial relief from tremors and rigidity during the initial stages of PD. After approximately 5 to 10 years of chronic use of levodopa, motor side effects are reported.[165] Those most often reported are dyskinesias and motor fluctuations. This "on-off" phenomenon is related to the levodopa dosage. A decrease in tremors and rigidity occurs during the "on" period after administration of levodopa, but the client may also experience various dyskinesias, such as abnormal movements of the limbs. As the dosage of levodopa wears off, the motor symptoms, specifically tremors and rigidity, associated with PD return.

Timing of the medication and the periods of "on-off" are important considerations in planning the client's daily activities. Even though abnormal movements are observed during the "on" period, the client has greater freedom of movement to complete functional activities.

As PD progresses, control of various motor symptoms through the use of levodopa becomes less effective.[165] Surgical intervention, known as **stereotactic surgery**, has been used. In this surgery, specific lesions are made in neurological structures to decrease the severity of PD symptoms. Stereotactic surgery of the globus pallidus internus has been used to decrease the severity of motor symptoms associated with PD and thus reduce the needed dosage of levodopa.[100,152] This surgical procedure is known as a pallidotomy. Pallidotomies have also been shown to reduce the dyskinesias associated with long-term use of levodopa.[165] Stereotactic surgery has also been used to create lesions in portions of the thalamus to reduce tremor and rigidity associated with PD.[104]

Neural transplantation has been used selectively for clients with PD.[30] This process involves harvesting fetal mesencephalic neural tissue and then transplanting this tissue into the basal ganglia of clients with PD.[44] The results of fetal brain transplants have been varied. In some clients, the tremors and rigidity were substantially reduced, but other clients experienced dyskinesias following the transplanted tissue.[164] The best success for this procedure has been reported when bilateral implants are placed in the putamen from multiple fetuses. The transplanted fetal tissue produces dopamine and thereby reduces the debilitating symptoms of progressive PD. Clients must continue to use levodopa but at a reduced dosage.

Role of the Occupational Therapist

Occupational therapy services vary depending on the client's stage of PD. Typically an OT program would provide compensatory strategies, client and family education, environmental and task modifications, and community involvement. Although OT services have been shown to be beneficial, there are still inconsistent referrals to provide OT services to those who have PD.[172] In a multisite randomized control trial, Sturkenboom and colleagues provided 10 weeks of occupational therapy for 124 clients diagnosed with PD.[201a] A control group of 67 clients with PD served as the comparison for the investigation. The Canadian Occupational Performance Measure (COPM) was used as both the assessment and outcome measure for this investigation. Following the 10 weeks of intervention, those who received OT services had significant improvements when compared to the control group for "self-perceived performance on prioritised activities." This multisite investigation provided strong evidence of the effectiveness of OT services in fostering functional, self-identified activities.

During the initial stages of the disease, the occupational therapist should develop an occupational profile with the client and significant others to establish intervention priorities.[180] Clients have expressed the desire to retain a sense of self and normalcy within their family, even in the face of deteriorating abilities. The focus of intervention is developing the habits and routines to foster participation in desired occupations as the disease process progresses. Educating the client and significant others regarding the course of the disease is an important step in this process, one that aids in the selection of occupations. For example, the case study at the end of this section introduces Carl. He identified traveling and painting as important occupations, and interventions were designed to help him continue participating in these occupations as the disease progressed.

During the early stages of the disease, the client and family should be informed of community resources and support groups. In one study, clients with PD were found to be far more dependent on others for personal care and household activities than were same-age peers without PD.[209] This dependence can place additional stress on the family. Involvement in a community-based group may provide the support needed to accommodate the changes in family roles and interaction.[180]

Even during the early stages of the disease process, clients with PD have difficulties with executive functioning.[67] An investigation by Foster and Hershey compared clients who had PD, but no dementia, with age-matched controls on several assessments of executive functioning. Clients with PD included in this investigation were in stage I or II. Clients with PD performed significantly worse on working memory and executive functioning compared to age-matched controls. Furthermore, lower executive functioning "was associated with reduced activity after controlling for motor dysfunction and depressive symptoms." The authors urge occupational therapists to assess executive functioning even during the early stages of PD and develop strategies to support client participation in desired occupations.

Modification of household items may decrease the impact of tremors during the initial stage of the disease process. Built-up handles for eating and writing utensils should be introduced during the initial stages of PD. Handwriting often becomes small and difficult to read during the initial stage of PD. Time management techniques should be introduced at this stage. Paying bills, signing forms, or doing other written work should be completed soon after taking levodopa, using utensils with built-up handles. Even though tremors are not severe during the early stages of PD, clothing fasteners should be modified. The use of slip-on shoes or Velcro closures for clothing should be considered at this time. Although a client may be able to fasten clothing during this stage of PD, the occupational therapist must consider the amount of energy and time needed to perform such a task.

In addition to the modification of specific tasks, household changes should be made at this time. Loose rugs should be removed from floors and furniture placed close to the wall to decrease obstacles. Chairs should have armrests to allow the client to push up from the chair to stand. Although balance is not significantly compromised during the early stages of PD, the family and client should become familiar with the new arrangement of furniture before this becomes a necessity. Bath and toilet railings and a raised toilet seat should be provided within the home. Because fatigue is a common complaint, clients should develop the habit of taking frequent breaks during the day. Modifying the household setting early in the course of PD allows the client and family members to adjust to changes and incorporate these changes into daily routines before they become a necessity.

A work evaluation should be performed during the early stage of the disease process to assess safety risks, potential hazards, and work simplification techniques that could be used. An ergonomic assessment of the work site and modifications to the tools would be appropriate. In the case of Carl, computer modifications were considered. A client may have the option of reducing the number of work hours, but that decision may reduce medical benefits. These decisions and available options are part of the OT intervention process during the early stage of the disease.

During the initial stage of PD, the occupational therapist should establish a daily exercise program addressing full range of motion.[199] It is preferable to have a client with PD perform a short exercise program for 5 to 10 minutes daily rather than a longer program three times a week. Exercises should include alternating movements from various planes, as many clients with PD display difficulties with smooth shifting of movements.[121] Postural flexibility exercises should be included in the program, with specific attention given to trunk extension. The most common postural change noted with the progression of PD is a stooped posture. In addition to the flexibility exercises, occupational therapists should instruct clients in the use of relaxation techniques and controlled breathing. Inhaling slowly through the nose and exhaling through pursed lips two or three times in succession, combined with improved postural alignment, can promote relaxation.

As the disease progresses, additional exercises can improve gait.[204] Rhythmic auditory stimulation in the form of music with an accentuated initial beat has been found to significantly improve stride length and speed in clients with PD. Dancing can also enhance gait patterns, in addition to providing a social environment for the client with PD. As akinesia becomes more apparent, the client with PD should be instructed to use a rocking motion to begin movement activities. Rocking forward and backward a few times while seated can produce the momentum needed to rise from a chair.

As a person with PD progresses to the middle stages of the disease, the client experiences further deterioration of motor skills, particularly the execution of skilled sequential movements.[49] These types of movements are needed to complete personal care and household tasks. Curra and associates[49] found that external cues improved the speed and sequential performance of novel motor tasks. The occupational therapist should suggest modifying activities to include visual cues, verbal prompts, and rehearsal of movements. These strategies increase a client's ability to perform personal care and household activities.

During the middle stages of PD, clients may have decreased oral motor control.[165] Dysphagia and drooling may embarrass them and further restrict social engagements. The occupational therapist should encourage oral motor exercises and provide education regarding food selection. Food consistencies can be altered to improve the client's ability to eat.

The ability to complete personal care tasks has been identified as a critical variable in a client's perception of quality of life.[64] Although progressive movement problems are characteristic of PD, the occupational therapist can minimize the impact the movement disorder has on functional activities. Tremors have less effect on the completion of personal care tasks than compensations for postural instability.[69] The use of group OT sessions has been demonstrated to be effective in reducing the impact of postural instability in clients with PD. An additional benefit of these group sessions is the reported improvement in the perception of quality of life in clients attending the sessions.

Access to community mobility and support programs should be included in the OT intervention plan during the middle stages of PD. A client with PD is often dependent on others for transportation. The use of community mobility services can decrease the client's dependence on family members for shopping and errands.

During the last stages of PD, movement disorders and rigidity may eliminate the client's ability to perform personal care tasks such as dressing and grooming.[89] Depression caused by the decreased ability to perform these tasks can significantly compromise a person's quality of life.[64] OT services should be provided to further modify the home environment for access and control. The use of environmental control units, such as a switch-operated television or radio, can be helpful. The switch plate should be activated with only light touch. Voice- or sound-activated environmental control units may not be as useful because of decreased vocal volume and poor articulation control during speech production. The client's ability to control the immediate environment can compensate for the losses experienced during the final stages of PD. The client may no longer be able to dress himself or herself, but through the use of various switches the client can select preferred television or radio programs, control room lighting, and operate a computer by using minimal motor action.

Section 5 Summary

Although PD is a progressive, neurodegenerative disorder, OT has much to offer the client with this disease.[64,69] The diminishing ability to perform personal care activities and engage in self-selected tasks has been identified as one of the variables contributing to depression and the decreased quality of life in clients with PD. Throughout the progressive course of PD, OT addresses the ability of the client to engage in meaningful activities. The client's wishes and family circumstances are incorporated into the OT intervention plan at every stage of the disease process.

Case Study

Carl

Carl is a 62-year-old college professor diagnosed with PD at the age of 57. He is married and lives in a small one-story home with his wife. He has two adult children, who live in another state. Carl reports that he enjoys traveling, reading, painting, and attending concerts.

Carl recently considered taking early retirement because of the increase in tremors in both of his hands, which made correcting papers difficult. He also reports some problems with endurance as a result of stiffness. Carl indicates that he is no longer able to paint because of the tremors in his hands. He also reports that he is unsure whether he should continue driving because of these tremors.

Results of the OT evaluation indicate that Carl is cooperative and motivated for therapy. Although he does not indicate that he is depressed, his wife reports features of depression, such as a decreased interest in going to concerts and planning summer vacations to see their adult children and grandchildren. His wife also reports that Carl seems depressed about his possible early retirement and loss of status as a college professor.

Carl is able to complete most personal ADLs independently but has difficulties stepping into and out of the tub and shower. His wife reports that she is afraid he will fall and that she often assists him in getting into and out of the shower. Carl also has difficulty tying his tie and buttoning his shirt. Tremors are noted bilaterally in his hands, and slight rigidity is present during passive range of motion (PROM). Dynamic balance is slightly compromised on uneven surfaces and stairs.

Carl has been taking Sinemet (levodopa and carbidopa medication) for the past 3 years to decrease the rigidity and tremors. He does not report any dyskinesias.

When asked about his personal goals, Carl replies, “I guess I'll have more time to read now.”

OT was initiated to accomplish the following:

1. Improve ADL performance

a. Instruct in use of a buttonhook

b. Make suggestions regarding clothing modifications such as clip-on ties and slip-on shoes

c. Instruct in use of momentum to initiate movement, such as rocking back and forth to rise from a chair

2. Modify home environment

a. Remove throw rugs and obstacles in walkways

b. Provide a tub seat and shower extension hose

c. Provide a raised toilet seat

d. Provide a cushion on dining room chairs

3. Assess work setting for modifications

a. Assess for computer access

b. Instruct in energy conservation, urging him to take frequent breaks and schedule activities during “on” phase of medications

4. Investigate leisure pursuits

a. Provide modifications to his easel, using forearm supports to allow him to continue to paint

b. Provide information regarding community-based Parkinson's disease support groups

5. Instruct in a daily active range-of-motion exercise program

a. Trunk extension and rotation exercises

b. Bilateral upper extremity exercise

c. Use of music during exercise program

Carl responded well to OT intervention. Although he was able to complete the academic school year, he decided to retire afterward. He stopped driving, but his wife began to drive them to concerts and art exhibits. He was able to complete personal ADLs safely with the use of adapted equipment and home modifications. He resumed painting during the “on” periods of his medications schedule, using the forearm supports attached to an angled table. He attended a Parkinson's support group two times a week and began to socialize with members from that group. Carl reported that the daily exercises seemed to decrease his stiffness, and he and his wife took frequent strolls in the park when weather permitted. He and his wife also joined a book club.

Review Questions

1. What are the symptoms of ALS at onset?
2. What is the underlying neurological process in ALS?
3. What bodily functions remain intact throughout the disease process?
4. What is the prognosis for ALS? Given this prognosis, what is the goal of the occupational therapist?
5. What are the symptoms of ALS at each stage of the disease?
6. What interventions are appropriate at each stage of ALS?
7. What are the initial symptoms of AD?
8. What underlying degenerative neurological process is associated with AD?
9. What changes in symptoms occur over the course of AD?
10. How do the changes in symptoms affect occupational performance in clients with AD?
11. What is the prognosis for a client with AD?
12. What OT interventions are appropriate for the client at each stage of AD?
13. What environmental modifications should be made to accommodate the client with AD?
14. What are the symptoms of MS at onset?
15. What is the underlying neurologic process in MS?
16. What are the three typical patterns of MS? How do they differ?
17. What symptoms of MS are managed with medication? What are the side effects of medication management?
18. How is medication management in the relapsing and remitting form of MS different than in the other forms of MS?
19. What does the OT evaluation include for the person with MS?
20. Why is it important to include the family in the evaluation and treatment process for the client with MS?
21. What are the initial symptoms of HD?
22. What underlying degenerative neurologic process is associated with HD?
23. What changes in symptoms occur over the course of the disease?
24. How do the changes in symptoms affect occupational performance?
25. What is the prognosis for a client with HD?
26. What OT interventions are appropriate for the client with HD at the various stages of the disease?
27. What environmental modifications should be made to accommodate the client with HD?
28. What are the initial symptoms of PD?
29. What underlying degenerative neurological process is associated with PD?
30. What changes in symptoms occur over the course of the disease?
31. How do the changes in symptoms affect occupational performance?
32. What is the prognosis for a client with PD?
33. What OT interventions are appropriate for the client with PD?
34. How does the medication schedule of levodopa affect a client's daily routine?
35. What environmental modifications should be made to accommodate the client with PD?

Spinal Cord Injury

Jennifer Bashar, Carole Adler Hughes

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, the student or practitioner will be able to do the following:

1. Understand the difference between a complete and an incomplete spinal cord injury and the classification system used to describe such levels of injury.
2. Recognize and identify the various spinal cord injury syndromes.
3. Briefly describe the medical and surgical management of the individual who has experienced a traumatic spinal cord injury.
4. Identify some of the complications that can limit optimal functional potential.
5. Describe the changes in sexual functioning in males and females after a spinal cord injury.
6. Identify the specific assessment areas that must be considered before developing intervention objectives.
7. Analyze the critical issues to consider when developing intervention objectives during the acute, post-acute, and outpatient phases of the rehabilitation process.
8. Identify the functional outcomes, including equipment considerations and personal and home care needs that can be reached at each level of complete injury under optimal circumstances.
9. Describe some of the special considerations that arise for a spinal cord injury in the pediatric population.

0. Analyze how the effects of a spinal cord injury accelerate the normal aging process, and explain how functional status may change.

KEY TERMS

Autonomic dysreflexia (AD)
Durable medical equipment provider
Heterotopic ossification (HO)
Paraplegia
Pressure ulcer
Quadriplegia
Spasticity
Tetraplegia

Acknowledgment

Jennifer Bashar would like to acknowledge Carole Adler's contributions to the success of this chapter throughout the first seven editions of this book. Her dedication to occupational therapy for evaluation and treatment of individuals with spinal cord injury educated and inspired generations of occupational therapists to provide cutting-edge treatments of the highest quality. It is an honor to contribute with her to the eighth edition.

Threaded Case Study

Jack, Part 1

Jack is a 23-year-old Caucasian male who sustained a C6 complete (AIS A) spinal cord injury (SCI) as a result of a motor vehicle accident. He works full-time in a bank and is studying to get a degree in business administration. He lives alone in a two-story house that he recently purchased and plans to renovate. His mother and stepfather live in the same city, and both work full-time.

Jack was initially airlifted from the accident site to a trauma hospital, where he underwent a posterior spinal fusion from C5-T1. While in the intensive care unit he was referred to and evaluated by occupational therapy (OT). OT services provided during the acute stage focused on addressing Jack's physical needs (providing range of motion and positioning devices to protect joint integrity and prevent skin breakdown) and environmental needs (nurse call light, television control, phone access). Spinal injury education with Jack and his family was initiated.

Upon transfer to the inpatient rehabilitation unit a comprehensive OT evaluation was conducted. Jack's occupational profile and history were obtained, in addition to a comprehensive evaluation of his strength, sensation, cognition, and vision. His specific manual muscle test revealed 3+ (Fair+) to 4 (Good) strength in deltoids, biceps, and radial wrist extensors and 2− (Poor−) strength in triceps. Sensory examination was intact to the C6 dermatome. He initially required assistance for all aspects of his activities of daily living (ADLs), including bed and wheelchair mobility. Jack's goals included being able to feed himself, get dressed by himself, be strong enough to push a manual wheelchair, live in his house again, and return to school to complete his degree.

Throughout this chapter, consider the short- and long-term consequences of Jack's injury to his ability to successfully engage and participate in his life contexts. Keep in mind the effects of his SCI on client factors, performance skills and patterns, and the relationship of activity demands to the selection of optimal equipment to enhance mobility and other areas of occupation.

Critical Thinking Questions

1. Considering Jack's level of SCI, what expectations would there be for functional recovery, and what interventions would the therapist provide to maximize his independence in performance of ADLs and instrumental activities of daily living (IADLs)?

2. What durable medical equipment and adaptive equipment will maximize efficiency in his mobility and ADLs?

3. How will the therapist approach OT interventions and realistic expectations regarding his specific goals of achieving independence in self-care, returning to school, living independently, and other important lifestyle options?

A spinal cord injury is a catastrophic and life-changing event that is defined as an injury to the spinal cord or spinal nerve roots that results in temporary or permanent change in an individual's motor, sensory, and/or autonomic function. According to the National Spinal Cord Injury Statistical Center (2015), there are approximately 276,000 people in the United States living with an SCI, and an estimated 12,500 new cases occur each year.[41] An SCI can be the result of a traumatic or nontraumatic event. Motor vehicle accidents are the most common cause of a traumatic SCI, followed by accidental falls, acts of violence (e.g., gunshot and stab wounds), sports accidents, and diving accidents. The average age at onset has risen from 29 years old in the 1970s to 42 years old since 2011; approximately 80% of SCIs occur among males.[41] Non–traumatic spinal cord dysfunction may be a result of multiple sclerosis, degenerative central nervous system diseases, tumors, vascular disease, inflammatory disease, spinal stenosis, myelomeningocele, or hydrosyringomyelia.[23] Although some of the intervention principles discussed may apply to the nontraumatic spinal cord conditions, this chapter will focus primarily on rehabilitation of the individual with a traumatic SCI.

Results of A Spinal Cord Injury

SCI results in tetraplegia (also known as **quadriplegia**) or paraplegia. **Tetraplegia** is paralysis caused by a cervical injury and involves any degree of paralysis of the four limbs and trunk musculature. There may be partial upper extremity (UE) function, depending on the level of the cervical lesion. **Paraplegia** is paralysis caused by a thoracic, lumbar, or sacral injury and involves any degree of paralysis of the lower extremities (LEs) with involvement of the trunk, legs, feet and toes, depending on the level of the lesion.[37,38]

The extent of neurological damage depends on the location and severity of the injury (Fig. 36.1). The neurological level of injury is determined by the International Standards for Neurological Classification of Spinal Cord Injury (ISNCSCI). A neurological exam is completed by a trained medical professional that involves testing of key muscles and sensory points (Fig. 36.2).[6] SCIs are referred to in terms of the regions (*C*, cervical; *T*, thoracic; *L*, lumbar; and *S*, sacral) of the spinal cord in which they occur and the numerical order of the neurological segments. The neurological level given is the most caudal segment of the cord where sensation is intact and muscle strength is at least 3/5. The results of the ISNCSCI exam also determine whether the injury is complete or incomplete and its classification on the ASIA Impairment Scale (AIS), which was established by the American Spinal Injury Association (ASIA).

★★	Participation possible but options and alternatives need to be discussed
	Not practical/probable for this injury level

FIG 36.1 Spinal cord levels and functions affected by spinal cord injury (SCI). (From Monahan FD, et al, editors: *Phipps' medical-surgical nursing health and illness perspectives,* ed 8, St Louis, 2007, Mosby.)

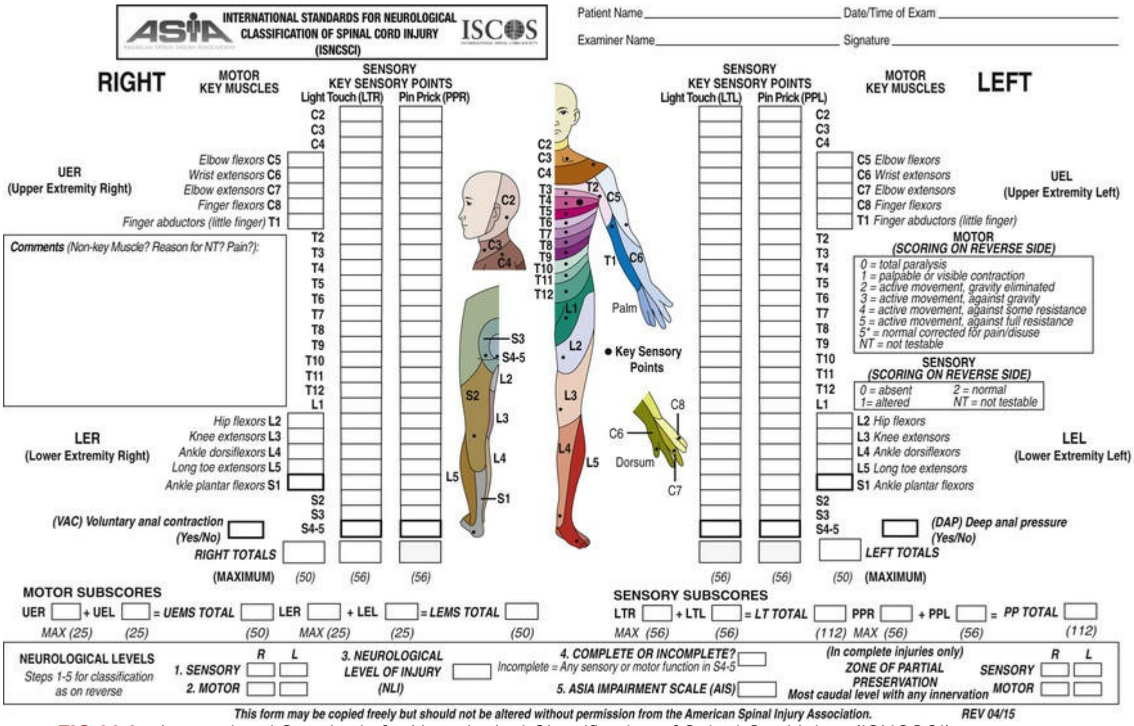

FIG 36.2 International Standards for Neurological Classification of Spinal Cord Injury (ISNCSCI). (From American Spinal Injury Association: *International standards for neurological classification of spinal cord injury*, Atlanta, 2008, The Association.)

Complete Versus Incomplete Neurological Classification

The difference between a complete and an incomplete injury is whether the individual has voluntary motor control or sensation in the anal area (S4-S5 segments of the spinal cord). A complete injury, classified as an AIS A, indicates that there is no motor or sensory function preserved at S4-S5. An individual with an AIS A SCI may have preservation of strength or sensation below the neurological level of injury; this is referred to as the zone of partial preservation (ZPP).[6]

In an incomplete injury, the individual has some degree of voluntary motor control or sensation preserved at S4-S5. An AIS B SCI (sensory incomplete) indicates that there is sensation, but not motor control, below the neurological level of injury, including at S4-S5. An AIS C SCI (motor incomplete) indicates that there is motor function preserved below the neurological level of injury, and more than half of the key muscles below the neurological level have a muscle grade of less than 3 (Fair). An AIS D SCI (motor incomplete) indicates that there is motor function preserved below the neurological level of injury, and more than half of the key muscles have a muscle grade of 3 (Fair) or more. An AIS E SCI indicates that the individual tests as having normal sensation and motor control.[6]

An ISNCSCI exam was completed with Jack upon arrival at the trauma center and at 72 hours post-onset. For both exams his sensory examination was intact to the C6 dermatome and absent below. The key muscles innervated at C6, radial wrist extensors, were graded at 3+/5 (Fair+). Because he had 2−/5 (Poor−) strength in his triceps (C7 key muscle) at the 72-hour exam, he was given a neurological level of C6 AIS A with a ZPP at C7.

Clinical Syndromes

Central Cord Syndrome

Central cord syndrome (CCS) is the most common incomplete spinal cord injury and occurs when there is more damage in the center of the cord than in the periphery. This damage is most frequently a result of a cervical hyperextension injury, such as a fall, and is commonly seen in older adults with arthritic changes that have caused a narrowing of the spinal canal. Symptoms include paralysis that is greater in the hands and arms than in the trunk and legs, bladder dysfunction, sensory loss below the level of injury, and painful sensations, including tingling, burning, or dull aching.[32,40]

Brown-Séquard Syndrome (Lateral Damage)

Brown-Séquard syndrome results when only one side of the cord is damaged, as in a stabbing or gunshot injury. Below the level of injury there is motor paralysis and loss of proprioception on the ipsilateral side and loss of pain, temperature, and touch sensation on the contralateral side.

Anterior Spinal Cord Syndrome

Anterior spinal cord syndrome results from injury that damages the anterior spinal artery or the anterior aspect of the cord. This syndrome involves paralysis and loss of pain, temperature, and touch sensation. Proprioception is preserved.

Conus Medullaris Syndrome

Conus medullaris syndrome involves injury of the sacral cord (conus) and lumbar nerve roots within the neural canal, which usually results in an areflexic bladder, bowel, and lower extremities.

Cauda Equina Syndrome

Cauda equina injuries involve peripheral nerves rather than directly involving the spinal cord. This type of injury usually occurs with fractures below the L2 level and results in a flaccid-type paralysis. Because peripheral nerves possess a regenerating capacity that the cord does not (at a rate of 1 to 2 mm per day[34]), this injury is associated with a better prognosis for recovery. Patterns of sensory and motor deficits are highly variable and asymmetric in cauda equina injuries.

Prognosis for Recovery

The most important indicator of the long-term prognosis after SCI is dependent on whether the lesion is complete or incomplete, as determined by an ISNCSCI exam completed 72 hours to 1 week post injury.[21,28] If there is no sensation or return of motor function below the level of lesion during this time period in carefully assessed complete lesions, motor function is less likely to return. However, partial to full return of neurological function one spinal nerve root level below the vertebral fracture can be gained and may occur in the first 6 to 9 months after injury. The majority of improvements will occur within the first year post injury but may continue up to 3 to 4 years post injury.[21] Among individuals with complete tetraplegia, 70% to 85% will gain at least one level by 1 year post injury. The rates of conversion from complete (AIS A) to incomplete (AIS B, C, or D) status at 1 year post injury range from 4% to 22%; the rates of conversion from incomplete (AIS B) to motor incomplete (AIS C or D) status range from 33.3% to 71.3%.[28,30] For Jack, it is reasonable to anticipate that he will regain one neurological level, from C6 AIS A to C7 AIS A, within the next year.[38]

With incomplete lesions, progressive return of motor function is possible but varies, depending on the type of lesion. Brown-Séquard syndrome has the best prognosis—75% to 90% of individuals ambulate independently at discharge from inpatient rehabilitation.[32] CCS also has a good prognosis for recovery but is age dependent; 97% who are younger than 50 years old will ambulate, compared with 41% of individuals older than age 50.[32] Anterior cord syndrome has a poor prognosis for functional improvement, with only a 10% to 20% chance of motor recovery.[32] Frequently, the longer it takes for recovery to begin, the less likely it is that it will occur.

Questions regarding the prognosis can be expressed at any point in time along the rehabilitation continuum by the individual with an SCI, the family, or friends. The therapist's response will depend on many factors, including the age, educational level, level of adjustment, and stage of recovery of the individual. It is important to acknowledge and respect any expressions of hope, uncertainty, loss, and helplessness while simultaneously fostering effective coping strategies and feelings of independence.[15] As you build a partnership with the individual, actively promote his or her understanding of the rehabilitation process. Take opportunities to educate the client in self-management and directing care strategies. Emphasize that the purpose of rehabilitation is to prevent further medical complications through education, to maintain and improve the strength and skills that are present, to maximize function and facilitate mobility, and to optimize lifestyle options for the individual and the family.

Medical and Surgical Management of the Person With A Spinal Cord Injury

After a traumatic event in which SCI is likely, careful examination, stabilization, and transportation of the patient may keep a temporary or minimal SCI from becoming more severe or permanent. Emergency medical technicians, paramedics, and air transport personnel are trained in SCI precautions and extrication techniques for moving a person who has sustained a possible SCI from an accident site. Axial traction on the neck should be maintained, and any movement of the spine and neck prevented during this process. Initial care is directed toward preventing further damage to the spinal cord and reversing neurological damage, if possible, by stabilization or decompression of the injured neurological structures.[15,25] The effects of steroids administered within the first 24 to 48 hours post injury continue to be actively researched and, while still used, are not definitively recommended.[15,21,25] Emerging acute medical therapies include the use of cooling measures (hypothermia) and pharmacologic neuroprotective agents; both are still in experimental phases.[21,24]

Anteroposterior and lateral x-ray films are commonly taken with the individual's head, neck, or spine immobilized to help determine the type of injury. A computed tomography (CT) scan or magnetic resonance imaging (MRI) may be needed to further determine the extent of injury. Open surgical reduction with internal fixation and spinal fusion are sometimes indicated in order to decompress the spinal cord and achieve spinal stability and normal bony alignment. Surgery is not always necessary, and adequate immobilization may allow the individual to heal. Specialized beds are recommended for patients with an unstable spine if they are going to be immobilized for an extended amount of time.[15] As soon as possible a means of portable immobilization is provided, usually a cervical collar or halo vest for cervical injuries and a thoracic brace or body jacket for thoracic injuries (Fig. 36.3). This approach enables the client to be transferred to a standard hospital bed and, subsequently, to be upright in a wheelchair and involved in an active therapy program as soon as there is medical and spinal stability.[15] Initiating an upright sitting tolerance program shortly after injury can substantially reduce the incidence and severity of further medical complications, such as deep vein thrombosis, joint contractures, and the general deconditioning that can result from prolonged bed rest.

FIG 36.3 Cervical collar and thoracolumbosacral orthosis (TLSO). (Courtesy Rancho Los Amigos National Rehabilitation Center, Downey, CA.)

The benefits of early transport to a specialized SCI center have been documented and include improved outcomes and fewer complications.[15,49] Spinal cord centers are equipped to offer a complete, multidisciplinary program executed by an experienced team of professionals who specialize in this unique and demanding disability. Clients treated in specialized SCI centers demonstrate reduced total lengths of stay, reduced incidence of pressure ulcers, lower rates of joint contractures, and increased neurological recovery. It has also been found that individuals sent to rehabilitation centers specializing in the treatment of SCI make functional gains with greater efficiency.[15,24]

Jack was airlifted from the accident site to a trauma hospital where a CT scan revealed significant fractures at C5-C6. He was intubated due to signs of respiratory failure, and a catheter was placed in his bladder to drain urine. He underwent a posterior spinal stabilization and fusion from C5-T1. After his surgery he was placed on a specialty bed to prevent pressure ulcers.

Complications After A Spinal Cord Injury

After an SCI there is potential for the individual to experience secondary complications as the body adjusts to disturbances in both body functions and body structures. It is imperative that the therapist understand the signs, symptoms, and potential effects these secondary complications could have on occupational performance. During each interaction the therapist must be vigilant in detecting the signs and symptoms of these complications, proactive in preventing their occurrence, and diligent about educating the client and identified caregivers.

Neurogenic Bladder and Bowel

SCI interrupts the communication between the nerves in the spinal cord that control bladder and bowel function. Signs of a neurogenic bladder include the inability to empty the bladder, incontinence, urinary frequency, and urinary tract infections. Signs of a neurogenic bowel include bowel incontinence, constipation, and impaction. After an SCI the manner by which the bladder and bowel works is dependent on the level of injury.

A spastic (reflex) bladder usually occurs in clients with an SCI at T12 and above; these individuals will have no control over when the bladder empties. A flaccid bladder usually occurs in clients with SCI T12 to L1, and they lose the ability to detect when the bladder is full. These individuals are at risk for the bladder wall to be overstretched and, in extreme cases, ruptured. The most common approach to managing both types of SCI bladder is intermittent catheterization.

The reflex or upper motor neuron bowel occurs in lesions above T12. The anal sphincter remains closed but opens on a reflex basis when the rectum is full. Management of the reflex bowel typically involves using digital rectal stimulation and stimulant medications. The areflexic bowel occurs in lesions in the lumbar or sacral level. There is reduced reflex control of the anal sphincter, and the individual is prone to accidental defecation. The areflexic bowel is typically managed by digital stimulation.

Occupational therapists are frequently involved in assisting clients with lesions below C5 achieve independence with bladder and bowel management. The clinical practice guidelines of the Consortium for Spinal Cord Medicine—"Bladder Management for Adults with Spinal Cord Injury: A Clinical Practice Guideline for Health-Care Providers" and "Neurogenic Bowel Management in Adults with Spinal Cord Injury"—are comprehensive and valuable resources on SCI bladder and bowel management.[12,14]

Pressure Injuries

A **pressure injury** (also referred to as pressure ulcer, pressure sore, decubitus ulcer, bedsore, or skin breakdown) is a lesion or an injury to the skin or underlying tissue that is caused by a loss of blood flow to the area. Sensory loss after SCI prevents messages of pain or discomfort from reaching the brain and increases the risk of a pressure ulcer. Too much pressure on the skin, shearing forces, and trauma (cuts, burns, bumps) are all causes of pressure ulcers. The areas most likely to develop skin breakdown are bony prominences over the sacrum, ischium, trochanters, elbows, and heels; however, other bony prominences, such as the iliac crest, scapula, knees, toes, occiput, and rib cage, are also at risk.

Pressure injuries are life-threatening, but most are preventable. All rehabilitation personnel must be aware of the signs of developing skin problems. Box 36.1 presents a description of the stages of pressure injuries. Pressure injuries can be prevented by having the client perform the following measures: regular pressure reliefs (also referred to as weight shifts, pressure reduction, or pressure redistribution); complete skin inspections; routine turning and repositioning in bed;, keeping the skin clean and dry; maintaining adequate nutrition and hydration; and wearing properly fitting clothing and shoes. Specialized mattresses and wheelchair seat cushions, proper transfer techniques, and protection of bony prominences with various types of padding are also essential to pressure injury prevention.

Box 36.1

Staging of Pressure Ulcers

Stage 1—Skin is hyperpigmented and blanches to the touch.

Stage 2—Skin is hyperpigmented but does not blanch to the touch.

Stage 3—Skin is open.

Stage 4—Skin is open, and underlying fascia (muscle, tendon, bone) is visible.

Unstageable—Depth or size of the pressure ulcer cannot be determined.

Occupational therapists play a key role in pressure injury prevention. During ADL training sessions the therapist will teach clients how to examine their skin using adaptive equipment, such as a mirror, and how to integrate skin inspection into their daily routine. Other strategies, such as directing others to watch for signs of developing problems or using technology such as smart phone apps for pressure relief reminders, may be introduced. Additional skin inspection is necessary when orthoses such as hand splints and body jackets are used because they can cause skin breakdown, particularly when protective sensation in those areas is impaired.

Orthostatic Hypotension

Orthostatic hypotension is defined as a decrease of 20 mm Hg or more of systolic blood pressure and is common during the acute phase of rehabilitation when the patient moves from a supine to an upright position or changes body position too quickly.[19] A lack of muscle tone in the abdomen and lower extremities leads to pooling of blood in these areas, with a resultant decrease in blood pressure (hypotension). Risk factors are prolonged bed rest, rapid changes in position, dehydration, and eating heavy meals.[19] Symptoms are dizziness, nausea, and loss of consciousness. With time this problem can diminish as sitting tolerance and level of activity increase; however, some people continue to have hypotensive episodes.

Therapists frequently encounter orthostatic hypotensive episodes when assisting the patient to sit upright for the first time. If this occurs, the client must be reclined quickly and, if sitting in a wheelchair, should be tipped back with the legs elevated until symptoms subside. Abdominal binders, compression garments, antiembolism stockings, and medications can help reduce symptoms. Allowing the patient's body to adjust to upright sitting more gradually by elevating the head of the bed prior to therapy interventions can also help reduce symptoms.

Autonomic Dysreflexia

Autonomic dysreflexia (AD), an abnormal response to a problem in the body below the level of the SCI, is a medical emergency and can be life-threatening. It is a phenomenon seen in individuals whose injury is at the T6 level and above. AD is caused by reflex action of the autonomic nervous system in response to some stimulus, such as a distended bladder or bowel, kidney or bladder stone, constipation or bowel impaction, infection, pressure sore, ingrown toenail, thermal or pain stimuli, deep vein thrombosis, or broken bone. The most dangerous sign of AD is a rapid rise in systolic blood pressure that is 20 to 40 mm Hg or higher than the individual's normal blood pressure; most individuals with an SCI have a baseline systolic blood pressure in the 90 to 110 mm Hg range. Other symptoms are an immediate pounding headache, anxiety, perspiration, flushing, goose bumps above the level of injury, nasal congestion, and bradycardia.[11,27]

If AD is suspected, the client should be placed in an upright position and anything restrictive, such as abdominal binders or antiembolism stockings, should be removed to reduce blood pressure. The bladder should be drained or leg bag tubing checked for obstruction. Blood pressure and other symptoms should be monitored until they return to normal. The occupational therapist must be aware of symptoms and treatment because AD can occur at any time after the injury. Individuals who are susceptible to this condition are encouraged to carry an emergency card describing the condition and treatment because many emergency departments and medical personnel may be unfamiliar with it.

Decreased Vital Capacity

Acute respiratory compromise and subsequent decreased vital capacity is a problem among individuals who have sustained cervical and high thoracic lesions. Individuals with injuries at C4 and above require mechanical ventilation to breathe secondary to paralysis of the diaphragm, intercostal muscles, and abdominal muscles. They will require caregiver assistance to maintain a patent airway (free of secretions). Individuals with injuries between C4 and T6 may have a tracheostomy. They will be able to breathe on their own but will have limited chest expansion and a decreased ability to cough because of weakness of the intercostal and abdominal muscles. Persons with tetraplegia who breathe on their own may still require the assistance of a caregiver to cough (assisted cough). Individuals with injuries between T6 and T12 will have an impaired cough due to weakness of intercostal and abdominal muscles. Sequelae of respiratory compromise include an increased risk for respiratory tract infections and a decreased endurance level for activity. Strengthening of the sternocleidomastoids and the diaphragm, manually assisted cough, and deep breathing exercises are essential to maintain optimal vital capacity.[21]

Jack's vital capacity was 50% of normal capacity for a person of his size. He required assistance to cough because he did not have the force to clear his secretions upon exhaling. His endurance was low, and he initially required frequent rest breaks during treatment sessions.

Spasticity

Spasticity is an involuntary muscle contraction below the level of injury that results from a disruption in the flow of signals between the spinal cord and the brain. Patterns of spasticity change over the first year, gradually increasing in the first 6 months and reaching a plateau about one year after the injury. Moderate spasticity can be helpful in the overall rehabilitation of the patient with an SCI. It helps to maintain muscle mass, assists in the prevention of pressure ulcers by facilitating blood circulation, and can be used to assist in range of motion (ROM) and bed mobility. A sudden increase in spasticity can alert the individual to other medical problems, such as urinary tract infections, constipation, skin breakdown, and fractures or other injuries below the level of injury.[36]

Severe spasticity can be frustrating to the client because it can be painful, cause a loss of joint ROM, interrupt sleep, and interfere with activities such as self-feeding and transferring to a wheelchair. Therapeutic interventions include consistent ROM exercises and stretching to help maintain flexibility; splints, braces, or serial casting can be used to provide continuous stretch to the muscle. Severe spasticity may need to be treated more aggressively with a variety of medications (e.g., baclofen, dantrolene, benzodiazepines) or with nerve or motor point blocks using chemodenervative agents (e.g., phenol, strains of botulinum toxin). In severe cases intrathecal medication therapy (e.g., baclofen pump) or neurosurgical procedures (e.g., myelotomy, rhizotomy, tendon lengthening) may be indicated.[27,36]

Heterotopic Ossification

Heterotopic ossification (HO) is bone that develops in abnormal anatomic locations. HO occurs in 16% to 53% of individuals with an SCI. It is most commonly seen in the muscles around the hip and knee, but it can also develop at the elbow and shoulder.[27] The onset of HO is usually 1 to 6 months after injury, and the first symptoms are swelling, warmth, and decreased joint ROM. Symptoms are often discovered during physical therapy (PT) or OT sessions, even when radiologic findings are negative. Early diagnosis and initiation of treatment can minimize complications. Treatment consists of medication and the maintenance of joint ROM during the early stage of active bone formation to preserve the functional ROM necessary for good wheelchair positioning, symmetric position of the pelvis, and maximal functional mobility.[26]

Pain

Pain is a serious obstacle for many individuals with an SCI and has the potential to negatively impact engagement in meaningful occupations. Acute pain begins suddenly and is usually described as a sharp pain; it may be mild or severe and usually disappears after the underlying cause of the pain is treated or healed. For individuals with an SCI, acute pain could be a result of broken bones, surgery, pressure areas or sores, burns, or a muscle tear. Chronic pain is persistent pain that does not go away and lasts months to years.[10] It is usually the result of nerve damage related to the SCI, but the cause may be unknown.

Types of pain an individual with an SCI may experience can be further differentiated between musculoskeletal pain, neuropathic (or neurogenic) pain, and visceral pain. Musculoskeletal pain is a result of muscular, joint, or bone damage and will usually get worse with movement and get better with rest.[35] Neuropathic pain is a result of damage to the nerve fibers; this damage creates abnormal communication between the spinal cord and the brain, causing the brain to misinterpret the intensity of signals it receives from the area of injury. Neuropathic pain is usually described as burning, stabbing, or tingling pain.[1] Visceral pain is usually described as cramping or aching in the abdomen and can be a result of a medical problem such as constipation, a kidney stone, ulcer, gallstone, or appendicitis.[35]

Neck and/or back pain is often reported by individuals with an SCI. Causes of neck and back pain include recent surgery to fuse the spine, soft tissue involvement (e.g., muscle strain, bruising), increased motion above and below the spinal fusion, and overuse by individuals who use mouth- or chin-operated joysticks to control their power wheelchairs.

The shoulder is the most common location of pain after an SCI, with the incidence and severity increasing over time post injury.[39] During the acute and post-acute phases of rehabilitation, shoulder pain is extremely common in individuals with C4 through C7 tetraplegia, causing decreased shoulder and scapular ROM and impacting participation in functional activities. Possible causes include scapular immobilization resulting from prolonged bed rest, nerve root compression subsequent to the injury, and subluxation at the glenohumeral joint. During the outpatient phase of rehabilitation, shoulder pain is common in individuals with C5 through C8 tetraplegia and all levels of paraplegia. Repetitive movements, such as pushing a manual wheelchair, doing pressure reliefs, and transfers, can cause muscle overuse and strain, chronic impingement syndrome, rotator cuff tears, and arthritic changes.[35] Shoulder pain should be thoroughly assessed and diagnosed so that proper intervention and activity or equipment modifications can be provided before the onset of chronic discomfort and functional loss.

Spinal Cord Injury Rehabilitation

Rehabilitation Team

SCI rehabilitation is best delivered under the auspices of a highly cohesive interdisciplinary team. The team, with the client at its center, is ideally composed of a rehabilitation physician (physiatrist) experienced in SCI, a rehabilitation nurse, OT, PT, speech therapist, psychologist, and social worker/case manager. Team members should have an understanding of the ISNCSCI classification system and how it applies to recovery; of common medical complications of an SCI and how to prevent them; and of the psychological and social ramifications of an SCI and how to assist clients and their families during the adjustment process. Team members should also be actively involved in the education of the client throughout the rehabilitation process.[7]

Goal of Rehabilitation

The goal of all phases of rehabilitation is to help the individual with an SCI reach his or her full potential after the injury. Because every individual is unique and each injury is different, the rehabilitation program can differ markedly from one individual to the next. The severity of injury, functional goals, adjustment to injury, and discharge options will all impact the length of time an individual spends in any one phase of rehabilitation.

Occupational Therapy Evaluation

The OT evaluation of the SCI client begins during the initial contact, continues during each subsequent interaction with the client, and lasts long after discharge on an outpatient follow-up basis. It is an ongoing, fluid process that requires the OT to continually evaluate the client's functional progress, the appropriateness of any OT intervention, and the utility of recommended adaptive equipment. The top-down and client-centered approaches outlined in the current Occupational Therapy Practice Framework (OTPF-3),[4] recommend that the OT evaluation contain a thorough occupational profile and analysis of occupational performance. Box 36.2 presents key OT assessments for SCI.

Box 36.2

Key OT Assessments for Spinal Cord Injury

- Occupational profile: Client factors, context, goals
- Sensation: Light touch, pinprick (per the guidelines established by the International Standards for Neurological Classification of Spinal Cord Injury [ISNCSCI]).
- Pain: Type, location, rating scale
- Range of motion: Active, passive
- Manual muscle test
- Grip and pinch strength
- Modified Ashworth Scale (MAS)
- Self-care function
- Vision
- Cognition

Prior to treating the client, the therapist must gather pertinent data from the medical chart, including personal information, a medical diagnosis, and a history of other relevant medical information. Specific medical precautions will be obtained from the primary and consulting physicians. Skeletal instability and related injuries or medical complications will affect the way in which the client is moved and the active or resistive movements allowed.

Occupational Profile

The occupational profile is the key to the evaluation process and will help shape and guide all therapeutic interventions. It is developed in close collaboration between the therapist and the client and should include the following information about the client: (1) occupational history and life experiences; (2) patterns of daily living (i.e., daily life roles, typical day); (3) values, interests, and needs; and (4) current understanding of his or her issues and problems.[4] This information can be gathered formally through a structured interview or informally during casual conversation. Often it is helpful to involve the client's family and friends if the client is unable to participate; however, once the client is able to participate in the process, his or her input is prioritized.

Keeping the client's priorities, occupational goals, and desired outcomes central to the intervention plan will maximize the individual's engagement in the rehabilitation program, and the more physical aspects (body structure and body functions) will be put into perspective as underlying and supportive to these occupational goals.

Psychosocial Status

By gathering the information required to build the client's occupational profile and beginning OT interventions, the occupational therapist has the opportunity to learn about and observe the client's psychosocial adjustment to the disability and life in general through the nature of the activities and occupations in which the client participates.[42] The evaluation phase is important for establishing rapport and mutual trust, which will facilitate participation and progress in later and more difficult phases of rehabilitation. The client's motivation, determination, and contexts—including socioeconomic background, education, family support, personal attitudes toward disability, problem-solving abilities, and financial resources—can prove to be invaluable assets or limiting factors in determining the outcome of rehabilitation. A therapist must carefully observe the client's status in each of these areas before recommending the course of intervention.

Clinical Picture

Body Functions and Structures

A thorough physical assessment of a client with an SCI will address (1) sensory functions, (2) neuromusculoskeletal and movement-related functions (joint mobility and joint stability), (3) muscle functions (power, endurance, tone), (4) movement functions (control of voluntary movement motor skills, involuntary movement reactions, gait patterns), and (5) mental functions (cognition, affect). It is also important to understand how the SCI is affecting the individual's cardiovascular, respiratory, voice and speech, digestive, genitourinary, reproductive, and skin functions (refer to previous section on medical complications of an SCI).

Key sensory functions to be assessed include: pain, touch (light touch, superficial pain), and proprioception (see Chapter 23). Vision should be screened for impairment, particularly in clients with a dual diagnosis (SCI and traumatic brain injury) and in clients with C1-C4 tetraplegia in which there may have been trauma to the brainstem (see Chapter 24).

The presence or absence of pain must be established prior to and during each intervention. If pain is present, a quantifiable client self-report measure, such as the Numeric Rating Scale or Visual Analog Scale, should be used to establish severity and track changes in pain in response to therapeutic intervention (see Chapter 28). The OT must take careful note of how the client describes his or her pain in order to differentiate neuropathic pain (described as burning, stabbing, or tingling), musculoskeletal pain (usually gets worse with movement and improves with rest), and visceral pain (located in the abdomen).

Sensation is evaluated for light touch and superficial pain (pin prick) according to ISNCSCI guidelines and determines areas of absent, impaired, and intact sensation. These findings are useful in establishing the level of injury and determining functional limitations (see Fig. 36.1).[6] Proprioception and kinesthesia testing (particularly with incomplete lesions), stereognosis testing, and monofilament testing (particularly with peripheral nerve injuries) may also be indicated to obtain an accurate picture of upper extremity functional use.

Passive range of motion (PROM) and active range of motion (AROM) should be measured before specific manual muscle testing to determine available pain-free movement. This evaluation also identifies the presence of or potential for joint contractures, which could suggest the need for preventive or corrective splinting and positioning (see Chapter 21).

Accurate assessment of muscle power, or strength, is critical in determining a precise diagnosis of neurological and functional level and for establishing a baseline for physical recovery and functional progress. Because the occupational therapist's skills in activity analysis greatly enhance the therapist's effectiveness in treating the client with an SCI, a precise working knowledge of musculoskeletal anatomy and specific manual muscle testing techniques is essential. Use of accepted muscle testing protocols ensures accurate technique during performance of this complex evaluation. The muscle test should be repeated as often as is necessary to provide an ongoing picture of the client's strength and progress (see Chapter 22).

Muscular endurance, the muscle's ability to perform contractions repeatedly over time before fatigue sets in, is important to consider prior to planning interventions. Endurance is assessed by engaging the client in various activities or exercises and tracking the length of time that the specific muscle group can be used to continue the activity. For example, Jack was only able to feed himself three bites of his meal during his first self-feeding session. Over time his endurance increased, and after 1 week he was able to feed himself an entire meal (see Chapter 20).

Spasticity is rarely noted in the acute phase because the client is still in spinal shock. When spinal shock subsides, increased muscle tone may be present in response to stimuli. The therapist should then determine whether the spasticity interferes with or enhances function. Use of a quantifiable measure, such as the Modified Ashworth Scale (see Chapter 19), will help track changes in spasticity and help justify specific interventions.

An evaluation of wrist and hand movement function determines the degree to which a client can manipulate objects. Informal assessment of wrist and hand function is based on observation while the client interacts with and moves objects around their immediate environment. Note whether any compensatory strategies are being used to manipulate and grip objects, such as using a two-hand hold, using extreme ranges, weaving objects, dragging objects, using the teeth or a table to stabilize an object, and/or tenodesis.[18] This information is used to suggest the need for equipment such as positioning splints or universal cuffs or, later, consideration of a tenodesis orthosis (wrist-driven flexor hinge splint). Formal assessment of tetraplegic hand function is strongly recommended and can be used to track a client's progress over time and as an outcome measure in clinical research. Factors such as the client's upright sitting tolerance and adjustment to disability will influence the selection of the appropriate outcome measure. Information on websites such as *http://www.rehabmeasures.org* and *http://www.scireproject.com* can be used to guide selection of the most appropriate measure. Gross grasp and pinch measurements indicate functional abilities and may be used as an adjunct to manual muscle testing to provide objective measurements of baseline status and progress for clients who have active hand musculature.

Clinical observation is used to assess oral motor control, head control, trunk control (righting reactions and static/dynamic sitting balance), lower extremity functional muscle strength, and total body function. Additional variables, such as age, obesity, limb length, and general flexibility, could impact the client's ability to achieve independence and should be recorded. More specific assessment in any of these areas may be required, depending on the client's specific needs.

Mental (cognitive, affective, and perceptual) function should be screened in all individuals with an SCI. From 25% to 64% of individuals with an SCI have some degree of traumatic brain injury (TBI) and are referred to as having a "dual diagnosis."[27] Variables that may indicate the presence of a TBI include loss of consciousness at the time of injury, tetraplegia from a high-energy deceleration crash, evidence of brainstem or cortical damage, and/or the need for initial respiratory support.[27] Others may have a history of mental illness, such as schizophrenia, bipolar affective disorder, or depression, and still others may be showing early signs of age-related dementia. It is important to assess the client's ability to initiate tasks, follow directions, carry over learning day to day, and handle problem-solving tasks. Understanding the client's learning style, coping skills, and communication style is also essential and contributes to the information base necessary for appropriate and realistic goal setting (see Chapters 25, 26, and 34).

Due to the nature of Jack's injury (motor vehicle accident), a screening of mental function was completed both in the intensive care unit and on the inpatient rehabilitation unit. The OT in the intensive care unit noted that Jack required additional time to process new information and also verbal cues to carry over tasks between sessions, such as remembering to use his universal cuff to hold his fork. By the time Jack was transferred to inpatient rehabilitation, his affect had improved and he was able to consistently demonstrate carryover of new learning between treatment sessions.

Functional Status

Observing as the client performs ADLs is an important part of the OT evaluation. The purpose of this observation is to determine present and potential levels of functional ability. If the client is cleared of bed rest precautions, evaluation and simultaneous intervention should begin as soon as possible after injury. Light activities such as feeding, light hygiene at the sink, and object manipulation may be appropriate, depending on the level of injury (see Chapter 10). Performance is scored using outcome measures such as the Inpatient Rehabilitation Facility-Patient Assessment Instrument (IRF-PAI, also referred to as the Functional Independence Measure, or FIM) or the Spinal Cord Independence Measure (SCIM). Box 36.3 presents IRF-PAI scoring guidelines.

Box 36.3

Scoring of the Inpatient Rehabilitation Facility Patient Assessment Instrument (IRF-PAI)*

Score	Assistance Level Required
7	Independent (no helper)
6	Needs assistive device, additional time; safety concern (no helper)
5	Needs supervision or setup
4	Patient does at least 75% of task
3	Patient does 50% to 74% of task
2	Patient does 25% to 49% of task
1	Patient does less than 25% of task or requires assistance of two people
0	Activity does not occur

*This assessment is also referred to as the Functional Independence Measure (FIM).

Establishing Intervention Objectives

Establishing intervention objectives in concert with the client and the rehabilitation team is vital. The primary objectives of the rehabilitation team may not be those of the client. Psychosocial factors, cultural factors, cognitive deficits, environmental limitations, and individual financial considerations must be identified and integrated into a comprehensive intervention program that will meet the unique needs of each individual. Every client is different; therefore, a variety of intervention approaches and alternatives may be necessary to address each factor that may affect goal achievement.[15] Tools for client-driven goal setting, such as the Canadian Occupational Performance Measure (COPM),[29] should be used to aid the client in identifying and prioritizing occupations that are meaningful at this point in his or her rehabilitation. Increased participation can be expected if the client's priorities are respected to the extent that they are achievable and realistic.

General objectives for OT intervention with the individual with an SCI are as follows:

1. Maintain or increase joint ROM and prevent problems associated with body functions and other body structures (skin) via preparatory activities, such as active and passive ROM, splinting, positioning, and client education.

2. Increase the strength of all innervated and partially innervated muscles and address problems associated with other body functions (e.g., sensation, higher level cognitive functions, psychosocial functions) through preparatory activities and engagement in purposeful activities and occupations.

3. Increase physical endurance and other performance skills and performance patterns through engagement in purposeful activities and occupations.

4. Maximize independence in performance in all areas of occupation, including ADLs, IADLs, rest and sleep, education, work, play, leisure, and social participation.

5. Aid in the psychosocial adjustment to disability.

6. Evaluate, recommend, and educate the client in the use and care of necessary durable medical and adaptive equipment.

7. Ensure safe and independent home and environmental accessibility through consultation and safety and accessibility recommendations.

8. Assist the client in developing the communication skills necessary for training caregivers to provide safe assistance.

9. Educate the client and family regarding the benefits and consequences of maintaining healthy and responsible lifestyle habits in relation to long-term function and the aging process.

Occupational Therapy Intervention

Phases of Recovery

Occupational therapists provide services across the continuum of care for individuals with an SCI. The acute care phase begins in the intensive care unit and is the time when the individual is most medically fragile. Once the client is medically stable, the post-acute/rehabilitation recovery phase begins; it is during this phase that the individual receives intense inpatient therapy (at least 3 hours a day, 5 to 6 days a week). The length of time spent in the post-acute/rehabilitation recovery phase is dependent on many factors and varies from individual to individual. The outpatient rehabilitation phase begins after discharge from acute/post-acute hospitalization and can take place in a variety of settings, including clinics, private or group homes, and specialty gyms. Beyond the outpatient phase, lifetime follow-up emphasizes keeping clients healthy and active.

Acute Phase

The role of the occupational therapist in the acute care setting with individuals with an SCI includes preserving joint integrity and mobility with positioning and early mobilization, restoring function through self-care training, initiating education and training of families and caregivers, and coordinating care, including preparation for transition to the next level of care.[2] The OT evaluation during this phase will give priority to determining the baseline neurological, clinical, and functional status from which to formulate an early intervention program. While initially addressing these critical physical client factors, the OT can be simultaneously engaging the client in an occupational profile, learning the client factors related to values, beliefs, and spirituality, along with the areas of occupation that comprise and give meaning to the client's life. Medical precautions must be followed at all times. The individual may be in traction, wearing a stabilization device (e.g., halo brace or body jacket), or have limitations on joint mobility and body movement.

Preservation of joint integrity and mobility includes an evaluation of total body positioning and hand splinting needs. For individuals with tetraplegia, the arms should be intermittently positioned in 80 degrees of shoulder abduction, external rotation with scapular depression, and full elbow extension to prevent the development of ROM limitations and shoulder pain (Fig. 36.4). Hand splints are introduced when muscle strength is not adequate to support the wrist and hands properly. If wrist extension strength is less than 3+/5 (Fair+/Normal), a splint that supports the wrist at neutral, keeps the thumb in opposition to maintain the thumb web space, and allows the fingers to flex slightly at the metacarpophalangeal (MP) and proximal interphalangeal (PIP) joints should be used (Figs. 36.5 and 36.6). If wrist extension strength is 3+/5 (Fair+/Normal) or greater, a short opponens splint should be considered to maintain the web space and support the thumb in opposition (Fig. 36.7). This splint can be used functionally while the client is trained to use a tenodesis grasp. Passive, active-assisted, and active ROM of all joints should be performed within strength, ability, and tolerance levels. Muscle reeducation techniques for the wrists and elbows should be used when indicated. Light progressive resistive exercises may be introduced as permitted by the medical team. During this time families and caregivers can be trained to assist with ROM exercises, splint use, and skin inspection.

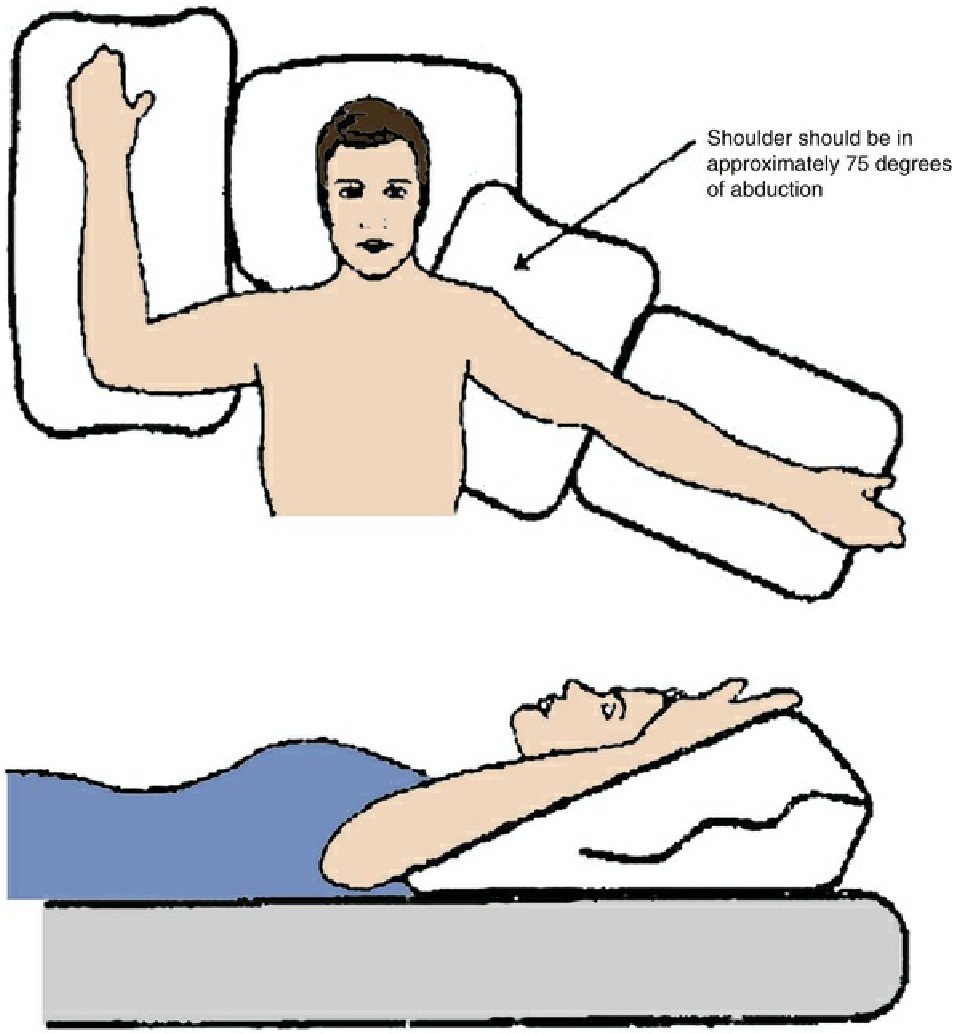

FIG 36.4 Supine bed positioning for individuals with tetraplegia. Using pillows: (1) Position arm out to the side in approximately 75 degrees of abduction. (2) Position other arm out to the side, hand back above the head, arm in abduction and external rotation, elbow bent. (3) Place pillows on either side of the legs with the railings up to help maintain the legs in a neutral position. (4) Place a pillow under the head and shoulders so that the head is not pushed forward. (Courtesy Rancho Los Amigos National Rehabilitation Center, Downey, CA.)

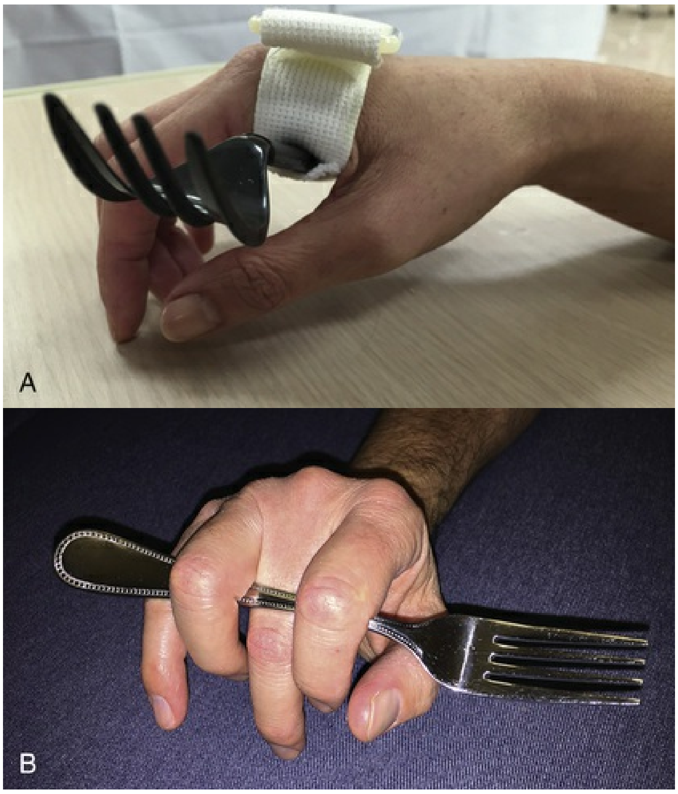
FIG 36.5 Resting hand splint. (Courtesy AliMed, Dedham, MA.)

FIG 36.6 Wrist support. (Courtesy Performance Health, Warrenville, IL.)

FIG 36.7 Thumb opponens splint. (Courtesy Rancho Los Amigos National Rehabilitation Center, Downey, CA.)

The client should be encouraged to engage in self-care activities (e.g., self-feeding, hygiene) using simple devices such as a universal cuff or built-up handle (Fig. 36.8). When indicated, access to bedside activities that might be of interest to the client, such as modified call systems, laptop computer setup on bedside tables, and avocational activities, can be explored. Even though the client may be immobilized in bed, discussion of anticipated durable medical equipment (DME), home modifications, and caregiver training should be initiated to allow sufficient time to prepare for discharge or transition to inpatient rehabilitation.



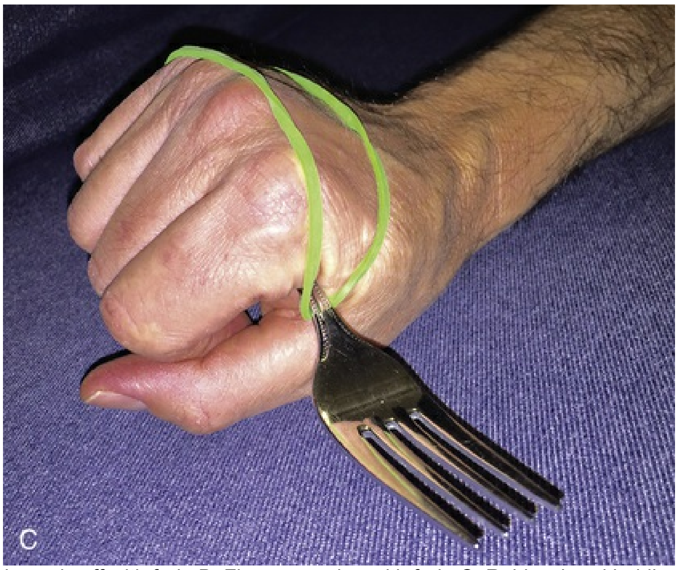


FIG 36.8 A, Universal cuff with fork. B, Finger weaving with fork. C, Rubber-band holding utensil. (Courtesy Rancho Los Amigos National Rehabilitation Center, Downey, CA.)

While Jack was in acute care, the OT assessed his arm strength and determined that he would benefit from bilateral short opponens splints. His parents were trained in passive and active-assisted ROM exercises. He was given a universal cuff for self-feeding and a stylus to access his tablet device.

Post-Acute Phase: Inpatient Rehabilitation

Some individuals will be transitioned to inpatient rehabilitation within the same facility and will require a quick reassessment of physical status. Others will be transferred from an acute care setting to a new facility for inpatient rehabilitation and will require a thorough OT evaluation. And still others may be admitted from skilled nursing facilities or from home; these individuals may be several months past their initial injury and are likely to have developed secondary complications, such as pressure ulcers and joint contractures. In all cases the beginning of the inpatient rehabilitation program is an opportunity for the OT to introduce the importance of self-management and to collaborate with the individual with an SCI in setting realistic and attainable goals.

Self-management skills, including being proactive, self-monitoring, problem solving, communicating effectively, staying organized, and managing stress, are emphasized by the rehabilitation team and taught by OT in individual and group sessions.[33] These skills have been found to be effective in increasing self-efficacy and improving health status and behaviors, decreasing pain, increasing compliance with medication programs, and decreasing overall healthcare costs.[33] These skills are essential to independence for all individuals with an SCI.

SCI education is integrated into every facet of the rehabilitation program and can be provided in many ways, including individual, small, or large group sessions; written materials, video, and online resources; and through peer mentors. Because individuals learn differently, it is important to identify the client's preferred learning style. Some topics to highlight for the individual with an SCI include transportation and driving resources, emergency preparedness, community resources, nutrition, finance management, how to select and direct caregivers, bladder management, bowel management, skin care and pressure relief, autonomic dysreflexia, pain management, and sexuality.

High tetraplegia/quadriplegia (C1-C4).

The intervention and equipment needs of clients with a high-level SCI (C4 and above) are unique and extremely specialized. Individuals with C1-C3 AIS A will be ventilator dependent and require total *physical* assistance from a caregiver to complete ADLs; however, these clients may be considered *independent in living* if they are able to direct a personal care assistant to satisfactorily assist them.[4] Individuals with C4 AIS A will initially be ventilator dependent and require total physical assistance from a caregiver to complete ADLs but may progress to breathing on their own and using equipment for self-feeding, such as a hand-free hydration system. Key muscles that may be innervated at the C1-C3 level include the sternocleidomastoid, platysma and cervical paraspinals; key muscles at the C4 level include the upper trapezius and diaphragm (Table 36.1).

TABLE 36.1

Common Functional Goals for Individuals With a Complete Spinal Cord Injury

Level of Injury	Physical Abilities	Functional Goals	Equipment Used
C1-C3	C3—Limited movement of head and neck	**Breathing:** Depends on ventilator for breathing.	Suction equipment to clear secretions, two ventilators with backup generator and battery
		Communication: Talking is sometimes difficult, very limited, or impossible. If the ability to talk is limited, communication can be accomplished with adaptive equipment.	Mouth stick and assistive technology (e.g., computer, communication board) for speech or typing
		Daily tasks: Requires full assistance from caregiver for turning in bed, transfers, and all self-care (including bowel and bladder management). Assistive technology can allow for independence in such tasks as reading a book or newspaper, using a telephone, and operating lights and appliances.	Mouth stick, environmental control unit (ECU)
		Mobility: Can operate an electric wheelchair by using a head control, mouth stick, sip and puff, or chin control. Power tilt function on wheelchair allows independence in pressure relief.	Power or manual lift, electric or semielectric hospital bed, power wheelchair with pressure-relieving cushion
C3-C4	Usually has head and neck control; with injury at C4 level, may shrug shoulders	**Breathing:** May initially require a ventilator for breathing; usually adjusts to breathing full time without a ventilator.	Cough-assist device
		Communication: Normal	
		Daily tasks: Requires full assistance from caregiver for turning in bed, transfers, and all self-care (including bowel and bladder management). May be able to use adaptive equipment to eat independently. May also be able to operate an adjustable bed and perform other tasks, such as painting, writing, typing, and using a telephone with assistive technology.	**Eating:** Sandwich holder on a gooseneck, feeder, long straw for liquids **Other activities:** ECU for operating bed (e.g., head or voice activated, mouth stick controller), hands-free devices, mouth stick for typing
		Mobility: Can operate a power wheelchair by using head control, a mouth stick, sip and puff, or chin control. Power tilt function on wheelchair allows for independence with pressure relief.	Power or manual lift, electric or semielectric hospital bed, power wheelchair with pressure-relieving cushion
C5	Typically has head and neck control, can shrug shoulders, and has some shoulder control; can bend elbows and turn palms up	**Daily tasks:** With specialized equipment, can be independent with eating and grooming (e.g., face washing, oral care, shaving, makeup application) after setup by caregiver. Requires total assistance from caregiver for bed mobility, transfers, and all other self-care. With adaptive equipment, may be able to assist caregiver with upper body dressing and some bathing.	**Eating:** Universal cuff for attachment of utensils, scoop plate, plate guard, long straw **Grooming:** Universal cuff for attachment of toothbrush, comb, or brush; adapted or electric razor, makeup applicators; wash mitt for face **Bathing:** Roll-in padded shower and commode chair, or padded tub transfer bench; wash mitt; adapted loofah
		Healthcare: Requires assistance from caregiver for cough assist. Can perform pressure relief with power tilt in power wheelchair.	Cough assist
		Mobility: May have strength to push a manual wheelchair for short distances over level surface; however, a power wheelchair with hand controls is required for daily activities. At this level, may be able to drive with specialized hand controls in a modified van with a lift, but still may require attendant to assist with transportation.	**Wheelchair:** Power or manual lift, electric or semielectric hospital bed, power wheelchair with pressure-relieving cushion **Bed:** Bed ladder, thigh straps, and bed rails for bed mobility
		Bowel and bladder management: Requires total assistance from caregiver for bowel and bladder management. May have indwelling catheter, or caregiver may perform intermittent catheterization for bladder management. Bowel management involves specialized equipment or medication.	**Bowel:** Roll-in padded shower and commode chair, or padded transfer tub bench **Bladder:** Leg bag emptier
C6	Has movement in head, neck, shoulders, arms, and wrists; can shrug shoulders, bend elbows, turn palms up and down, and extend wrists	**Daily tasks:** With some specialized equipment and setup by caregiver, can be independent with most feeding, grooming, and upper body dressing. Still requires some assistance for lower body dressing. and is able to assist with upper body during bathing. With some or total assist from caregiver, can perform sliding board transfers to padded shower commode chair and/or tub bench for toileting and bathing. Can perform some light meal preparation tasks.	**Feeding:** Universal cuff, built-up utensils, scoop plate, long straw, plate guard **Grooming:** Universal cuff, adapted electric razor or toothbrush **Dressing:** Dressing stick, leg lifter, thigh straps, dressing hook splints, adapted or specialized clothing **Bathing:** Adapted loofah, long-handled sponge with universal cuff **Transfers:** Power or manual lift, sliding board, padded drop-arm bedside commode, padded tub bench with cutout, padded shower and commode chair
		Healthcare: Can independently perform pressure relief with power tilt; may require some or no assist for forward or lateral lean pressure relief.	
		Mobility: With use of special equipment, may require some or no assist for turning in bed. With some or no assistance from caregiver, may be able to perform sliding board transfers on level surfaces. Can use a ultralight manual wheelchair for mobility, but some may use a power wheelchair for greater ease over uneven terrain. Can be independent driving a power wheelchair or with manual wheelchair propulsion with specialized equipment.	**Bed:** Bed ladder, thigh straps, bed rails **Wheelchair:** Wheelchair pegs, specialized wheelchair gloves, and rubber tubing on wheels. Also, power-assist wheels can be used for independence with manual wheelchair propulsion **Transportation:** Modified van with lift, specialized hand controls, tie-downs
		Bowel and bladder management: Requires some or total assist with adaptive equipment for management of bowel and bladder.	**Bowel:** Digital stimulation splint device, enema insertion device **Bladder:** Catheter inserter, penis positioner, thigh spreader with mirror
C7-T1	Has movement similar to C6 level, with added ability to straighten elbows. With injury at C8-T1 level, has added strength and precision of hands and fingers	**Daily tasks:** With equipment, is independent with all feeding, grooming, and upper body dressing. May require some or no assistance with lower body dressing and bathing with equipment. With some or no assistance, can perform sliding board transfers to padded shower commode chair and/or tub bench for toileting and bathing.	**Feeding:** Universal cuff, built-up handles, curved utensils, long straw, plate guard, adapted techniques for grasp **Grooming:** Universal cuff, splint material to adapt devices **Dressing:** Leg lifter, dressing stick, zipper pull, hooks on shoes **Bathing:** Adapted loofah, long-

			handled sponge with universal cuff **Transfers:** Sliding board, padded drop-arm bedside commode, padded tub bench with cutout, padded shower and commode chair
		Healthcare: Independent with wheelchair pushup or lateral lean for pressure relief.	
		Mobility: Independent with manual wheelchair propulsion and level surface sliding board transfers. May require some assistance from caregiver for uphill transfers. Can be independent with driving if able to load and unload wheelchair.	**Wheelchair:** Rigid or folding lightweight wheelchair, wheelchair pegs, wheelchair gloves **Transportation:** Hand controls, modified van if unable to perform transfer or load/unload chair
		Bowel and bladder management: Depending on hand function, requires some or total assist for bowel management, with use of adaptive equipment or medication. Can be independent or need some assist for bladder management with ICP or condom catheter.	**Bowel:** Digital stimulation splint device, enema insertion device, toileting aid **Bladder:** Catheter inserter house hold (for men), thigh spreader with mirror (for women)
T2-T12	Has normal function in head, neck, shoulders, arms, hands, and fingers. Has increased use of rib and chest muscles, or trunk control. At the T10-T12 level, more improvements in trunk control due to increase in abdominal strength	**Daily tasks:** Independent with self-care, including bowel and bladder management, with adaptive equipment if necessary.	**Dressing:** Thigh straps, reacher, dressing stick, sock aid **Bathing:** Long-handled sponge **Transfers:** Sliding board, padded drop-arm bedside commode, padded tub bench with cutout, padded shower/commode chair **Bowel/bladder:** Mirror
		Healthcare: Independent with wheelchair pushup for pressure relief.	
		Mobility: Independent with all bed mobility and transfers, with or without use of equipment. Independent with wheelchair propulsion on uneven and even surfaces and up and down curbs. Able to load and unload wheelchair independently for driving with hand controls.	**Wheelchair:** Ultra-lightweight wheelchair **Transfers:** Sliding board, leg straps **Transportation:** Hand controls
L1-L5	Has additional return of motor movement in hips and knees	**Mobility:** Independent with all bed mobility and transfers, with or without use of equipment. Independent with wheelchair propulsion on uneven and even surfaces and up and down curbs. Can ambulate with specialized leg braces and walking devices. Functionality of ambulation depends on strength and movement in legs. Ability to ambulate depends primarily on individual's level household distances. May use a wheelchair for community mobility. Able to load and unload wheelchair independently for driving with hand controls.	**Wheelchair:** Ultra-lightweight wheelchair if necessary **Walking:** Leg braces that extend to the hip, the knee, or just the ankle/foot and varying assistive devices **Transportation:** Hand controls
S1-S5	Depending on level of injury, various degrees of return of voluntary bladder, bowel, and sexual function	**Mobility:** Increased ability to walk with fewer or no bracing or assistive devices.	**Walking:** Braces that support ankle/foot

TABLE 36.2
Levels of Spinal Cord Injury and Key Muscles Affected

Level of Injury	Key Muscles Affected
C1-C3	Sternocleidomastoid, cervical paraspinal, neck accessories
C3-C4	Upper trapezius, diaphragm, cervical paraspinal muscles
C5	Deltoid, biceps, brachialis, brachioradialis, rhomboids, serratus anterior (partially innervated)
C6	Clavicular pectoralis supinator, extensor carpi radialis longus and brevis, serratus anterior, latissimus dorsi
C7-T1	Latissimus dorsi; sternal pectoralis; triceps; pronator quadratus; extensor carpi ulnaris; flexor carpi radialis; flexor digitorum profundus and superficialis; extensor communis; pronator/flexor/extensor/abductor pollicis; lumbricals [partially innervated]; intrinsics of the hand, including thumbs and lumbricals; flexor/extensor/abductor pollicis
T2-T12	Internal and external intercostals, erector spinae
L1-S5	Fully intact abdominals and all other trunk muscles; depending on level, some degree of hip flexors, extensors, abductors, adductors; knee flexors, extensors; ankle dorsi, flexors, plantar flexors

Individuals with high tetraplegia begin to develop upright sitting endurance when medically stable and will require a tilt-in-space or recliner wheelchair with room to accommodate a ventilator. A mechanical lift or dependent transfer technique is used to move the individual between surfaces (e.g., between bed and wheelchair, wheelchair and car) and a pressure-relieving cushion is required. Opportunities for education include teaching the client and family members about dependent pressure relief techniques, orthostatic hypertension, and proper body mechanics.

Upper extremity management for the individual with high tetraplegia includes evaluating neck and arm positioning in bed and in the wheelchair. As in the acute rehabilitation phase, while the client is in bed, the arms should be intermittently positioned in 80 degrees of shoulder abduction, external rotation with scapular depression, and full elbow extension to assist in preventing the development of ROM limitations and shoulder pain. A lap tray, bilateral arm troughs, or pillows can be used to support the arms with the elbow at 90 degrees while the client is in the wheelchair; remember to consider what will happen to arm position when the individual is reclined or tilted back for a pressure relief. The use of hand splints is continued to maintain available ROM.

Passive and active-assisted/active ROM is started for both the neck and arms to maximize strength in available musculature in preparation for participation in functional activities and to prevent undesirable contractures. Mouth stick training is started, and activities are chosen to reflect each client's functional goals. Card games, drawing, painting, page turning, and typing are some activities that may be used to improve neck ROM and endurance.

Paul, Jack's roommate, a 25-year-old with a C4 AIS A injury secondary to a gunshot wound, had expressed a goal of being able to use his iPad to communicate with friends and family. At the beginning of his rehabilitation program, he was only able to shrug his shoulders and slightly turn his head. To strengthen these muscles, mouth stick training was initiated. His iPad was placed on a mounting device, and he was given a mouth stick stylus to interact with the touch screen surface. A mouth stick docking station was positioned so that he could independently set the stylus down when he needed to rest. As his neck strength and active ROM increased, his therapist challenged him by changing the position of the iPad and docking station and providing more challenging activities, such as typing emails and navigating the Internet.

Paul had also expressed a goal of being able to attend his daughter's first birthday party. The OT used this goal as a springboard to motivate Paul to learn to direct his care needs, including bladder and bowel management, charging his ventilator and wheelchair batteries, organizing accessible transportation, and understanding the purpose and timing of medications.

Assistive technology can be used to enhance performance skills (e.g., typing with a mouth stick to increase neck ROM and endurance) or as preparatory methods and tasks used concurrently with occupations and activities (e.g., using a laptop with voice recognition software to complete a homework assignment for school).[3] Commercially available products, such as smart phones, electronic readers, and laptop computers, many with built-in accessibility options, have greatly enhanced the options available to high-level tetraplegics, as have resources such as free adaptive telephone programs and technology lending libraries. If available, an assistive technology specialist can help determine the appropriate equipment to assist the client in reaching both short- and long-term occupational goals.

Specialized equipment, such as turning mattresses, bathing equipment (e.g., inflatable bed bath or padded tilt-in-space and reclining commode chair), and power wheelchairs should be used on a trial basis during the rehabilitation phase. Individuals with C1-C4 SCI can be independent with operating a power wheelchair using a head control, sip-and-puff, or chin control and can be independent with pressure relief when using a power tilt-in-space wheelchair (Fig. 36.9). Accessible transportation options (e.g., a van with a lift) and community transportation services are introduced. Funding resources and grant opportunities should be explored to assist the clients in obtaining this equipment. A home visit with the client as early as possible in the rehabilitation phase helps identify architectural barriers and helps the client and family prepare for discharge.

FIG 36.9 Wheelchair skills, including navigating curb cuts and uneven surfaces, are practiced during an OT-led community outing.

Tetraplegia (quadriplegia)/high paraplegia (C5-T1).

Individuals with C5-T1 tetraplegia will require varying degrees of caregiver assistance (Table 36.2). Key muscles at the C5 level include deltoids and biceps. Individuals with C5 AIS A will be dependent on caregivers for bed mobility. Bed and wheelchair positioning is similar to that of individuals with C1-C4 injuries with one exception: these individuals are at high risk for elbow flexion and supination contractures and their forearms should be positioned in pronation. Elbow extension splints and/or pronation splints may be necessary to maintain ROM as spasticity increases. Splinting or casting of the elbows may be indicated to correct contractures that are developing. Support should also be provided for the wrist and hand; a wrist support can be used during the day and a resting hand splint at night (see Fig. 36.5).

Upper extremity management will include daily passive and active-assisted ROM and activities to maximize strength. Progressive resistive exercise can be introduced through the use of upper extremity skateboard tables. Mobile arm supports are used both to strengthen weak shoulders and elbow flexors and to increase independence in desired tasks. (See the case study for Matt in Chapter 30 to learn about an individual with C4 AIS A with C5 return who uses mobile arm supports and adaptive equipment to engage in his desired occupations, including feeding, computer use, and environmental control.)

The use of adaptive equipment will allow an individual with C5 AIS A to be independent with self-care tasks such as self-feeding and grooming after setup by the caregiver. Key adaptive equipment introduced at the C5 AIS A level includes wrist support used in conjunction with a universal cuff, scoop dish, long straw, swivel spork, long-handled utensils, long-handled comb/brush, Wanchik writer, wrist support, and mobile arm support. Independence in power wheelchair mobility can be achieved using hand controls; adequate trunk support must be provided, and a mobile arm support may initially be used to facilitate driving with a joystick control.

Individuals with C6 AIS A tetraplegia, such as Jack, will have expected functional outcomes that reflect greater independence from caregivers. Key muscles at the C6 level include the extensor carpi radialis brevis, extensor carpi radialis longus, clavicular pectoralis, and serratus anterior. The serratus anterior stabilizes and assists with rotating the scapula, allowing for better control and endurance when flexing the glenohumeral joint, as in putting a T-shirt over one's head. The clavicular pectoralis allows for horizontal adduction, enabling crossing of the midline and assisting with rolling in bed, turning a steering wheel, and participating in some bimanual activities. Elbow contractures should never be allowed to develop. Full elbow extension is essential for allowing propping to maintain balance during static sitting and for assisting in transfers. With zero triceps strength, an individual with C6 AIS A tetraplegia can maintain forward sitting balance by shoulder depression and protraction, external rotation, full elbow extension (“locked elbows”) and full wrist extension. Special care should be taken to preserve tenodesis during sliding board transfers and sitting balance activities (Fig. 36.10).

FIG 36.10 Individual with C6 AIS A preserving tenodesis grasp during sitting balance activities. (Courtesy Rancho Los Amigos National Rehabilitation Center, Downey, CA.)

The presence of wrist extension allows a functional tenodesis grasp: when the wrist is extended, the fingers automatically flex and allow the individual to grasp objects (Fig. 36.11). It is desirable to develop some tightness in the long finger flexor tendons in order to give some additional tension to the tenodesis grasp and to maintain the thumb interphalangeal (IP) joint in extension in order to attain alignment of the thumb to the index finger. Tenodesis is maintained by ranging finger flexion with the wrist fully extended and finger extension with the wrist flexed, thus never allowing the flexors or extensors to be in full stretch over all of the joints that they cross (Fig. 36.12).[31] Wrist extensors should be strengthened to maximize natural tenodesis function. Those who have weak wrist movement may use a wrist-driven wrist/hand orthosis, sometimes referred to as a tenodesis hand splint, to properly position their fingers for palmar prehension or a three-jaw chuck pinch (thumb with index and middle fingers) (Fig. 36.13). Neuromuscular electrical stimulation can also be used to strengthen weak wrist extensors.[8]

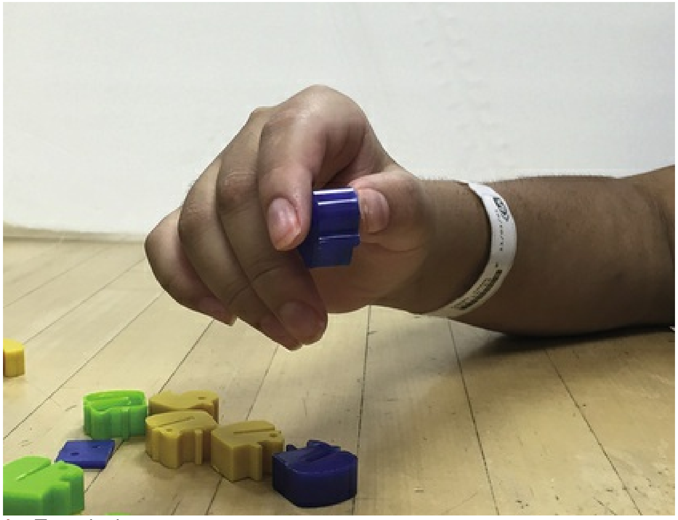

FIG 36.11 Tenodesis grasp. (Courtesy Rancho Los Amigos National Rehabilitation Center, Downey, CA.)

FIG 36.12 Tenodesis ranging. (Courtesy Rancho Los Amigos National Rehabilitation Center, Downey, CA.)

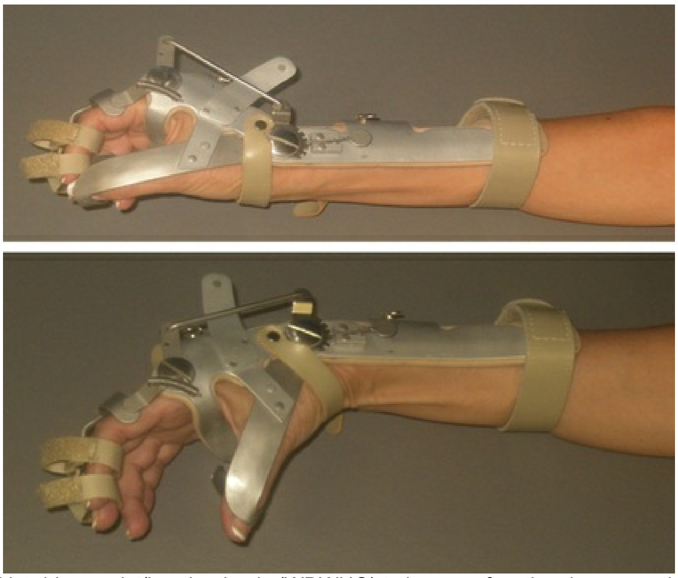

FIG 36.13 Wrist-driven wrist/hand orthosis (WDWHO) to improve functional grasp and pinch. (Courtesy Rancho Los Amigos National Rehabilitation Center, Downey, CA.)

Functional goals for the individual with C6 AIS A range from setup with adaptive equipment to independent for self-feeding, grooming, and upper body dressing. Adaptive equipment to be considered includes a universal cuff, scoop dish, built-up utensils, and a buttonhook. Some to total assistance will likely be required for lower body dressing, toileting, and bathing. Adaptive equipment such as a dressing stick, leg lifter, adapted long-handled sponge, wash mitt, padded tub bench, or padded rolling commode chair may be considered. Simple adaptations can be made to clothing, including widening the button hole, adding loops at the waist band, and using zip ties as zipper pulls to limit the use of adaptive equipment.

During Jack's inpatient rehabilitation stay he was introduced to the peer-mentoring program on the SCI unit. The peer mentors, individuals with an SCI who have completed their own rehabilitation programs and received specialized training, were instrumental in facilitating Jack's adjustment to his SCI. The peer mentors offered Jack motivation and emotional support, demonstrated self-care and body handling skills during therapy sessions, and shared valuable resources and experiences. After watching a peer mentor with a similar level of SCI demonstrate independence in lower body dressing on a standard bed and independence with depression transfers, Jack became more motivated and confident during therapy sessions, pushing himself outside of his comfort zone and challenging his problem-solving and body-handling skills.

Individuals with C7-T1 AIS A injuries will show greater independence with self-care tasks and mobility (see Table 36.2). Key muscles at the C7 level include triceps and latissimus dorsi. The triceps muscle gives individuals the ability to extend their elbows and reach overhead; the combination of triceps and latissimus dorsi allows shoulder depression, which assists with sitting balance, transfers, pressure relief, and bed mobility. Key muscles at the C8-T1 level include the flexor carpi radialis, extrinsic thumb and finger musculature, and intrinsic thumb and finger musculature. The addition of these muscles gives greater strength, control, and precision to the hands and fingers.

Upper extremity management for individuals with a C6-T1 level of injury includes strengthening through a variety of interventions, including the use of occupations (e.g., completing a morning routine, including feeding and dressing oneself), activities (e.g., playing a game of dominoes with a friend, preparing fruit smoothies), preparatory methods (e.g., daily ROM, the use of physical agent modalities such as neuromuscular electrical stimulation), and preparatory tasks (e.g., therapy putty, resisted clothespins, exercise bands). Progressive resistive exercise and resistive activities can be applied to both innervated and partially innervated muscles. Shoulder musculature is strengthened so as to promote proximal stability, with emphasis on the serratus anterior, latissimus dorsi (shoulder depressors), deltoids (shoulder flexors, abductors, and extensors), and the remainder of the shoulder girdle and scapular muscles. The triceps, pectoralis, and latissimus dorsi muscles are strengthened to increase independence with transfers and pressure relief when the client is in the wheelchair. Strengthening the intrinsic and extrinsic hand musculature is emphasized to create a stronger grasp and pinch. The intervention program should be graded to increase the amount of resistance that can be tolerated during activity. As muscle power and endurance improve, increasing the amount of time in wheelchair activities will help the individual participate in activities and occupations throughout the day.

Principles of energy conservation, in addition to self-management techniques, are important to introduce to individuals with C5-T1 tetraplegia. Jack, for example, can become capable of performing the majority of his self-care, including dressing and bathing, but these tasks require a considerable amount of time and energy for him to complete. On days when he will need to be at work or attend classes, he may choose to have a caregiver come early to help him complete his self-care routine.

Individuals with a C6-T1 level of injury are expected to be independent with pressure relief over time. If the individual with a C6 level of injury has at least 3+/5 shoulder and elbow flexor strength bilaterally, pressure can be relieved on the buttocks by leaning the client forward over the feet. Simple cotton webbing loops are secured to the back frame of the wheelchair. A person who has low tetraplegia (C7 with 3+/5 or better triceps) or paraplegia with intact upper extremity (UE) musculature can perform a full depression weight shift off the arms or wheels of the wheelchair. Some clients with C6 tetraplegia can also perform this type of weight shift by mechanically locking the elbows in extension while simultaneously externally rotating the shoulders and using their strong shoulder muscles to support their weight. Pressure relief should be performed every 30 to 60 minutes until skin tolerance is determined.

Paraplegia (T2-T12, L1-L5).

Individuals with paraplegia have normal function of the head, neck, and upper extremities and in general have functional goals of independence for all self-care tasks, wheelchair mobility, and health management (see Table 36.1). Factors that may influence goal setting during inpatient rehabilitation include obesity, length of limbs, body handling, spasticity, age, flexibility/ROM, endurance, and psychosocial adjustment. The rate at which these individuals achieve their goals may also vary. For example, individuals with T2-T9 paraplegia have weak or no trunk control, which directly affects their sitting balance, reach, and ability to complete bimanual activities. Individuals with T10-T12 and L1-L5 paraplegia have intact trunk control and will have a reduced fear of falling, a better base of support with increased stability, and an increased ability to perform bimanual activities.

Self-care interventions typically begin at the bed level and progress to the wheelchair level. Modified techniques are introduced to enable an individual to perform tasks efficiently. Adaptive equipment such as a reacher, dressing stick, sock aid, or leg lifter may initially be necessary to accomplish tasks; however, every attempt should be made to have the client perform the task with no equipment or with as little equipment as possible. Some common progressions for self-care include:

- *Lower body dressing:* Begin in the hospital bed with the head of the bed elevated. As sitting balance and bed mobility improve, progress to using a flat bed with the bed rails up and then with the rails down (Fig. 36.14). If possible, practice on a regular bed (similar to the bed the client will have at home). Once bed level dressing has been mastered, have the individual try from the wheelchair. Note that skin inspection using a mirror must be integrated into the client's daily self-care routine.

FIG 36.14 Paraplegic lower body dressing on a flat surface. (Courtesy Rancho Los Amigos National Rehabilitation Center, Downey, CA.)

- *Bathing:* Initially bathing will be performed at bed level. Once the individual has adjusted to upright sitting, have him or her shower using a padded rolling commode chair. As dynamic sitting balance and transfer skills improve, progress to using a padded tub bench. If a sliding board is used for wet tub/shower transfers, the sliding board should be covered with a pillowcase and the client should be instructed to complete a series of depression lifts across the board. Equipment needs may include grab bars, a handheld shower hose, and a long-handled sponge. The discharge bathroom setup will guide the selection of bathing equipment.
- *Bowel management:* Initially the bowel program will be performed at bed level for suppository insertion, perineal care, and clothing adjustment. As dynamic sitting balance and transfer skills improve, progress to using a padded rolling commode chair or a padded, height-adjustable commode chair placed over the toilet. Equipment needs may include a mirror, suppository inserter, digital stimulator, and toilet paper aid (see Chapter 10 for additional methods).

UE management for individuals with paraplegia will focus on strengthening and endurance in order to achieve the clients' functional goals of independence. As with individuals with tetraplegia, occupations, activities, preparatory methods, and tasks will be used and will be specific to each individual. Shoulder preservation strategies should be incorporated into therapy sessions and home exercise programs. The clinical practice guideline established by the Consortium for Spinal Cord Medicine, “Preservation of Upper Limb Function Following Spinal Cord Injury: A Clinical Practice Guideline for Health-Care Professionals,” is a comprehensive resource for this purpose.[13]

Vanessa, another client undergoing rehabilitation with Jack and Paul, is a 19-year-old college student who was injured in a motor vehicle accident and has a T10 AIS A SCI. Her goals for inpatient rehabilitation were established with her OT using the COPM. They include being able to get dressed by herself, meet friends for coffee, and return to college. Early in her inpatient stay, Vanessa and her OT went on a community outing to a nearby coffee shop. During the outing Vanessa worked on endurance training, community safety, and wheelchair skills. One week prior to discharge, Vanessa, her OT, and her PT went on an outing to her college. To prepare for this outing, Vanessa focused on being independent with bladder management from the wheelchair in a public restroom and being able to place items in a backpack on her wheelchair. She also researched resources available through her college to assist persons with disabilities.

Community reintegration activities, such as those completed with Vanessa, are an essential component of the OT program. These activities provide opportunities not only for practicing skills learned in therapy sessions, but also for psychosocial adjustment, client/caregiver training, and collaboration with interdisciplinary team members. Restaurant outings, work site visits, school visits, grocery store outings, and leisure activities, such as going to the movies, fishing, and going to the park, are just some of the possibilities (Fig. 36.15). These outings also provide opportunities for Jack, Paul, and Vanessa to support each other's accomplishments and to share ideas for solutions, in addition to their feelings about reintegration into the community. The OT leading the outing is in a perfect position to facilitate discussions as they arise.

FIG 36.15 Patients practice grocery shopping skills during a community outing with an occupational therapist.

A home evaluation should be completed for all individuals with an SCI prior to discharge home; this also is an excellent opportunity for hands-on individual and family training. The individual with an SCI should accompany the therapy team whenever possible. Consider completing a home evaluation early during the inpatient rehabilitation stay so that the family has sufficient time to make any necessary modifications and then again closer to discharge so that the individual can practice skills learned at home and with the equipment he or she will have at discharge. The results of the home evaluation should be well documented, and recommendations should be shared with the individual, his or her caregiver, the interdisciplinary team, and third-party payer sources (particularly when specific equipment is recommended).

Jack went on a home visit with his therapists and parents to his two-story home. Together they assessed the safety and accessibility of his home. Jack practiced propelling an ultra-lightweight manual wheelchair throughout the first floor to make sure all the doorways were wide enough. He practiced tasks such as transferring to a padded tub bench, opening the refrigerator and kitchen cabinets to retrieve a snack, and turning on lights. Some of the immediate recommendations for Jack and his parents included building ramps to access both the front and back entrances of the home, relocating his bedroom from the second floor to the first floor, using furniture risers to raise the height of his bed to facilitate transfers, removing the glass sliding doors in the bathtub and replacing them with a curtain, and placing grab bars in the bathtub. Other options for home accessibility that are more costly involve extensive structural modification, and require the services of a contractor well versed in the provisions of the Americans with Disabilities Act of 1990 (ADA; see Chapter 15), include modifying the bathroom to have a roll-in shower and accessible sink and installing a stair lift or elevator in order for Jack to access the second floor independently.

Incomplete SCI/clinical syndromes.

For individuals with an incomplete SCI, functional outcomes are harder to predict. Therapy interventions will be guided by the clinical presentation and will rely on a thorough OT evaluation. Motor return will be greater and occur over a longer period of time, and the potential for ambulation must be considered. UE management may have the added complexity of protecting a weak shoulder girdle and preventing shoulder subluxation when the client is standing or ambulating. Supportive devices such as slings and waist/fanny packs can be used to support the shoulder but may require caregiver assistance to put on. Treatment interventions such as neuromuscular electrical stimulation can be used to strengthen partially innervated muscles and can be used in conjunction with taping to provide support.[43]

Equipment

The assessment, ordering, and fitting of durable medical equipment (e.g., wheelchairs, seating and positioning equipment, mechanical lifts, beds, and bathing equipment) are extremely important parts of the rehabilitation program. This equipment should be specifically evaluated and should be ordered only when definite goals and expectations are known. Inappropriate equipment can impair function and cause further medical problems, such as skin breakdown or trunk deformity. The therapist must take into account all functional, positioning, environmental, psychological, and financial considerations in evaluating the client's equipment needs. The desired equipment—especially wheelchairs, seat cushions, back supports, positioning devices, and bathing equipment—should be available for demonstration and trial by the client before final ordering. The therapist involved in the evaluation and ordering of this costly and highly individualized equipment should be familiar with and have considerable experience with currently available products and also should be knowledgeable about ordering equipment that will provide the client with optimal function and body positioning on a short- and long-term basis. A good working relationship with an experienced and certified assistive technology provider (ATP) (i.e., a **durable medical equipment provider** who assists in the selection of custom assistive technology for the consumer's needs and provides training in the use of the selected devices) is preferable. Advances in technology and design have provided a wide variety of equipment from which to choose, and working with another professional specializing in such equipment will help ensure correct selection and fit (see Chapter 11, Section 2, for a more detailed discussion of wheelchairs, seating, and positioning equipment.)

In addition to enhancing respiratory function by supporting the client in an erect, well-aligned position that maximizes sitting tolerance and optimizes UE function, wheelchair seating must assist in the prevention of deformity and the development of pressure ulcers. An appropriate and adequate wheelchair cushion helps distribute sitting pressure, assists in the prevention of pressure ulcers, stabilizes the pelvis as necessary for proper trunk alignment, and provides comfort. Whether it is the OT's or the PT's role to evaluate and order the wheelchair and cushion, the two should work closely together to ensure consistent training and use for the individual needs of each client.

Outpatient Rehabilitation

Decreases in the amount of time devoted to inpatient rehabilitation have moved the extended phase of intervention to an outpatient basis or home therapy context. Adaptive driving, home management, leisure activities (Fig. 36.16), and work skill assessments are feasible and appropriate intervention modalities for evaluating and increasing UE strength, coordination, and trunk balance; however, they may not have been a priority during inpatient hospitalization. OT training in such activities can improve the client's socialization skills and can also assess and improve problem-solving skills and potential work habits. (See Chapter 11, Section 3, and Chapters 14, 16, and 17 for additional information on these topics.)

FIG 36.16 Patient participates in trick-or-treating activity during an OT session.

OT services can offer valuable evaluation and exploration of the vocational potential of individuals with an SCI. The occupational therapist can assess the client's level of motivation, functional aptitudes, attitudes, interests, and personal vocational aspirations during the process of the intervention program and through the use of ADLs, IADLs, mobility, and work simulation occupations. The therapist can observe the client's attention span, concentration, problem-solving ability, judgment, and other high-level cognitive functions, in addition to his or her manual ability with splints and devices, accuracy, speed, perseverance, work habits, and work tolerance level. The therapist can serve as a liaison between the client and the vocational rehabilitation counselor by offering valuable information gleaned from observation during the client's performance of activities and occupations. When suitable vocational objectives have been selected, they may be pursued in an educational setting or in a work setting, usually out of the realm of OT.

Throughout the inpatient and outpatient rehabilitation phases, the occupational therapist should provide psychosocial support by allowing and encouraging clients to express frustration, anger, fears, and concerns. The OT clinic in an SCI center can provide an atmosphere in which clients can establish support groups with other inpatients and outpatients, who can share their experiences and problem-solving advice with those in earlier phases of rehabilitation. Direct OT intervention to address psychosocial issues of an SCI can include training in stress management; coping skills training; and education regarding social connectedness, sexuality, relationship-building strategies, and the connection between occupation and emotional health.

Sexual Function

Sexual drive and the need for physical and emotional intimacy are not altered by an SCI. However, the ability of the individual with an SCI to engage, develop, and explore sexuality is affected. Education is essential for the individual with an SCI and all clinicians. In addition, as an important area of occupation (both in ADLs and social participation), it is a critical part of the rehabilitation process.

In males with an SCI, the two most common issues affecting sexual function are the ability to have and maintain erections and ejaculation. These problems vary, depending on the location of and type of SCI and should be evaluated individually. Pharmacological interventions (oral medications, penile injection therapy), vacuum pumps, and penile prostheses are some options that may assist with erections. The decreased ability to ejaculate and decreased motility of sperm in males with an SCI can affect fertility. Penile vibrostimulation (inexpensive, used at home) and rectal probe electroejaculation (more costly, done at a fertility clinic) are two of the methods used to produce ejaculation; however, the assistance of a fertility clinic is often needed to fertilize the egg, and these methods can be costly.[9,22]

Females with an SCI will usually experience changes in lubrication of the vagina during sexual activity and an interruption of menses for weeks to months after injury. In contrast to males, there is no change in female fertility. Females with an SCI can conceive and give birth. Special attention must be given to the interaction of pregnancy and childbirth with the SCI, especially with regard to blood clots, respiratory function, bladder infections, autonomic dysreflexia, and the use of medications during pregnancy and breast-feeding.[16,44]

The occupational therapist can address sexuality across all phases of SCI recovery. The type of intervention will be guided by the individual with the SCI and influenced by the developmental and life stages of the individual, the nature of the physical impairment, and the client's psychosocial adjustment to the SCI, readiness to learn, and sociocultural influences and expectations. OT interventions may include health promotion (e.g., education on changes in sexual function after an SCI, leading support group discussions on body image), remediation (e.g., introduce gentle stretching techniques for spastic muscles as part of foreplay, develop social interaction skills), and modification (e.g., adapt a sexual device for an individual with limited hand function, teach optimal bed positioning using pillows).[3] Recent discussions in the literature emphasize the need for more timely discussions regarding the effects of an SCI on sexual intimacy, family planning and parenthood, and developing sexual self-confidence and relationship skills.[20,22] The clinical practice guideline from the Consortium for Spinal Cord Medicine, "Sexuality and Reproductive Health in Adults with Spinal Cord Injury: A Clinical Practice Guideline for Health-Care Providers," is a comprehensive and valuable resource on the impact of SCI on sexuality.[13] There are also many consumer-driven resources available regarding SCI and sexuality (see Resources at the end of this chapter; also see Chapter 12).

Sleep and Rest

Sleep disturbances for individuals with an SCI can be attributed to physiological, psychological, and/or environmental factors. Physiological factors that influence the quality of sleep may include respiratory compromise from muscle weakness (diaphragm, abdominals), spasticity, and pain. Psychological factors include anxiety and depression. Environmental factors include the need for frequent turning in bed to prevent pressure ulcers, the need for intermittent catheterization, side effects of medications to control pain and spasticity, and poor sleep hygiene (e.g., frequent napping throughout the day). Promoting optimal sleep and rest patterns and quality is essential to enhancing the quality of life for individuals with an SCI. The occupational therapist can help the individual with an SCI establish a predictable sleep hygiene routine; identify ideal positioning in bed to decrease pain, prevent pressure ulcers, and prevent ROM limitations; promote self-management and caregiver management skills; and explore equipment options (e.g., turning mattresses) that will limit sleep disturbances (see Chapter 13 for more on the OT's role in promoting sleep and rest).

Children and Adolescents With A Spinal Cord Injury

Of the 12,500 new cases of spinal cord injury each year, approximately 3% to 5% affect children and adolescents under the age of 16.[47] Unique manifestations of SCI in children include birth injuries, lap belt injuries, and SCI without radiographic abnormality (SCIWORA), in addition to an increased incidence of higher cervical injuries (C1-C3) versus lower cervical injuries (C4-C8) in younger children.[47] Motor vehicle accidents and sports injuries are the leading cause of injury in teenagers, and violence is the leading cause of injury in African American and Hispanic teenagers.[5,47] Special considerations are required during the ISNCSCI exam for the pediatric population; these guidelines are available at the website *http://www.asialearningcenter.org*. Equipment ordered for children and adolescents with an SCI must allow for growth; measures should be taken to prevent the formation of scoliosis and hip deformities. Power wheelchair mobility may be appropriate for children with an SCI as young as 20 months old; readiness can be assessed via developmental screening tools such as the Pediatric Powered Wheelchair Screening Test.[46]

OT intervention for the pediatric SCI population needs to be developmentally appropriate and family centered. Participation in age-appropriate play, school, leisure, and social activities is integrated into the rehabilitation program. Mouth stick activities could include playing board games and making invitations to a tea party. Upper extremity ROM and strengthening could include word games played on an incline table. Balance and postural retraining activities could be done on a mat or the floor while the child plays with siblings. For children and adolescents with an SCI, an area of focus must be the transition to adulthood and the development of independent living skills, vocational exploration, social skill development, and a healthy lifestyle.

Consider the story of Julia, who sustained a T10 AIS A SCI as a result of a gunshot wound from a drive-by shooting when she was 9 years old. During her inpatient rehabilitation program she participated in self-care activities such as dressing and bathing, and her mother was trained in bladder and bowel management. Her mother worked full-time and wanted Julia to be independent with bladder management at school. The OT first introduced self–intermittent catheterization techniques to Julia using a doll, and over time she was able to learn how to complete her own catheterization.

Julia was a fourth-grade student at the time of her injury, and she was eager to go back to school and be with her friends. A school site visit was completed with Julia and her mother; during this visit the OT was able to assess the accessibility of the school and make recommendations to school administrators, speak to Julia's teacher about modifications she may need in the classroom (e.g., wheelchair-accessible desk), and allow Julia the opportunity to interact with her classmates for the first time since her injury while having the support of her mother and the OT.

As the years passed, Julia became involved in a local wheelchair sports program for children and returned to the SCI clinic to participate in a support group for adolescents with SCI. She graduated from high school, and with the encouragement of her support system, pursued a college degree, learned how to drive, and became a peer mentor for newly injured individuals with an SCI.

Aging With A Spinal Cord Injury

Aging with an SCI is a multifaceted topic, and several distinct themes must be considered: the onset of an SCI at an advanced age, the changing definition of independence as one adjusts to life with an SCI, and the consequences of aging with a SCI.

There are increasing numbers of individuals age 65 or older who are diagnosed with SCI; they account for 11.5% to 22.2% of new injuries each year.[48] As mentioned earlier, there has also been a rise in the average age at onset, from 29 years old in the 1970s to 42 years old since 2011.[41] The primary cause of injury for individuals over age 65 is falls, followed closely by motor vehicle accidents. These injuries result predominantly in incomplete tetraplegia, typically CCS. There is also an increased likelihood that these individuals will present with comorbidities that may negatively influence their long-term prognosis for recovery.[48] OT interventions for these individuals may include integration of chronic disease management strategies (e.g., consistently monitoring blood pressure or glucose levels and administering insulin) into daily self-care routines (see Chapter 46).

The primary goals of the individual with an SCI and the clinician are to maximize independence in all areas of occupation during the initial phases of rehabilitation. The role of the OT during these initial phases is to introduce the possibilities and mechanisms for independence while simultaneously teaching concepts of directing caregivers, energy conservation, and work simplification. It is ultimately up to the individual with an SCI to determine his or her own definition of independence, with the understanding that this definition is fluid and will change throughout the lifespan. For example, after several months at home Jack became physically independent with his morning routine; however, he required 3 hours to complete this routine and was exhausted after doing so. He decided to hire a caregiver to complete the tasks in a fraction of the time so he could focus his energy on other activities, such as school. Jack is still considered independent with his morning routine because he is in control and directing the actions of the caregiver.

Physical aging is a natural, inevitable process. The signs of the process can occur at varying rates for each individual, and aging affects most systems of the body (see Chapter 46). Individuals with an SCI are susceptible to an increased rate of changes in their health and abilities as they age. The aging process is accompanied by enhanced secondary effects of the disability, including pressure ulcers, infections (urinary and respiratory), muscular imbalance, pain, and joint degeneration secondary to overuse.[17] Regular screening should be performed for chronic health conditions such as diabetes, cardiovascular disease, high cholesterol, and cancer and appropriate maintenance therapies provided.[45]

When an SCI is compounded by the increased fatigue and weakness often associated with normal aging, the functional status of the individual with an SCI may decline. Occupational therapists may cite this change to justify additional services or equipment. Many considerations must be weighed to make appropriate short- and long-term decisions. Consulting experienced experts who have a perspective on both acute and long-term injuries and issues can provide valuable insight into intervention decisions. Approximately 20 years after injury appears to be a point at which some of the aging problems begin to increase. Thus, an individual with an SCI who was independent during transfers at home and with loading a wheelchair into and out of the car may now require assistance getting into and out of bed because his or her shoulders have deteriorated. The client may have to trade the car for a van that requires costly modifications. Similarly, someone who is at a level normally associated with functional independence (e.g., T10-level paraplegia) may now need personal care assistance and possibly a power assist or power wheelchair because of degenerative changes in the shoulders, elbows, and wrists. The occupational therapist should incorporate shoulder preservation strategies (e.g., the Strengthening and Optimal Movements for Painful Shoulders [STOMPS]) protocol) into the earliest stages of the rehabilitation program.[39]

Research

Current research conducted in clinical settings and scientific laboratories around the world focuses on understanding the nature of an SCI and defining the nervous system's response to this injury. There is now a sense of optimism in the scientific community that it will be possible to restore function after an SCI. This optimism is based on the combined research efforts of scientists in many disciplines. It is important for occupational therapists treating clients with an SCI to be aware of the scientific and technological advances so as to better educate their clients, while at the same time providing them with the most realistic and comprehensive rehabilitation interventions for their immediate and long-term needs. There are many trusted resources, such as the American Spinal Injury Association (*http://asia-spinalinjury.org/elearning/clintrials.php*) and the U.S. National Institutes of Health (*http://www.clinicaltrials.gov*) that can provide clinical trials advice to consumers.

Threaded Case Study

Jack, Part 2

Upon discharge from acute inpatient rehabilitation, Jack returned to his two-story home, and his mother moved in as his caregiver. Jack's father and friends built ramps for the front and back entrances and moved his bed and clothing to a room on the first floor. Bathroom modifications, including removing the glass doors and installing grab bars, were also completed. Initially his mother assisted him with lower body dressing, bathing, bladder and bowel management, sliding board transfers, and other home-making tasks, such as meal preparation. He required a padded transfer tub bench for bathing and a padded rolling commode for his bowel program, which his mother performed for him.

He was evaluated for an ultra-lightweight manual wheelchair to offer him independent manual wheelchair mobility at home and in his community. He did not wish to use a power wheelchair at this time; however, he is aware that he may require one in the future. He was educated on the premature degenerative changes that will likely occur in his shoulders from pushing a manual wheelchair and transferring himself to many necessary surfaces. He was also educated on skin care and the need for a maximal pressure-relieving wheelchair cushion. He was specifically evaluated for the optimal wheelchair sitting position that will offer him good trunk and pelvic alignment and pressure relief.

Over time Jack's need for caregiver assistance decreased, and he decided to hire a caregiver to assist him in the morning as he prepared for his day and in the evening as he prepared for bed. He regularly visits a neighborhood gym to maintain upper extremity strength and endurance, and he will soon be driving a modified van. He and his occupational therapist had many discussions regarding how he could return to college. Jack decided to return to school with a reduced class schedule and used services available at his school for note taking.

Jack has continued his involvement with the peer-mentoring program at the SCI clinic and loves to interact with clients who have been recently injured, sharing his own tricks and techniques that he has learned since leaving the hospital. He continues to set goals and challenge himself; currently he is learning to play quad rugby and hopes to one day travel to tournaments with his team and without his caregiver.

Summary

An SCI can result in substantial paralysis of the limbs and trunk. The degree of residual motor and sensory dysfunction depends on the level of the lesion, whether the lesion was complete or incomplete, and the area of the spinal cord that was damaged. The goal of OT is to aid the individual with an SCI in achieving optimal independence and functioning by exposing him or her to what is possible and prioritizing what is important. Areas of focus are physical restoration of available musculature; self-care; independent living skills; short- and long-term equipment needs; environmental accessibility; and educational, work, and leisure activities. The psychosocial adjustment of the client is instrumental, and the occupational therapist offers emotional support and intervention toward this end in every phase of the rehabilitation program.

Review Questions

1. List three causes of SCI. Which is the most common?
2. What is the difference between tetraplegia and paraplegia?
3. What testing is completed for an accurate diagnosis of neurological level?
4. Describe the difference between complete and incomplete lesions.
5. When one refers to a "C5 level" of tetraplegia, what is meant in terms of level of injury and functioning muscle groups?
6. What is the prognosis for recovery of motor function in complete lesions and incomplete lesions?
7. What are the purposes of surgery in management of SCI?
8. What are some medical complications common among clients with SCI that can limit achievement of functional potential?
9. How should orthostatic hypotension be treated?
10. How should autonomic dysreflexia be treated?
11. What is the role of the occupational therapist in the prevention of pressure sores?
12. Why is vital capacity affected in individuals with SCI?
13. What effect does reduced vital capacity have on the rehabilitation program?
14. Which level of injury features full innervation of the rotator cuff musculature, biceps, and extensor carpi radialis and partial innervation of the serratus anterior, latissimus dorsi, and pectoralis major?
15. What additional muscle power does the client with C6-level quadriplegia have over the client with C5-level quadriplegia? What is the major functional advantage of this additional muscle power?
16. What are the additional critical muscles that the client with C7-level quadriplegia has, as compared with the client with C6-level quadriplegia?
17. What additional functional independence can be achieved because of this additional muscle power?
18. What is the first spinal cord lesion level that features full innervation of the UE musculature?
19. Which assessments do occupational therapists use to evaluate the client with SCI? What is the purpose of each?
20. List five goals of OT for the client with SCI.
21. How is wrist extension used to affect grasp by the individual with tetraplegia?
22. How does the individual with C6-level tetraplegia substitute for the absence of elbow extensors?
23. What contracture is encouraged in clients with SCI? Why? How is it developed?
24. What splint allows the client with C6-level tetraplegia to achieve functional prehension in the presence of weak wrist extensors?
25. What are some of the first self-care activities that the client with a C6-level SCI should be expected to accomplish?
26. List four assistive devices commonly used by persons with tetraplegia and tell the purpose of each.
27. How can ordering an ill-fitting wheelchair affect the UE function and skin care of someone with C6-level tetraplegia?
28. Describe the role of OT in the vocational evaluation of a client with SCI.
29. What are two considerations when predicting the future functional outcomes for a 25-year-old

client with T4-level paraplegia?

30. Why would a person with paraplegia require homemaking assistance if they are independent in all self-care and mobility activities?

Disorders of the Motor Unit*

Alison Hewitt George

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, the student or practitioner will be able to do the following:

1. Describe the characteristics of motor unit disorders.
2. Discuss the clinical manifestations of motor unit disorders.
3. Discuss the impact of motor unit disorders on occupational performance.
4. Identify assessments and interventions for an occupational therapy program for the various motor unit disorders discussed in this chapter.

KEY TERMS

Brachial plexus

Guillain-Barré syndrome

Lower motor neuron system

Motor unit

Muscular dystrophy

Myasthenia gravis

Peripheral nerve injuries

Peripheral neuropathies

Poliomyelitis

Postpolio syndrome

Threaded Case Study

Edith, Part 1

Although this case study is specific to Guillain-Barré syndrome, many of the aspects of Edith's occupational profile and occupational performance needs apply to the other diagnoses in this chapter.

At age 67, Edith had been enjoying her retirement, primarily spending time with her husband, three children, and five grandchildren. She had recently recovered from the flu and was looking forward to a day at the park with her family. While showering, she suddenly lost strength in her legs and collapsed. While lying on the shower floor, she noticed that her arms also felt weak. Her cognition was intact, but she was physically helpless. Her husband called 9-1-1. It was fortunate that she received immediate medical care because she later required mechanical assistance to breathe. After extensive neurologic testing, Edith was diagnosed with Guillain-Barré syndrome (GBS). Neither she nor her family had ever heard of GBS.

Edith suddenly found herself dependent in all of her life roles and occupations. She was hospitalized in the intensive care unit (ICU) for several weeks, was dependent on a ventilator to breathe, and needed physical assistance because of her total body paralysis. Her muscles were painful, sore, and tender, and pain medications helped to manage the discomfort.

Jen, the occupational therapist assigned to the ICU, interviewed Edith, and together they identified the occupational needs and client factors that should be addressed. Jen performed passive range of motion (ROM) exercises, fabricated static hand splints to maintain a functional resting position and to prevent contractures, provided proper bed positioning, and taught the family about GBS. Jen also provided support, encouragement, and active listening, employing therapeutic use of self during the intervention. Edith often spoke about her spiritual beliefs and reported that she found hope and strength with prayer and meditation. She spoke of her favorite previous performance pattern of reading her Bible every morning, and said she felt depressed because she was now unable to physically hold a book or turn pages. After receiving training and modifications from Jen, Edith was able to listen to the Bible on CD, using a mouth switch to turn it on and off; this modification allowed her to resume her previous valued morning routine.

Edith made slow but steady gains in physical abilities and was transferred to an acute rehabilitation hospital to actively participate in an intensive interdisciplinary therapy program. Lara, the occupational therapist on the rehabilitation unit, evaluated Edith's specific functions as they related to supporting performance and engagement in occupations and activities targeted for intervention. The goals for Edith as determined by the Canadian Occupational Performance Measure[24] included the following: (1) to be able to feed herself, brush her teeth, and shower; (2) to cook for her family; (3) to go shopping at the mall with her granddaughter; and (4) to drive to her friend's house to play cards. Detailed upper extremity manual muscle testing, muscle belly tenderness screening, ROM measurements, and sensation testing were completed during the evaluation phase.

Intervention strategies focused on using compensatory methods and improving strength and endurance. Lara taught Edith adaptive strategies to eat, groom, and bathe. The use of adaptive equipment, work simplification, and energy conservation techniques were encouraged while Edith engaged in activities such as cooking and light cleaning. Lara supported Edith's community mobility and accompanied Edith to the mall with her granddaughter. After the brief outing, Edith expressed a sense of increased self-confidence and accomplishment. She practiced playing cards with other clients in a group environment. She also participated in a daily individualized strengthening program.

Lara provided Edith with community resources to aid in her independence. For example, the Guillain-Barré Syndrome/Chronic Inflammatory Demyelinating Polyneuropathy (GBS/CIDP) Foundation International offers local support groups, literature, and conferences to GBS survivors and caregivers.[14] In addition, her family received extensive training from the interdisciplinary team members to help Edith to apply the learned strategies and equipment in the home and community. Driving was not addressed at an inpatient level, but Edith was referred to an outpatient training program.

Critical Thinking Questions

1. What are the phases of Guillain-Barré, and what occupational therapy interventions might be used in each phase?

2. In what ways were the client's psychosocial needs addressed during recovery?

3. Describe energy conservation techniques that you think would be appropriate for Edith while engaging in her valued occupation of cooking.

This chapter examines the symptoms, course, medical treatment, and occupational therapy (OT) assessment and intervention for clients who have motor unit disorders most commonly seen in OT practice. The **motor unit** is the basic functional unit of the peripheral nervous system and consists of four elements: the cell body of the motor neuron located in the anterior horn of the spinal cord; the axon of the motor neuron, which travels via spinal nerves and peripheral nerves to muscle; the neuromuscular junction; and the muscle fibers innervated by the neuron (Fig. 37.1). Disorders of the motor unit may be of neurogenic, neuromuscular, or myopathic origin and generally cause muscle weakness and atrophy of skeletal muscle. Those with a neurogenic basis are referred to as lower motor neuron disorders, affecting the cell bodies and peripheral nerves of the motor unit. Those with a neuromuscular or myopathic origin affect the neuromuscular junction or the muscle itself.[7]

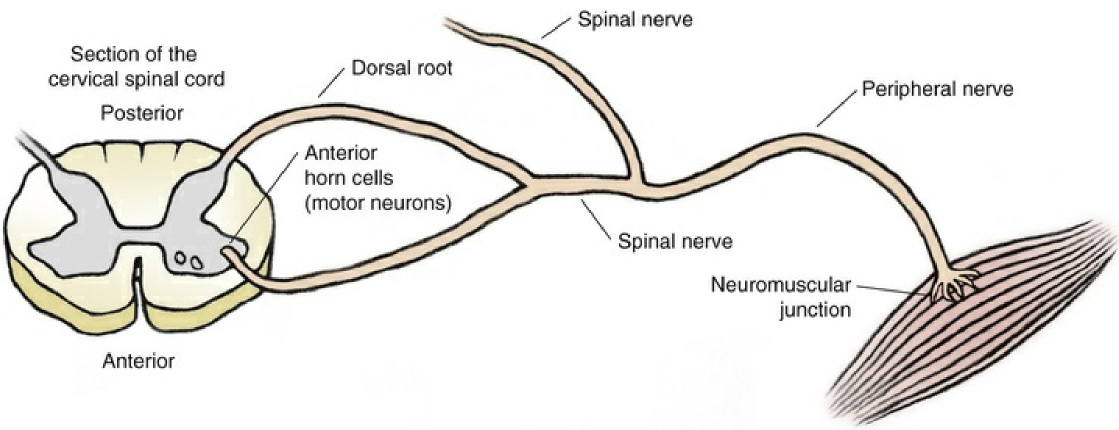

FIG 37.1 Motor unit consisting of motor neuron cell body in the anterior horn of the spinal cord, the axon of the motor neuron (which travels via spinal nerves and peripheral nerves to muscle), the neuromuscular junction, and the muscle fibers innervated by the neuron.

This chapter also discusses the physical, psychosocial, and emotional factors that occupational therapists address when assessing and providing interventions for people with motor unit disorders.

Occupational therapists, with their holistic view of persons with physical disabilities, are uniquely positioned to recognize and include interventions that address mental health concerns for persons with disorders of the motor unit. The sudden onset of severely disabling peripheral neuropathies, such as Guillain-Barré, or the chronic aspects of living with fatigue and experiencing role alterations will have ramifications for the client, the family, and their social network as described in Edith's case study.

Neurogenic Disorders

Peripheral Neuropathies

The motor neurons in the anterior horn of the spinal cord mediate voluntary movement and reflexes that produce motor behavior. Muscle strength and endurance contribute to coordinated and skilled movement and the ability to move through available range of motion. The characteristics of movement are determined by the pattern and firing frequency of specific motor units. Muscle contraction is the output of the motor system.[7]

The **lower motor neuron system** includes the cell bodies in the anterior horn of the spinal cord and their axons (which pass by way of the spinal nerves and peripheral nerves to the neuromuscular junction) and the nuclei of cranial nerves III through X (located in the brainstem) and their axons. The motor fibers of the lower motor neurons contain somatic motor components, including the alpha motor neurons, which innervate skeletal muscles (extrafusal fibers), and gamma motor neurons, which innervate muscle spindles (intrafusal fibers). A lesion in any of these neurologic structures results in peripheral neuropathy or a lower motor neuron dysfunction.[7]

Peripheral neuropathies involve lesions of the lower motor neuron system and may be located in the anterior horn cells of the spinal cord, spinal nerves, peripheral nerves, and cranial nerves or their nuclei in the brainstem. Lesions can result from nerve root compression, trauma (eg, bone fractures and dislocations, lacerations, traction, or penetrating wounds and friction), toxins (eg, lead, mercury, alcohol), infections (eg, poliomyelitis, Epstein-Barr virus or herpes varicella zoster), neoplasms (eg, neuromas and multiple neurofibromatosis), vascular disorders (eg, arteriosclerosis, diabetes mellitus, or peripheral vascular anomalies), and congenital malformations.[35] "Like static on a telephone line, peripheral neuropathy distorts and sometimes interrupts messages between the brain and the rest of the body."[35]

OT assessments for motor unit disorders follow a similar sequence and are described in Table 37.1. An occupational profile is developed during an interview with the client and caregivers. The Canadian Occupational Performance Measure[24] is an excellent instrument for establishing goals and measuring intervention outcomes. Performance skills, performance patterns, client factors, and activity demands in context must also be clinically assessed. Specific assessments such as range-of-motion evaluations, manual muscle testing, scales designed to measure coping and depression, and activities of daily living assessments are appropriate for each of the motor unit disorders described in this chapter.

TABLE 37.1

Occupational Therapy Assessments and Descriptions

Assessments	Descriptions
Occupational profile	Interview client (and family members and caregivers, if appropriate) to gain information about problems and concerns, successful and unsuccessful strategies when engaging in occupations, ways in which contexts influence functional abilities, activity demands, and priorities of meaningful occupations.
Canadian Occupational Performance Measure[24]	The interview is conducted before and after intervention to describe problems, level of satisfaction with performing activities, and level of perceived performance abilities in areas of self-care, productivity, and leisure. Testing methods must be measurable to assess intervention results.
Performance skills in areas of occupation: activities of daily living, instrumental activities of daily living, education, work, play, leisure, social participation	Following the occupations that the client prioritizes in the occupational profile, the therapist can perform formal assessments and observation of the client's performance during activity engagement in the appropriate context, with attention paid to motor, process, and communication/interaction skills. (See Chapter 18 for additional assessment details and Chapter 16 for a description of specific leisure assessments.)
Performance patterns	Client (independently or with assistance from caregivers or occupational therapist) maintains a log of activities and symptoms to analyze. In collaboration with the occupational therapist, the client uses this information to discover habits and routines that are detrimental or helpful to occupational performance. Reestablishment or adjustment of roles should be discussed and implemented.
Client factors: manual muscle testing, range of motion testing, eating and swallowing assessments, pain scale, sensory testing, depression scale, Ways of Coping Scale, clinical observations during activities of daily living.	The therapist should perform specific assessments of the client's bodily function, including systems that support participation in meaningful occupations (eg, neuromusculoskeletal, pain, joint range of motion, sensation, cardiovascular, respiratory, swallowing, skin). Because fatigability is so prevalent in these disorders, assessments should be adequately spaced and preferably performed when clients are feeling their best (often in the morning). Assessment of emotional stability, motivation, sexual activity, depression, ways of coping, and so forth is critical to forming an overall picture of the client's strengths and weaknesses.
Activity demands	Analysis of the required sequence, body functions, and body structures is necessary to complete the activity. Analysis must include assessment of the tools or equipment used to perform the activity and any adaptations that could be made to ensure success.
Contexts	The therapist should always consider the client's culture, physical environment, socioeconomic status, personal and spiritual beliefs, temporal aspects, and virtual contexts.

Data from American Occupational Therapy Association: Occupational therapy practice framework: domain and process, 3rd edition, *Am J Occup Ther* 68:S1–S51, 2014.

Two complex syndromes, Guillain-Barré and postpolio, are discussed in detail in the following section. The concepts are applicable to the other motor unit disorders described later in the chapter.

Guillain-Barré Syndrome

Guillain-Barré (ghee-YAN bah-RAY) **syndrome** (also known as acute idiopathic neuropathy, infectious polyneuritis, and Landry's syndrome) is an acute inflammatory disorder in which the body's own immune system attacks part of the peripheral nervous system. The immune system destroys the myelin sheath that surrounds the axons of many peripheral nerves or even the axons themselves, damaging the nerves' ability to transmit signals to the muscles. Guillain-Barré syndrome (GBS) has no known cause or cure, and no one knows why this disorder strikes some people and not others.[32] The onset of GBS often occurs after an upper respiratory or gastrointestinal viral infection, usually within 1 to 2 weeks. The syndrome is also occasionally triggered by surgery or vaccinations and occasionally occurs with no known precipitating event.[4,32]

This acute and complex disorder came to public attention when it struck a number of people who received the 1976 swine flu vaccine. It continues to claim thousands of new victims each year, striking any person, at any age, regardless of gender or ethnic background.[14] Affecting males and females equally, the annual incidence of GBS in the United States is approximately 1.6 to 1.79 persons in 100,000.[46]

The initial symptoms of Guillain-Barré syndrome most often include varying degrees of weakness and sensory changes in the legs. GBS is characterized by rapidly progressive ascending symmetric weakness of bilateral extremities, usually proceeding from distal to proximal (feet to trunk). Descending paralysis with predominant proximal muscle weakness rarely appears.[4,32] Because the myelin sheaths of the peripheral nerves are injured or degraded, the nerves cannot transmit signals efficiently. The muscles begin to lose their ability to respond to the brain's commands. The brain also receives fewer sensory signals from the rest of the body, resulting in an inability to feel textures, heat, pain, and other sensations. Clients often report initial sensations such as tingling, "crawling skin," or painful sensations. The signals to and from the arms and legs must travel the longest distances, so they are most vulnerable to interruption. Therefore muscle weakness and tingling sensations usually first appear distally in the hands and feet and progress proximally.[32]

Typically, the weakness and abnormal sensations first noticed in the legs progress to the arms and upper body, and some muscles are almost totally paralyzed. As the demyelination continues, the client may experience problems with breathing, speaking, swallowing, blood pressure, or heart rate. The client may require use of a respirator to assist with breathing and is monitored closely for an abnormal heart rhythm, infections, blood clots, and high or low blood pressure. After the initial clinical manifestations of the disease, the symptoms can progress over the course of days or weeks. By the third to fourth week of the illness, 90% of all clients are at their weakest. Some may be completely paralyzed and dependent on a respirator for breating.[32]

The typical progression of GBS occurs in three phases. The *initial, or acute, phase* begins with the client's first conclusive symptoms and lasts until there is no further decline in physical status. This phase may last for up to 4 weeks. The *plateau phase* begins when the client's physical state stabilizes, with no further deterioration of physical status and no evidence of physical recovery. The plateau phase generally lasts a few weeks, during which the physical status of the client remains unchanged. The *recovery phase* is that period when the client slowly begins to recover physical abilities and symptoms gradually decrease. Recovery can occur over 6 months up to 2 years, depending on the extent of paralysis. Although complete recovery is possible, many individuals (20%-30% of those diagnosed with GBS) will experience long-term residual deficits.[29,46]

Being paralyzed is a frightening experience for people with GBS, their family members, and friends. Clients can be expected to proceed through varying stages of adapting to the acute and residual effects of this physical disability.[38] However, the prognosis is generally good for the majority of clients; therefore it is appropriate to be optimistic during intervention sessions and encourage clients and families to look forward to recovery (Table 37.2).

TABLE 37.2

Guillain-Barré Syndrome: Prognosis and Outcomes

Recovery Status	Percentage of Clients	Description
Recover well spontaneously	85%	20%-30% of those who recover well have some residual deficits such as distal numbness, weakness, fatigue; these may interfere with some daily functions but usually are not severe; 3% experience a relapse of muscle weakness and tingling sensation years after initial attack.
Significant impairments	10%	Fatigue and severe weakness in specific muscle groups significantly impair daily function.
Death	5%	Death is usually the result of pneumonia, sepsis, adult respiratory distress syndrome, autonomic dysfunction, or pulmonary embolism.

Data from National Institute of Neurological Disorders and Stroke: *Guillain-Barré syndrome fact sheet.* www.ninds.nih.gov/disorders/gbs/gbs.htm; Walling AD, Dickson G: Guillain-Barré syndrome. *Am Fam Physician* 87:191–197, 2013.

There is no known cure for GBS. However, there are interventions that lessen the severity of the illness and accelerate the recovery in most individuals. There are also a number of ways to treat the complications of the disease.[32] Immunomodulatory therapy (plasmapheresis or intravenous immunoglobulin IVIg) is the recommended medical treatment at the onset of GBS. Plasmapheresis has shown clinical improvements, reducing the time required for ventilation and critical care, time to achieve ambulation, and hospital length of stay.[4,46] This process is used to separate the whole blood from the plasma and then return the whole blood to the client without the plasma to reduce the length of the acute phase. Intravenous immunoglobulin therapy involves the injection of proteins that the immune system uses naturally to fight invading organisms. High doses of these immunoglobulin proteins can lessen the immune attack on the nervous system and hasten recovery.[32,46]

Role of the Occupational Therapist

The client with GBS may be referred to OT when medically stable. An occupational profile of the client will be developed through OT assessments related to the level of dysfunction that the client is experiencing. For example, physical abilities are assessed using range of motion (ROM) and manual muscle testing (MMT), sensation testing, and a swallowing assessment. Functional assessments of quality of movement, coordination, and self-care may also be performed. It is critical to assess emotional and psychosocial factors of the client and family. (See Table 37.1 for OT assessments.)

After the initial OT evaluation, an intervention plan is developed to meet the client's needs throughout the disease process. Frequent revisions may be necessary, depending on the client's recovery status. During the initial phases of intervention (the acute phase and plateau phase of the disease), problematic client factors are addressed in conjunction with the healthcare team. These may include providing daily passive ROM, positioning, and splinting to prevent contracture and deformity and to protect weak muscles. Passive ROM should begin with gentle movement of the joints and should not exceed the point of pain. Particular attention should be paid to determining residual weakness in the intrinsic muscles of the hands. Passive activities (eg, watching television) and nonstrenuous social visits from family and friends are encouraged. Muscle belly tenderness (a flu-type muscle soreness) is closely monitored, and activities are modified as needed.[6] Many clients may benefit from the use of electronic aids for daily living (EADLs). EADLs increase the level of independence in the client's control of the environment through the use of technology. For example, a client with GBS might lack the strength and motor skills to operate the television, lights, telephone, and radio in the environment. With the use of EADLs, the client may be able to use the head, mouth, or other parts of the body to operate switches and successfully control the environment.

An intensive interdisciplinary rehabilitation program is typically implemented during the recovery phase as the client begins to regain physical movement. After the evaluation process, the OT intervention plan, developed in collaboration with the client, must be carefully designed to respect muscle belly tenderness and to prevent fatigue and further damage to the nerves. Because muscle belly tenderness usually decreases in the proximal musculature before it decreases distally, proximal musculature movements can be facilitated first while distal joints continue to be supported (eg, using mobile arm supports).[6] Activity is gradually increased with close monitoring of pain or fatigue after each intervention session. The therapist should continue to monitor for increased muscle belly tenderness, muscle imbalance, and substitution patterns. Progressive resistive exercises should be used conservatively, with attention to joint protection and fatigue. Throughout the course of recovery, the therapist should guard against fatigue and irritation of the inflamed nerves. Instruction to the client and family in key concepts such as energy conservation, work simplification, avoidance of overstretching, and overuse of muscles is critical to recovery.[41]

As the client's strength increases, activities promoting more resistance can be incorporated into the intervention program. Self-care (grooming, eating, dressing, bathing, and toileting) and other activities of daily living (ADLs), instrumental activities of daily living (IADLs), and leisure occupations should be included as soon as the client is capable of participating in them. Activities should be graded for success as strength and endurance improve. Adaptive equipment, frequent rest breaks, and creative strategies are typically necessary during this phase. Mobile arm supports may be used to alleviate muscle fatigue, promote active assistive use of upper extremities, and encourage independence with occupations. Activities and occupations should be varied among gross motor, fine motor, resistive, and nonresistive exercises to prevent undue fatigue.[41]

OT Practice Notes

Engagement in light occupations that are meaningful to the client is essential for building the self-confidence necessary to resume previous life roles and interests. For example, a client may be able to participate in enjoyable leisure occupations such as scrapbooking, surfing the web, planning a family gathering, and reading books to grandchildren (see Chapter 16).

People with GBS face not only physical difficulties but emotionally painful periods as well.[28] It is often extremely difficult for clients to adjust to sudden paralysis and dependence on others for help with routine daily activities.[38] Eisendrath, Matthay, and Dunkel found that clients experienced severe anxiety, fear, and panic during the acute progressive phase.[11] When clients reached the plateau phase, they often expressed anger and depression. When improvement began during the recovery phase, severe depression occurred as clients contemplated the long, slow convalescence and the possibility of permanent neurologic deficits. An occupational therapist can support the client by facilitating feelings of self-worth, a positive attitude, and encouragement through the engagement in valued occupations.[38,44] A psychologist or physician should also closely monitor the client's mood and provide necessary interventions as a member of the intervention team.

After becoming medically stable and being discharged from the hospital, many GBS survivors find themselves living at home without proper medical follow-up and therapy. Families are left to their own devices to successfully create real-life solutions to functional limitations and to locate and use resources. Schmidt conducted a survey of 90 voluntary participants from the Guillain-Barré Syndrome Foundation International to explore the extent of functional limitations within home, work, community, and leisure roles after hospitalization.[41] The majority of the participants stated that they had to independently research information about GBS because their doctors and team members either lacked the knowledge or did not provide them with any verbal or written information. One participant noted, "My family had to learn everything about GBS on the Internet. My doctors and nurses didn't know anything about it. We had to educate them (doctors, nurses, therapists, etc.)." These families reported feeling most frustrated about the fact that healthcare professionals did not address significant psychosocial issues such as depression, anxiety, fear, and hopelessness. Physically demanding tasks that required fair to good strength and endurance were scored the lowest in satisfaction and ability by participants. The great majority of respondents (98%) reported that they were living with factors that limited their ability to participate in life, such as fatigue, weakness, pain, sensation disturbances, coordination problems, and psychosocial changes. Nearly half of the participants agreed that they would benefit from OT services to improve the use of their upper extremities and to learn ways to manage daily fatigue and maintain their current health status. This study indicates the need for continued OT services to optimize occupational performance and occupational roles many years after the onset of the syndrome and apparent recovery.

The complex process of adjusting to the disabling condition, problem solving, learning, and redesigning a life for a GBS survivor is a long-term, therapeutic experience. The lifestyle redesign process can be initiated by the occupational therapist during the inpatient rehabilitation phase; however, there must be a continuum of care established for follow-up treatment. An occupational therapist working in an outpatient or home setting can skillfully guide clients back to the resumption of their previous life roles, assist clients in returning to productive community involvement and leisure occupations (see Chapter 16), and teach engagement and participation in meaningful occupations.[26,28,41]

Poliomyelitis and Postpolio Syndrome

Transmission of the **poliomyelitis** virus has been severely curtailed throughout the world as a result of the Global Polio Eradication Program; only 223 confirmed cases of polio were reported globally in 2012, and polio was endemic in only three countries.[8] The number of polio cases in the United States peaked in 1952, with more than 21,000 persons paralyzed. According to the Centers for Disease Control and Prevention (CDC), the last case of indigenous polio acquired in the United States was in 1979. A program to eradicate polio in the Western hemisphere, led by the Pan American Health Organization, eliminated polio in this region of the world in 1991.[8] Poliomyelitis is a highly contagious viral disease that enters through the mouth via the fecal-oral route (ie, it is spread in unsanitary conditions with poor hand-washing techniques). The virus moves from the throat into the digestive tract and is shed through fecal material for several weeks. The poliovirus enters the bloodstream and, in some cases, infects the motor neurons of the anterior horn and brainstem. Up to 72% of individuals who contract the disease are asymptomatic but can still spread the disease. According to the CDC, flaccid paralysis results in less than 1% of all polio infections, and most people recover completely. If weakness or paralysis lasts more than 12 months, it is usually permanent.[8]

The CDC recognizes three types of paralytic polio: spinal polio, bulbar polio, and bulbospinal polio. Spinal polio was the most commonly diagnosed type between 1969 and 1979, involving 79% of the reported cases. This type produces asymmetric flaccid paralysis predominantly in the legs. Bulbar polio (2% of reported cases) infects the cranial nerves, leading to muscle weakness in oral and facial musculature, and a combination of the two types results in bulbospinal polio (19% of cases).[8] With paralytic polio, marked atrophy can be seen in the involved extremities, and deep tendon reflexes are often absent. Sensation and cognition remain intact. The asymmetry of muscles pulling on various joints sometimes produces deformities, such as subluxation, scoliosis, and contractures.[8]

Even though substantial efforts have dramatically reduced the presence of poliomyelitis, the effects of polio still exist. Between 12 million and 20 million people in the world who had polio are still alive. After an interval of 15 to 40 years, 25% to 40% of these adults will experience new muscle pain, exacerbation of existing weakness, and the development of new weakness or paralysis. This exacerbation is referred to as **postpolio syndrome** (PPS).[8] According to the CDC,

Factors that increase the risk of postpolio syndrome include increasing length of time since acute poliovirus infection,[8] presence of permanent residual impairment after recovery from the acute illness, and being female. The pathogenesis of postpolio syndrome is thought to involve the failure of oversized motor units that were created during the recovery process of paralytic poliomyelitis. Postpolio syndrome is not an infectious process, and persons experiencing the syndrome do not shed poliovirus.[8]

According to the National Institute of Neurological Disorders and Stroke,[36] the following criteria should be considered for the diagnosis of PPS: previous paralysis due to poliomyelitis, period of partial or complete functional recovery, slowly progressive and persistent new muscle weakness, or decreased endurance, new difficulties with breathing and swallowing (less common), these symptoms persisting for a year or more, and other causes of symptoms ruled out (Table 37.3). PPS progresses slowly with intermittent periods of stability. People who had severe cases of acute polio experience a greater degree of disability resulting from PPS than do those whose initial response to the poliovirus was mild. Fatigue is the most debilitating symptom because it limits activity. The fatigue may be severe and out of proportion to the apparent physical demands of the activity, and it can be overwhelming. People with PPS risk additional disabling problems such as muscle atrophy, scoliosis, osteoporosis, fractures, contractures, and depression.[17,51,52] An increase in difficulty with ADLs and IADLs accompanies the symptoms. Problems with ambulation, transfers, stairs, home management, driving, dressing, eating and swallowing, and bladder and bowel control may occur, and people report a poorer functional status and health-related quality of life.[23,51] Unless there is severe pulmonary or swallowing involvement in postpolio syndrome, the symptoms are rarely life threatening.

TABLE 37.3

Six Criteria for Postpolio Syndrome

Criteria	Description
Prior paralytic poliomyelitis	Documented history of acute polio diagnosis, motor neuron loss, residual weakness, muscle atrophy, and electromyography (EMG) showing denervation of muscles
Period of partial or complete recovery	Evidence of acute paralytic polio with recovery and stable neurological functions for an interval of about 15 years or more
Gradual or sudden onset of progressive and persistent new muscle weakness or abnormal muscle fatigability	Decreased endurance, muscle and joint pain; onset possibly occurring after surgery, trauma, or periods of inactivity
New difficulties with breathing and swallowing	Unlikely but possible development of problems with breathing and swallowing
Symptoms as listed here that may persist for at least a year	Length of time that client reports having symptoms sometimes relevant in the diagnosis of postpolio syndrome
Other causes of these symptoms ruled out	Exclusion of other neurologic, medical, and orthopedic problems

Data from Jubelt B, Agre JC: Characteristics and management of postpolio syndrome, *J Am Med Assoc* 284:412, 2000; National Institute of Neurological Disorders and Stroke: *Post-polio syndrome fact sheet*. www.ninds.nih.gov/disorders/post_polio/detail_post_polio.htm.

Role of the Occupational Therapist

Occupational therapists should consider that the psychological and emotional aspects of PPS may be as disabling as the physical symptoms. Persons who originally had polio most likely assumed that the disease was over, that disability was in the past, and that any residual weakness was static. Therefore the onset of new symptoms and the accompanying disruption of occupational performance and lifestyle may be devastating as the client, family, and friends are confronted for a second time with the notion of being disabled. A supportive and realistic approach by the healthcare team, along with client and family education, is the key to lifestyle modification.[51,52]

Case Study

George

During his seventh birthday party, in February of 1955, George fell after another child kicked a ball, which hit George's legs. By the next morning, he could not get out of bed or stand on his own. He was admitted to a hospital and diagnosed with polio. George was placed in an iron lung that did the breathing for him. This was at the height of the polio epidemic, and the hospital wards and even the halls were filled with children in iron lungs. The complete confinement was terrifying, as was the constant presence of medical staff and equipment.

Over the years, George gradually recovered and was able to walk unassisted and participate fully in life. However, at the age of 60, George began experiencing new weakness in his legs, muscle pain, disproportionate fatigue related to activities, and an unstable gait. He was afraid that he was getting polio again. George quit his full-time job, stopped playing tennis, and became disengaged from his social life because he feared the full reemergence of polio and did not want anyone to know. His wife was very concerned and scheduled an appointment for George with their doctor, who prescribed occupational therapy, physical therapy, and counseling.

Analysis

George is among the many people worldwide who are affected by postpolio syndrome. Through occupational and physical therapy and counseling, he will be able to resume a near normal life. His fears must be addressed because they will hamper whatever remaining function he has. Through occupational therapy, George can learn to pace his activities, protect his joints, recognize fatigue before it becomes severe, and modify his leisure occupations so that he can lead an enjoyable life.

Occupational therapy has an important role to play in helping the client to stabilize function. Goals to adjust lifestyle may be accomplished by collaborating with the client and family to use work simplification, energy conservation, and adaptive equipment as needed. These measures, along with a healthy diet and enjoyment of remaining abilities, may improve the client's engagement in meaningful occupations and participation in the various contexts of his or her life.[36,52]

When assessing a client with the diagnosis of PPS, the occupational therapist collaborates with the client and caregivers (if appropriate) to develop the occupational profile. After discussing the client's problems and concerns, the therapist can explore what strategies the client has used and how useful the client reports those strategies to be. The occupational therapist selects specific assessments, such as ROM, MMT, and assessment of client's equipment for proper fit and function, to provide additional needed information (see Table 37.1).

Information gained from the evaluation process is used to prioritize and select valued, relevant activities for the client with PPS. The Knowledge of Polio Test can reveal what the client and family understand about polio and its sequelae.[50] Education about the effects of polio when the client was a child, combined with information about current symptoms, is important.

Fatigue and pain are the two symptoms most frequently mentioned by clients with PPS. Scoliosis is found in nearly all survivors of polio. Even though scoliosis itself generally does not produce pain, the strain it puts on joints and muscles through abnormal biomechanics can produce degenerative disk disease, as well as pain in the shoulders, knees, and other joints and muscles.[48] Decreased vital capacity and difficulty breathing with deventilation during sleep is observed frequently in these clients. If the client complains of frequent awakening during the night or breathing problems, the therapist should refer the client to a pulmonologist immediately.[48,52]

A client-centered intervention plan is designed to help the client and caregiver improve functional outcomes. Adaptive strategies and preventive measures are key factors to include in the OT intervention plan. The prognosis and selection of intervention methods depend on the progression of the disorder. Functional and leisure activities that are meaningful to the client are used in combination with work simplification, pacing the activity for energy conservation, passive and active ROM exercises, muscle reeducation, proper posture and body mechanics, joint protection, and training in the use of assistive and adaptive devices and mobility aids, as needed. In all cases, the therapist must teach the client to carefully monitor fatigue level and to modify or stop the activity when necessary.[52] Prioritizing goals is critical to reach the desired outcome, and intervention goals should be coordinated with the client and members of the interdisciplinary team for a comprehensive rehabilitation program. Psychosocial aspects of the disorders must be addressed in the intervention plan.[20,38]

Understanding the client's psychosocial reactions to the various disabilities associated with PPS will help the therapist and client select interventions that will facilitate rehabilitation efforts and the patient's adjustment to new limitations. Changes in physical capacities, abnormal fatigue, and curtailment of valued life skills confront the client with psychological issues of coping, adjustment, and adaptation. These changes may be as traumatic as they were at the time of the original illness. It is important to be aware of the stages of adapting to a chronic disabling condition.[38,39] Feelings of denial, anger, and hopelessness and the sense of being a burden should be identified and addressed as a part of the OT intervention. Helping clients and families connect with support groups can make a difference in psychosocial acceptance and motivation.[52] If the client's psychological needs are beyond the scope of the OT practice, referral to a psychologist is appropriate.

Because the client with PPS may be psychologically fragile when facing increasing levels of disabilities, the occupational therapist should introduce lifestyle changes gradually because modifying performance patterns and introducing adaptive equipment could threaten the client's self-image. Small changes may be more acceptable than major ones, even if the latter are obviously necessary. The client's spiritual beliefs must be considered when developing an intervention plan, and “activities of the spirit” may be helpful to foster a sense of hope.[9]

The benefits of exercise are controversial. Muscles affected by PPS may actually function at levels of strength lower than estimated from the results obtained on the MMT, and upper extremity strength varies markedly throughout the ROM. Thus careful observation is essential during engagement in occupations. Exercise must be carefully supervised because it may aggravate pain and overwork muscles innervated by a limited number of motor units.[12,52] Signs of excessive activity are further weakness, discomfort, pain, muscle spasm, and chronic fatigue.[36,51,52]

Chronic pain can be managed or alleviated by prescribed pharmaceuticals, improving body mechanics during occupations, supporting weakened muscles through splinting and adaptive equipment, and promoting lifestyle and role modifications through a multidisciplinary treatment approach based on cognitive-behavioral therapy (CBT), a method that is frequently used by chronic pain management programs and may be employed by occupational therapists. CBT teaches clients about the dynamics of pain and coping strategies such as stress management, relaxation and visualization, appropriate use of play and humor, recognition of fatigue and implementation of activity pacing, monitoring of self-talk, and family training.[10,22,42,48] Strategies can be taught to reduce or eliminate nonessential activities, thus reducing overuse of muscles and resultant pain. Energy conservation for the most valued activities may mean delegating less valued ones to others or performing them with the assistance of equipment, such as orthoses, assistive devices, or ambulation aids.[51,52] Body weight reduction may be medically recommended for some clients to reduce pain, and occupational therapists can work in conjunction with dietitians to address weight loss through cooking groups that create the recommended high-protein diet.[39]

It is important to make referrals to appropriate healthcare professionals depending on the needs of the client and family. These healthcare professionals may include an orthotist, physical therapist, pulmonologist, and psychologist.[52]

GBS and PPS are two disorders that require OT services; they have been presented in detail to outline the process used for individuals with these disorders. The remaining portion of this chapter describes other disorders related to the motor unit that result in compromised occupational performance. The principles behind the interventions described for both GBS and PPS apply to the following disorders as well.

Peripheral Nerve Injuries

Thus far, this chapter has described diseases affecting the anterior horn cell and peripheral nerves. This section covers three specific upper extremity **peripheral nerve injuries**: axillary nerve, brachial plexus, and long thoracic nerve injury. The **brachial plexus** includes the nerves from C5 through T1.[37] These nerve fibers, both sensory and motor, intertwine closely to the vertebral column. The fibers join to form trunks of the brachial plexus, and from the trunks arise the divisions at which further interweaving of fibers occurs. The divisions give rise to the cords of the brachial plexus, and from the cords the terminal branches or named peripheral nerves arise. From an anatomic presentation, this complexity has the potential to preserve function if one root is compressed. For example, the radial nerve is composed of fibers originating from C6, C7, C8, and T1. For a list of nerves, muscles innervated, and actions performed, see Table 37.4. (See Chapter 39 for additional information on peripheral nerve injuries, peripheral pain syndromes, and the management of these disorders.)

TABLE 37.4

Clinical Manifestations of Peripheral Nerve Lesions of the Brachial Plexus

Spinal Nerves	Nerve	Motor Distribution	Clinical Manifestations
C5	Dorsal scapular	Rhomboid major and minor, levator scapulae	Loss of scapular elevation, adduction, downward rotation
C5-6	Suprascapular	Supraspinatus, infraspinatus	Weakened lateral rotation of humerus
C5-6	Subscapular	Subscapularis, teres major	Weakened internal rotation of humerus
C5-6	Axillary	Deltoid, teres minor	Loss of shoulder abduction, flexion, and external rotation and extension
C5-7	Musculocutaneous	Biceps brachii, brachialis, coracobrachialis	Loss of forearm flexion and supination
C5-7	Long thoracic	Serratus anterior	Winging of the scapula
C6-8	Thoracodorsal	Latissimus dorsi	Loss of arm adduction and shoulder extension
C6-8, T1	Radial	All extensors of arm, wrist, fingers, thumb, abductor pollicis longus, supinator, brachioradialis	Wrist drop, extensor paralysis, inability to supinate
C6-8, T1	Median	Flexors of wrist, hand, and digits; forearm pronators; opponens pollicis; abductor pollicis brevis; flexor pollicis brevis; first and second lumbricales	"Ape-hand" deformity, weakened grip, thenar atrophy, unopposed thumb
C8-T1	Ulnar	Supplies muscles on ulnar side of forearm and hand; adductor pollicis, abductor digiti minimi, opponens digiti minimi, flexor digiti minimi brevis, flexor digitorum profundus (digits 4, 5), third and fourth lumbricales, flexor carpi ulnaris, palmaris brevis, dorsal and palmar interossei, flexor pollicis brevis (deep head)	"Claw-hand" deformity, also known as an intrinsic minus hand deformity; interosseus atrophy, loss of thumb adduction

From Hislop HJ, Avers D, Brown M: *Daniels and Worthingham's muscle testing: techniques of manual examination*, ed 9, Philadelphia, 2013, WB Saunders.

Many people are injured every year by car accidents, falls, sports mishaps, gunshots, and violent acts (eg, blunt and sharp wounds) that result in severed, crushed, compressed, or stretched peripheral nerves.[35] The most obvious manifestation of peripheral nerve injury is muscle weakness or flaccid paralysis, with symptoms depending on the extent of the nerve damage. Deep tendon reflexes are depressed or absent. Sensation along the cutaneous distribution of the nerve is also altered or lost. Trophic changes, such as dry skin, hair loss, cyanosis, brittle fingernails, painless skin ulcerations, and slow wound healing in the area of involvement, may be present.

Extensive peripheral nerve damage may produce deformity if contractures, joint stiffness, and poor positioning are allowed to occur. Disfigurement of the hands is particularly noticeable and may produce psychological distress. Other complications may include osteoporosis of bone and epidermal fibrosis of the joints. See Table 37.4 for descriptions of clinical manifestations of peripheral nerve lesions of the brachial plexus.

Axillary Nerve Injury

The axillary nerve is composed of the C5-C6 spinal nerves and arises from the upper trunk of the brachial plexus. The motor branches of the axillary nerve innervate the deltoid muscle and the teres minor muscle (see Table 37.4).[19] The axillary nerve is "the most commonly injured nerve in the shoulder, and the most common cause of injury is anterior dislocation of the shoulder or fracture of the neck of the humerus."[25] Nerve damage may occur as a result of the actual dislocation or of the reduction; other causes include compression (eg, crutches) or trauma (eg, blunt or lacerating wounds). As a result, the client has weakness or paralysis of the deltoid muscle, which causes limitations in shoulder flexion, abduction, extension, and weakness in lateral rotation of the arm. In addition to the loss of muscle power, atrophy of the deltoid muscle produces asymmetry of the shoulders, which may cause issues with body image.[25]

See Table 37.1 for OT assessments. ROM assessment and MMT, as well as clinical observation of the client's ability to use the arm functionally, are critical.

Interventions for axillary nerve injury require that the shoulder dislocation be reduced and that the arm be supported for a brief time in a sling. When the physician prescribes OT for rehabilitation of shoulder function, interventions include passive and active ROM of shoulder flexion and extension and shoulder abduction and adduction exercises while the client is supine or lying on the noninjured side to minimize gravity (Table 37.5). Functional movements are graded as the muscles become stronger.

TABLE 37.5

Occupational Therapy Interventions for Peripheral Nerve Injuries

Nerve Injury	Intervention	Example of Activities
Axillary nerve	Passive ROM to prevent deformity and improve circulation; necessary to protect teres minor and deltoid muscles from stretch during the passive ROM activities	Passive ROM performed two or three times daily while client is supine or lying on uninjured side to minimize effects of gravity; family or caregiver instructed in techniques; client instructed in self-ranging techniques performed on a daily basis
	Adaptive equipment	Instruction in use of long-handled assistive devices to compensate for upper extremity abduction deficit
	Joint protection	Instruction in joint protection to allow nerve time to heal and to prevent further injury; instruction in adaptive equipment, as needed for activities of daily living and leisure, work, and play occupations
	EMG biofeedback	Biofeedback potentially beneficial in providing the client with visual and auditory incentives during muscle reeducation sessions
	Retrograde massage	Use of retrograde massage if edema occurs in hand or arm; client, family, or caregivers instructed in technique to be performed several times per day
	Graded activities	Shoulder movement critical to recovery; incorporation of long, sweeping shoulder movements in the client's meaningful activities; graded from horizontal to vertical
Brachial plexus	Passive ROM to maintain joint flexibility	Passive ROM performed while supine twice daily, with emphasis on shoulder flexion, abduction, and external rotation; family or caregiver instructed in techniques
	Tactile stimulation to upper extremity to increase awareness	Massage, vibration, application of various textures to the arm
	Proprioceptive stimulation to upper extremity	Joint approximation through progressive weight bearing to increase awareness; always necessary to ensure proper alignment of joints
	Bilateral integration to improve body scheme	Use of developmentally appropriate bilateral activities (eg, toys, crafts, or activity that requires two hands)
	Pool therapy	Therapeutic exercises with gravity minimized in water; swimming or weight lifting possible as client's strength improves
	Electrical stimulation	As prescribed by physician after EMG
	Slings	For damage to C5 and C6, sling fabricated to fit around humerus to support arm and allow hand to engage in occupations; especially important if arm is flaccid and the individual is able to walk—prevents further traction injury to nerves
	Splints	Resting splint for flaccid hand/wrist seen with damage to C8 and T1 to maintain part in functional position and prevent contractures; other splints available or fabricated for specific joints; air splints sometimes used to provide stability in elbow extension to bear weight with damage to C7
	Retrograde massage	For edema in hand or arm; client, family, or caregivers instructed in technique to be performed several times per day
Long thoracic nerve	Shoulder stabilized to limit scapular motion while nerve heals	After medical treatment, encouragement of maximal functional independence during activities and education in use of long-handled devices to compensate for shoulder limitations
	If nerve regeneration is not complete, possible consideration of surgery to relieve the excessive mobility of the scapula	
	Retrograde massage	For edema in hand or arm; client, family, or caregivers instructed in technique to be performed several times per day

EMG, electromyography; *ROM*, range of motion.

Brachial Plexus Injuries

The nerve roots that innervate the upper extremity originate in the anterior rami between the C5, C6, C7, C8, and T1 spinal segments. This network of peripheral nerves is collectively called the brachial plexus. This important nerve complex can be palpated just behind the posterior border of the sternocleidomastoid as the head and neck are tilted to the opposite side.[15]

Case Study

William

William, a 60-year-old husband and teacher, was in a car accident that dislocated his right dominant shoulder. He was taken to the emergency room, given a sling, and sent home. Over the next few days, he noticed that he could neither flex nor abduct his humerus more than approximately 45 degrees. His physician reviewed his x-rays, repositioned the humerus, and diagnosed axillary nerve injury. Once the glenohumeral joint was stable, she prescribed occupational therapy to recover arm function.

During his therapy sessions, Marla, his occupational therapist, instructed William and his wife about joint protection, ROM exercises, and use of a reacher. As William's strength improved, Marla explored meaningful activities with him. After he enthusiastically mentioned a map project illustrating the places where he and his family had traveled, the two of them worked together to mount the map on poster board. Marla graded the activity and encouraged William to use long, sweeping movements of his right shoulder in flexion/extension and abduction/adduction when spreading the glue. William then sanded the frame and painted it, again using gliding shoulder movements. His home program also included smooth, gliding shoulder movements (eg, wiping the counters, which his wife happily endorsed).

Analysis

Injury to the axillary nerve is one of the most common peripheral nerve injuries. Once the dislocation of the humerus has been reduced and the nerve begins to regenerate, rehabilitation of function may be possible. In this case, the occupational therapist was able to identify an activity that related to William's role as husband and home project enthusiast. This meaningful occupation caught his attention and engaged him in participation to accomplish the task.

Most brachial plexus injuries are typically unilateral and occur during birth.[31] Obstetric brachial plexus injury occurs if the baby's shoulders become impacted during delivery, which causes the brachial plexus nerves to stretch or tear. For example, if the infant's shoulder is stuck in the birth canal during delivery and the head is pulled, the neck is stretched, which can subsequently stretch or tear the brachial plexus. In adults, traumatic brachial plexus injuries are caused by damage to the nerve roots from a variety of causes (eg, car or motorcycle accidents, sports misadventures, falls, blows to the neck with blunt or sharp objects, radiotherapy).[30] The two types of brachial plexus lesions are Erb-Duchenne syndrome and Klumpke's (Dejerine-Klumpke) syndrome.[15,31,40] These disorders are also referred to as Erb's palsy and Klumpke's palsy.

Erb-Duchenne syndrome is seen with lesions to the upper trunk of the brachial plexus, which consists of C5 and C6 nerve fibers. The incidence among newborns is 2 to 5 per 1000 births with 80% to 90% full recovery within 3 to 24 months.[43] The incidence among adults is not known. Typically, the muscles of the shoulder and elbow are affected, whereas hand movement is retained. Paralysis and atrophy occur in the deltoid, brachialis, biceps, and brachioradialis muscles (see Table 37.4). Upon observation, the arm hangs limp in internal rotation and adduction of the shoulder. The elbow is extended, the forearm pronated, and the wrist flexed, resulting in the “waiter's tip position.” Even though hand muscles are unaffected, functional movement of the upper extremity is extremely limited.[15,25,43]

Klumpke's syndrome results from compression or traction to the lower trunk of the brachial plexus (comprising nerves arising from C8 and T1) and is seen less often than Erb-Duchenne syndrome. Traction during birth or later in life that is caused by a strong upward pull on the upper extremity when it is in an abducted position can result in this disorder. The involved nerves innervate muscles whose actions are wrist and finger flexion and abduction and adduction of the fingers (see Table 37.4). Consequently, paralysis to the distal musculature of the wrist flexors and the intrinsic muscles of the hand results in a “claw-hand deformity,” also referred to as an intrinsic minus hand deformity (Fig. 37.2).[14,25,43] (See Table 37.1 for OT assessments.)

FIG 37.2 Klumpke's syndrome: paralysis to the distal musculature of the wrist flexors and the intrinsic muscles of the hand that results in a “claw-hand deformity” or intrinsic minus hand. (From Chung KC, Yang LJS,

McGillicuddy JE. *Practical management of pediatric and adult brachial plexus palsies*, Edinburgh, 2012, Saunders.)

OT interventions initially involve partial immobilization and positioning. Passive ROM is critical for maintaining joint flexibility, and the client's family or caregiver should be taught to perform these exercises with the client two or three times daily. Intervention includes a variety of tactile and proprioceptive sensory input exercises to increase sensory awareness. Preventing contractures is critical to a functional outcome. For individuals with Erb-Duchenne syndrome, performance of passive and active assistive exercises and fabrication of a sling that fits around the humerus to support the arm are important. If strength improves, resistive exercises and activities can be implemented, and the sling may be removed or used intermittently during walking to support the shoulder.[40,43] For those with Klumpke's syndrome, a short opponens hand splint that supports the thumb in opposition is often used. It is important to provide occupations that are appropriate to developmental ages and stages and that appeal to the client and encourage active use of the extremity in bilateral activities. Surgery to improve nerve growth and upper extremity function may be recommended if improvement is not spontaneously observed within a few months.[40,43] Other interventions are described in Table 37.5.

Long Thoracic Nerve Injury

The long thoracic nerve, arising from C5-C7 nerve roots, innervates the serratus anterior muscle, which anchors the apex of the scapula to the posterior of the rib cage. The serratus anterior's action is scapular abduction and upward rotation (see Table 37.4).[19] Although injury to this nerve is not common, the nerve can be injured in a number of ways: carrying heavy weights on the shoulder (eg, backpacks), blows to the neck, compression caused by prolonged lying on the lateral trunk, and wounds. The resulting clinical picture involves "winging" of the scapula where the inferior angle and lower portion of the medial border of the scapula is protruding off the thoracic rib cage. The individual experiences difficulty flexing the glenohumeral joint above shoulder level and protracting the shoulder or performing scapula abduction and adduction.[15,25] Asking the client to perform a wall pushup is a commonly used screening assessment technique. If the long thoracic nerve is impaired, the scapula on that side will elevate and move medially, with the inferior angle rotating medially to produce a winging of the scapula.[25] Other OT assessments are described in Table 37.1.

Lesions of the radial, median, and ulnar nerves and cumulative trauma disorders affecting the hand are discussed in Chapter 39.

Psychosocial Interventions for Peripheral Nerve Injuries

Brachial plexus, thoracic, and axillary nerve injuries are life changing, affecting the psychological and emotional states of clients and their families and friends. Clients often experience depression, which may be a reaction to the traumatic event that caused the injury or may become chronic and serious. Occupational therapists can be helpful in this regard by discovering activities that are meaningful to the client and adapting them for success. The client's self-image is challenged and may require revision to accommodate the client's changed health status. For example, if the deltoid muscle has atrophied, the client can wear a foam or thermoplastic pad under clothing to round out the shoulders. Use of these aesthetic pads may increase the client's willingness to venture out into society. Referrals to support groups or a psychologist also may help clients adjust to a changed appearance.[38]

Participation in leisure occupations has been found to help people with physical disabilities redefine themselves (see Chapter 16), and occupational therapists should consider leisure as an important area of occupation to include in an intervention plan.[2]

Neuromuscular Disorders

Neuromuscular Junction: Myasthenia Gravis

Myasthenia gravis (MG) is the most common chronic disease involving a disorder of chemical transmission at the nerve-muscle synapse, or neuromuscular junction. The term *myasthenia gravis* is derived from Greek and Latin and means "grave muscle weakness."[21,34,49] It is caused by an autoimmune response in which antibodies are produced that block, alter, or destroy the nicotinic acetylcholine receptors on the postsynaptic membrane and interfere with synaptic transmission at the nerve-muscle junction. Because neurotransmission is defective, skeletal (voluntary) muscles, typically the cranial muscles, become weak and easily fatigued. The incidence of MG in the United States is approximately 14 to 20 in a population of 100,000, but it may be underdiagnosed, especially among very old persons. The latest statistics show that with the aging of the population, men are diagnosed more often than women, with symptoms beginning after 50 years of age.[3,7,21,45]

Most clients diagnosed with MG initially experience symptoms in the oculomotor muscles that cause eyelid drooping, referred to as ptosis, and double vision, referred to as diplopia. Oropharyngeal muscle weakness, which results in difficulty in chewing, swallowing, and speaking, is seen in some clients. Weakness of limb musculature is not typically an initial symptom. People with MG tend to be stronger in the morning, but their strength and endurance decrease as the day progresses and muscles fatigue. Therefore the client may experience increased double vision, severe drooping of the eyelids, difficulty with speech or swallowing, and fatigue with repetitive activity as muscles tire (Table 37.6).

TABLE 37.6

Myasthenia Gravis: Initial Symptoms, Description, and Percentage of Clients With Symptoms

Initial Symptoms	Description	Approximate Percentage of Clients With Initial Symptoms
Oculomotor dysfunction	Severe drooping of eyelids (ptosis), double vision (diplopia), inability to move eyes in certain directions	70%
Otopharyngeal muscle weakness	Difficulty chewing, swallowing, speaking; in severe cases, problems breathing and coughing resulting in aspiration	20%
Limb weakness	May be limited to specific muscles or may progress to generalized fatigue	10%

Data from Cabrera CS, et al: Myasthenia gravis: the otolaryngologist's perspective, *Am J Otolaryngology* 23:169, 2002; Howard JF: *Myasthenia gravis: a summary.* www.myasthenia.org/information/summary; Brown RH, Cannon SC, Rowland LP: Diseases of the nerve and motor unit. In Kandel ER, et al, editors: *Principles of neural science,* ed 5, New York, 2012, McGraw-Hill; Kernich CA, Kaminski HJ: Myasthenia gravis: pathophysiology, diagnosis and collaborative care, *J Neuroscience Nurs* 27:207, 1995; Yee CA: Getting a grip on myasthenia gravis, *Nursing* 32:1, 2002.

Most clients with MG have abnormalities of the thymus glands, and some have thymic tumors. Removal of the thymus gland (thymectomy) is standard therapy for most clients, but response time for symptom reduction varies with individuals and may take as long as 2 to 5 years after surgery. Clients without thymomas have a better response to surgery than those with a tumor. Clients are also treated with corticosteroids (prednisone) and immunosuppressive and cholinesterase-inhibiting drugs.[7,21] High-dose intravenous immune globulin has been reported to decrease symptoms in 50% to 100% of clients for a period of weeks to months. For clients with symptoms that suddenly worsen, those about to have surgery, or those who have not responded well to other interventions, plasma exchange is used as a short-term treatment. Nearly all people with MG improve for weeks to months after plasma exchange.[21]

Most people with MG usually experience maximal weakness during the first year after diagnosis. The course of the disease fluctuates but is usually progressive. However, according to the Myasthenia Gravis Foundation of America (www.myasthenia.org), the current prognosis for most patients with this disease is good; most live normal or nearly normal lives. Remissions or a decrease in symptoms and an improvement in strength and function can last for years. However, emotional upset, extended exertion, infections, medications, thyroid conditions, elevated body temperature, or childbirth may induce exacerbations of unpredictable severity.[21] With modern diagnosis and treatment effectiveness, the mortality rate of MG is nearly zero.[45]

Role of the Occupational Therapist

Because similarities exist among the diagnoses of motor unit disorders, OT evaluation follows the same pattern, with specific assessments selected according to the disorder (see Table 37.1). A significant area for assessment in MG is eating and swallowing because of the dangers of aspiration. Because some clients may experience difficulty with diaphragmatic and intercostal muscle strength, they may have trouble coughing to clear secretions. An occupational therapist with advanced training in dysphagia should assess and treat clients with severe eating and swallowing dysfunction (see Chapter 27).

Case Study

Jan

For several months, Jan, a 45-year-old photographer, had noticed unusual changes in her body. Her eyelids felt heavy, and her vision would blur after she was reading for a short period of time; it felt as if she was cross-eyed. Jan's speech became slurred if she was in a lengthy conversation. More recently, she had become aware that when she was drinking thin liquids, such as coffee, she would frequently choke. When she visited her doctor and received the results of medical tests, she was shocked to hear that she had an autoimmune disorder called myasthenia gravis. Jan's physician referred her to a surgeon for removal of her thymus gland, and she was given a prescription for prednisone.

Jeri, an occupational therapist trained in dysphagia, assessed Jan's swallowing abilities and recommended that thickening agents be added to liquids to decrease choking. As Jan improved, Jeri performed ongoing swallowing assessments and was able to gradually add thinner liquids so that Jan could again enjoy coffee. Jan reports that the most important thing that anyone did for her was when Jeri helped her enroll in a myasthenia gravis support group, where she experienced empathy, was given resources, and, to her surprise, found herself laughing again.

Analysis

People with myasthenia gravis can be helped through a variety of therapies to lead a near normal life. When a swallowing disorder is present, an occupational therapist with advanced training must perform a dysphagia assessment and make recommendations to prevent aspiration and pneumonia. A social support system is critical to the well-being and recovery of people with this disease.

Interventions for clients with MG depend on the results of the OT evaluation, which includes client and caregiver goals. The therapeutic program should not cause fatigue; therefore the therapist must be aware of the client's medication regimen, ability to tolerate activity, and the time of day that the client has the most energy. The client's muscle strength must be monitored on a regular basis, and the occupational therapist keeps a running record to document any important changes that must be reported to the medical team. Specific intervention protocols for MG are scarce, but one study described the ways in which subjects with MG self-managed fatigue. “Effective self-care actions include stress reduction techniques, pacing all activities, and increased rest and sleep.”[13]

An important aspect of treatment is to educate the client and family members to use energy conservation and work simplification strategies when engaging in ADLs, IADLs, and leisure occupations (see Chapters 10, 14, and 16). Adaptive and assistive devices may be introduced to decrease effort during daily activities. Because vision may be impaired, the occupational therapist should visit the client's home to assess architectural barriers, bathroom safety, and furniture arrangements; otherwise, the client might fall. If chewing and swallowing are problems, an eating program should be designed and monitored by an experienced occupational therapist (see Chapter 27).

Because of the client's facial appearance (eg, drooping eyelids), fear of choking, or steroid-related changes in appearance, the psychosocial effects of MG may be distressing to clients and their family and friends. The therapist should always treat the client with empathy and encourage honest discussion. For general well-being, the client must be able to express his or her feelings about these physical changes.[38] The client and family members may also be referred to an MG support group, a psychologist, or both.

Myopathic Disorders

Muscular Dystrophies

The muscular dystrophies are a group of more than 30 genetic diseases. The dystrophies have in common the progressive degeneration of muscle fibers while the neuronal innervation to muscle and sensation remains intact. As the number of muscle fibers declines, each axon innervates fewer and fewer of them, resulting in progressive muscle weakness. Some forms of **muscular dystrophy** (MD) have an onset in childhood, whereas others may not appear until middle age or later. The disorders also differ in terms of the distribution and extent of muscle weakness, rate of progression, and pattern of inheritance.[33] The major types of MD—Duchenne, Becker, facioscapulohumeral, myotonic, and limb girdle—are described in Table 37.7.

TABLE 37.7

Major Types of Muscular Dystrophy

Type	Description	Age of Onset and Progression
Duchenne	Affects boys only because it is inherited as an X-linked recessive trait	Onset age: 3-5 years—begins in muscles of pelvic girdle and legs
	Results from gene mutation that regulates the protein involved in maintenance of muscle integrity	By 12 years unable to walk; uses wheelchair
		Weakness spreads upward to shoulder girdle and trunk
		By 20 most need respirator to breathe, with death usually occurring by age 30
Becker	Similar to Duchenne, with milder symptoms	Onset age: 2-16 years
	X-linked recessive, affects boys	Slower progression of weakness
		Survival into middle age
Fascioscapulohumeral	Affects both genders	Onset age: Adolescence
	Autosomal dominant	Slow progression of weakness resulting in a near normal lifespan
	Affects primarily the muscles of the face and shoulder girdle (hence its name)	
Myotonic	Affects both genders	Onset age: Varies, often adult
	Causes weakness but also myotonia—prolonged muscle spasm or delayed muscle relaxation after vigorous contraction—especially in fingers and face; floppy, high-stepping gait; appearance of long face and drooping eyelids	Involves cranial muscle and distal limb weakness rather than proximal
		May be mild or severe
		Associated symptoms progress to involve cardiac abnormalities, endocrine disturbances, cataracts, and, in men, testicular atrophy and baldness
Limb girdle	Affects both genders	Onset age: teens to early adulthood
	Progressive weakness affecting pelvic girdle and shoulder girdle first	Weakness leads to loss of ability to walk within 20 years
		Relatively slow progression
		Death in mid to late adulthood

From the National Institute of Neurological Disorder and Stroke: *Muscular dystrophy: hope through research*, March 4, 2016; Brown RH, Cannon SC, Rowland LP: Diseases of the nerve and motor unit. In Kandel ER, et al, editors: *Principles of neural science*, ed 5, New York, 2012, McGraw-Hill.

Because this group of diseases is degenerative, the decline of muscle function cannot be prevented. As yet, there is no cure. Medical management is largely supportive. Drug therapy includes corticosteroids to slow the rate of muscle degeneration, immunosuppressants to delay some damage to dying muscle cells, drugs to provide short-term relief from muscle spasms and weakness, anticonvulsants to control seizures and some muscle activity, and antibiotics to fight respiratory infections. Various treatment therapies are currently being investigated but are not yet available. These include gene replacement, gene modification, and cell-based and drug-based therapy.[33]

Rehabilitation measures are vital in delaying deformity and achieving maximal function within the limits of the disease and its debilitating effects. In addition to occupational therapy, rehabilitation may include physical therapy, speech therapy, and respiratory therapy services.[33]

Role of the Occupational Therapist

The primary goal of OT is to help the client with MD maintain maximal independence as long as possible. Self-care activities and assistive devices that promote independence during home, school, leisure, and work activities are a vital part of the treatment program.[40] Leisure occupations need to be considered in a comprehensive OT intervention plan to ensure balance in all areas of the client's life. Play and laughter are particularly important to the health, well-being, and social adjustment of the growing youth (see Chapters 6 and 16).

A comprehensive team evaluation of the client's abilities and disabilities should be administered. The team includes the physician, occupational therapist, physical therapist, and psychologist. A social worker may advise the family on community resources. The occupational therapist assesses the client's functional status in ADLs and IADLs, ROM exercises, and muscle strength, as well as the fit and proper use of adaptive equipment, engagement in leisure activities, and emotional status. (See Table 37.1 for assessments.)

After the evaluation process is complete, an OT intervention plan is developed to address specific concerns. Active exercise may help the client to maintain strength, but overexertion and fatigue must be prevented. Because people with MD may experience cardiac complications, occupational therapists must be aware of the client's medical history and use exercise judiciously, observing cardiac precautions when necessary. Incorporating exercise into meaningful, age-related activities that are monitored by a therapist can promote engagement in participation. Parachute games, obstacle courses, and swimming may be implemented with frequent built-in rest breaks.[16]

Two pilot studies involving clients with MD and exercise show that improvements are possible; investigators recommend further research. Clients with myotonic dystrophy showed significant improvement in hand function and self-rated occupational performance on the Canadian Occupational Performance Measure after a 3-month hand training OT intervention.[1] An experimental pilot study quantitatively evaluated qigong and determined that it may be used as an adjunct therapy program. Subjects with MD reported perceived maintenance of general health and positive coping when compared to the control group. The treatment group tended to "maintain balance function during training and performance of qigong whilst there was a decline when not training." The researchers concluded that qigong decreased the rate of decline and is worthy of further study.[47]

Adaptive equipment and environmental modifications are often used as OT interventions. Instruction in work simplification and energy conservation—as well as in creative and effective strategies to perform ADLs, IADLs, and various other occupations—is important in the OT program.[16,40] A powered wheelchair, a wheelchair lap board, suspension slings, or mobile arms supports may facilitate greater independence in self-feeding, writing, reading, computer use, and tabletop leisure activities when there is substantial shoulder girdle and upper limb weakness. Built-up utensils are helpful when grip strength declines. Home and workplace modifications will be necessary for most clients. Client and family education is an important part of a team rehabilitation program.[40] A supportive approach to the client and family is helpful as function declines and new mobility aids, assistive devices, and community resources become necessary.[16]

Wheelchair prescription and mobility training in either a manual or powered wheelchair are included in the OT intervention program. The wheelchair may require a special seating system or supports to minimize the development of scoliosis, hip and knee flexion contractures, and ankle plantar flexion deformity.[16,40] Powered wheelchairs are often recommended to conserve energy and decrease strain on shoulders and trunk. Instruction in methods to maneuver power chairs can cause overexertion, and this activity, like any other, must be graded for difficulty. One study found that young people (ie, those between 7 and 22 years of age) diagnosed with either MD or cerebral palsy who were inexperienced powered wheelchair drivers significantly improved their wheelchair driving performance through the use of simulator training. The researchers concluded that this method of instruction conserved energy and was effective.[18]

Chronic pain in children, adolescents, and young adults (ie, persons between 8 and 20 years of age) with physical disabilities has not been widely studied, but research indicates that chronic pain interferes with ADLs and IADLs in young people with MD, cerebral palsy, spinal cord injury, acquired and congenital limb deficiency, and spina bifida.[27] Pain appears to be more prevalent in female subjects than male subjects during the performance of daily routines, it interfered most often with physical activities, and it negatively affected mood. McKearnan noted that the young people in this study frequently reported pain associated with physical therapy, OT, and therapeutic home programs.[27] They also complained that the use of splints, orthotics, and prosthetics was sometimes painful. Therapists must be aware of their client's pain levels and modify activities, splints, and orthotics as needed. Helping clients with MD to manage pain will most likely lead to improved quality of life.

The sense of self is challenged as clients with MD realize that they will experience a progressive loss of bodily function. Occupational therapists must realize that these clients are constantly forced to redefine themselves as they go through life, making "continuous trade-offs as function is lost."[38] A critical element in OT intervention is to help the client and family members find meaningful activities in which to participate either as individuals or as a family. For example, connecting with spiritual activities that engage clients and families on the deepest level could be critical to a sense of hope and well-being.[9] Alternatively, encouraging families to use humor and to play and laugh together can promote bonding, reduce fear and anxiety, and produce positive physical and emotional feelings.[5]

Psychosocial issues related to MD involve the whole family. Parents go through phases of shock, fear, and despair when the diagnosis is made and as the child ages and function decreases (eg, when the wheelchair is prescribed). Encouraging parents not to be overprotective and to continue to promote their child's independence is an important aspect of therapy. Further, therapists can anticipate times in the growing child's life when psychosocial support will be most essential and can offer education and support during intervention sessions. Some potentially disturbing developmental milestones for the client and family occur when the child starts school (at approximately age 5), when the child loses the capacity for independent ambulation (at 8 to 12 years), when adolescent social life is limited, and, of course, when young adulthood arrives with the expectation that death is imminent.[16,40] Referral to a psychologist, family counselor, or spiritual adviser during these times should be considered.

Summary

The motor unit consists of the lower motor neuron, neuromuscular junction, and muscle. Some motor unit dysfunctions are reversible, and others are degenerative. The role of the occupational therapist is to assess functional capabilities in all occupational performance areas and contexts. ADLs and IADLs (including self-care, home management, mobility, and work-related tasks), energy conservation, work simplification, joint protection, spiritual approaches, and appropriate humor may be used to restore or maintain function. Proper positioning, exercise programs, and pain management techniques are used as indicated to facilitate recovery and increase functional capacity. Orthoses, assistive devices, communication aids, and mobility equipment and training in their use may be necessary. Psychosocial considerations and client and family education are important aspects of the OT program.

Threaded Case Study

Edith, Part 2

Return to the case study presented at the beginning of this chapter, and compare your answers with the ones given here.

1. What are the phases of Guillain-Barré, and what occupational therapy interventions might be used in each phase?

The typical progression of GBS occurs in three phases. The initial, or acute, phase begins with the client's first conclusive symptoms and lasts until there is no further decline in physical status. This phase may last from 1 to 4 weeks.[29] During this phase, Edith's condition progressed from generalized weakness to paralysis of her extremities and muscles of the trunk and diaphragm. She was completely dependent in activities of daily living and required a ventilator to breathe. Jen, the occupational therapist assigned to the intensive care unit, established four goals with Edith and her family.

Goal	Intervention
Maintain full ROM in all joints.	Perform passive ROM two times per day to all joints.
Prevent contractures.	Fabricate resting hand splints, and educate client, family, and nursing aides in proper ways to position Edith in bed.
Teach Edith and family about GBS.	Provide and discuss handouts, reading materials, and GBS websites.
Provide a strategy for Edith to listen to the Bible.	Instruct Edith in ways to use the control switch with her tongue to turn the CD player on and off.

Phase 2, the plateau phase, began when Edith's physical status stabilized, with no further deterioration. She was transferred to a regular hospital unit. She was able to breathe on her own, speak softly, and sit up in bed in a semireclining position with pillows positioned for support. Some strength had returned to her proximal musculature, but her hands remained paralyzed and she fatigued easily. The plateau phase lasted a few weeks during which Edith's physical status remained unchanged. The goals for this phase were essentially the same as for the acute phase except that now Edith could choose to either read the Bible by turning the pages with a mouth stick or listen to the CD using the mouth stick to turn the player on and off. She could also control the television set with the mouth stick and was able to view her favorite shows. Family and friends were encouraged to visit but were cautioned not to fatigue her.

The recovery phase began when Edith's strength and sensation began to return to her distal extremities. She was transferred to the rehabilitation unit. The occupational therapist, Lara, and Edith came up with four goals during the recovery phase. The use of adaptive equipment such as built-up handles, work simplification and energy conservation techniques (eg, breaking the task down into steps and resting between steps), and the use of electric appliances were encouraged during activities. Edith practiced playing cards with other clients in a group environment. Lara set her up with a cardholder and a battery-powered card shuffler when her hands were too weak to hold the cards, but Edith eventually was able to play independently. Edith went to the mall with her granddaughter and Lara. During the outing, Lara taught them, in the context of shopping, how to gauge fatigue and to rest for 5 or 10 minutes when feeling tired. She also served as a role model, pacing the activity by limiting the initial shopping trip to 30 minutes and encouraging gradual lengthening of the experience over time. Lara provided Edith with community resources to aid in her independence. For example, the Guillain-Barré Syndrome Foundation International (GBSFI) offers local support groups, literature, and conferences to all GBS survivors and caregivers. In addition, Edith's family received extensive training from the interdisciplinary team members on how to continue the learned strategies and use the equipment in the home and community. Driving was not addressed at an inpatient level, but Edith was referred to the OT driver training program, where she would be assessed when her strength returned.

2. In what ways were Edith's psychosocial needs addressed during recovery?

Edith's fears about being paralyzed were addressed in several ways. Edith and her family were taught about the disease and encouraged to have hope because most people with GBS recover well. Edith's spiritual needs were met by making it possible for her to continue her morning Bible routine; she initially used a tongue switch to turn a Bible CD on and off and then was able to use a mouth stick to turn pages until her hands recovered strength. Edith expressed a desire to be as independent as possible in activities of daily living, to cook for her family, and to enjoy family outings and card playing. These activities were all made possible through occupational therapy adaptive interventions. Her family members and friends were encouraged to visit, gradually increasing the length of time that they stayed.

3. Describe energy conservation techniques that you think would be appropriate for Edith while engaging in her valued occupation of cooking.

First, Edith and Lara reviewed the recipe and listed the necessary items while seated at the kitchen table. Edith used a wheeled kitchen cart to gather items and carry them to the counter. Lara provided her with a reacher to obtain items on high shelves. When the items were assembled, Edith sat and rested on a bar stool near the counter while she and Lara reviewed the next step. Electric appliances were used to chop and stir the ingredients. Edith rested after this step. Lara showed Edith how to slide containers along the counter to the stove without lifting them. They walked back to the table to play a game of cards while the meal cooked. When the food was cooked, Edith placed plates and utensils on the kitchen cart with the one-dish meal and wheeled the cart to the table to enjoy her meal.

Review Questions

1. Name the components of the motor unit and one disorder that may result in dysfunction for each component.
2. Describe Guillain-Barré syndrome and the occupational therapy interventions used for clients with this disorder.
3. Describe the symptoms of postpolio syndrome.
4. What are the elements of the occupational therapy program for the client with postpolio syndrome?
5. List at least six clinical manifestations of peripheral nerve injury.
6. Describe the occupational therapy treatment strategies, including any contraindications, for peripheral nerve injuries.
7. Describe a method of managing pain that an occupational therapist may use.
8. Discuss the clinical signs of myasthenia gravis.
9. Describe the role of occupational therapy for clients who have myasthenia gravis.
10. What is the primary treatment precaution in myasthenia gravis?
11. Name and differentiate the four types of muscular dystrophy.
12. What are the treatment goals for muscular dystrophy?
13. Discuss ways that occupational therapists address the psychosocial needs of clients with each of the motor unit disorders.

Arthritis

Lisa Deshaies

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, the student or practitioner will be able to do the following:

1. Understand the distinct disease processes of osteoarthritis and rheumatoid arthritis.
2. Describe common similarities and differences in the symptoms of osteoarthritis and rheumatoid arthritis.
3. Identify joint changes and hand deformities commonly seen with osteoarthritis and rheumatoid arthritis.
4. Recognize medications commonly used in the treatment of arthritis and their side effects.
5. Understand the physical and psychosocial effects of arthritis and their impact on occupational functioning.
6. Identify important areas to evaluate in clients with arthritis.
7. Identify the intervention objectives of occupational therapy for clients with arthritis.
8. Design an appropriate individualized intervention plan based on diagnosis, stage of disease, limitations in functional activity, and client goals and lifestyle.
9. Identify key resources helpful to persons with arthritis and to healthcare providers.
10. Identify evaluation and treatment precautions related to arthritis.

KEY TERMS

Arthritis

Crepitus

Gelling

Joint laxity

Tenosynovitis

Threaded Case Study

Nina, Part 1

Nina is a 52-year-old woman with a 4-year history of rheumatoid arthritis. She lives with her husband in a large two-story home. Her primary roles are managing her household and caring for her two grandchildren (ages 7 and 9) after school. Additionally, she is self-employed as an accountant who contracts her services to three small companies in nearby cities. Nina values being active and productive. Her part-time job serves as both a source of enjoyment and needed household income. In her leisure time, she participates in church activities and attends her grandchildren's school and sporting events.

Nina was referred to outpatient occupational therapy after an exacerbation of her arthritis that resulted in increased pain, fatigue, and difficulty engaging in many important daily occupations. On initial evaluation, Nina identifies her primary concerns as maximizing her functional level and reducing her pain so that she can resume full participation in work, housecleaning, and child care. Clinical examination reveals pain and limitations in active range of motion in all upper extremity joints, especially her wrists and fingers. Mild synovitis is present at her wrist and metacarpophalangeal joints, but no other joint changes are noted. Pain and stiffness are interfering with daytime activities and are also making sleep difficult. Her energy level has significantly decreased, and she reports feeling tired all the time. Although she still manages to watch her grandchildren for 2 hours each afternoon, she is unable to care for her house to her liking and is able to work only half of her usual 20 hours a week; she is fearful of losing her contracts.

Critical Thinking Questions

1. What components of evaluation would you choose to assess regarding Nina's prior and current clinical and functional status?

2. Which aspects of the disease process are most problematic, and what are the major performance skills, performance patterns, contexts, activity demands, and client factors influencing Nina's ability to engage in her employment and other areas of occupation?

3. What interventions would you use to help Nina reach her goal of being able to continue working?

Overview of Rheumatic Diseases

The term **arthritis** is of Greek derivation and literally means "joint inflammation." It is used to describe different conditions that fall under the larger umbrella of rheumatic diseases. Rheumatic diseases encompass more than 100 conditions characterized by chronic pain and progressive physical impairment of joints and soft tissues (eg, skin, muscles, ligaments, tendons). These conditions include osteoarthritis (OA), rheumatoid arthritis (RA), systemic lupus erythematosus, ankylosing spondylitis, scleroderma, gout, and fibromyalgia. One in every five adults in the United States has signs and symptoms of arthritis, increasing to nearly 50% in persons over the age of 65.[24] Arthritis is a major public health problem that costs the U.S. economy nearly $128 billion in medical care and indirect expenses annually.[26] Rheumatic diseases are a leading cause of disability with significant economic, social, and psychological impact[25] resulting in worse health-related quality of life for those affected than for those without arthritis.[41] Between 2010 and 2012, approximately 52.5 million Americans were affected by arthritis and other rheumatic conditions, with an estimated 43% experiencing limitations in their ability to participate in daily activities and 31% limited in their ability to work.[24,118] As the population continues to age, the prevalence of arthritis-related conditions is expected to increase to an estimated 67 million by the year 2030, with disability occurring in 37%.[24]

Occupational therapists are likely to encounter clients with rheumatic diseases in their practice settings, whether the condition is manifested as a primary or secondary type. To recognize problem areas and plan effective intervention strategies, the occupational therapist should know the unique features of each disease, its underlying pathology, and its typical clinical findings; the therapist should also be familiar with commonly prescribed medications and their adverse reactions. Given the scope and intended purpose of this book, it is neither appropriate nor possible to adequately describe every rheumatic disease. Therefore this chapter focuses on two of the most prevalent diseases: OA and RA. Armed with an understanding of the noninflammatory and inflammatory disease processes that they represent, the therapist can apply many of the evaluation and intervention principles to other rheumatic conditions. Table 38.1 provides a quick summary of the contrasting features of OA and RA.[3,12,24,32,59,91,108,110,113]

TABLE 38.1

Primary Features of Osteoarthritis and Rheumatoid Arthritis

	Osteoarthritis	Rheumatoid Arthritis
Prevalence	Affects 27 million Americans	Affects 1.5 million Americans
Peak incidence	Increases with age, <50 years old more common in males and >50 years old more common in females	Ages 40–60, 3 : 1 female-to-male ratio
Onset	Usually develops slowly over period of years	Usually develops suddenly, within weeks or months
Systemic features	None	Fever, fatigue, malaise, extraarticular manifestations
Disease process	Noninflammatory, characterized by cartilage destruction	Inflammatory, characterized by synovitis
Joint involvement	Individual	Polyarticular, symmetric
Joints commonly affected	Neck, spine, hips, knees, MTPs, DIPs, PIPs, thumb CMCs	Neck, jaw, hips, knees, ankles, MTPs, shoulders, elbows, wrists, PIPs, MCPs, thumb joints
Morning stiffness	<30 minutes	At least 1 hour, often >2 hours

CMC, carpometacarpal, *DIP*, distal interphalangeal; *MCP*, metacarpophalangeal; *MTP*, metatarsophalangeal; *PIP*, proximal interphalangeal.

Osteoarthritis

Osteoarthritis (OA), also referred to as degenerative joint disease, is the most common rheumatic disease and affects approximately 27 million people in the United States.[59,91] It ranks third among health problems in the developed world.[16] Its prevalence strongly correlates with age. In fact, evidence of characteristic cartilage damage is almost universal in persons older than 65 years.[16] Before the age of 50, men are more likely to have OA; past the age of 50, women predominate.[12] In addition to age and gender, risk factors include heredity, obesity, anatomic joint abnormality, injury, and occupation leading to overuse of joints.[12] It is interesting to note that because RA may cause malalignment or instability of joints, it often results in premature OA.[27]

OA is classified as primary or secondary. Primary OA has no known cause and may be localized (ie, involvement of one or two joints) or generalized (ie, diffuse involvement generally including three or more joints). Secondary OA can be related to an identifiable cause, such as trauma, anatomic abnormalities, infection, or aseptic necrosis.[16,32]

OA is a disease that causes the cartilage in joints to break down, with resultant joint pain and stiffness. Unlike RA, which is **systemic** (affecting the entire body), OA limits its attack to individual joints. Also in contrast to RA, the basic process of OA is noninflammatory, although secondary inflammation caused by joint damage is common. Once considered simply "wear and tear" arthritis, OA is now thought to involve more than just the passive deterioration of cartilage. The agent that initiates OA is not well understood, but it is known to involve a complex dynamic process of biomechanical, biochemical, and cellular events.[59] These are affected by local, systemic, genetic, environmental, and mechanical factors, which directly or indirectly influence the vulnerability of cartilage.[12] It is, in essence, the "final common pathway" for a variety of conditions.[16]

A healthy joint is lined by articular cartilage that is relatively thin, highly durable, and designed to distribute loads and limit stress on subchondral bone (Fig. 38.1).[16] OA destabilizes the normal balance of degradation and synthesis of articular cartilage and subchondral bone and involves all of the tissues of a diarthrodial (ie, synovial-lined) joint.[12,16] OA is basically a two-part process: deterioration of articular cartilage and reactive new bone formation.[73] This breakdown of joint tissue occurs in several stages. First, the smooth cartilage softens and loses its elasticity, which makes it more susceptible to further damage. Eventually, large sections of the cartilage wear away completely and result in reduced joint space and painful bone-on-bone contact. The ends of the bone thicken, osteophytes (bony growths) are formed where ligaments and capsule attach to bone, and the joint may lose its normal shape (Fig. 38.2). Fluid-filled cysts may form in the bone near the joint, and bone or cartilage particles may float loose in the joint space.[3,72]

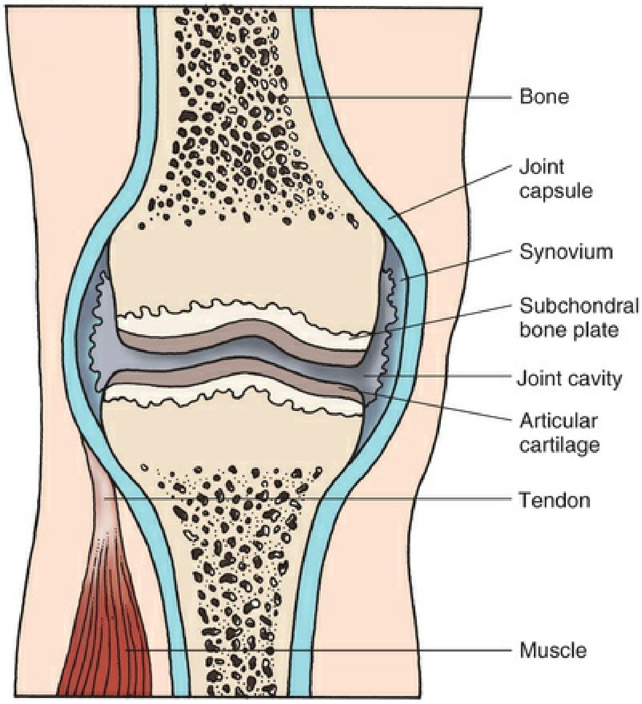

FIG 38.1 Normal joint structures. (From Ignatavicius DD, Workman ML: *Medical-surgical nursing: patient-centered collaborative care,* ed 7, St. Louis, 2013, Saunders.)

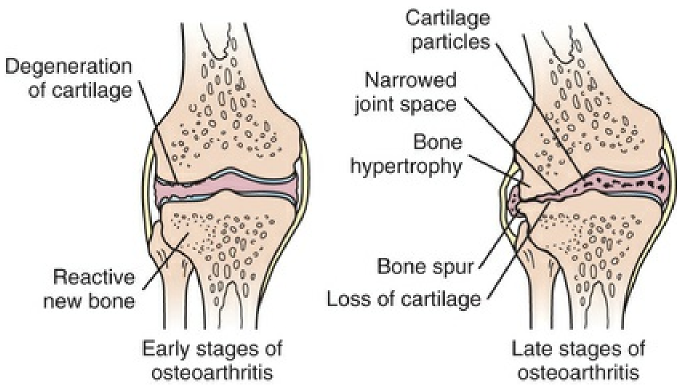

FIG 38.2 Joint changes in osteoarthritis. (From Magee DJ, et al, editors: *Pathology and intervention in musculoskeletal rehabilitation,* ed 2, St. Louis, 2016, Elsevier.)

Clinical Features

OA is characterized by joint pain, stiffness, tenderness, limited movement, variable degrees of local inflammation, and **crepitus** (an audible or palpable crunching or popping in the joint caused by the irregularity of opposing cartilage surfaces).[32,52] It can affect both axial and peripheral joints. The most common joints are the distal interphalangeal (DIP), proximal interphalangeal (PIP), and first carpometacarpal (CMC) joints of the hand; the cervical and lumbar apophyseal joints; the first metatarsophalangeal (MTP) joints of the feet; and the knee and hip joints.[32,59] Symptoms are usually gradual and may begin as a minor ache with motion. Pain and stiffness typically occur with activity and are relieved by rest, but eventually they become present at rest and at night. Morning stiffness (lasting less than 30 minutes) and stiffness after periods of inactivity (known as **gelling**) may develop. With advanced disease, patients may complain of the "bony" appearance of their joint, which is a result of osteophyte formation and possibly muscle atrophy.[32,59]

Diagnostic Criteria

The diagnosis of OA is initially made on the basis of the patient's history and physical examination, with a lack of systemic symptoms ruling out inflammatory disorders such as RA. The cardinal symptoms are use-related pain and stiffness or gelling after inactivity. The clinical diagnosis is typically confirmed with radiographs of the affected joint, which will show osteophyte formation at the joint margin, asymmetric joint space narrowing, and subchondral bone sclerosis.[32] Magnetic resonance imaging (MRI) may be used to improve diagnostic imaging; MRI is able to more sensitively detect loss of cartilage, osteophytes, and subchondral cysts.

Medical Management

OA currently has no cure. Goals in the treatment of OA are to relieve symptoms, improve function, limit disability, and avoid drug toxicity.[59,94] Pharmacologic treatment may be systemic or local. Commonly prescribed systemic medications include analgesic agents and antiinflammatory agents (Table 38.2).[5] Analgesic agents provide relief to painful joints and may be non-narcotic (nonopioid) or narcotic (opioid) for advanced and severe OA that fails to respond to other measures. Antiinflammatory agents relieve pain, with the added benefit of decreasing local joint inflammation. Because of the risk for gastrointestinal and renal toxicity, these drugs are typically used when analgesics are ineffective. Nonsteroidal antiinflammatory drugs (NSAIDs) and cyclooxygenase-2 (COX-2) inhibitors fall into this category. Though proved effective in treating OA, NSAIDs must be chosen and monitored carefully to minimize potentially serious side effects. COX-2 inhibitors provide clinical benefits similar to NSAIDs but with a lower incidence of gastric problems; however, they carry a black box warning due to links with an increased risk for heart attack and stroke.[5] Local pharmacologic treatment of OA includes topical agents and intraarticular corticosteroid injections, alone or as an adjunct to systemic medications. Among topical agents are aspirin and capsaicin creams, as well as the first topical NSAID approved for treating OA pain (Voltaren gel).[5] Cortisone injections in a joint are often limited to fewer than three per year because of the possible risk for progressive cartilage damage.[21]

TABLE 38.2

Common Arthritis Medications and Side Effects

Class	Medication	Possible Side Effects
Analgesics		
Nonopioid	Excedrin, Tylenol	Usually none if taken as prescribed
Opioid	Norco, Tylenol with codeine, Vicodin	Constipation, dizziness or lightheadedness, drowsiness, mood changes, nausea, vomiting, drug tolerance, and physical dependence with long-term use
Nonsteroidal Antiinflammatory Drugs (NSAIDs)		
Traditional	Advil, Aleve, Feldene, Indocin, Motrin, Naprosyn, Voltaren	Abdominal pain, dizziness, drowsiness, gastric ulcers and bleeding, greater susceptibility to bruising or bleeding, heartburn, indigestion, lightheadedness, nausea, tinnitus, kidney and liver effects
COX-2 inhibitors	Celebrex	Same as traditional NSAIDs, except less likely to cause gastric ulcers and susceptibility to bruising or bleeding; black box warning for increased risk for heart attack and stroke
Salicylates	Anacin, Bayer, Bufferin, Ecotrin	Abdominal cramps, diarrhea, gastric ulcers, headache, heartburn, increased bleeding tendency, confusion, dizziness, tinnitus, nausea, vomiting, deafness
Corticosteroids		
	Cortisone, Methylprednisolone, Prednisone	Cushing's syndrome (weight gain, moon face, thin skin, muscle weakness, osteoporosis), bruising, cataracts, hypertension, elevated blood sugar, insomnia, mood changes, nervousness or restlessness; black box warning for increased risk for cardiovascular problems and gastric bleeding
Disease-Modifying Antirheumatic Drugs (DMARDs)		
	Imuran	Immunosuppression
	Methotrexate	Liver and blood effects, decreased fertility
	Plaquenil	Visual damage with long-term use
Biologic Response Modifiers (Subset of DMARDs)		
	Enbrel	Dizziness, fatigue, headache, injection site irritation, nausea; black box warning for increased risk for serious infection
	Humira	Injection site irritation; black box warning for increased risk for serious infection
	Remicade	Infusion reaction, injection site irritation; black box warning for increased risk for serious infection

COX, cyclooxygenase.

Use of nonpharmacologic agents, also known as nutraceuticals, is extremely common in persons with OA as alternative or complementary treatments and continues to gain favor in the general public.[6,57,59,94] These agents include nutritional supplements such as glucosamine sulfate and chondroitin sulfate. Although they may have some effect in improving symptoms or slowing the progression of OA, studies citing their efficacy have not yet been of optimal quality.[59] However, even if their benefits have not been proved convincingly, use of nutraceuticals typically carries little risk. Even so, patients should be aware that supplements are not regulated like prescription medications. Use of complementary and alternative treatments should be discussed with one's physician to minimize potential negative effects.[57]

Surgical Management

Operative intervention may be performed to slow joint deterioration, improve joint integrity, restore joint stability, or reduce pain, with the overarching goal of improving the patient's overall function. Common surgical procedures for OA include arthroscopic joint debridement, resection or perforation of subchondral bone to stimulate the formation of cartilaginous tissue, use of grafts to replace damaged cartilage, joint fusion, and joint replacement.[21,59]

Rheumatoid Arthritis

Rheumatoid arthritis (RA) is a chronic, systemic inflammatory condition that affects approximately 1.5 million Americans.[91] The etiology of RA is not well understood, other than that a yet-unknown trigger causes an autoimmune inflammatory response in the joint lining of a genetically predisposed host.[110,113] Onset can take place at any age, but prevalence does increase with age. The peak incidence occurs between 40 and 60 years of age, with the rate of disease two to three times higher in females.[4,108,113] Its onset is commonly insidious, with symptoms developing over a period of several weeks to several months.

The disease manifests itself as **synovitis**, which is inflammation of the synovial membrane that lines the joint capsule of diarthrodial joints. The function of normal synovial tissue is to secrete a clear fluid into the joint for the purpose of lubrication.[2,27] In RA, synovial cells produce matrix-degrading enzymes that destroy cartilage and bone. Joint swelling results from excessive production of synovial fluid, enlargement of the synovium, and thickening of the joint capsule. This weakens the joint capsule and distends tendons and ligaments. As the inflammatory process continues, the diseased synovial membrane forms a pannus that actively invades and destroys cartilage, bone, tendon, and ligament (Fig. 38.3). Scar tissue can form between the bone ends and cause the joint to become permanently rigid and immovable.

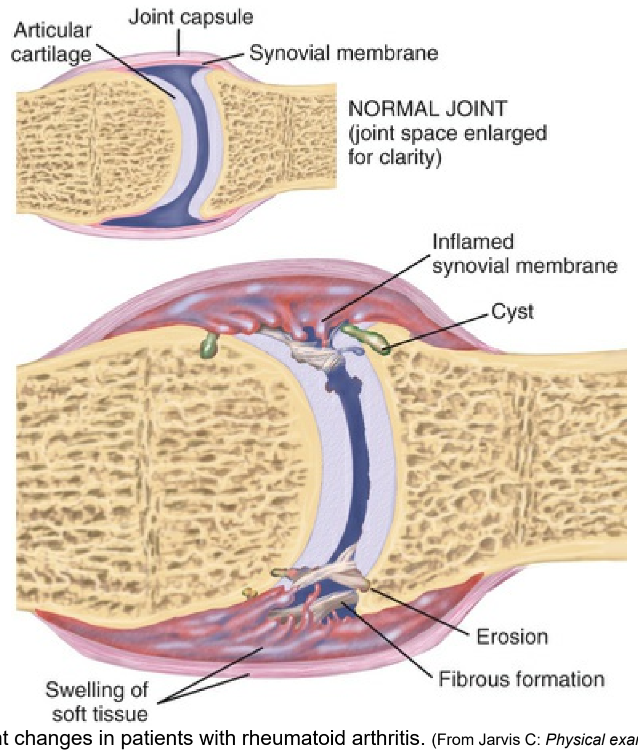

FIG 38.3 Joint changes in patients with rheumatoid arthritis. (From Jarvis C: *Physical examination and health assessment*, ed 7, St. Louis, 2016, Elsevier.)

Articular manifestations of RA fall into two categories: (1) reversible signs and symptoms related to acute inflammatory synovitis and (2) irreversible cumulative structural damage caused by recurrent synovitis over the course of the disease. Structural damage typically begins between the first and second years of the disease and progresses as a linear function of the amount of prior synovitis.[40,108] Almost 90% of joints ultimately affected by RA become involved during the first year.[88,108] Progressive joint damage in the majority of patients results in significant disability within 10 to 20 years.[110]

The course of RA is variable from person to person. Approximately 20% of those affected have a single episode of inflammation with a long-lasting remission. The majority of people with RA experience a series of exacerbations and remissions, with periodic flares of inflammation followed by complete or incomplete remissions.[108,113] Outcomes are similarly variable. Patients' functional abilities vary according to the course of the disease, the severity of the symptoms, and the amount of joint damage. Because RA is a systemic disease, certain extraarticular features occur in about half of patients.[108,113] These features include fatigue, rheumatoid nodules, and vasculitis. Ocular, respiratory, cardiac, gastrointestinal, renal, and neurologic manifestations are also seen as secondary complications. Patients with severe forms of RA may die between 10 and 15 years earlier than expected as a result of accompanying infection, pulmonary and renal disease, gastrointestinal bleeding, and especially cardiovascular disease.[78]

Clinical Features

RA is characterized by symmetric polyarticular pain and swelling, prolonged morning stiffness, malaise, fatigue, and low-grade fever. Joints most commonly affected are the PIP, metacarpophalangeal (MCP), and thumb joints of the hands, as well as the wrist, elbow, ankle, MTP, and temporomandibular joints; the hips, knees, shoulders, and cervical spine are also frequently involved.[108,110] Even though joint involvement is bilateral, disease progression may not be equal on both sides. For instance, a patient's dominant hand may show more severe involvement and different joint changes or deformities than the other hand. Clinical features vary from patient to patient and also in individual patients over the course of their disease. Pain can be acute or chronic. Acute pain occurs during disease exacerbations, or flare-ups. Chronic pain results from progressive joint damage. Synovial inflammation is manifested as warm, spongy, and sometimes erythematous, or red, joints. This is seen in active phases of the disease process. Rheumatoid **nodules**, a cutaneous manifestation of RA, develop in 25% to 30% of persons with RA during periods of increased disease activity. These soft tissue masses are commonly found over the extensor surface of the proximal end of the ulna or at the olecranon.[108,110] Morning stiffness is an almost universal feature of RA. Unlike the shorter-duration stiffness seen with OA, RA morning stiffness can last 1 or 2 hours. It frequently disappears during periods of disease remission. The duration of morning stiffness tends to correlate with the degree of synovial inflammation, and its presence and length are useful measures for monitoring the course of RA.[78] Feelings of malaise, fatigue, and depression also fluctuate, with many patients experiencing worse symptoms in the afternoon. These nonspecific symptoms may precede other typical signs of RA by weeks or months.[108]

The inflammatory process has been described as having four stages: acute, subacute, chronic active, and chronic inactive.[72] Stages may overlap, and patients may move back or forward through them, depending on the course of their disease. Clinical symptoms seen in the acute stage include limited movement; pain and tenderness at rest that increase with movement; overall stiffness, weakness, tingling, or numbness; and hot, red joints. In the subacute stage, the limited movement and tingling remain. A decrease in pain and tenderness indicates that the inflammation is subsiding. Stiffness is limited to the morning, and the joints appear pink and warm. The chronic active stage is characterized by less tingling, pain, and tenderness and increased tolerance of activity, although endurance remains low. No signs of inflammation are present in the chronic inactive stage. The patient's low endurance and pain and stiffness at this stage result from disuse. Overall functioning may be decreased as a result of fear of pain, limited range of motion (ROM), muscle atrophy, and contractures.[72]

The characteristic joint deformities will develop as late manifestations of the disease in more than 33% of patients with RA. Deformity of the small joints of the hand will develop within the first 2 years in more than 10%.[110] Wrist radial deviation, MP ulnar deviation, and swan neck and boutonnière deformities of the digits are the joint changes most often seen. Joint changes, or deformities, can result from a variety of mechanisms, including joint immobility, destruction of cartilage and bone, and alterations in muscles, tendons, and ligaments.[97] **Tenosynovitis** (inflammation of the tendon sheath) and the presence of nodules within the flexor tendon sheaths can cause trigger finger. Patients may also exhibit symptoms of nerve compression of the median or ulnar nerves at the wrist. Tendon rupture may also be seen, usually in the extensor tendons of the fifth, fourth, and third digits. Stages of the disease based on joint deformity and radiographic changes are defined in Box 38.1.

Box 38.1

American College of Rheumatology Classification of Progression of Rheumatoid Arthritis

Stage I: Early

No destructive changes on roentgenographic examination*

Possible presence of radiographic evidence of osteoporosis

Stage II: Moderate

Radiographic evidence of osteoporosis, with or without slight subchondral bone destruction; possible presence of slight cartilage destruction*

No joint deformities, although possible limitation of joint mobility*

Adjacent muscle atrophy

Possible presence of extraarticular soft tissue lesions, such as nodules and tenosynovitis

Stage III: Severe

Radiographic evidence of cartilage and bone destruction, in addition to osteoporosis*

Joint deformity, such as subluxation, ulnar deviation, or hyperextension, without fibrous or bony ankylosis*

Extensive muscle atrophy

Possible presence of extraarticular soft tissue lesions, such as nodules and tenosynovitis

Stage IV: Terminal

Fibrous or bony ankylosis*

Criteria for stage III

*These criteria must be present to permit classification in any particular stage or grade.

Data from Steinbrocker O, Traeger CH, Batterman RC: Therapeutic criteria in rheumatoid arthritis, *JAMA* 140:659, 1949.

Diagnostic Criteria

No single test leads to a definitive diagnosis of RA. Diagnosis is based on clinical evaluation of characteristic signs and symptoms, laboratory findings, and radiologic findings.[78,108,110] A positive laboratory test is not necessary to establish a diagnosis of RA, but such tests may help confirm the clinical impression. Rheumatoid factor is an antibody found in the blood serum of approximately 85% of persons with RA, but it can also be found in other inflammatory diseases associated with synovitis. The presence of rheumatoid factor correlates with increased severity of symptoms and increased systemic manifestations. The erythrocyte sedimentation rate correlates with the degree of synovial inflammation and is useful in ruling out noninflammatory conditions such as OA and tracking the course of inflammatory activity.[108,110] Radiographs may show nothing other than soft tissue swelling early in RA, but in more than half of patients radiographic changes will develop within the first 2 years after onset of the disease.[78,108,110]

Medical Management

RA currently has no known cure. The major goals in the treatment of RA are (1) reducing pain, swelling, and fatigue; (2) improving joint function and minimizing joint damage and deformity; (3) preventing disability and disease-related morbidity; and (4) maintaining physical, social, and emotional function while minimizing long-term toxicity from medications.[79,110] Maintaining normal joint anatomy can be accomplished only by controlling the disease before irreversible damage occurs. Major advances in the treatment of RA have occurred as a result of improved understanding of the pathogenetic mechanisms of the disease, development of therapies that more specifically target the pathophysiologic processes, and recognition that early initiation of aggressive drug therapies can alter the outcome and reduce the severity of physical disability and psychological distress of RA.[79,80,110]

Drug categories used for RA include NSAIDs, corticosteroids, and disease-modifying antirheumatic drugs (DMARDs; see Table 38.2).[5] Because the fast-acting NSAIDs can decrease joint pain and swelling but cannot alter progression of the disease, they are rarely, if ever, used alone for the treatment of RA. The antiinflammatory effects of the large number of medications in this category are about equal. COX-2 inhibitors show no evidence of greater efficacy than other NSAIDs but are thought to pose a lower risk for serious gastrointestinal side effects.[108] Corticosteroids have a long history in the medical management of RA and remain a key element. They produce rapid and potent suppression of inflammation with improvement in joint pain and fatigue. Because of the significant adverse effects of corticosteroids, they are frequently used on a temporary basis in patients with active disease and significant functional decline while awaiting the full therapeutic effect of DMARDs. DMARDs lack a pain relief effect, but they may actually affect the course of the disease. Because of their slow-acting nature, weeks or months of drug therapy may be necessary before a clinical benefit is recognized. The potency of these drugs requires that patients be closely monitored for side effects; they carry a black box warning for increased risk of serious infection.

Traditionally, the approach to treatment of RA began with less toxic medications such as NSAIDs and progressed to the stronger drugs needed later in the disease course. The approach is now more aggressive, with early use of DMARDs to control the disease process as soon as possible, as completely as possible, and for as long as possible.[78,120] Drug therapy constantly changes, depending on the patient's needs and response to treatment, as well as the physician's treatment philosophy. This uncertainty can be frustrating for the patient, who may have to experiment with myriad new medications when current drugs become ineffective or side effects too severe. It is important for the occupational therapist and other team members to know the specific medications that the patient is taking and what adverse reactions may arise.

Surgical Management

Because of the extensive joint damage caused by RA, surgical intervention is frequently indicated to relieve pain and improve function. Several surgical procedures may be of benefit to patients with RA. Synovectomy (excision of diseased synovium) and tenosynovectomy (removal of diseased tendon sheaths) are performed to relieve symptoms and slow the process of joint destruction, but they do not prevent progression of the disease. These procedures are most commonly performed in the wrist and hand. Tendon surgery, including relocation of displaced tendons, repair of ruptured tendons, and release of shortened tendons may be performed to correct hand impairments. Tendon surgery occurs most frequently on the extensor tendons of the wrist and hand. Tendon transfers and peripheral nerve decompression (such as carpal tunnel release) are also performed to optimize function. Arthroplasty (joint reconstruction) and arthrodesis (joint fusion) are options when joint restoration is not possible. These procedures may be performed to relieve pain, provide stability, correct deformity, and improve function. Common sites for arthroplasty include the hip, knee, and MCP joints. Common sites for arthrodesis include the wrist, thumb MCP and interphalangeal (IP) joints, and cervical spine.[21,72]

Occupational Therapy Evaluation

It is important to recognize that every client with arthritis has a unique manifestation of clinical problems and functional impairment. A strong client-centered and occupation-based approach is helpful in determining each client's specific needs. The evaluation process for clients with arthritis includes many of the same elements as for any physical disability. Special considerations related to arthritis include closer attention to pain, joint stiffness, joint changes/deformity, fatigue, and coping strategies, especially as they relate to limitations in activity. Because clients with arthritis typically experience good days and bad days, many symptoms and problems are unpredictable. Thorough systematic assessment of the client's functional, clinical, and psychosocial status is key to prioritizing problems and planning effective intervention.

The extent of specific components of the evaluation will often be driven by the main reason for referral. Clients seen for preoperative hand assessment, postoperative hip replacement, education after diagnosis, splinting while in a flare-up, or a decline in functional status will all require the therapist to customize evaluation priorities.

Because of the chronic nature of rheumatic diseases, some clients are able to clearly state their specific needs and should be afforded the opportunity to do so. Other clients may be overwhelmed by multiple problems or a newly made diagnosis and will look to the therapist to guide the intervention process. Regardless of the client's status, close collaboration and partnership among the client, family, therapist, and other team members is crucial in helping deliver the best treatment possible.

The occupational therapy (OT) evaluation process consists of (1) a client history; (2) occupational profile; (3) occupational performance status; (4) cognitive, psychological, and social status; and (5) clinical status.

Client History

A thorough history should be obtained through review of the client's report and medical record. Important details include diagnosis, dates of onset and diagnosis, secondary medical conditions, current medications and medication schedule, alternative or complementary therapies, and surgical history.[99] Asking the client questions—“What type of arthritis do you have?” “How long have you had it?” “What medications are you currently taking?” and “What other things are you doing to manage your arthritis?”—can provide insight regarding the client's level of understanding about his or her condition, medical treatment, and health habits. Previous experiences with OT and physical therapy should also be ascertained to build on them. The therapist must ask and actively listen to the client's current primary complaints through questions: “What is bothering you most about your arthritis?” “How is your arthritis limiting your ability to do things right now?” “What are you hoping therapy can help you with?”

This was Nina's first referral to OT. She was knowledgeable about her diagnosis and medications but uncertain about the potential benefits of therapy. Through her responses to key questions, Nina was able to clearly state that her pain and difficulty performing household and work activities were her main priorities.

Occupational Profile

It is helpful to begin the process of assessing occupational performance with an occupational profile. Obtained through an open-ended interview, the profile yields important details about the client's previous and current roles, occupations, overall activity level, and ability to participate in meaningful activities. It can also provide insight into the client's sense of self-efficacy, adjustment to disability, and themes of meaning in his or her life.[60,68] An effective method to obtain a client's occupational profile is to have the client describe how he or she spends a typical day. This typical-day assessment allows the therapist to become familiar with the client's routines, use of time, sleep/wake habits, energy and fatigue patterns, important people and environments, activity contexts, and other details that may not otherwise come up in conversation. Because arthritis involves fluctuant symptoms, the client should be asked to describe how time is spent on a good day and a bad day so that the therapist can compare the two and understand how arthritis affects the client's daily life and how effectively the client is able to balance activity and rest. It is helpful to ask the client to estimate the percentage of good versus bad days per week or month. It may also be advantageous to explore time spent on weekend days versus weekdays; the client may reveal other occupations, such as those involving spirituality, social participation, and leisure. This fluid dialogue also develops rapport, establishes the client as the valued expert in his or her occupations and lifestyle, and frames the role of OT in the client's rehabilitation.

Occupational Performance Status

Once the client's typical and preferred occupations are identified, his or her level of independence engaging in these functional activities can be assessed by interview or by observation. If observation is used, the activity should occur as close as possible to the time that it is normally performed because the client's abilities may fluctuate at different times of the day. For instance, stiffness and pain may make dressing very difficult in the early morning, but if this task is assessed in the afternoon, the client's status may appear much better. Ideally, the activity should also be done in the client's own home, community, or work contexts.[7] In addition to assessing the client's level of independence during activities of daily living (ADLs), instrumental activities of daily living (IADLs), school, work, sleep and rest, play, leisure, and social engagements, it is important to note any assistive devices (eg, mobility aids or adaptive equipment) and compensatory techniques that the client may use. The activity demands of the occupation performed (eg, tools, equipment, and skills required), as well as the specific contexts in which it is performed (eg, the client's living situation, others in the home, and architectural set-up relative to occupational performance), should be detailed in tandem with existing physical, environmental, or social barriers. Finally, the amount of time required to complete certain activities should be explored. A client who experiences significant morning stiffness or limited endurance often chooses to accept assistance in an activity such as dressing to save time or conserve energy to participate in a more meaningful occupation later in the day. This strategy may contribute to the client's overall satisfaction with and participation in life, and it should be respected as such.

In RA, functional status may be classified according to the American College of Rheumatology's revised criteria for the classification of functional status in clients with RA (Table 38.3). This system was devised for rapid, global assessment of functional status by health professionals.[52] The therapist should be familiar with this system because it is often used in clinical research and can provide a general framework for defining advancing disability.[49,122] Nina's status would be considered class III because of limitations in her work activities.

TABLE 38.3

American College of Rheumatology Classification of Global Functional Status in Patients With Rheumatoid Arthritis

Classification	Description
Class I	Completely able to perform usual activities of daily living (self-care,* vocational, and avocational)
Class II	Able to perform usual self-care and vocational activities, but limited in avocational activities
Class III	Able to perform usual self-care activities, but limited in vocational and avocational activities
Class IV	Limited in ability to perform usual self-care, vocational, and avocational activities

*Usual self-care activities include dressing, feeding, bathing, grooming, and toileting. Avocational (recreational or leisure) and vocational (work, school, homemaking) activities are client desired and age and sex specific.

Courtesy American College of Rheumatology ©2004.[52]

A decrease in occupational functioning in clients with arthritis may be due to pain, joint changes or instability, loss of motion, weakness, fatigue, change in the living environment, or change in social support, among other contributing circumstances. The effects of medication can also limit performance. The challenge for the therapist is not only to identify deficits in occupational performance but also to determine the factors that are causing them. Asking the client why an activity cannot be done yields the important client perspective.[7] Nina was having difficulty with many occupations, including sleeping, playing actively with her grandchildren, managing her home, and performing her job to her level of satisfaction. She reported having to give up or cut back on activities because of increased pain, stiffness, and fatigue from her recent flare-up.

Cognitive, Psychological, and Social Status

The effects of arthritis are not merely physical and functional. Clients with arthritis should be screened for cognitive and psychosocial deficits. Although arthritis does not directly affect cognition, pain, sleep disturbances, depression, and medication can all have profound effects on attention span, short-term memory, and problem-solving skills.[72, 83] People with a chronic illness must develop coping strategies to deal with the disability. Coping strategies are particularly crucial for persons with arthritis, who may face serious changes in physical function, life roles, and appearance because of deformity and pharmacological side effects. Because arthritis is both unpredictable and painful, normal responses to the disability include depression, denial, need to control the environment, and dependence. Psychosocial adaptation is affected by the complex interplay of physical, psychological, and situational factors.[60,82] Approximately 20% of persons with RA are estimated to suffer from a major depressive disorder, with as high as 48% having significant depression symptoms.[70] About half of individuals with RA or OA may experience loss of social relationships.[121] Constant pain and fear of pain, changed body image, perception of self as a sick person, continuous uncertainty about the course and progression of the disease, sexual dysfunction, altered roles, and loss of income resulting from inability to work can lead to significant psychological stress.[60,82] Evidence has shown that the disability associated with RA relates to psychosocial factors almost to the same extent as to biomedical factors.[37] Occupational therapists must understand the ways in which their clients manage stress in their lives because these stressors may exacerbate the disease.[60] Family relationships and cultural backgrounds also affect the client's healthcare behavior and response to disability.[87] The therapist should be sensitive to all factors that will influence rehabilitation. Referral to other health professionals (such as psychiatrists, psychologists, and social workers) should be made if needed.[82]

Nina reported that she had increasing difficulty concentrating on tasks because she was unable to get adequate restful sleep. She expressed frustration about her inability to keep her house in order and anxiety about losing income because she was unable to work her customary hours. She was also fearful about her health because her arthritis had been adequately controlled for the past few years and she had not experienced any flares.

Clinical Status

For clients with arthritis, the elements of inflammation, ROM, strength, hand function, stiffness, pain, sensation, joint instability and deformity, physical endurance, and functional mobility should be included through either brief screening or detailed evaluation. As with assessment of function, the time of day and antiinflammatory or analgesic medications taken should be noted because these factors may influence the results. In addition, future reevaluations should be performed under the same conditions.[72] When the client's functional deficits are identified first, assessment of client factors can be much more focused. Additionally, asking the client a question such as “What joints are you having the most problems with?” can help prioritize assessment needs. Given Nina's initial findings, the detailed evaluation focused primarily on synovitis, pain, stiffness, ROM, strength, physical endurance, and functional mobility. Even though joint deformities were not immediately evident, the therapist was careful to search for signs of instability that would place Nina's joints at risk for deformity.

The clinical evaluation may take considerable time. It should be approached in a systematic manner with the results clearly documented. The occupational therapist may need to perform assessments over several sessions, especially if the client is experiencing significant pain or fatigue. Intervention can begin immediately and does not necessarily depend on completion of the evaluation. The evaluation actually begins with a general observation of the client's posture, willingness to move, and pain behavior during the initial interview.

The presence and location of inflammation or synovitis should be noted because these signs indicate an active disease process. Several types of swelling may be present and should be described. An effusion (excess fluid in the joint capsule) is seen as fusiform swelling that is spindle shaped and conforms to the shape of the joint. Boggy swelling is thin and full of fluid. Puffy, spongy, and soft to the touch, boggy swelling is seen in the early active stages of synovitis. Chronic synovitis feels firm because the joint fills with synovial tissue.[72]

Active and passive ROM can be measured. Depending on the reason for referral and the client's complaints, the therapist may not find it necessary to obtain goniometric measurements of all joints but instead focus only on the joints of most concern. Active motion will allow the therapist to see the amount of mobility that the client has available for function, whereas passive motion will elicit the joint's capacity to move. The client's range of active motion may be significantly less than the range of passive motion; this is known as lag and is caused by pain, weakness, or the mechanical inefficiencies attributable to joint damage. Goniometric measurement of hand joints may be difficult in the presence of deformity. Assessment of composite (combined motion of all joints) flexion, composite extension, and thumb opposition can provide more functional information.[9] Active opening and closing of the hand can be measured by the distance from the fingertips to the tabletop in maximal extension (opening) when the dorsal side of the hand is resting on the table and by the distance from the fingertips to the distal palmar crease (closing). While performing the ROM assessment, the therapist should note whether the client's joints feel stiff or unstable. A hard end-feel in the presence of contracture indicates bony blockage.[73] A firm end-feel that still has some give indicates that the joint capsule or ligaments are limiting motion.[51] The presence and location of crepitus, along with the motions that cause it, should also be noted because crepitus often indicates extensive joint damage. The source of crepitation may be bony, synovial, bursal, or tendinous (see Chapters 20 through 22 for additional information).[9,72]

Gross strength should be assessed with more specific manual muscle testing as indicated. One important detail to understand is that strength testing in clients with arthritis differs from normal testing procedures. Resistance is applied at the end range of pain-free motion rather than at the true end of the ROM. It is not unusual for clients with arthritis to have pain in the last 30 to 40 degrees of joint motion. When resistance is applied within the pain-free range, inhibition of muscle strength by pain will be avoided. It is also important to consider joint protection principles when applying resistance and to discontinue resistance if the client experiences pain. If use of resistance is contraindicated (as may be the case in an acute or active phase of arthritis, in which resistance may be harmful to inflamed tissue and joints), functional muscle or motion testing may be substituted.[72]

Hand strength and function are important to test, but care must be taken to not stress painful or vulnerable joints during assessment. Grip and pinch may be measured by standard meters, but in the presence of severe weakness or hand deformity, adapted methods, such as use of a blood pressure cuff to measure force in millimeters of mercury, may be indicated.[9,72] Although it is more comfortable for the client, the results of strength testing in this manner are less reliable, with no established norms. Other specific devices for measuring grip strength in hands with arthritis, including pneumatic bulb dynamometers, are commercially available. As a result of joint deformity, the client may not be able to assume the standard testing positions for lateral and palmar pinch. Because it is important to assess pinch strength relative to function, pinch should still be tested, with notation made of the client's prehensile pattern (eg, "4 pounds of pinch with the meter placed in web space between thumb and second metacarpal"). The presence and location of muscle atrophy should be recorded because it indicates severe weakness and possible nerve compression that may require further investigation. Intrinsic atrophy can be seen as flattening of the thenar and hypothenar eminences and as hollowing between the metacarpals on the dorsal aspect of the hand.

Hand function can be assessed through standardized tests (eg, the Jebsen-Taylor Hand Function Test)[55] or observation of the client performing common functional tasks that involve various grasp and prehensile patterns. These tasks can include opening a medication bottle, writing, holding a glass, picking up small pins, turning a doorknob and key, cutting with a knife, and fastening buttons. In addition to noting whether the client is able to perform each task, the value of this testing lies in observation of how the client uses his or her hands and determination of which factors interfere most with activity: instability, lack of motion, deformity, pain, weakness, or something else. The therapist cannot predict function solely on the basis of the hand's appearance. Deformities caused by arthritis often develop slowly, and many clients learn how to adapt their hand function gradually over time. It may be surprising to see significantly deformed hands performing tasks with relatively good function. The therapist should remember this when planning an intervention because it might eliminate a problem that is actually functional for the client.

Joint stiffness is a distinct feeling of excessive stiffness that eventually wears off.[72] It can occur as a result of low-grade inflammation, effusion, synovial thickening, muscle shortening, or spasm.[13,73] The stiffness experience, its impact on daily life, and adaptations clients need to make greatly vary.[79] The therapist can determine the extent of joint stiffness by asking the client which joints experience stiffness, under what conditions, and for how long. Morning stiffness and gelling should be considered separately and can be measured in hours or minutes. The duration of morning stiffness is often used as an objective indicator of the degree of disease activity present. The gelling phenomenon, stiffness after prolonged periods of inactivity, is so named because fluid in the joint and surrounding tissues sets up like gelatin.[73]

Because pain is often the primary clinical manifestation of arthritis, it should be closely evaluated. Pain that interferes with the client's ability to engage in occupations should be of primary concern. The presence and location of joint pain should be noted. The therapist should ask questions to elicit important details ("When does the pain occur?" "What tends to make the pain worse?" "What seems to make the pain better?"). An attempt should be made to distinguish between articular (joint) pain and periarticular (soft tissues surrounding the joint) pain. Secondary conditions such as tendonitis and bursitis are frequent causes of pain. Pain has different meanings for individuals and is often difficult to describe.[100] The therapist can obtain measurements of pain intensity by asking the client to rate the pain on a numeric scale of "1" (no pain) to "10" (greatest pain) or on a visual analog scale in which the client places a mark along a 10-cm line.[54] These scales can also be used to measure other subjective symptoms, including fatigue and degree of stiffness.[48] Because pain related to arthritis is fluctuant, the client may be asked to rate pain at its current level, at its best, at its worst, and at various times of the day or to compare pain at rest versus pain with motion or activity. Interestingly, pain caused by acute inflammation in the early stages of RA tends to be greater than pain at the end stages, when severe deformities are present.[9] The presence and location of joint tenderness should also be noted. Tenderness is assessed by applying manual compression to the medial/lateral aspects of the joint (see Chapter 28 for additional information).[72]

Sensation should be evaluated if the potential for peripheral nerve damage or compression caused by swelling exists. The therapist should obtain a subjective report from the client with regard to the presence of numbness or tingling. This report can be followed by screening of the touch/pressure threshold of the fingertips with monofilaments.[10] If sensory impairment is noted, further assessment may be indicated. This may include provocative tests to replicate or aggravate symptoms so that areas of compression can be localized. Examples of these tests are the Phalen and Tinel tests in individuals with suspected median nerve compression at the carpal tunnel.[92] When cervical spine involvement is known or suspected, dermatomal light touch, sharp-dull sensation, and proprioception should be evaluated (see Chapters 23 and 39 for additional information).

The examiner assesses **joint laxity** (instability) by applying stress to individual joints in the medial/lateral and anterior/posterior directions. When testing medial/lateral stability of the MCP joints, the examiner must first place the MCP joints in flexion to tighten the collateral ligaments, which are naturally loose during MCP extension. Unstable joints should be noted. Ligamentous laxity can be described as slight (5 to 10 degrees in excess of normal), moderate (10 to 20 degrees in excess), or severe (20 or more degrees in excess).[72] In the hand joints, instability with medial/lateral motion indicates laxity of the collateral ligaments, whereas excessive anterior/posterior motion is caused by laxity of the joint capsule and volar plate. Normal joint stability is highly variable, and whenever possible, it is helpful to compare it to the client's uninvolved joints.[72]

Evaluation of joint deformities is done primarily by observation and palpation. The location and type of deformity should be noted. Comparison with previous evaluations, if available, allows the therapist to see how the deformities have progressed over the course of the disease. If a deformity is correctable, either actively or passively, it is considered flexible; if the deformity cannot be reduced, it is considered fixed. Patterns of deformity can be different in a client's two hands, and a person with RA can also exhibit deformities caused by osteoarthritic joint damage.

Common hand deformities in persons with arthritis include the following:

- A boutonnière deformity is characterized by flexion of the PIP joint and hyperextension of the DIP joint (Fig. 38.4). This zigzag collapse represents an alteration in muscle-tendon balance. Pathology begins at the PIP joint with secondary changes in the DIP joint. It occurs when synovitis weakens, lengthens, or disrupts the dorsal capsule and central slip of the extensor mechanism and consequently causes incomplete or weak to absent extension at the PIP joint. The lateral bands of the extensor mechanism displace volarly below the axis of the PIP joint and become flexors of that joint. Increased force on the lateral bands at the DIP joint, where they insert, causes hyperextension. Function of the finger is compromised by the inability to straighten the finger and the loss of flexion at the fingertip for pinching.[2,8,9,72]

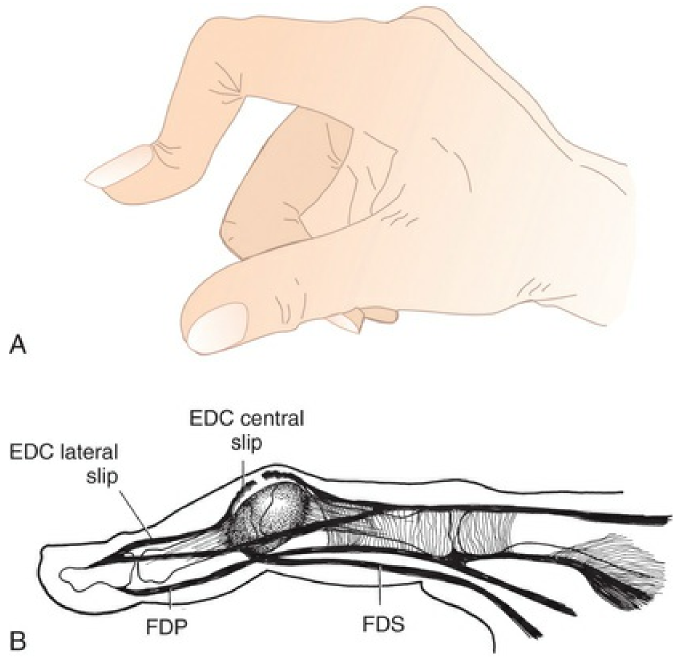

FIG 38.4 **A,** A boutonnière deformity results in distal interphalangeal hyperextension and proximal interphalangeal flexion. **B,** Boutonnière deformity caused by rupture or lengthening of the central slip of the extensor digitorum communis tendon. (A, From Black JM, Hawks JH: *Medical-surgical nursing, clinical management for positive outcomes,* ed 8, Philadelphia, 2009, Saunders.)

- A swan neck deformity is characterized by hyperextension of the PIP joint and flexion of the DIP joint, with possible flexion of the MCP joint (Fig. 38.5). This zigzag collapse is also a result of muscle-tendon imbalance and joint laxity. It can originate from abnormalities at any finger joint. Causes of this deformity include intrinsic muscle tightness, stretching or rupture of the terminal extensor tendon at the DIP joint, and chronic synovitis that leads to stretching of the volar capsular supporting structures at the PIP joint. Here, the lateral bands of the extensor mechanism slip above the axis of the PIP joint, thereby hyperextending the PIP joint and flexing the DIP joint. Function of the finger is compromised by an inability to flex the PIP joint, with loss of the ability to make a fist or hold small objects.[2,8,9]

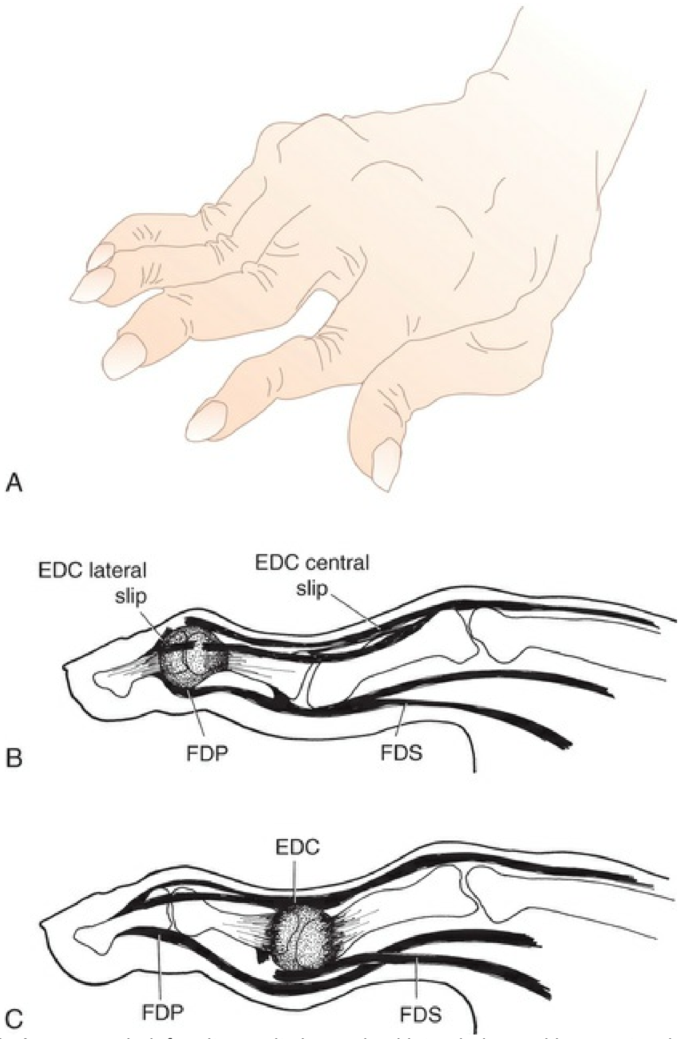

FIG 38.5 **A,** A swan neck deformity results in proximal interphalangeal hyperextension and distal interphalangeal flexion. **B,** Swan neck deformity resulting from rupture of the lateral slips of the extensor digitorum communis tendon. **C,** Swan neck deformity as a result of rupture of the flexor digitorum superficialis tendon. (A, From Black JM, Hawks JH: *Medical-surgical nursing, clinical management for positive outcomes,* ed 8, Philadelphia, 2009, Saunders.)

- A mallet finger is characterized by flexion of the DIP joint. This is caused by rupture of the terminal extensor tendon as it crosses the DIP joint. The finger loses the ability to extend the distal phalanx.
- **Nodes** are bony enlargements that indicate cartilage damage caused by OA. Joints affected by RA can also have degenerative joint disease, so nodes may be seen in clients with RA as well. These osteophytes are hard to the touch and are typically not painful. They are most commonly seen at the DIP joint (Heberden's nodes) and the PIP joint (Bouchard's nodes; Fig. 38.6).[9,16,72,73]

FIG 38.6 Osteophyte formation in the proximal interphalangeal joints (Bouchard's nodes) and the distal interphalangeal joints (Heberden's nodes) is a common finding with osteoarthritis.

- Nodules are granulomatous and fibrous soft tissue masses that are sometimes painful. They usually occur along weight-bearing surfaces such as the ulna or at the olecranon (Fig. 38.7) and can be prognostic of the severity of RA.[9]

FIG 38.7 Rheumatoid nodule present on the extensor surface of the elbow. (From Tilstra JS, Lienesch DW: Rheumatoid nodules, *Dermatol Clin* 33:361–371, 2015.)

- Deviation is characterized by a change in the normal joint position. It is typically described as radial or ulnar. In RA the most common pattern of deviation is radial deviation of the wrist and ulnar deviation (commonly referred to as ulnar drift) of the MCP joints (Fig. 38.8). Deviation is caused by ligament weakening or disruption. Small joints are especially vulnerable because daily activities involving gripping and pinching apply strong forces to them.[9,72]

FIG 38.8 Ulnar drift of the metacarpophalangeal joint. (From Schlenker E, Roth SL: *Williams' essentials of nutrition and diet therapy,* ed 7, St. Louis, Mosby, 2007.)

- **Subluxation** is characterized by volar or dorsal displacement of joints. It is any degree of malalignment in which the articular structures are only in partial contact. In RA the most common sites of subluxation are the wrist and MCP joints.[72] Volar subluxation of the wrist occurs as the carpal bones slip relative to the distal end of the radius as a result of weakening of the supporting ligaments by chronic synovitis. Because of their condyloid nature, the MCP joints have more planes of movement and are inherently less stable than the IP joints. Volar subluxation of the MCP joints occurs frequently and is often accompanied by ulnar drift and lateral displacement of the extensor tendons into the ulnar valleys between the metacarpal heads (Fig. 38.9).[2,8,9,72]

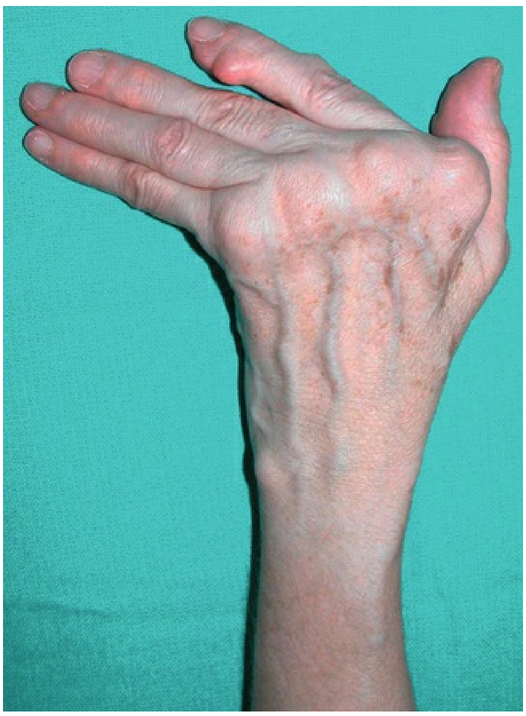

FIG 38.9 Volar subluxation and ulnar deviation of the metacarpophalangeal joints with lateral displacement of the extensor tendons characteristic of rheumatoid arthritis. (From Chung KC: *Hand and upper extremity reconstruction with DVD.* A volume in the Procedures in Reconstructive Surgery Series, Edinburgh, 2009, Saunders.)

- Dislocation is characterized by joints whose articulating surfaces are no longer in contact. In severe cases of RA, volar dislocation of the carpals on the radius or dislocation of other joints can result from complete destruction of ligamentous integrity.[2,72]
- Ankylosis (fusion of the bones of a joint) is characterized by lack of joint mobility. This spontaneous joint fusion can be bony (caused by ossification within or around the joint) or fibrous (caused by growth of fibrous tissue around the joint).[72]
- Extensor tendon rupture is characterized by the inability to actively extend a joint in the absence of muscle weakness (Fig. 38.10). The extensor digiti minimi is often the first to rupture. The extensor pollicis longus and extensor digitorum communis of the third, fourth, and fifth digits are also vulnerable.[2,9] Tendon rupture can occur as a result of rubbing of the tendon over rough bony surfaces or tendon damage caused by direct synovial invasion or increased pressure that decreases blood supply to the tendon.

FIG 38.10 Extensor tendon rupture of the fourth and fifth digits resulting in loss of active extension. Tenosynovitis of the extensor tendons and volar subluxation of the wrist caused by rheumatoid arthritis are contributing factors. (From Evans RC: *Illustrated orthopedic physical assessment,* ed 3, St. Louis, 2009, Mosby.)

- Trigger finger is characterized by inconsistent limitation of finger flexion or extension. It is often caused by a nodule on a flexor tendon or stenosis of a tendon sheath, which impedes the tendon's ability to glide.[8,9,72] The client often experiences “catching” or “locking” of a finger into flexion and has to passively extend the finger out of the flexed position.
- Mutilans deformity is characterized by floppy joints with redundant skin (Fig. 38.11). The cause is unknown, but the result is resorption of the bone ends, which shortens the bones and renders the joints completely unstable. This is most commonly seen at the MCP and PIP joints of the hands and the radiocarpal and radioulnar joints of the wrist.[72]

FIG 38.11 Mutilans deformity. (From Weisman MH, Weinblatt ME, Louie JS: *Targeted treatment of the rheumatic diseases,* Philadelphia, 2010, Saunders.)

- Thumb deformities can be manifested as any of the deformities previously described. Nalebuff has classified six patterns of thumb deformity (Table 38.4).[109] Type I is the most common in RA, followed by type III, seen in both OA and RA.[72,109] A boutonnière deformity (type I) is characterized by MCP joint flexion and IP joint hyperextension. A swan neck deformity (type III) is characterized by CMC joint subluxation, adduction, and flexion; MCP joint hyperextension; and IP joint flexion. Also common in RA and OA is an adduction contracture of the thumb CMC joint caused by subluxation of the first metacarpal, radial deviation of the MCP joint, or shortening or weakness of intrinsic muscles.[72,109] Subluxation causes a characteristic squared appearance of the CMC joint (Fig. 38.12). Disruption of thumb biomechanics often leads to significant loss of hand function, especially given the fact that the thumb is thought to account for as much as 60% of hand function.[46]

TABLE 38.4
Rheumatoid Thumb Deformities

Type	CMC Joint	MCP Joint	IP Joint
I (boutonnière)	Not involved	Flexed	Hyperextended
II (uncommon)	CMC flexed and adducted	Flexed	Hyperextended
III (swan neck)	CMC subluxed, flexed, and adducted	Hyperextended	Flexed
IV (gamekeeper's)	CMC not subluxed; flexed and adducted	Hyperextended, ulnar collateral ligament unstable	Not involved
V	May or may not be involved	Volar plate unstable	Not involved
VI (arthritis mutilans)	Bone loss at any level	Bone loss at any level	Bone loss at any level

CMC, carpometacarpal; IP, interphalangeal; MCP, metacarpophalangeal.

FIG 38.12 Osteoarthritis of the thumb carpometacarpal joint resulting in squaring and subluxation of the base of the thumb. (From Abhishek A, Doherty M: Diagnosis and clinical presentation of osteoarthritis, *Rheum Dis Clin North Am* 39:45–66, 2013.)

Physical endurance can be evaluated by observation during the assessment process and by client report. Pain, weakness, deconditioning, lack of sleep, and emotional stress can all lead to decreased stamina. The pattern and severity of fatigue should be noted.[99] Functional mobility, including ambulation, sitting and standing tolerances, and ability to transfer, should be assessed relative to occupational performance. It is also important to assess for fall risk as increased likelihood of falling has been reported in clients with lower extremity arthritis.[33]

Goal Setting

The goals of therapy should be determined by careful consideration of the client's stated goals, the client's individual needs, and the stage of the disease process. The Canadian Occupational Performance Measure (COPM) is a useful client-centered tool that can be used for setting goals, planning treatment, and measuring outcomes.[58] It is designed to detect change in a client's self-perception of occupational performance over time. It engages the client in defining problems in activity and helps the client more clearly understand the purpose of OT. The COPM involves a semistructured interview in which the client is asked to identify occupations that the client needs to, wants to, or is expected to perform but are not done satisfactorily. Occupational goals in the areas of self-care, productivity, and leisure (based on the Canadian Model of Occupational Performance [CMOP]) are listed, and the client is then asked to rate his or her self-perception of the importance of, current performance of, and satisfaction with performance of each occupation. Through this process of collaboration with the client, occupation-based therapy goals can be identified, priorities determined, and a treatment plan designed to facilitate optimal outcome. The rating process is repeated at time of discharge for outcome purposes. The COPM has been used with people who have arthritis in both inpatient and outpatient settings.[7] COPM goals for Nina were to return to work 20 hours a week, to clean her house independently, and to be able to take her grandchildren to the park after school.

Intervention Objectives and Planning

Treatment of clients with arthritis must take into account the progressive nature of the disease.[27] The overarching goal of therapy is to decrease pain, protect joints, and increase function. General objectives of OT are to (1) maintain or increase the ability to engage in meaningful occupations; (2) maintain or increase joint mobility and strength; (3) maximize physical endurance; (4) protect against or minimize the effect of deformities; (5) increase understanding of the disease and the best methods of dealing with its physical, functional, and psychosocial effects; and (6) assist with adjustment to disability.[72]

The intervention plan should be designed for the individual client and based on the stage of disease, the severity of symptoms, general health status, lifestyle, and mutually agreed goals. Given the limited time for therapy, prioritizing treatment is essential. The therapist should focus on addressing the most important factors by answering the following question: "What are the essential interventions necessary to enable the client to function at an optimal level?" It is important for the client and significant others to be active participants throughout therapy. Everyone involved must understand the disease process and the rationale for the intervention methods. Because therapy intervention will most likely be intermittent throughout the client's course of disease, the client's ability to follow through with and self-manage interventions at home will greatly influence the ultimate success of treatment.

Table 38.5 outlines some common symptoms, general objectives, and OT interventions typically appropriate for each stage of inflammatory disease; it can be used as a starting point for planning treatment.[9,72] Nina was in the subacute stage of her RA flare-up. All six general objectives listed previously were important to address in her OT program.

OT Practice Notes

As always, the occupational therapist's clinical judgment of each client's unique status is crucial for tailoring programs appropriately.

TABLE 38.5

Treatment Objectives by Stage of Inflammatory Disease

Stage	Symptoms	Objectives	Treatment Considerations
I. Acute	Pain; inflammation; hot, red joints; tenderness; overall stiffness; limited motion	Decrease pain and inflammation	Splinting for localized rest day and night, increased bedrest, joint protection, assistive devices, physical agent modalities
		Maintain ROM	Gentle active ROM or passive ROM to point of pain (no stretch), proper positioning
		Maintain strength and endurance	Functional activities to tolerance, isometric exercises
II. Subacute	Inflammation subsiding; warm, pink joints; decreased pain and tenderness; stiffness limited to the morning	Decrease pain and inflammation	Less restrictive splinting during the day, splinting continued at night, joint protection, assistive devices, physical agent modalities
		Maintain ROM	Active ROM or passive ROM with gentle stretch, proper positioning
		Maintain strength and endurance	Increased functional activities to tolerance, isometric exercises
III. Chronic active	Minimal inflammation, less pain and tenderness, increased activity tolerance, low endurance	Decrease pain and inflammation	Joint protection, splinting as needed, assistive devices as needed, physical agent modalities as needed
		Increase ROM	Active ROM or passive ROM with stretch at end range
		Increase strength and endurance	Resistive exercises (isometric or isotonic if no risk of overstressing joints), cardiovascular exercises, increased functional activities
IV. Chronic inactive	No inflammation, pain and stiffness from disuse, low endurance	Decrease pain	Joint protection, splinting as needed, assistive devices as needed, physical agent modalities as needed
		Increase or maintain ROM	Active ROM or passive ROM with stretch at end range
		Increase strength and endurance	Resistive exercises (isometric or isotonic if no risk of overstressing joints), cardiovascular exercises, increased functional activities

Occupational Therapy Intervention

Treatment methods useful in the remediation of clinical or functional problems include rest, physical agent modalities (PAMs), therapeutic exercise and activity, splinting, occupational performance training, and client education. It is important to foster the client's self-efficacy in his or her ability to follow through with treatment at home, given the influences of the home contexts, because building the client's confidence will probably lead to the desired behavior. Asking the client a question such as "How certain are you that you can perform this activity at home as well as you did in the clinic?" can provide feedback on the need for further training and practice.[63] The interventions chosen should reflect the individual client's needs and choices whenever appropriate. General treatment precautions related to arthritis are listed in Box 38.2.

Box 38.2

Treatment Precautions Related to Arthritis

Respect pain.

Avoid fatigue.

Avoid placing stress on inflamed or unstable joints.

Use resistive exercise or activity with caution.

Be aware of sensory impairments.

Be cautious with fragile skin resulting from systemic disease or pharmacologic side effects.

Sleep and Rest

Rest should be considered an active means of reducing inflammation and pain. Rest and relaxation can effectively break the vicious cycle of pain, stress, and depression by allowing the body time to heal itself. Rest can be either systemic or local. Whole-body general rest, including recuperative sleep, is necessary for health. However, individuals with arthritis are at risk for sleep problems because of pain and depression.[97] During periods of active systemic inflammatory disease, at least 8 to 10 hours of sleep at night and half-hour to 1-hour morning and afternoon rest periods are recommended.[11,99] The amount of systemic rest needed varies by individual, from complete bedrest to an extra nap during the day. Localized rest of joints with symptoms of RA and OA may include wearing a splint, avoiding or modifying activity, or positioning during the day or at night to prevent joint stress.[27] Repetitive joint loading or motion with activity should be alternated with rest. The effectiveness of rest will be seen as an improved energy level with less joint swelling, pain, and fatigue.

Nina required both general rest for her body and localized rest for her inflamed wrists and hands. It was important to help her realize the physiologic need for rest during recovery from her flare-up. This assurance permitted her to feel less guilty about tasks left undone and enabled her to understand that taking care of herself in the short term would allow her to return to activity in the long term.

Physical Agent Modalities

Physical agent modalities (PAMs) may help to relieve pain or to maintain or improve ROM. Although modality use alone has not been shown to provide sustained benefits in rheumatic disease, clients do report less pain and stiffness from a clinical standpoint.[9,111,116] The most commonly used PAMs are superficial heat and cold agents. Benefits of heat in clients with arthritis include increased blood flow, pain relief, and increased tissue elasticity, with a negative effect of increasing inflammation also possible.[17,50] Benefits of cold include reduced inflammation and decreased pain threshold, with possible negative effects of increased tissue viscosity and decreased tissue elasticity causing more joint stiffness.[17,50] Heat can be delivered through hot packs, paraffin, fluid therapy, hydrotherapy in a heated pool, and even a warm shower or bath; cold can be delivered through ice packs or gel packs. When selecting the proper modality, the therapist must consider the activity and stage of the disease process. Acutely inflamed joints may be exacerbated by heat, whereas ice may be more helpful in reducing pain and inflammation. In the subacute or chronic stages, heat or cold may be equally effective.[17] Nina preferred the use of heat and found it helpful in loosening her joints and lessening her pain. Even though she was in the subacute phase, some inflammation was still present; therefore her response to heat was closely monitored so that it did not worsen her inflammation. She was educated in the safe use of warm baths and microwave packs at home.

Some medical conditions associated with rheumatic disease contraindicate the use of thermal agents. For example, use of cold is contraindicated in clients with Raynaud's phenomenon, a vasospastic disorder of the digits.[17,50] Clients with RA often have unstable vascular reactions to heat and cold that cause greater than normal heat retention with heat agents or increased coldness and stiffness with cold exposure.[50] Careful monitoring of client responses to PAMs is crucial. Client preference and ease of home application should also be considered before choosing an agent to use. Home paraffin units, microwave packs, and continuous low-level heat wraps are increasingly accessible and affordable in community stores and thus provide clients with more options.[74] Safety should always be a primary concern. Clients and significant others should be carefully instructed in proper application techniques to prevent burns or other tissue damage. Before using any modality, the therapist must fully understand tissue responses and related precautions and be competent in safe delivery of the agent. This typically requires specific education beyond entry-level preparation. Therapists must also adhere to any state licensure or training requirements.

Therapeutic Exercise

The purpose of exercise in the treatment of arthritis is to keep muscles and joints functioning as normally as possible by maintaining muscle strength, preventing disuse atrophy, and maintaining or improving ROM.[119] There is evidence that hand exercise can increase strength, reduce pain, and improve ROM and hand function in OA[111] and that ROM, dynamic, and aerobic exercise can have positive effects in RA.[36,67] Regular physical activity can also alleviate depression.[117] It is helpful to find out what exercises the client may already be performing and whether these exercises were suggested by a professional or a well-meaning family member or friend; many self-initiated exercises can be harmful to a person with arthritis. There is no universal exercise program suitable for all clients with arthritis. Exercise programs should be designed with regard to individual client needs and tolerances. As a good rule of thumb, pain lasting greater than 1 or 2 hours after completion of exercise signals a need to modify or decrease an exercise.[72,119] General guidelines for exercise in clients with arthritis are to avoid undue joint stress, avoid pain and joint swelling, and work within the client's comfortable ROM.[9,61,119] The client should be taught to perform exercises slowly, smoothly, and with proper technique. The client must also understand the rationale behind the prescribed exercises.[119] Exercises to maintain ROM should be performed at least once daily, even during a flare. For RA each major joint should be taken through its full comfortable ROM. This includes the neck and possibly the jaw if symptomatic. The stiffest joints require the most attention. The type of ROM exercise selected depends on the disease activity and location of the joint. Active ROM is typically preferred, with assisted or passive ROM if pain or weakness precludes it. In cases of active synovitis, active ROM can exert more stress on a joint than gentle passive ROM, so passive ROM exercises may be safer.[72] Performing shoulder exercises is often easier in a supine position, which eliminates the effects of gravity. The number of repetitions should be weighed against the potential inflammatory response. On good days, 10 repetitions may be appropriate; on bad days, 3 or 4 repetitions within a smaller arc of motion may be indicated.[119] If the goal of exercise is to increase joint mobility, active or passive stretch can be incorporated. This is appropriate for the subacute or chronic phases of disease but never for the acute phase.[72] Box 38.3 presents general active ROM exercises for RA.

Box 38.3

Range-of-Motion Exercises for Rheumatoid Arthritis

Instructions

1. Start with 5 of each exercise, 1 or 2 times each day.

2. Progress to 10 of each exercise, 1 or 2 times each day.

3. Do all exercises slowly and smoothly.

4. If in a flare, cut down on exercises but do not discontinue them entirely.

Jaw

5. Open your mouth wide and then close it.

6. With your mouth open, move your jaw from side to side.

7. Bring your lower jaw forward and then relax.

Neck

8. Look up toward ceiling and then look down to the floor.

9. Bend your head toward one shoulder and then bend your head toward the other shoulder.

. Slide your chin forward and then relax.

. Slide your chin toward the back of your neck and then relax.

Shoulders and Elbows

. Shrug your shoulders up and down.

. With your hands on your shoulders, make circles clockwise and then counter-clockwise.

. With your hands behind your head (or if unable, on your shoulders), bring your elbows together in front of you and then spread your elbows apart.

. Touch your shoulders with your hands and then straighten your elbows.

Forearms and Wrists

. With your elbows partially bent and kept at your sides, turn your palms up and then down.

. Lift your hands backward, letting your fingers curl, and then bend your hands down, letting your fingers straighten.

Fingers

. Make fists and then open your hands and straighten your fingers.

. Touch your thumb tips to the tips of each finger.

. With your palms on your thigh or a table, move your thumbs away from your fingers and then slide each finger toward your thumbs.

Courtesy Occupational Therapy Department, Rancho Los Amigos National Rehabilitation Center, Downey, California.

Exercises for strengthening can be dynamic (isotonic) or static (isometric) and should be aimed toward recovery of function.[30,72,117] Strengthening must be approached cautiously so that pain is not increased, deforming forces are not created, and joint stability is not compromised. Grip-strengthening exercises, even those using light putty, can impart large forces to unstable hand joints.[19] Additionally, this type of dynamic exercise may aggravate joints or pose a risk for potential deformity and in general should be avoided in clients with rheumatoid hand involvement.[9] Resistive exercise of any kind should never be performed during periods of acute flare or inflammation but may be used at other stages. Isometric exercises are usually the least painful for clients with RA because they eliminate joint motion and can be as effective or more effective in improving muscle strength and endurance.[72] Isometric contractions are generally held for 6 to 12 seconds[30] Programs to maintain strength vary depending on the client's overall activity level. Clients who are sedentary may require a daily program, whereas clients who are active may need to perform only specific exercises once a week.[72] Gradual progression of repetitions or resistance is recommended.[117]

Exercises to promote general health and fitness are recommended for all adults as part of a healthy lifestyle and should be encouraged in clients with arthritis. Current evidence supports the benefits of well-designed aerobic and conditioning exercise for people with hip and knee OA, as well as aerobic and strength training in adults with stable RA.[36,53,67,117] Stationary bicycling, walking, and low-impact aerobic dancing, once thought to cause joint damage, have been found to increase flexibility, strength, endurance, and cardiovascular fitness without aggravation of symptoms. T'ai chi has been reported to have positive effects on self-efficacy, quality of life, general health status, pain, stiffness, and physical functioning in older adults with lower extremity OA[47,98] and is being used for clients with RA as well.

Whether the client is exercising to address ROM, strengthening, or overall conditioning, the occupational therapist should work closely with the client to help ensure that any exercise program can be successfully integrated into the client's typical daily routine with a proper balance of rest and activity. Exercises should ideally be done when the client feels most limber and has the least pain. Community land- and water-based exercise classes specifically designed for people with arthritis are available through the Arthritis Foundation. They offer the added benefits of social interaction and peer support and have been shown to be safe and effective in increasing fitness and strength and decreasing pain and difficulty in daily functioning.[14,36,53,102,106]

Daily upper body active ROM exercises with gentle stretch and isometric exercises for the shoulders and elbows were prescribed to improve Nina's motion and strength. It was decided that the best time to perform these exercises was after her morning shower, when she felt less stiff and least fatigued. The therapist recommended that Nina become involved in an Arthritis Foundation exercise class, once her flare subsided, to build her endurance and cardiovascular conditioning. She was interested in joining and planned to attend classes on the days that she worked fewer hours.

Therapeutic Activity

Performance of therapeutic activities offers many benefits, both physical and psychological. Discussing current and past hobbies or having the client complete an interest survey can help the therapist determine activities that may be most appropriate for the client. New activities may be suggested or previously enjoyed activities reintroduced. A carefully chosen and graded activity can be an effective means of encouraging ROM and strength. When selecting therapeutic activities, the therapist should apply the same principles as with exercise.[72] Activities should be nonresistive, avoid patterns of deformity, and not overstress joints; instead, they should offer enough repetition of movement to help improve ROM and strength. The effect of the activity on all joints should be considered.

It is typically recommended that clients with RA not engage in activities that require use of the hand in prolonged static positions. However, sometimes the psychological benefits of doing activities that one enjoys outweigh the risks involved, especially if the risks can be minimized. Examples of activities that are often frowned on include knitting and crocheting. These activities are truly contraindicated only if there is active MCP synovitis, a developing swan neck deformity, or thumb CMC joint involvement.[72] Potential problems may be averted by having the client wear a hand or thumb splint to support the vulnerable joints while performing the activity. Additionally, educating the client to incorporate frequent rest breaks and stretching exercises for the intrinsic muscles will help limit risks (see Chapter 29 for additional information regarding therapeutic exercise and activity).[31,72]

Splinting

Indications

Splinting is often an integral component of the treatment of arthritis. Splints can be used for numerous reasons, with the fundamental goal of maximizing function. It is important for the therapist to understand the pathomechanics of the disease process when prescribing an appropriate and feasible splinting plan. Inappropriate use of splints can be harmful. Indications for splinting in clients with arthritis include reducing inflammation, decreasing pain, supporting unstable joints, properly positioning joints, limiting undesired motion, and increasing ROM. Although it is generally agreed that splinting has a place in the acute phase of RA,[36] there are few documented or well-established protocols for splinting in later stages.[39] Table 38.6 summarizes the potential splinting indications on the basis of progression of the joint destruction in RA.[9,72]

TABLE 38.6

Splinting Indications by Classification of Progression of Rheumatoid Arthritis

Stage	Symptoms/Radiographic Changes	Splinting Indications
Stage I: Early	No destructive changes; possible osteoporosis	Resting splints to decrease acute inflammation, decrease pain, protect joints
Stage II: Moderate	Osteoporosis with or without slight subchondral bone destruction, slight cartilage destruction, no joint deformities, limited joint mobility possible, muscle atrophy, extraarticular soft tissue lesions possible	Day splints to provide comfort Night splints to relieve pain or protect joints against potential deformity Splints to increase ROM
Stage III: Severe	Cartilage and bone destruction, joint deformity, extensive muscle atrophy, extraarticular soft tissue lesions possible	Day splints to improve function (decrease pain, provide stability, limit undesired motion, properly position joints) Night splints to provide positioning and comfort
Stage IV: Terminal	Criteria for stage III, with fibrous and bony ankylosis	Day splints to improve function (decrease pain, provide stability, limit undesired motion, properly position joints) Night splints to provide positioning and comfort

Ultimately, the individual needs of each client must be determined carefully. What are the primary goals for splinting? What benefits will a splint provide? What limitations will a splint impose? Which joints are involved and should be incorporated into a splint design? What effect will splinting have on unsplinted joints? Is the client receptive to splinting? What splints has the client tried or worn before? When should the splint be worn? These factors should be considered when deciding on an appropriate splinting plan.

Considerations

There are some special considerations for splinting in clients with RA. Because the added weight of a splint puts additional stress on the upper extremity and may cause problems with pain and fatigue, a splint should be as lightweight as possible. Forces are also transferred from splinted to adjacent unsplinted joints. For example, a thumb splint leaving the wrist and IP joints free may cause these joints to become more symptomatic. Skin tolerance can be an issue because skin is often more fragile as a result of the RA disease process and effects of medication. The presence of sensory impairments may also require closer monitoring for signs of pressure. Finally, splint straps may need to be modified to allow increased ease and decreased joint stress during donning and doffing of splints.

Options

If splinting is indicated, the therapist must then determine which type of splint will work best. The growing array of commercial products has led to a greater number of choices. Should the splint be rigid, semirigid, or soft? This will often be decided by the splint's proposed purpose and the client's preference. Rigid splints provide maximal immobilization or stability, soft splints allow more freedom of motion, and semirigid splints combine elements of both. Should the splint be prefabricated or custom made? This decision is based on many splint- and client-related factors, including splint availability, cost to purchase or fabricate, durability, weight, ease of care, ease of donning and doffing, cosmetic appearance, and extent of the client's existing deformity.

Providing the client with choices will enhance splint use and client satisfaction. Studies have shown that the following additional factors may encourage splint wear: flexibility of the splinting regimen and vigorous client education regarding the splint's purpose and wearing schedule, individualized splint prescriptions based on the client's comfort and preference, strong family support, positive attitudes and behaviors exhibited by healthcare providers, and benefits that are immediately obvious to the client.[22,38,43,77,81,104] Rapport, trust, sensitivity to clients' learning styles, splint trial evaluations, and providing clients with the opportunity to voice their concerns and frustrations can also enhance the collaborative process and splinting outcome.[28] The therapist can recommend splinting, but ultimately the client will decide whether the splint's benefits outweigh the limitations that it imposes.

Commonly Used Splints for Arthritis

A resting hand splint is useful for the treatment of acute synovitis of the wrist and hand. Its primary function is to provide localized rest to the involved joints. It can also relieve pain, decrease muscle spasm, and protect joints vulnerable to contracture or deformity from synovitis. Joints are rested in positions that place the least internal pressure on them and are opposite that of potential deformity.[9] The recommended joint positions during rest are slight wrist extension (0 to 20 degrees) and ulnar deviation (10 to 20 degrees), MCP flexion (20 to 30 degrees), slight PIP and DIP flexion (10 to 30 degrees), and slight thumb extension and abduction at the CMC joint with slight flexion of the MCP and IP joints.[39,72] However, the client's comfort should always take precedence, and joints should never be forced into the ideal position. The splint is worn continually for the duration of the flare-up and removed at least once a day for skin hygiene and gentle ROM exercises. Splint use should continue full-time for at least 2 weeks after the flare subsides, with a gradual decrease in wearing time to allow the joints to recover.[39,72] In the later stages of disease, the splint is often used at night only to increase comfort and protect against deforming positions. If bilateral splints are needed, clients may alternate splints or wear the splint on the most symptomatic hand.

Commercial splints, such as those made from wire-foam or a malleable metal frame covered by soft padding (Fig. 38.13), may be used if the limited adjustments that they allow can provide the client with a proper fit. This is often not possible in clients with established joint deformities. A custom-fabricated thermoplastic splint will allow a precise individualized fit. Joints that are asymptomatic may not need to be included in the splint. Modified resting splints with the uninvolved joints left free (Fig. 38.14) may lessen joint stiffness related to splint wear, allow some degree of hand function while the splint is worn, and improve splint wear and comfort.

FIG 38.13 Prefabricated resting hand splint. (Courtesy Occupational Therapy Department, Rancho Los Amigos National Rehabilitation Center, Downey, California.)

FIG 38.14 Prefabricated wrist-hand splint with thumb left free. (Courtesy Occupational Therapy Department, Rancho Los Amigos National Rehabilitation Center, Downey, California.)

Although the benefits of resting hand splints are recognized by healthcare professionals, studies have shown that client adherence to splint wear is moderate at best.[1,38] In a study comparing the use of soft and hard resting splints in clients with RA, pain was significantly decreased with splint wear, with 57% preferring the soft splint, 33% the hard splint, and 10% no splint at all. The rate of compliance was greater for the soft splint than for the hard splint.[20]

A wrist splint is often used to provide wrist stability, decrease pain, and improve function. Supports may be custom-fabricated (Fig. 38.15) or prefabricated. Because they are intended to provide support while allowing functional use of the hand, fit and comfort are crucial. A variety of commercial splints made from many materials that offer a full range of soft to rigid support are available. Aside from support, clients with arthritis frequently report a benefit from the neutral warmth that many fabrics provide. A systematic review did conclude that wrist splints were effective in reducing pain in clients with RA.[85] Studies have shown conflicting results of different splint styles in grip strength, dexterity, pain reduction, hand function, comfort, security during performance of tasks, effects of stiffness, or muscle atrophy related to wearing of wrist splints in clients with RA.[79,85,104] In a study of splint preference, most clients were able to identify their preferred splint within only a few minutes of wear when given three styles to try.[103] These studies illustrate the importance of offering a wide variety of splints for each client to try. When the MCP joints are symptomatic, a splint can be used to support them along with the wrist (Fig. 38.16).

FIG 38.16 Prefabricated wrist and metacarpophalangeal joint soft support. (Courtesy Occupational Therapy Department, Rancho Los Amigos National Rehabilitation Center, Downey, California.)

MCP ulnar deviation splints may be beneficial in providing relief of pain, stability, alignment, and reduced stress on painful, subluxed, or deviated joints. They may slow the progression of deformity, but they will not prevent or correct it.[9,71,84] Splints can be fabricated or obtained commercially, with support ranging from soft to rigid (Fig. 38.17). Despite the variety of splint designs and materials, MCP ulnar deviation splints are reported to be infrequently prescribed and used by clients.[75] Immobilization of the MCP joints can impede functional use of the hand or increase pain and stress on adjacent PIP joints.[46,71,83] Bulky or volar-based splints can also interfere with palmar sensation or impair the ability to grasp objects. However, some clients benefit from the pain relief and improved digital alignment. High client satisfaction rates have been reported for a custom dorsal-based design.[86] Soft splints are commercially available or can be custom-fabricated.[42] The client's preference for use and selection of an MCP ulnar deviation support should be the primary factor in decision making.[46,71]

FIG 38.17 Rigid prefabricated wire-foam metacarpophalangeal joint ulnar deviation splint. (Courtesy Occupational Therapy Department, Rancho Los Amigos National Rehabilitation Center, Downey, California.)

A swan neck splint, also known as a PIP hyperextension block, is used to restrict unwanted PIP hyperextension motion. Swan neck deformities often cause difficulty in hand closure because the PIP tendons and ligaments can catch during motion and the finger flexors have less of a mechanical advantage to initiate flexion when the PIP joint is in a hyperextended position. By blocking the PIP joint in slight flexion, the client can flex the PIP joint more efficiently, thus improving hand function. Swan neck splints can be custom-fabricated from thermoplastics for short-term or trial use. For long-term use or for use on adjacent fingers, commercial products made of metal or polypropylene are preferable because they are more durable, less bulky, more easily cleaned, and more cosmetically appealing[112] (Fig. 38.18). Swan neck splints or splints of similar design can also be used to provide lateral stability to unstable IP joints of the fingers or thumb.[9,46]

FIG 38.18 Splints for swan neck deformity: custom-fabricated thermoplastic, commercial custom-sized metal, and prefabricated polypropylene. (Courtesy Occupational Therapy Department, Rancho Los Amigos National Rehabilitation Center, Downey, California.)

Flexible boutonnière deformities may benefit from boutonnière splints to block the PIP joint in extension and leave the DIP joint free to flex. These can be fabricated by the therapist or custom-ordered from the same companies that manufacture swan neck splints. As a result of the direct pressure that they exert over the dorsum of the PIP joint, the skin must be monitored closely.

Clients may reject wearing these splints during the day if limiting PIP flexion impedes function. Night splinting with the PIP joint in maximal extension can be used in an attempt to maintain ROM.[9]

Thumb splinting can provide positioning opposite that of the developing deformity in early stages of disease and a more stable and pain-free pinch for function in later stages.[9] Hand-based short thumb spica splints or opponens splints leave the wrist and IP joints free and can be used for problems at the MCP or CMC joints. Splinting for the CMC joint may sometimes necessitate inclusion of the wrist or MCP joints, but both hand-based and forearm-based (long thumb spica) types have been found to be effective.[46,107,114] Several thermoplastic splint designs exist, as do numerous prefabricated splints made from a variety of materials. Depending on the client's symptoms and stage of disease, a soft support (Fig. 38.19, A) may suffice, or the client may require a rigid support (see Fig. 38.19, B) to counteract the stressors applied to joints during functional use. In studies comparing a short neoprene thumb spica splint and a custom thermoplastic hand-based splint for OA of the CMC joint, both splints improved pain and function and reduced subluxation. The thermoplastic splint reduced subluxation more, but the neoprene splint provided better pain relief and was preferred by clients.[96,115] Systematic reviews found fair evidence of the effectiveness of splinting in relieving pain and improving function in OA of the CMC joint, no evidence of a particular splint superiority, and varying patient preferences.[35,56]

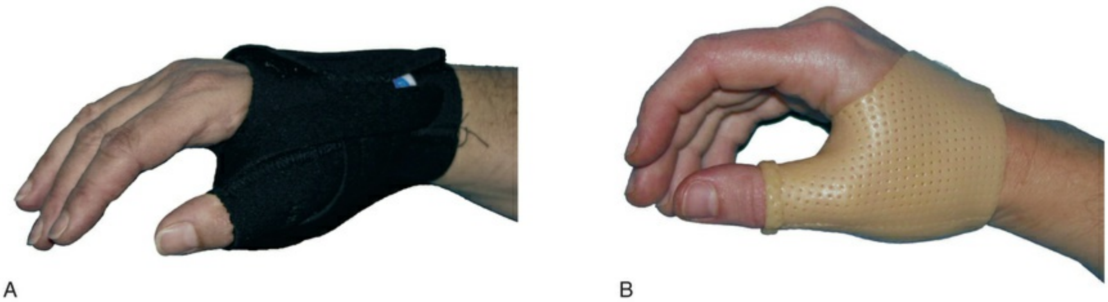

FIG 38.19 **A,** Prefabricated soft thumb support. **B,** Custom-fabricated thermoplastic short thumb spica splint. (Courtesy Occupational Therapy Department, Rancho Los Amigos National Rehabilitation Center, Downey, California.)

Dynamic splints and serial static splints may be used to regain ROM lost by shortening of periarticular structures or to maximize motion after surgical procedures such as joint arthroplasty. If the joint space is preserved (as determined by radiographs), there is a soft end-feel, and no more than minimal inflammation is present, gentle splinting may be indicated. The program should be monitored closely for adverse signs of increased pain and swelling. Static splints are often better tolerated than dynamic ones because they apply lesser amounts of force on the joint.[46]

Finally, silicone-lined digital sleeves and pads (Fig. 38.20) may be helpful in protecting painful nodes or nodules from external trauma.

FIG 38.20 Silicone-lined digital sleeve and pad. (Courtesy Occupational Therapy Department, Rancho Los Amigos National Rehabilitation Center, Downey, California.)

The splinting program for Nina focused on decreasing her inflammation and pain and protecting her vulnerable joints. Because she had no established deformity, prefabricated splints were a viable option, one that she preferred. Bilateral lightweight resting hand splints were selected for use at night. To afford her some ability to function, semirigid wrist splints were prescribed for use during the day. She was taught to monitor her symptoms and intermittently use the resting hand splints as needed if daytime activity led to increased pain or inflammation. Splint straps were modified by attaching loops to one end so that she could more easily manage them (see Chapter 30 for additional information).

Occupational Performance Training

An effective means of maintaining functional motion and strength with arthritis is to have clients perform daily occupations.[72] During active stages of the disease, occupations may be limited to just a few, such as feeding and hygiene. As the client's condition improves, usual life activities should be resumed because this will promote physical status and psychological well-being. An important but sometimes neglected aspect of ADL training is sexual counseling. Given the pain, fatigue, and ROM limitations resulting from arthritis or movement restrictions imposed postoperatively after joint replacement, an open discussion of issues and illustrations of more comfortable and safe positions for intercourse may prove helpful for clients and their partners. Excellent resources for sexual functioning with disabilities are available (see Chapter 12 for additional information).[29,90,95]

Analysis of activity demands and activity contexts is a critical component in helping clients maintain, restore, or enhance their engagement in desired activities and occupations. Environmental modifications, alternative methods, or assistive devices often make a difference by increasing clients' independence, ease, and safety in completing meaningful occupations with less pain and stress on their joints. Creative problem solving with the client as an active participant can lead to solutions for unique challenges. Understanding the client's perspective, the meaning of roles, and the cultural and physical environment will allow the therapist to propose a more effective intervention.[7]

Assistive Devices

Numerous assistive devices can be fabricated or purchased commercially. The therapist should be familiar with the types of devices available and sources where they can be obtained at minimal expense. Many devices that were previously available exclusively from medical suppliers can now be found in retail stores at a much lower cost. Commonly used in arthritis interventions are extended-handle devices (eg, reacher, bath sponge, shoe horn, dressing stick, comb; Fig. 38.21, A), to compensate for loss of proximal ROM and strength, and devices with built-up handles (eg, hairbrush, toothbrush, writing implement, eating utensil, knob turner; Fig. 38.21, B), to compensate for limited hand function (Table 38.7). The therapist should carefully consider the client's goals, factors, activity demands, and contexts when suggesting assistive devices.[72] Most relevant to clients with arthritis are the following: Is the client receptive to using a device? Will the device successfully reduce pain, joint stress, energy demands, or time expenditure? Is the device easy to use? Is the device acceptable to the client in terms of appearance, cost, and maintenance needs? Is the device compatible with the physical environment and others in the environment? Is the device likely to cause any negative effects?

FIG 38.21 **A,** Extended-handle devices. **B,** Built-up handle devices. (Courtesy Occupational Therapy Department, Rancho Los Amigos National Rehabilitation Center, Downey, California.)

TABLE 38.7

Commonly Used Assistive Devices for Arthritis

Activity	Assistive Devices
Dressing	Dressing stick, shoe horn, sock aid, button hook, zipper pull, elastic shoelaces
Bathing	Handheld shower hose, bath bench, grab bars, long-handled sponge
Toileting	Raised toilet seat, grab bars, extended perineal hygiene aid
Hygiene and grooming	Built-up or extended-handle toothbrush, suction denture brush, extended-handle hairbrush or comb, suction nail brush, mounted nail clipper
Feeding	Built-up or extended-handle utensils, lightweight T-handled mug
Meal preparation	Electric can and jar openers, adapted cutting board, utensils with built-up handles, ergonomic right-angled knives, rolling utility cart, knob turner for stove, reacher
Miscellaneous	Doorknob levers, built-up or extended key holder, extended-handle dust pan, built-up pen, loop or spring-loaded scissors, speaker phone

Having sample equipment on hand for the client to try can be helpful in finding the best device for each client. In some cases it may be necessary to modify existing devices before the client can use them successfully. For example, the handle of a dressing stick may be built up for a client with limited grasp. Surprisingly little research has been done on assistive devices for clients with arthritis and on the characteristics of device users and nonusers, but clinical experience shows that clients are less likely to use devices that they perceive as not helpful, too complicated, too expensive, or too bothersome to others sharing the environment.[89,105] A study of device use in frail elderly clients, including some with arthritis, demonstrated that they were willing to use the devices but required assistance in identifying sources for devices.[65,66] Some clients may need to use assistive devices only during a flare or on more symptomatic days. On good days, it may be appropriate to encourage clients to perform tasks without them to promote strength and mobility.

Client and Family Education

Providing clients with as much information as possible regarding their conditions and treatment is a crucial component of OT and should be integrated throughout all phases of the program. Whether it is the client's first visit or one of many therapy encounters, educational needs should always be explored. Health literacy must be considered and fostered as it has been found to be strongly associated with functional status.[23] The client's estimation of the therapist's credibility, the quality of the therapeutic relationship, and whether the client's experience confirms the therapist's statements are important factors tied to success in changing the client's knowledge and beliefs.[63] Client education has been shown to empower clients and lead to positive changes in pain reduction, psychological status, disease management, self-efficacy, and overall health promotion.[18,20,36,45,62,64,67-69]

Ethical Considerations

Information should be presented at a level appropriate for each client and significant other, along with sensitivity to learning styles; socioeconomic status; educational level; cultural implications; and personal values, beliefs, and feelings.

Rather than focusing exclusively on providing basic information and generic skills, encouraging client self-reflection and transformation of client perspectives has been suggested as a helpful part of rehabilitation.[34] Repetition, reinforcement, and real-life application to the client's situation are other keys to education. By focusing on the client's symptoms and concerns, the therapist can capitalize on teachable moments to provide present-oriented and problem-focused learning activities.[15] It may be helpful to provide both verbal and written instructions. The following are some important educational aspects to cover: disease process, symptom management, joint protection and fatigue management, and community resources.

Disease Process

Does the client understand the type of arthritis, basic underlying pathology, medications, and medication side effects? Does the client understand that prolonged synovitis in RA can lead to irreversible joint damage and potential disability? Does the client feel comfortable discussing questions with the physician, nurse, or other treating clinicians? Does the client know of available resources to learn more?

Symptom Management

Does the client know how to monitor for signs and symptoms of inflammation? Does the client understand that pain lasting for more than 1 or 2 hours after an activity signals a need to modify or cease doing that task? Does the client understand the rationale behind, demonstrate appropriate use of, and appropriately integrate rest, exercise, splinting, and PAMs into a daily routine? Do family members understand the client's abilities and when they should or should not assist the client with activities? Does the client know to take a cautious approach to nontraditional arthritis remedies to avoid falling prey to medical quackery?

Joint Protection and Fatigue Management

Does the client understand the rationale and general principles of joint protection and fatigue management? More important, does the client successfully integrate them into daily activities? It can be challenging not just to help the client understand the potential implications but also to translate learning into action. The purpose of joint protection is to reduce internal and external joint stress, pain, and inflammation in the involved joints and preserve the integrity of joint structures during the performance of daily activities.[72] Although it has not been proved that use of joint protection techniques prevents deterioration, knowledge of the disease process and pathomechanics of deformity and clinical experience suggest that joint protection is a sound idea.[27,67] Studies have shown that clients who experience pain relief or improved function may be more receptive to changing their behavior.[31,44,76] Fatigue management, a more contemporary term for energy conservation, is aimed toward saving and expending energy wisely (Box 38.4). Organizing the environment, pacing activity, and resting can successfully moderate fatigue.[31] Instruction of principles should be based on teaching key concepts rather than general rules and should be specifically applied to each client's lifestyle and pattern of occupation with the aim of achieving occupational balance.[72,93,101] Practice in the therapy setting can help with carryover because following these principles often necessitates a change in lifelong habits. General principles for joint protection and fatigue management are especially helpful for clients with RA or clients with OA involving the hands, hips, or knees.[27,31,72]

Box 38.4

Principles of Fatigue Management

Attitudes and Emotions

Remove yourself from stressful situations.

Refrain from concentrating on things that make you tense.

Close your eyes and visualize pleasant places and thoughts.

Body Mechanics

When lifting something that is low, bend your knees and lift by straightening your legs. Try to keep your back straight.

Avoid reaching (use reachers). Avoid stretching, bending, carrying, and climbing. If you have to bend, keep your back straight.

Incorporate good posture into your activities.

Whenever possible, sit when working.

To get up from a chair, slide forward to the edge of the chair. With your feet flat on the floor, lean forward and push with your palms on the arms or seat of the chair. Stand by straightening your legs.

Before you get tired, stop and rest.

Work Pace

Plan on getting 10 to 12 hours of rest daily (naps and nights).

Work at your own pace.

Spread tedious tasks throughout the week.

Do the tasks that require the most energy at the times when you have the most energy.

Alternate easy and difficult activities, and take a 10- to 15-minute rest break each hour.

Leisure Time

Devote a portion of your day to an activity that you enjoy and find relaxing.

Check out what is available in the community.

Work Methods

Keep items within easy reach.

Use good light and proper ventilation and room temperature.

Use joint protection techniques.

Work surfaces should be at a correct height.

Organization

Plan ahead; do not rush or push yourself.

Decide which jobs are absolutely necessary.

Share the workload with family and friends.

How to Begin

Plan ahead by charting your daily routine.

Make a list of tasks, and spread them out in your schedule.

Include daily rest periods and rest breaks during energy-consuming times.

Weekly Schedule

Time	Sun	Mon	Tues	Wed	Thurs	Fri	Sat
7:00							
8:00							
9:00							
10:00							
11:00							
12:00							
1:00							
2:00							
3:00							
4:00							
5:00							
6:00							
7:00							
8:00							
9:00							
10:00							

Check your schedule for the following factors:

Is there 1 day in the week that is longer than the others?

Are heavier tasks distributed through the week?

Is there a long task that could be done in several steps?

Will your plan allow flexibility?

Have you devoted part of your day to a relaxing activity?

Does your plan use the principles of energy conservation?

Joint protection and fatigue management principles are as follows (more detailed information can be found in the sources just cited):

- *Respect pain.* Pain is a signal from the body that something is wrong. Clients often feel that they can ignore and work through pain, but the result is often more pain. If pain is present from an acute episode of inflammation, rest and avoidance of activity are indicated so that the pain and inflammation are not worsened. In chronic stages, pain that lasts for more than 1 or 2 hours after completion of an activity indicates that the activity should be modified or avoided. Clients should be encouraged to be aware of their limits and stop activities before pain occurs. Disregarding pain can lead to joint damage.
- *Maintain muscle strength and joint ROM.* Joints that are less stiff and have balanced strength will be less susceptible to further injury. Limited motion at one joint transmits force to another and may require exaggerated motions at other joints to accomplish a task. For example, loss of MCP motion will affect the PIP joint. Daily functioning and exercise programs should be done with all joint protection principles in mind to ensure that they are as least stressful as possible.
- *Use each joint in its most stable anatomic and functional plane.* This plane is the point at which resistance to motion is provided by muscle rather than ligament. Following this principle minimizes excessive stress on ligaments and allows muscle power to be used with the greatest mechanical advantage. Examples include not leaning to either side when rising from a seated position to lessen rotational forces on the knees and pinching with the pad of the thumb and the IP joint in a flexed position to minimize force on the ulnar collateral ligament.
- *Avoid positions of deformity.* The customary way of performing tasks may cause forces to be applied in directions of deformity. Tasks involving tight squeezing, pinching, or twisting motions are especially stressful. Opening a jar lid, turning a doorknob, cutting food with a knife, and lifting a coffee cup are all activities promoting MCP ulnar deviation. Instead, clients with hand involvement can be encouraged to open lids with the palm of their hand and shoulder motion or with a jar opener; to turn a doorknob with an adapted lever; to cut food with a dagger-type grip,

rolling pizza cutter, or adapted knife; and to lift coffee mugs with two hands. Static positioning should also be considered. For example, clients should be discouraged from leaning their chin on the back of the fingers because this applies considerable force to the flexed MCP joints.

- *Use the strongest joints available.* Using larger, inherently stronger joints reduces the stress on smaller joints. Carrying bags and purses on the shoulder or elbow lessens strain on the wrist and hand. Properly fitting backpacks or waist packs are other good alternatives, as is pushing or pulling a rolling cart instead of carrying items on the body. The palms rather than the fingers should be used to lift, push, or take weight to better distribute the forces.
- *Ensure correct patterns of movement.* The client may adopt incorrect patterns because of pain, deformity, muscle imbalance, or habit. For example, the client may use the dorsum of the fingers to push up from a seated position. This movement places deforming forces toward MCP flexion. A more suitable pattern is to use the flat surface of the palm (Fig. 38.22). In the hand, use of the long extensors during finger movement should be maintained. Finger flexion should be initiated at the DIP joints while maintaining extension at the MCP joints versus leading motion with the intrinsic muscles.

FIG 38.22 Use of palms to push off a chair helps protect finger joints. (Courtesy Occupational Therapy Department, Rancho Los Amigos National Rehabilitation Center, Downey, California.)

- *Avoid staying in one position for long periods.* Prolonged static positions can lead to joint stiffness and muscle fatigue. Positional stress is then transmitted to the joint ligaments, which may already be in a weakened state. Changing body positions and gripping postures, taking frequent breaks, and integrating active motion exercises during activities such as computer keyboarding, writing, gardening, and knitting can prevent fatigue, soreness, stiffness, and resulting poor movement patterns.
- *Avoid starting an activity that cannot be stopped immediately if it becomes too stressful.* This will prevent the load from going to the joint capsule and ligaments if muscles tire. Continuing a task that causes sudden or severe pain is likely to cause joint damage, and severe fatigue can cause poor movement patterns and safety risks. Realistic planning of options can help prevent these situations. For example, clients can keep a bath bench available in case they need to rest while standing in the shower. Clients also can note the location of benches in a mall in relation to the stores where they plan to shop.
- *Balance rest and activity.* Chronic pain and a systemic disease such as RA can drain both physical

and psychological resources. Helping the client understand the physiologic need for proper rest can facilitate this often difficult lifestyle change. The key to increasing functional endurance is to rest before becoming overfatigued, which could mean napping or taking breaks during or between activities. Clients with arthritis often relate similar stories of feeling a need to take advantage of good days by trying to complete as many tasks as possible. These good days are more than likely followed by several bad days as their bodies try to recover. Balancing activities during the day and longer-term across the week or month can be accomplished through planning and establishing priorities.

- *Reduce force and effort.* Less force and effort equate to less joint stress, less pain, and less fatigue. Using built-up handles, levers, more even distribution of loads, alternative methods, and other aforementioned joint protection and fatigue management techniques can help toward this end. For example, rearranging the kitchen environment to have everything within easy reach, planning tasks and gathering all needed items, sitting down while at the sink or stove, and using assistive devices all contribute to easier meal preparation.

Community Resources

Does the client know of and use available resources? Clients should be made aware and encouraged to take advantage of them. Reading materials, exercise and educational programs, and support groups can supplement medical and therapy intervention and promote lasting positive self-management behavior. The Internet, libraries, YMCAs, and senior centers are sources of information and activity or exercise programs. The Arthritis Foundation, a national organization with many local chapters throughout the country, is an excellent resource for clients, families, and clinicians. Among other services, the Arthritis Foundation offers educational pamphlets, exercise programs, self-help tips, and support designed exclusively for persons with arthritis. Box 38.5 highlights some programs and materials of special relevance to persons with RA and OA.

Support

Arthritis Foundation Community at Inspire (www.inspire.com/groups/arthritis-foundation)

Occupational performance training was an important component of Nina's OT intervention. Her ability to continue working was addressed through a combination of modification of activities, use of assistive devices, and client education. Client education focused on her ability to better understand her disease process, manage her symptoms, and integrate joint protection and fatigue management principles into her life. Nina and the therapist reviewed her typical weekly schedule and together planned one that allowed a more suitable balance of rest and activity given her patterns of fatigue and peak energy. The therapist recommended ways to improve Nina's computer workstation at home, including moving the keyboard and monitor to more appropriate heights, adjusting her chair for optimal body positioning, using a pad to support her wrists, and switching from a standard mouse to a trackball device. Assistive devices were recommended for other occupations, such as cooking and managing her home. Mutual problem solving identified solutions that allowed Nina to gradually return to her previous number of work hours. Among these solutions were having Nina do much more work from her home, where she could rest as needed, and to spread out visits to her contracted businesses over several weeks and only when needed. Planning and taking an afternoon rest before picking up her grandchildren from school gave her the energy to take them to the park more frequently.

Summary

Arthritis is a chronic condition that can impose devastating limitations on a person's ability to engage in meaningful occupations. It is important for the therapist to understand the different disease processes and pathomechanics of the joint destruction found in OA and RA. Through a carefully crafted program based on a thorough evaluation of the physical, psychosocial, and functional barriers, OT can decrease pain, protect joints, foster self-management, and enable increased participation in life skills.

Threaded Case Study

Nina, Part 2

Critical evaluation components in assessing Nina's previous and current functional status were the occupational profile and typical-day assessment; assessment of clinical status included pain, inflammation, stiffness, range of motion, strength, endurance, and functional mobility. The aspects of the disease process most problematic to Nina were inflammation, pain, and fatigue from a flare of her rheumatoid arthritis. Her ability to engage in her employment was affected by her motor and process performance skills; roles and routines performance patterns; physical, social, personal, temporal, and virtual contexts; object, space, body functions, and body structures activity demands; and sleep, energy, attention, joints, and muscle function client factors.

Nina benefited from splinting, exercise, heat, and occupational performance training with activity modification, assistive devices, and client education in symptom management, joint protection, fatigue management, and available resources. A collaborative approach throughout the therapy process was essential in promoting lasting benefits and engagement in meaningful occupations.

Hand and Upper Extremity Injuries*

J. Martin Walsh, Nancy Chee

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, the student or practitioner will be able to do the following:

1. Discuss the incidence of upper extremity (UE) injuries and their effects on occupational performance.
2. Identify three upper quarter screening tests and explain their significance in developing an intervention plan.
3. Discuss the importance of joint mobility in regaining the motor performance skill of hand

function.
4. Describe the four categories of tests used to evaluate peripheral nerve function and explain how the results would be used in developing an intervention plan.
5. Compare the standardized tests used to assess the motor performance skill of hand function.
6. Describe the sensory and motor innervation patterns of the three major nerves; differentiate between the effects of proximal and distal lesions in each of the nerves; and explain how they might affect occupational performance.
7. Discuss complex regional pain syndrome and the intervention approaches that should be included in the occupational therapy (OT) intervention plan for that disorder.
8. Compare techniques used in the rehabilitation of tendon injuries.
9. Describe the significance of edema with regard to wound healing and joint mobility.
10. Discuss the role of the occupational therapist in the evaluation and rehabilitation of injured workers.

KEY TERMS

Complex regional pain syndrome

Cumulative trauma disorders

Edema

Ergonomic

Functional capacity evaluation

Orthotics

Peripheral nerve injuries

Provocative tests

Tendon injuries

Upper quadrant

Threaded Case Study

Gerry, Part 1

Gerry is a 32-year-old man who is self-employed as a cabinetmaker. He sustained a table saw injury to his nondominant left hand while working. The thumb, index, and middle fingers of Gerry's left hand were amputated at the level of the proximal phalanges as a result of the saw injury and were subsequently replanted by a hand surgeon using microsurgical techniques. Gerry is single, lives with a roommate, and is in business with his father in a small but busy cabinet shop. Gerry is extremely active at work and during his free time. He is very social and has an extensive network of supportive friends and family.

Gerry was referred to hand therapy as an inpatient 5 days after the replantation surgeries, as soon as he was discontinued from the anticoagulation medications. The initial interview between Gerry and his occupational therapist/CHT (Certified Hand Therapist) took place at bedside. He was to be discharged from the hospital the next day with instructions to return for outpatient hand therapy. A protective orthosis was fabricated at the first therapy session, and Gerry was taught about postsurgical precautions, wound care, and dressing changes. During the initial evaluation Gerry said that he was very distressed about the potential loss of function of his left hand and that he wanted to accomplish three of his most valued occupations in the months to come. The first occupation was to return to work with his father, making cabinets in the family business; the second was to resume playing softball with his team; and the third was to play golf again. The first occupation was one he valued not only as a source of livelihood, but also as a profession in which he demonstrated great skill and from which he derived joy. The second two occupations were important to him not only as a source of relaxation but, more important, as a primary venue for social interaction with friends and family.

Gerry initiated hand therapy in the hospital during the acute phase of his recovery. He was followed in hand therapy for 15 months from the date of his injury, and through several additional surgeries and all phases of his rehabilitative process: the acute or immobilization phase, the intermediate (mobilization) phase, and the late or strengthening phase.[17] During the initial evaluation, Gerry clearly expressed a desire to return to three specific occupations of value to him: working as a cabinetmaker, playing golf, and playing softball.

Critical Thinking Questions

1. How will the intervention plan change over the course of Gerry's recovery? What specific intervention approaches will be used during the three phases of his recovery?

2. What specific tools or instruments will be used to assess Gerry's performance skills during the different phases of his recovery?

3. What are some of the specific preparatory methods and purposeful activities that may be used in preparation for Gerry's occupation-based performance activity of golf?

Treatment of the upper extremity (UE) is important to all occupational therapists who work with people with physical disabilities. The incidence of UE injuries is significant; they account for about one third of acute injuries overall[64] and 26% of work-related injuries.[101] In addition, disease and congenital anomalies contribute to UE dysfunction, and it is estimated that only about 15% of those who experience a severe cerebrovascular accident recover hand function.[64]

The hand is vital to human function and appearance. It flexes, extends, opposes, and grasps thousands of times daily, allowing the performance of necessary daily activities. The hand's sensibility allows feeling without looking and provides protection from injury. The hand touches, gives comfort, and expresses emotions. Loss of hand function through injury or disease thus affects much more than the mechanical tasks that the hand performs. Hand injury may jeopardize a family's livelihood and, at the least, affects every daily activity. The occupational therapist with training in physical and psychological assessment, prosthetic evaluation, fabrication of orthoses, assessment and training in the activities of daily living (ADLs), and functional restoration is uniquely qualified to treat UE disorders.

Hand rehabilitation, or hand therapy, has grown as a specialty area of occupational therapy (OT) and physical therapy (PT). Many of the intervention techniques used for clients with a hand injury have evolved from the application of therapy and a knowledge of both specialties, as used by the hand therapist. It is not the purpose of this chapter to instruct the OT student in physical agent modalities; rather, intervention techniques that have been found to be beneficial to clients with hand injuries are presented. It is assumed that the therapists best trained to provide them will provide these techniques.

As used in this chapter *hand therapy* is a term that includes interventions for the entire **upper quadrant**, which includes the scapula, shoulder, and arm. Upper quadrant and UE are used interchangeably. UE rehabilitation requires advanced and specialized training for both occupational and physical therapists. A practice analysis study of the theory and knowledge that serve as the underpinning for hand therapy has been reported.[40] Intervention techniques, whether thermal modalities or specifically designed exercises, are used as a bridge to reach a further goal of restoring functional performance. Thus, some modalities may be used as adjunctive or enabling modalities in preparation for functional use. It is within this context that intervention techniques are presented in this chapter.

Intervention for a UE injury is a matter of timing and judgment. After trauma or surgery a healing phase must occur in which the body performs its physiologic function of wound healing. After the initial healing phase, when cellular restoration has been accomplished, the wound enters its restorative phase. It is in this phase that hand therapy is most beneficial. Early intervention in this restorative phase is ideal and in some cases essential for optimal results.

Although sample timetables may be presented, the therapist should always coordinate the application of any intervention with the referring physician. Surgical techniques may vary, and inappropriate treatment of the client with a hand injury can result in failure of a surgical procedure.

Communication among the surgeon, therapist, and client is especially vital in this setting. A comfortable environment that allows group interaction may increase the client's motivation and cooperation. The presence of the therapist as an instructor and evaluator is essential, but without the client's cooperation, limited gains will be achieved. Treating the psychological loss suffered by the client with a hand injury is also an integral part of the rehabilitative therapy.

OT Practice Notes

Hand therapy is provided in a number of intervention settings, ranging from private therapy offices to outpatient rehabilitation clinics and hospitals or even in the workplace. Reimbursement for services may come directly from the client or through private medical insurance, workers' compensation insurance, or a variety of managed care programs. Changes in reimbursement have driven changes in the marketplace and employment patterns. In the future, OT will be provided in a variety of new settings, and OT intervention will continue to evolve.

In UE rehabilitation, changes have been manifested as changes in the delivery of services. In some cases therapists are not members of the approved provider panel and are no longer able to treat clients who are members of a health maintenance organization. Reimbursement patterns have altered the provision of services by limiting the number of visits authorized. Therapists are being asked to provide functional outcome data that support the need for services. They also need high-quality information on which to base clinical decisions, which points to the need for evidence-based practice.[67]

Evidence-based practice uses the best evidence, in conjunction with clinical expertise and the client's values, to make clinical decisions.[17] It is likely that outcome-based or evidence-based intervention plans with functional goals and analysis of goal achievement will become the standard for reimbursement of OT services. In addition the client's satisfaction and perception of his or her health status have become crucial to the delivery of medical care in a consumer-based economy. Continuous, quality improvement documentation often is required for participation in managed care programs. With fewer authorized visits, the therapist must be more adept in instructing the client in self-management of the condition being treated. Hand therapists and rehabilitation providers are also subject to intense scrutiny and review by multiple regulatory agencies. In addition insurance companies and government agencies review clients' records and billing documentation. Reimbursement for therapy services relies on detailed documentation of services provided and reassessments of the need for ongoing services. The best way to assure compliance with all these agencies is to perform frequent reviews of clients' medical records in the form of chart reviews.[50a]

Presently and continuing into the future, occupational therapists should anticipate a greater need to justify intervention as part of the national challenge to control medical costs. Aides, certified assistants, and other support personnel are being used increasingly, but the quality of services provided must continue to meet all professional and ethical standards. This climate of change also presents unique opportunities for the occupational therapist. Clinical specialists are finding new roles as consultants and trainers. Just as OT teaches the client to adapt to changes in health status, the OT profession will need to continue to adapt to social and economic changes to remain a leader in health management.

Examination and Evaluation

Using a client-centered approach, the occupational therapist must gather information about the client's occupational history, including a detailed description from the client's perspective of how the hand injury may interfere with the resumption of daily life activities that are most important to him or her. Developing this occupational profile includes consideration of a client's performance of daily tasks, interests, values, and needs.[2,3] Armed with this occupational profile the therapist and client continue the evaluation process. The therapist must be able to evaluate the nature of the injury and the limitations it has caused. First, the injured structures must be identified by consulting with the hand surgeon, reviewing operative reports and x-ray films, and discussing the injury with the client. Assessment of the wound, bone, tendon, and nerve function must be performed, using standardized assessment techniques whenever possible.

The client's age, occupation, and hand dominance should be taken into account in the initial evaluation. The type and extent of medical and surgical treatment that has been received and the length of time since such intervention are important in determining an intervention plan. Any further surgery or conservative intervention that is planned should also be noted. A written intervention plan should have the approval of the referring physician. Most physicians welcome observations and evaluation-based recommendations from the therapist regarding the client's care.

The purposes of hand evaluation are to identify physical limitations, such as loss of range of motion (ROM); functional limitations, such as an inability to perform daily tasks; substitution patterns to compensate for loss of sensibility or motor function; and abnormalities, such as joint contracture.

The movement of the arm and hand must be coordinated for maximal function. Shoulder motion is essential for positioning the hand and elbow for daily activities.[22] The wrist is the key joint in the position of function.[11a] Skilled hand performance depends on wrist stability. Although a mobile wrist is preferable, function is possible as long as the wrist is positioned to maximize movement of the fingers. Function also depends on arm and shoulder stability and mobility for fixing or positioning the hand for activity. The thumb is of greater importance than any other digit. Effective pinch is almost impossible without a thumb, and attempts are made to salvage or reconstruct an injured thumb whenever possible. In the hand the proximal interphalangeal (PIP) joint is critical for grasp and is considered the most important small joint. Limitations in flexion or extension result in significant functional impairment.

The hand therapy evaluation should consist of two concurrent stages. One stage consists of assessing the client's occupational profile to help the therapist select an effective intervention that addresses the client's occupational priorities. The other stage consists of assessing specific performance skills, such as coordination and strength, and client factors, such as sensory functions, neuromusculoskeletal and movement-related functions, and the functions of the hand and related structures. Evaluating both the client's occupational profile and the individual's performance skills ensures that the client's priorities are addressed and makes the intervention more meaningful.

Observation and Topographic Assessment

The occupational therapist should observe the appearance of the entire UE. The position of the hand and arm at rest and the carrying posture can yield valuable information about the dysfunction. The therapist should observe the way the client treats the disease or injury. The occupational therapist should note whether the hand and arm are overprotected, carefully guarded, or ignored, and whether the client carries the arm close to the body, in an awkward posture, or even covered.

The cervical and shoulder area posture should be observed for evidence of abnormalities in cervical and thoracic curvature that may reduce the potential for shoulder movement. Muscle atrophy may be evident in the scapular area if the client has had significant long-term weakness or if the rotator cuff is torn. The scapula may appear asymmetric or altered if muscle imbalances of length or strength are present.

The skin condition of the hand and arm also should be noted. In particular the therapist should note any lacerations, sutures, or evidence of recent surgery; whether the skin is dry or moist; whether scales or crusts are present; and whether the hand appears swollen or has an odor. Normally palmar skin is less mobile than dorsal skin. The therapist should determine the degree of mobility and elasticity and the adherence of scars. The therapist also should observe trophic changes in the skin. To assess the vascular system, the therapist should observe the skin color and temperature of the hand and evaluate for the presence of **edema** (swelling). Any contractures of the web spaces should be noted. The therapist should observe the relationship between hand and arm function as the client moves about and performs test items or tasks.

The therapist should ask the client to perform some simple, bilateral ADLs, such as buttoning a button, putting on a shirt, opening a jar, and threading a needle; the occupational therapist observes the amount of spontaneous movement and use of the affected hand and arm. Similar screening tests can be used to determine shoulder mobility, such as reaching overhead or placing the hand behind the back and behind the head, simulating self-care and hygiene activities.

Assessment of Performance Skills and Client Factors

A number of standardized tests can be used to determine physical limitations in the UE. Joint measurement and manual muscle testing are crucial and are described in other chapters (see Chapters 21 and 22). Special tests used by the hand therapist are described here in a general sense, but the student should consult other textbooks for detailed instructions in such areas as assessment of adverse neural tension.[15]

Screening the Cervical Neck and Shoulder

A screening examination of the cervical neck and shoulder regions should be included in evaluation of hand conditions to determine whether these areas are contributing to the client's symptoms or limitations in function.

Active movements of the neck should be conducted, with attention paid to complaints of UE symptoms during cervical extension or lateral flexion to the same side. Complaints during these movements may suggest nerve root irritation. Hand symptoms with opposite side bending may be a sign of adverse neural tension. Few occupational therapists are knowledgeable in the intervention of cervical conditions, and care must be taken not to aggravate an existing condition. The therapist should return the client to the referring physician with recommendations for referral to an appropriate practitioner if the results of this testing are positive.

Assessment of Movement

The effect of trauma or dysfunction on anatomic structures is the first consideration when evaluating hand function. The joints must be assessed for active and passive mobility, fixed deformities, and any tendency to assume a position of deformity. The ligaments must be assessed for laxity or contracture and their ability to maintain joint stability. Tendons must be examined for integrity, contracture, or overstretching; muscles are tested for strength and function.[46]

Limited movement in the shoulder.

Examples of conditions in the shoulder region that lead to reduced strength, reduced ROM, or pain in the shoulder are presented in Table 39.1. Comparing the initial responses with the results of follow-up evaluations helps document a positive response to intervention. Patterns of impairments in UE range of motion and strength, in addition to a positive response to provocative testing, should be reported to the referring physician if these would affect the client's planned intervention or outcome. Therapists must not attempt to treat conditions that are beyond their scope of knowledge. Referral to an appropriate practitioner should be discussed with the physician if indicated.

TABLE 39.1

Clinical Tests for Specific Dysfunction in the Shoulder

Condition	Pattern of Impairment	Characteristic Findings/Special Tests
Adhesive capsulitis	Loss of active and passive shoulder motion with the most pronounced loss in external rotation and, to a lesser degree, abduction and internal rotation	• Capsular end feel to passive motions in restricted planes of movement
Subacromial impingement	Painful arc of motion between approximately 80 and 100 degrees of elevation or at end range of active elevation	• In early stages, muscle tests may be strong and painless despite positive impingement test
Rotator cuff tendinitis	Painful active or resistive use of rotator cuff muscle	• Painful manual muscle test of scapular plane abduction or external rotation • Pain-free passive motion end ranges • Tenderness at tendons of supraspinatus or infraspinatus.
Rotator cuff tear	Significant substitution of scapula with attempted arm elevation	• Positive drop arm test

		• Very weak, less than three-fifths abduction or external rotation

Impingement tests.

The examiner passively overpressures the client's arm into end range elevation; this movement causes jamming of the greater tuberosity against the anterior inferior acromial surface.[26] The test result is positive if the client's facial expression shows pain. An alternative test is described by Hawkins and Kennedy.[56] The examiner forward-flexes the arm to 90 degrees and then forcibly internally rotates the arm. Pain indicates a positive test result.

Drop arm test.

To assess a suspected rotator cuff injury, the client's arm is passively abducted by the examiner to 90 degrees with the client's palm down. The client then is asked to lower the arm actively. Pain or inability to lower the arm smoothly with good motor control is considered a positive test result.[47,73]

Soft tissue tightness.

Joints may develop dysfunction after trauma, immobilization, or disuse. Joint play or accessory motions are described as movements that are abnormal, physiologic, and can be performed only with assistance from someone else. Examples of accessory motions are joint rotation and joint distraction. If accessory motions are limited and painful, the active motions of that joint cannot be normal. Therefore, it is necessary to restore joint play through the use of joint mobilization techniques before attempting passive or active ROM.

Joint mobilization may date back to the fourth century BC, when Hippocrates first described the use of spinal traction.[45] In the 1930 an English physician, James Mennell, encouraged physicians to perform manipulation without anesthesia, a practice that is advocated today by James Cyriax,[33] who explored the use of manipulation of the intervertebral disks. Current theorists include Cyriax, Robert Maigne, F.M. Kaltenborn, G.D. Maitland, Stanley Paris, and John Mennell, son of James Mennell. Although physicians originally practiced manipulation, therapists have adapted the techniques, which are now called joint mobilization.

The techniques used to assess joint play are also used in the treatment of joint dysfunction. During the assessment the evaluator determines the range of accessory motion and whether pain is present by taking up the slack only in the joint. Some practitioners advocate use of a high-velocity, low-amplitude thrust or graded oscillation to regain motion and relieve pain.[57]

Guidelines must be followed in applying joint mobilization techniques, and the untrained or inexperienced practitioner should not attempt to use the techniques. Postgraduate courses are offered in joint mobilization of the extremities, and the therapist must be familiar with the orthokinematics of each joint, in addition to the techniques used.

Joint mobilization is generally indicated with restriction of accessory motions or when pain is present because of tightness of the joint capsule, meniscus displacement, muscle guarding, ligamentous tightness, or adherence. Contraindications to mobilization include infection, recent fracture, neoplasm, joint inflammation, rheumatoid arthritis, osteoporosis, degenerative joint disease, and many chronic diseases.

Limitations in joint motion may also be caused by tightness of the extrinsic or intrinsic muscles and tendons. If the joint capsule is not tight and accessory motions are normal, the therapist should test for extrinsic and intrinsic tightness.

To test for extrinsic extensor tightness, the metacarpophalangeal (MP) joint is passively held in extension and the PIP joint is moved passively into flexion. Then the MP joint is flexed, and the PIP joint is again passively flexed. If the PIP joint can be flexed easily when the MP joint is extended but not when the MP joint is flexed, the extrinsic extensors are adherent.[4]

With extrinsic flexor tightness the PIP and distal interphalangeal (DIP) joints will be positioned in flexion, with the MP joints held in extension. The fingers cannot be pulled into complete extension. If the wrist is then held in flexion, the IP joints will extend more easily because slack is placed on the flexor tendons.

Tightness of the intrinsic musculature is tested by passively holding the MP joint in extension and applying pressure just distal to the PIP joint. This action is repeated with the MP joint in flexion. If more resistance is felt when the MP joint is extended, intrinsic tightness is indicated.[4]

If passive motion of the PIP joint remains the same whether the MP joint is held in extension or flexion and PIP joint flexion is limited in any position, tightness of the joint capsule is indicated. The therapist should assess the joint for capsular tightness if this has not already been done.

Provocative tests used to assess ligament, capsule, and joint instability are summarized in Table 39.2. For more detailed and comprehensive information regarding administration of these tests, the reader is referred to textbooks dedicated solely to hand therapy or to the specific topic.[47,73]

TABLE 39.2

Clinical Tests for Specific Dysfunction in the Wrist

Condition	Pattern of Impairment	Special Tests
Thumb ulnar collateral ligament (gamekeeper's or skier's thumb)	Pain and instability of the thumb metaphalangeal (MP) joint	• Movement greater than 35 degrees when valgus instability stress is applied to the thumb MP joint
Instability of the scaphoid	Pain in the area of the scaphoid bone (anatomic snuffbox) or "clunking" with movement of the wrist	• Watson's test • Pain or sound associated with subluxation of the dorsal pole of the scaphoid while performing test
Instability of the distal radioulnar joint	Pain and tenderness in the wrist	• "Piano keys" test • Hypermobility and pain associated with pressure on the distal ulna
Lunate dislocation	Pain or instability in the central wrist	• Murphy's sign • Head of the third metacarpal level with the second and fourth metacarpals while making a fist
Lunotriquetral instability	Pain or instability in the central or ulnar wrist	• Lunotriquetral ballottement test • Crepitus; laxity or pain with isolated movement of the lunate
Triangular fibrocartilage complex (TFCC) tear	Pain and instability in the ulnar wrist	• Wrist arthrogram or MRI • Piano keys test • Press test • Ulna fovea test

Assessment of Peripheral Nerve Status

Nerve dysfunction can occur at any point from the nerve roots through the digital nerves in the fingers. A good understanding of the peripheral nervous system is essential for appropriate treatment of the UE. Determining the approximate location of nerve dysfunction can assist intervention planning.

Categories of tests.

A variety of tests may be required to assess nerve function adequately. These tests can be divided into four categories: (1) modality tests for pain, heat, cold, and touch pressure; (2) functional tests to assess the quality of sensibility, or what Moberg[79] described as tactile gnosis; (3) objective tests that do not require the client's active participation; and (4) provocative tests that reproduce symptoms.

Examples of functional tests are stationary and moving two-point discrimination and the Moberg Pick-Up Test; objective tests include the wrinkle test, the Ninhydrin sweat test, and nerve conduction studies.[17] Electrodiagnostic testing is the most conclusive and widely accepted method of determining nerve dysfunction.

Provocative tests are highly suggestive of a nerve lesion if the results are positive, but they do not rule out a problem if the results are negative. Tests of nerve dysfunction are summarized in Table 39.3. Instructions for administration of the most common tests are presented in the following sections.

TABLE 39.3

Clinical Tests for Specific Nerve Dysfunction in the Upper Extremity

Condition	Pattern of Impairment	Characteristic Findings/Special Tests
Thoracic outlet syndrome	Nonspecific paresthesias or heaviness with sustained positioning or activity above shoulder level or behind the plane of the body	• Adson's test • Roos test
Adverse neural tension	Nonspecific pain or paresthesias with reaching in positions that place tension on brachial plexus nerves	• Positive upper limb screening test
Carpal tunnel syndrome	Pain and numbness, primarily in the thumb, index, and middle fingers	• Tinel's sign at the wrist • Phalen's test
	Usually worse at night and may be associated with activity	• Reverse Phalen's test • Carpal compression test
Cubital tunnel syndrome	Compression of ulnar nerve at elbow	• Elbow flexion test
Ulnar nerve paralysis	Paralysis of the adductor pollicis muscle	• Froment's sign • Jeanne's sign • Wartenberg's sign

Adson maneuver.

The examiner palpates the radial pulse on the test arm. The client then rotates the head toward the arm being tested. The client extends the head and holds a deep breath as the arm is laterally rotated and extended. Disappearance or slowing of the pulse rate is considered a positive test result, suggesting presence of thoracic outlet syndrome.[1,73]

Roos test.

The client maintains a position of bilateral arm abduction to 90 degrees, shoulder external rotation, and elbow flexion to 90 degrees for 3 minutes while slowly alternating between an open hand and a clenched fist. Inability to maintain this position for the full 3 minutes or the onset of symptoms is considered a positive test result for thoracic outlet syndrome.[73,89]

Upper limb tension test (brachial plexus tension test).

This test is designed to screen for symptoms produced when tension stress is placed on the brachial plexus. The maneuver described primarily stresses the median nerve and C5–C7 nerve roots. Adverse neural tension in the ulnar or radial nerves may also be tested. However, we have found that using the median nerve test as a screening device establishes a marker against which to gauge the success of intervention. Although some authors recommend using the neural tension tests both for intervention and for assessment, this has not been our practice. The occupational therapist should use this screening process to rule out or confirm the involvement of more proximal structures.

The client is positioned supine, and the examiner takes the client's arm into abduction and external rotation behind the coronal plane at the shoulder. The shoulder girdle is fixed in depression. The elbow is then passively extended with the wrist in extension and the forearm in supination. Symptoms of stretch or ache in the cubital fossa or tingling in the thumb and first three fingers indicates tension on the median nerve. Lateral flexion of the neck to the opposite side will amplify symptoms by increasing tension on the dura mater. Elbow extension ROM should be compared with the uninvolved side to indicate the degree of restriction.[15,73]

Tinel's sign.

The examiner taps gently along the course of a peripheral nerve, starting distally and moving proximally, to elicit a tingling sensation in the fingertip. The point where tapping begins to elicit a tingling sensation is noted and indicates the approximate location of nerve compression. This test is also used after nerve repair to determine the extent of sensory axon growth.[73]

Phalen's test and reverse Phalen's test.

Phalen's test is performed by fully flexing the wrists with the dorsum of the hands pressing against each other. Reverse Phalen's test is performed by holding the hands in the "prayer" position for 1 minute. The test results are positive if the client reports tingling in the median nerve distribution (thumb, index, middle and radial aspect of the ring finger) within 1 minute.[73]

Carpal compression test.

The examiner places pressure over the median nerve in the carpal tunnel for up to 30 seconds. The test result is positive if tingling occurs in the median nerve distribution. The combination of wrist flexion and compression of the median nerve for 20 seconds has been found to be more sensitive than other provocative tests used alone.[98]

Elbow flexion test.

The elbow flexion test is used to screen for cubital tunnel syndrome (compression of the ulnar nerve in the cubital tunnel). The client is asked to fully flex the elbows with the wrists fully extended for 3 to 5 minutes. The test result is positive if tingling is reported in the ulnar nerve distribution of the forearm and hand (ulnar ring finger and small finger).[73]

Quick tests for motor function in the peripheral nerves.

The ulnar nerve may be tested by asking the client to pinch with the thumb and index finger and then palpating the first dorsal interosseous muscle. Another test for ulnar nerve paralysis involves asking a client to grasp a piece of paper between the thumb and index finger. When the examiner pulls away the paper, the tip of the thumb flexes because of the absence of the adductor pollicis muscle (Froment's sign). If the MP joint of the thumb extends at the same time, this is known as Jeanne's sign. Wartenberg's sign for ulnar nerve compression is positive if the client is unable to adduct the small finger when the hand is placed palm down on the table with the fingers passively abducted.

The radial nerve may be tested by asking the client to extend the wrist and fingers. Median nerve function is tested by asking the client to oppose the thumb to the fingers and flex the fingers.[73]

Sensory mapping.

Detailed sensibility testing can begin with sensory mapping of the entire volar surface of the hand.[16] The hand must be supported by the examiner's hand, or it may be resting in a medium (e.g., therapy putty) to stabilize it during testing. The examiner draws a probe (usually the eraser end of a pencil) lightly over the skin from the area of normal sensibility to the area of abnormal sensibility. The client must immediately report the exact location where the sensation changes. Directionally this is done from proximal to distal and from radial and ulnar to medial. The areas are carefully marked and transferred to a permanent record. Mapping should be repeated at monthly intervals during nerve regeneration.[7a]

Sympathetic function.

Recovery of sympathetic response, such as sudomotor (sweating), vasomotor (temperature discrimination), pilomotor (gooseflesh), and trophic (skin texture, nail, and hair growth) responses, may occur early but does not correlate with functional recovery.[36] O'Riain observed that denervated skin does not wrinkle.[82] Therefore, nerve function may be tested by immersing the hand in water for 5 minutes and noting the presence or absence of skin wrinkling. This test may be especially helpful in diagnosing a nerve lesion in young children. The ability to sweat is also lost with a nerve lesion. A Ninhydrin test evaluates sweating of the finger.[79]

The wrinkle test and the Ninhydrin test are objective tests of sympathetic function. Recovery of sweating has not been shown to correlate with the recovery of sensation, but the absence of sweating correlates with the lack of discriminatory sensation. Other signs of sympathetic dysfunction are smooth, shiny skin; nail changes; and "pencil pointing," or tapering of the fingers.[43]

Nerve compression and nerve regeneration.

Sensibility testing is performed to assess the recovery of a nerve after laceration and repair; to detect a nerve compression syndrome and the return of nerve function after surgical decompression; and to determine the efficacy of a conservative intervention in reducing compression. Therefore, tests such as vibratory tests may be interpreted differently, depending on the mechanism of nerve dysfunction. In the next section, tests are described and differences drawn as appropriate to assist the therapist in selecting the correct assessment technique and in planning treatment based on the evaluative measures.

During the first 2 to 4 months after nerve suture, axons regenerate and travel through the hand at a rate of about 1 mm per day, or 1 inch (2.54 cm) per month. Tinel's sign may be used to follow this regeneration. As regeneration occurs, hypoesthesias develop. Although this hypersensitivity may be uncomfortable for the client, it is a positive sign of nerve growth. An intervention program for desensitization of hypersensitive areas can be initiated as soon as the skin has healed and can tolerate gentle rubbing and immersion in textures. (Desensitization is discussed further in the Intervention section.)

Vibration.

Dellon was an early advocate of the use of tuning forks with frequencies of 30 cycles per second (cps) and 256 cps to assess the return of vibratory sensation after nerve repair, as regeneration occurs, and as a guideline for initiating a sensory reeducation program.[35-37] However, many clinicians found that use of a tuning fork was not discrete enough to detect sensory abnormalities.

Lundborg et al. described the use of commercial vibrometers to detect abnormal sensation.[71] This method was less subjective and thought to be more reliable. In a study of induced median nerve compression, Gelberman et al. found that vibration and touch perception, as measured by Semmes-Weinstein monofilaments, are altered before two-point discrimination because they measure a single nerve fiber innervating a group of receptor cells.[51,52] Two-point discrimination is a test of innervation density that requires overlapping sensory units and cortical integration. Thus, two-point discrimination is altered after nerve laceration and repair but remains normal if the nerve is compressed, as long as links to the cortex exist. Bell-Krotoski has also found normal two-point values with decreased sensory function.[7]

Vibration and the Semmes-Weinstein test are more sensitive in picking up a gradual decrease in nerve function in the presence of nerve compression where the nerve circuitry is intact. They also correlate with decreases in the potential amplitude of sensory nerve action as measured by nerve conduction studies.[97] Therefore, Semmes-Weinstein and electrical testing are reliable and sensitive tests for early detection of carpal tunnel syndrome and other nerve compression syndromes. The Semmes-Weinstein test can be performed in the clinic; it causes no discomfort for the client, and it is an excellent screening tool when nerve compression is suspected.

Touch pressure.

Moving touch is tested using the eraser end of a pencil. The eraser is placed in an area of normal sensibility and, with application of light pressure, is moved to the distal fingertip. The client notes when the perception of the stimulus changes. Light and heavy stimuli may be applied and noted.[34] Constant touch is tested by pressing with the eraser, first in an area with normal sensibility and then placing the eraser distally by lifting up the pencil before placement. The client responds when the stimulus is altered; again, light and heavy stimuli may be applied.[34]

The Semmes-Weinstein monofilaments are the most accurate instruments for assessing cutaneous pressure thresholds.[7a] The original testing equipment consisted of 20 nylon monofilaments housed in plastic, handheld rods. Many therapists today use the smaller five-pack filaments. These five monofilaments correspond to the categories of light touch sensation (described later). The monofilaments increase in diameter, and when applied correctly, they exert a force ranging from 4.5 mg to 447 g. Markings on the probes range from 1.65 to 6.65 but do not correspond to the grams of force of each rod. Normal fingertip sensibility has been found to correspond to the 2.44 and 2.83 probes.

The monofilaments must be applied perpendicular to the skin and just until the monofilament bends. The skin should not blanch when the monofilament is applied. Probes 1.65 through 2.83 are bounced three times; probes 3.22 to 4.08 are applied three times with a bend in the filament; and probes 4.17 to 6.65 are applied once. The larger monofilaments do not bend; therefore, skin color must be observed to determine how firmly to apply the probe.

The examiner should begin with a probe in the normal range and progress through the rods in increasing diameters to find the client's threshold for touch throughout the volar surface.[7] A grid should be used to record the responses so that varying areas of touch perception can be demonstrated. Two correct responses from three applications are necessary to consider an area as having intact sensibility. Placing the monofilaments randomly, rather than concentrating on an area, is preferable because this allows the nerves a recovery time. When a filament is placed three times, it should be held for a second, rested for a second, and reapplied. Results can be graded from normal light touch (probes 2.83 and above) to loss of protective sensation (probes 4.56 and below). Diminished light touch and diminished protective sensation are in the range reflected by the central probes (probes 3.22 to 4.31).[7]

Two-point and moving two-point discrimination.

Discrimination, the second level of sensibility assessment, requires the client to distinguish between two direct stimuli. Static (or stationary) two-point discrimination measures the slowly adapting fibers. The two-point discrimination test, first described by Weber in 1853, was modified and popularized by Moberg,[79] who was interested in a tool that would assess the functional level of sensation. A variety of devices have been proposed for measuring two-point discrimination. A bent paper clip is inexpensive but often has burrs on the metal tip. Other devices include industrial calipers (Central Tool Company of Germany*; available from Anthony Products) and the Disk-Criminator (available from Smith & Nephew).[72]

A device with parallel prongs of variable distance and blunted ends should produce replicable results. Testing with such a device is performed as follows[70]:

1. The client's vision is occluded.

2. An area of normal sensation is tested as a reference, using blunt calipers or a bent paper clip.

3. The calipers are set 10 mm apart and are randomly applied, starting at the fingertip and moving proximally and longitudinally in line with the digital nerves, with one or two points touching. The caliper should not blanch the skin.

4. The distance is decreased until the client no longer feels two distinct points, and that distance is

measured.

Three to 4 seconds should be allowed between applications, and 4 correct responses out of 5 administrations are required. Because this test indicates sensory function, it is usually administered at the tips of the fingers. It may be used proximally to test nerve regeneration. Normal two-point discrimination at the fingertip is 6 mm or less.

Moving two-point discrimination measures the innervation density of the quickly adapting nerve fibers for touch. It is slightly more sensitive than stationary two-point discrimination. The test is performed as follows[36]:

1. The client's vision is occluded.

2. An area of normal sensation is tested as a reference, using blunt calipers or a bent paper clip.

3. The fingertip is supported by the examining table or the examiner's hand.

4. The caliper, separated 5 to 8 mm, is moved longitudinally from proximal to distal in a linear fashion along the surface of the fingertip. One and two points are randomly alternated. The client must correctly identify the stimulus in 7 of 8 responses before the examiner can proceed to a smaller value. The test is repeated down to a separation of 2 mm.

Two-point values increase with age in both genders; the smallest values occur between the ages of 10 and 30 years. Women tend to have smaller values than men, and no significant difference has been noted between dominant and nondominant hands.[70] (See Chapter 23 for further information on the evaluation of sensation.)

Modified Moberg pick-up test.

Recognition of common objects is the final level of sensory function. Moberg used the term tactile gnosis to describe the ability of the hand to perform complex functions by feel. Moberg described the pickup test in 1958,[79] and it was later modified by Dellon.[36] This test is used either for a median nerve injury or for an injury to a combination of median and ulnar nerves. The tests take twice as long to perform with the vision occluded as with the vision unimpaired. The procedure is as follows:

1. Nine or 10 small objects (e.g., coins or paper clips) are placed on a table, and the client is asked to place them, one at a time, in a small container as quickly as possible while looking at them. The client is timed.

2. The test is repeated for the opposite hand with vision.

3. The test is repeated for each hand with the vision occluded.

4. The client is asked to identify each object one at a time, with and then without vision.

It is important to observe any substitution patterns that may be used when the client cannot see the objects.

Edema assessment.

Hand volume is measured to assess for extracellular or intracellular edema. The volume measurement generally is used to determine the effect of intervention and activities. By measuring the volume at different times of the day, the therapist can measure the effects of rest versus activity, in addition to the effects of orthotics or intervention designed to reduce edema.

A commercial volumeter[31] may be used to assess hand edema. The volumeter has been shown to be accurate to 10 mL[102] when used in the prescribed manner. Variables that have been shown to reduce the accuracy of the volumeter include use of a faucet or hose that introduces air into the tank during filling; movement of the arm within the tank; inconsistent pressure on the stop rod; and use of a volumeter in a variety of places. The same level surface should always be used.[102] The evaluation is performed as follows (Fig. 39.1):

1. A plastic volumeter is filled and allowed to empty into a large beaker until the water reaches spout level. The beaker then is emptied and dried thoroughly.

2. The client is instructed to immerse the hand in the plastic volumeter, being careful to keep the hand in the midposition.

3. The hand is lowered until it rests gently on the dowel rod between the middle and ring fingers. It is important that the hand not press onto the rod.

4. The hand remains still until no more water drips into the beaker.

5. The water is poured into a graduated cylinder. The cylinder is placed on a level surface, and a reading is made.

FIG 39.1 A volumeter is used to measure the volume of both hands for comparison. Increased volume indicates the presence of edema.

A method of assessing edema of an individual finger or joint is circumferential measurement using either a circumference tape (DeRoyal LMB; DeRoyal Industries) or a jeweler's ring-size standards. For combined wrist and hand edema, a tape measure may be wrapped in a figure-eight pattern to measure hand size.[84] Measurements should be made before and after intervention and especially after the application of thermal modalities or orthoses. Although clients often have subjective complaints about swelling, objective data on circumference or volume will help the therapist assess the response of the tissues to intervention and activity. Edema control techniques are discussed later in this chapter.

Grip and Pinch Strength

UE strength is usually assessed after the healing phase of trauma. Strength testing is not indicated after recent trauma or surgery. Testing should not be performed until the client has been cleared for full resistive activities, usually 8 to 12 weeks after injury.

A standard adjustable-handle dynamometer is recommended for assessing grip strength (Fig. 39.2). The client should be seated with the shoulder adducted and neutrally rotated, the elbow flexed at 90 degrees,[50,92] the forearm in the neutral position, and the wrist between 0 and 30 degrees of extension and 0 and 15 degrees of ulnar deviation. Three trials are performed on each hand, with the dynamometer handle set at the second position.[49,77] The examiner should hold the dynamometer lightly to prevent accidental dropping of the instrument. A mean of the three trials should be reported. The uninjured hand is used for comparison. Normative data may be used to compare strength scores.[9,63,76,77] Variables such as age will affect the strength measurements.

FIG 39.2 The Jamar dynamometer is used to evaluate grip strength in both hands.

Pinch strength should also be tested, using a pinch gauge. The pinch gauge has been found to be the most accurate.[77,92] Two-point pinch (thumb tip to index fingertip), lateral or key pinch (thumb pulp to lateral aspect of the middle phalanx of the index finger), and three-point pinch (thumb tip to tips of index and middle fingers) should be evaluated. As with the grip dynamometer, three successive trials should be performed and the results compared bilaterally (Fig. 39.3).[92]

FIG 39.3 A pinch gauge is used to evaluate pinch strength in a variety of prehension patterns of pinch.

Manual muscle testing also is used to test UE strength. Accurate assessment is especially important when the client is being prepared for tendon transfers or other reconstructive surgery.

The student who wishes to study kinesiology of the UE is referred especially to the work of Brand and Hollister.[12] In addition, muscle testing is addressed in Chapter 22.

Maximal voluntary effort during grip, pinch, or muscle testing will be affected by pain in the hand or extremity, and the therapist should note whether the client's ability to exert full force is limited by subjective complaints. Localization of the pain symptoms and consistency in noting pain will help the therapist evaluate the role that pain is playing in the recovery from injury. Pain problems are discussed in more detail later in this chapter.

Functional Assessment

Assessment of hand function or performance is important because the physical assessment does not measure the client's ingenuity and ability to compensate for loss of strength, ROM, sensation or abnormalities.

The physical assessment should precede the functional assessment because awareness of physical dysfunction can result in a critical analysis of functional impairment and an understanding of the reasons the client functions as he or she does.

The occupational therapist should observe the effect of the hand dysfunction on the use of the hand during ADLs. In addition some type of a standardized performance test (e.g., the Jebsen Hand Function Test[49] or the Quantitative Test of Upper Extremity Function[22]) should be administered. The Jebsen test was developed to provide objective measurements of standardized tasks with norms for client comparison. It is a short test that is assembled by the administrator, and it is easy to administer and inexpensive. The test consists of seven subtests, which test writing a short sentence, turning over 3 × 5-inch cards, picking up small objects and placing them in a container, stacking checkers, simulated eating, moving empty large cans, and moving weighted large cans. Norms are provided for dominant and nondominant hands for each subtest and further categorized by gender and age. Instructions for assembling the test and specific instructions for administering it are provided by the authors. This has been found to be a good test for overall hand function.

The Quantitative Test of Upper Extremity Function, described by Carroll, was designed to measure the ability to perform general arm and hand activities used in daily living.[22] It is based on the assumption that complex UE movements used to perform ordinary ADLs can be reduced to specific patterns of grasp and prehension of the hand, supination and pronation of the forearm, flexion and extension of the elbow, and elevation of the arm.

The test consists of six parts: grasping and lifting four blocks of graduated sizes to assess grasp; grasping and lifting two pipes of graduated sizes to test cylindrical grip; grasping and placing a ball to test spherical grasp; picking up and placing four marbles of graduated sizes to test fingertip prehension or pinch; putting a small washer over a nail and putting an iron on a shelf to test placing; and pouring water from pitcher to glass and glass to glass. In addition, to assess pronation, supination, and elevation of the arm, the therapist instructs the client to place his or her hand on top of the head, behind the head, and to the mouth, and to write his or her name. The test uses simple, inexpensive, and easily acquired materials. Details of the materials and their arrangement, test procedures, and scoring can be found in Carroll's work.[22]

Other tests useful in the assessment of hand dexterity are the Crawford Small Parts Dexterity Test, Bennett Hand Tool Dexterity Test,[8] the Purdue Pegboard Test, and the Minnesota Manual Dexterity Test.[49] A number of standardized tests have been developed (Valpar Assessment Systems; Valpar International) that measure an individual's ability to perform work-related tasks. They provide information about the test taker's results as compared with industry performance standards. All these tests include comparison with normal individuals working in a variety of industrial settings. This information can be used to help predict the likelihood of a successful return to a specific job. The tests are especially useful in a work capacity evaluation. They may be purchased, and they include instructions for administering the test and the standardized norms. Further discussion of vocational evaluation can be found in Chapter 14.

Intervention

Fractures

In treating a hand or wrist fracture, the surgeon attempts to achieve good anatomic position through either a closed (nonoperative) or an open (operative) reduction. Internal fixation with Kirschner wires, metallic plates, or screws may be used to maintain the desired position. External fixation may be used in addition to internal fixation. The hand usually is immobilized in wrist extension and MP joint flexion, with extension of the distal joints whenever the injury allows this position. Trauma to bone may also involve trauma to tendons and nerves in the adjacent area. Intervention must be geared toward the recovery of all injured structures, and this fact may influence treatment of the fracture.

OT may be initiated during the period of immobilization, which usually lasts 3 to 5 weeks. The uninvolved fingers of the hand must be kept mobile through the use of active motion. Edema should be carefully monitored, and elevation is required whenever edema is present.

As soon as sufficient bone stability has been achieved, the surgeon allows mobilization of the injured part. The surgeon should provide guidelines for the amount of resistance or force that may be applied to the fracture site. Activities that correct poor motor patterns and encourage use of the injured hand should be started as soon as the hand is pain free. Early motion will prevent the adherence of tendons and reduce edema through stimulation of the lymphatic and blood vessels.

As soon as the brace or cast has been removed, the client's hand must be evaluated. If edema is still present, edema control techniques (described later in the chapter) can be initiated. A baseline ROM should be established, and the application of an appropriate orthosis may begin. An orthosis may be used to correct abnormal joint changes that have resulted from immobilization, or it may be used to protect a finger from additional trauma to the fracture site (e.g., a Velcro "buddy" orthosis [Fig. 39.4]). A dorsal block orthosis that limits full extension of the finger may be used after a fracture or dislocation of the PIP joint. A dynamic orthosis may be used to achieve full ROM or to prevent the development of further abnormal joint changes at 6 to 8 weeks after fracture.

FIG 39.4 A Velcro "buddy" orthosis may be used to protect the finger after a fracture or to encourage movement of a stiff finger. (Courtesy of North Coast Medical & Rehabilitation Products. http://www.ncmedical.com.)

Intraarticular fractures may result in injury to the cartilage of the joint, causing additional pain and stiffness. An x-ray examination will indicate whether the joint surface has been damaged, which might limit treatment of the joint. Joint pain and stiffness after fracture without joint damage should be alleviated by a combination of thermal modalities, restoration of joint play, or joint mobilization and a corrective and dynamic orthosis, followed by active use. Resistive exercise can be started when bony healing has been achieved.

Wrist fractures are common and may present special problems for the surgeon and therapist. Colles fractures (dorsal displacement and angulation of the distal radius) are the most common injury to the wrist from a fall on an outstretched hand (FOOSH).[11] This may result in limitations in wrist flexion and extension, as well as pronation and supination resulting from the involvement of the distal radioulnar joint.

Conservative management (i.e., closed reduction and cast immobilization) may be used if stability of the fracture can be achieved and maintained. A long arm cast extending past the elbow is applied for 2 to 3 weeks to prevent mobility of forearm rotation and wrist. A change to a shorter cast, with the elbow free, is then made, and the cast is worn for an additional 4 to 6 weeks, depending on fracture healing as shown on x-ray films.[59] This approach often is considered in the management of wrist fractures in young children and in situations when surgery is not an option because of a client's medical status.

If a fracture is unstable or not reducible, surgical strategies for repair may include internal or external fixation. With recent improvements in volar plating systems, open reduction and internal fixation (ORIF) of distal radial fractures is more commonly used to help restore the bone alignment and joint anatomy, and to allow for earlier motion of the wrist once that has been cleared with the surgeon.[90] A wrist orthosis is applied upon referral from the surgeon, and active range of motion (AROM) is initiated for forearm rotation to the wrist in all planes and to the unaffected fingers to prevent joint stiffness. Wear of the orthosis is decreased gradually at 3 to 6 weeks, depending on the bone healing seen on x-ray films and the client's progress with motion, strength, and return to ADLs.[24]

Less commonly used, external fixation may be applied with more comminuted fractures to assist with attaining the proper alignment and length of the distal radius. The external fixation framework (the fixator) is anchored by surgical pins in holes drilled into both the distal radius proximally and the index metacarpal distally. Traction then is applied across the wrist to correct length and angulation and/or to reduce any other bony fragments.[90] The therapist should instruct the client in proper care of the pin sites while the fixator is in place. In addition the client should be instructed to perform AROM exercises of the unaffected proximal elbow, distal thumb, and fingers to prevent joint stiffness and contractures. After the fixator has been removed, an orthosis may be fabricated to further support the wrist; the client is gradually weaned from the orthosis as he or she improves in ROM and strength and returns safely to ADLs.[24]

The scaphoid is the second most commonly injured bone in the wrist; it often is fractured when the hand is dorsiflexed at the time of injury.[11] Fractures of the proximal pole of the scaphoid may result in nonunion because of poor blood supply to this area. Scaphoid fractures require a prolonged period of immobilization, sometimes up to several months in a cast, with resulting stiffness and pain. Care should be taken to mobilize uninvolved joints early.

Trauma to the lunate bone of the wrist may result in avascular necrosis of the lunate, or Kienböck's disease, which may result from a one-time accident or repetitive trauma. Lunate fractures are usually immobilized for 6 weeks. Kienböck's disease may be treated with a bone graft, removal of the proximal carpal row, or partial wrist fusion.

Stiffness and pain are common complications of fractures. However, control of edema, coupled with early motion and good client instruction and support, will minimize these complications.

Nerve Injuries

Nerve injury may be classified into three categories:

- *Neurapraxia* is contusion of the nerve without wallerian degeneration. The nerve recovers function without intervention within a few days or weeks.
- *Axonotmesis* is an injury in which nerve fibers distal to the site of injury degenerate, but the internal organization of the nerve remains intact. No surgical intervention is necessary, and recovery usually occurs within 6 months. The length of time may vary, depending on the level of injury.
- *Neurotmesis* is a complete laceration of both nerve and fibrous tissues. Surgical intervention is required. Microsurgical repair of the fascicles is common. Nerve grafting may be necessary when a gap exists between nerve endings.

Peripheral nerve injuries may occur as a result of disruption of the nerve by a fractured bone, laceration, or crush injury. Symptoms of nerve injuries include weakness or paralysis of muscles that are innervated by motor branches of the injured nerve and also sensory loss to areas that are innervated by sensory branches of the injured nerve. Before evaluating the client for nerve loss, the therapist must be familiar with the muscles and areas that are innervated by the three major forearm nerves. A summary of UE peripheral neuropathic conditions can be found in Table 39.4.

TABLE 39.4

Nerve Injuries of the Upper Extremity

Nerve	Location	Affected	Test
Radial nerve (posterior cord, fibers from C5, C6, C7, C8)	Upper arm	Triceps and all distal motors	• MMT
		Sensory to SRN	• Sensory test
Radial nerve	Above elbow	Brachioradialis and all distal motors	• MMT
		Sensory to SRN	• Sensory test
Radial nerve	At elbow	Supinator, ECRL, ECRB, and all distal motors	• MMT
		Sensory to SRN	• Sensory test
Posterior interosseous nerve	Forearm	ECU, EDC, EDM, APL, EPL, EPB, EIP	• Wrist extension; if present, indicates PIN rather than high radial nerve
		No sensory	
Radial nerve at ECRB, radial artery, arcade of Frohse, origin of supinator	Radial tunnel syndrome	Weakness of muscles innervated by PIN	• Palpate for pain over extensor mass • Pain with wrist flexion and pronation
		No sensory loss	• Pain with wrist extension and supination • Pain with resisted middle finger extension
Median nerve (lateral from C5, C6, C7, medial cord from C8, T1)	High lesions (elbow and above)	Paralysis/weakness of FCR, PL, all FDS, FDP I and II	• MMT
		FPL, PT, PQ, OP, APB, FPB (radial head), lumbricals I and II	• Sensory test
		Sensory cutaneous branch of median nerve	
Median nerve	Low (at wrist)	Weakness of thenars only	• Inability to flex thumb tip and index fingertip to palm • Inability to oppose thumb • Poor dexterity
Median nerve under fibrous band in PT, beneath heads of pronator, arch of FDS, origin of FCR	Pronator syndrome	Weakness in thenars but not muscles innervated by AIN	• Provocative tests to isolate compression site
		Sensory in median nerve distribution in hand	
Median nerve under origin of PT, FDS to middle	Anterior interosseous nerve syndrome	Pure motor, no sensory	• Inability to flex IP joint of thumb and DIP of index
		Forearm pain precedes paralysis	• Increased pain with resisted pronation
		Weakness of FPL, FDP I and II, PQ	• Pain with forearm pressure
Median nerve at wrist	Carpal tunnel syndrome	Weakness of medial intrinsics	• Provocative tests
		Sensory	• Tinel's sign • Sensory test
Ulnar nerve at elbow (branch of medial cord from C7, C8, T1)	Cubital tunnel syndrome	Weakness/paralysis of FCU, FDP III and IV, ulnar intrinsics	• Pain with elbow flexion and extension
		Numbness in palmar cutaneous and dorsal cutaneous distribution	
		Loss of grip and pinch strength	
Ulnar nerve at wrist	Compression at canal of Guyon	Weakness and pain in ulnar intrinsics	• Reproduced by pressure at site

AIN, Anterior interosseus nerve; *APB*, abductor pollicis brevis; *APL*, abductor pollicis longus; *DIP*, distal interphalangeal joint; *ECRB*, extensor carpi radialis brevis; *ECRL*, extensor carpi radialis longus; *ECU*, extensor carpi ulnaris; *ED*, extensor digitorum; *EDC*, extensor digitorum communis; *EDM*, extensor digitorum minimus; *EIP*, extensor indicis proprius; *EPB*, extensor pollicis brevis; *EPL*, extensor pollicis longus; *FCR*, flexor carpi radialis; *FCU*, flexor carpi ulnaris; *FDP*, flexor digitorum profundus; *FDS*, flexor digitorum superficialis; *FPB*, flexor pollicis brevis; *FPL*, flexor pollicis longus; *IP*, interphalangeal; *MMT*, manual muscle test; *OP*, opponens pollicis; *PIN*, posterior interosseous nerve; *PL*, palmaris longus; *PQ*, pronator quadratus; *PT*, pronator teres; *SRN*, superficial radial nerve.

Radial Nerve

The radial nerve innervates the extensor-supinator group of muscles of the forearm, including the brachioradialis, extensor carpi radialis longus, extensor carpi radialis brevis, supinator, extensor digitorum communis, extensor carpi ulnaris, extensor digiti minimi, abductor pollicis longus, extensor pollicis brevis, extensor pollicis longus, and extensor indicis proprius. The sensory distribution of the radial nerve is a strip of the posterior upper arm and the forearm, the dorsum of the thumb, the index and middle fingers, and the radial half of the ring finger to the PIP joints. Sensory loss of the radial nerve does not usually result in dysfunction.

Clinical signs of a high-level radial nerve injury (above the supinator) are pronation of the forearm, wrist flexion, and the thumb held in palmar abduction as a result of the unopposed action of the flexor pollicis brevis and the abductor pollicis brevis. Injury to the posterior interosseous nerve spares the extensor carpi radialis longus and brevis. Posterior interosseous nerve syndrome is marked by normal sensation and wrist extension with loss of finger and thumb extension. Clinical signs of low-level radial nerve injury include incomplete extension of the MP joints of the fingers and thumb. The interossei extend the interphalangeal (IP) joints of the fingers, but the MP joints rest in about 30 degrees of flexion.

A dynamic or static orthosis, applied to the dorsum of the hand, that provides wrist extension, MP extension, and thumb extension should be provided to protect the extensor tendons from overstretching during the healing phase and to position the hand for functional use (Fig. 39.5). A dynamic orthosis is commonly provided.

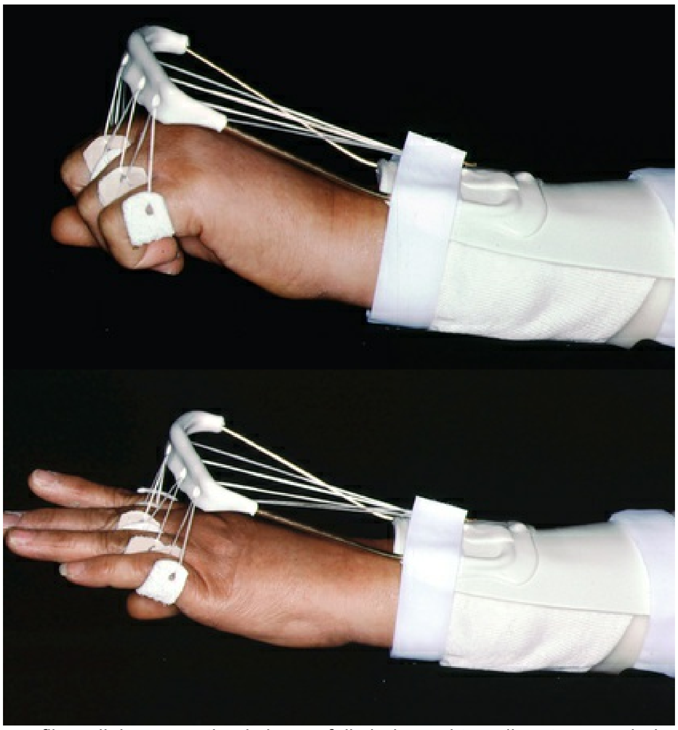

FIG 39.5 A low-profile radial nerve orthosis is carefully balanced to pull metacarpophalangeal (MP) joints into extension when the wrist is flexed, and to allow the MP joints to fall into slight flexion when the wrist is extended; it thus preserves the normal balance between two joints and also joint contracture. (Courtesy of Judy C. Colditz, HandLab.)

Median Nerve

The median nerve innervates the flexors of the forearm and hand. It is often called the "eyes" of the hands because of its importance in sensory innervation of the volar surface of the thumb, index, and middle fingers. Median nerve loss may result from lacerations and also from compression syndromes of the wrist (e.g., carpal tunnel syndrome).

Motor distribution of the median nerve is to the pronator teres, flexor carpi radialis, flexor pollicis longus, flexor digitorum profundus of the index and middle fingers, pronator quadratus, flexor digitorum superficialis, palmaris longus, abductor pollicis brevis, opponens pollicis, superficial head of the flexor pollicis brevis, and first and second lumbricals.

Sensory distribution of the median nerve is to the volar surface of the thumb, index, and middle fingers; the radial half of the ring finger and dorsal surface of the index and middle fingers; and the radial half of the ring finger distal to the PIP joints.

Clinical signs of a high-level median nerve injury are ulnar flexion of the wrist caused by loss of the flexor carpi radialis, loss of palmar abduction, and opposition of the thumb. Active pronation is absent, but the client may appear to pronate with the assistance of gravity. In a wrist-level median nerve injury, the thenar eminence appears flat and a loss of thumb flexion, palmar abduction, and opposition is noted.

The sensory loss associated with median nerve injury is particularly disabling because there is no sensation to the volar aspects of the thumb and index and middle fingers and the radial side of the ring finger. When blindfolded the client substitutes pinch to the ring and small fingers to compensate for this loss. An injury in the forearm that involves the anterior interosseous nerve does not result in sensory loss. Motor loss includes paralysis of the flexor pollicis longus, the flexor digitorum profundus of the index and middle fingers, and the pronator quadratus. The pronator teres is not affected. Pinch is affected.

Orthoses that position the thumb in palmar abduction and slight opposition increase functional use of the hand (Fig. 39.6). If clawing is noted in the index and middle fingers, an orthosis should be fabricated to prevent hyperextension of the MP joints. Clients report that they avoid use of the hand with a median nerve injury because of lack of sensation rather than muscle paralysis. Nevertheless, the weakened or paralyzed muscles should be protected.

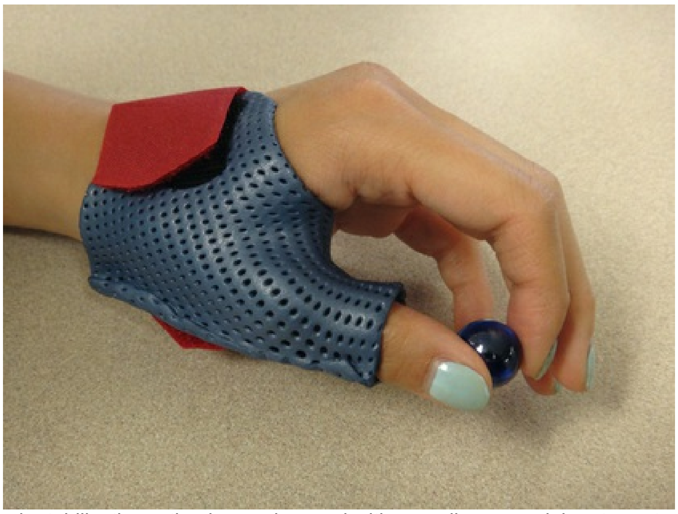

FIG 39.6 A thumb stabilization orthosis may be used with a median nerve injury to protect the thumb and to improve functioning by placing the thumb in a position of pinch. Normal pinch cannot be achieved with a median nerve injury because of paralysis of the thumb musculature.

Ulnar Nerve

The ulnar nerve in the forearm innervates only the flexor carpi ulnaris and the medial half of the flexor digitorum profundus. It travels down the volar forearm through the canal of Guyon and innervates the intrinsic muscles of the hand, including the palmaris brevis, abductor digiti minimi, flexor digiti minimi, opponens digiti minimi, dorsal and volar interossei, third and fourth lumbricals, and medial head of the flexor pollicis brevis. The sensory distribution of the ulnar nerve is the dorsal and volar surfaces of the small finger ray and the ulnar half of the dorsal and volar surface of the ring finger ray.

A high-level ulnar nerve injury results in hyperextension of the MP joints of the ring and small fingers (also called clawing) as a response to overaction of the extensor digitorum communis that is not held in check by the third and fourth lumbricals. The IP joints of the ring and small fingers do not demonstrate a great flexion deformity because of the paralysis of the flexor digitorum profundus. The hypothenar muscles and interossei are absent. The wrist assumes a position of radial extension caused by the loss of the flexor carpi ulnaris. In a low-level ulnar nerve injury, the ring and small fingers claw at the MP joints and the IP joints exhibit a greater tendency toward flexion because the flexor digitorum profundus is present. Wrist extension is normal.

Clinical signs of a high-level ulnar nerve injury may include claw hand deformity (as described previously) with a loss of the hypothenar and interosseous muscles. In a low-level ulnar nerve injury, the flexor digitorum profundus and flexor carpi ulnaris are present and unopposed by the intrinsic muscles. Froment's sign is positive. Longstanding compression of the ulnar nerve in the canal of Guyon results in flattening of the hypothenar area and conspicuous atrophy of the first dorsal interosseous muscle.

With a low-level ulnar nerve injury a small orthosis may be provided to prevent hyperextension of the small and ring fingers without limiting full flexion at the MP joints. Stabilization of the MP joints will allow the extensor digitorum communis to extend the IP joints fully (Fig. 39.7).

FIG 39.7 A static ulnar nerve orthosis blocks the hyperextension of metacarpophalangeal (MP) joints that occurs with paralysis of the ulnar intrinsic muscles; it also allows MP flexion, which maintains a normal range of motion for the MP joints.

Sensory loss of the ulnar nerve results in frequent injury, especially burns, to the ulnar side of the hand. Clients must be instructed in visual protection of the anesthetic area.

Postoperative Management of Nerve Repair

After nerve repair the hand is placed in a position that minimizes tension on the nerve. For example, after repair of the median nerve, the wrist is immobilized in a flexed position. Immobilization usually lasts 2 to 3 weeks, after which protective stretching of the joints may begin. The therapist must exercise great care not to put excessive traction on the newly repaired nerve. A repaired digital nerve will also be protected with flexion of the PIP joint.

Correction of a contracture may take 4 to 6 weeks. Active exercise is the preferred method of gaining full extension, although a light dynamic orthosis may be applied with the surgeon's supervision. The use of **orthotics** to assist or substitute for weakened musculature may be necessary for an extended period during nerve regeneration. Orthoses should be removed as soon as possible to allow active exercise of the weakened muscles. However, it is important to instruct the client in correct patterns of motion so that substitution is minimized.

Intervention is initially directed toward the prevention of deformity and the correction of poor positioning during the acute and regenerative stages. Clients must be instructed in visual protection of the anesthetic area. ADLs should be assessed, and new methods or devices may be needed for independence. Use of the hand in the client's work should be assessed, and the client should be returned to employment with any necessary job modifications or adaptations of equipment.

Careful muscle, sensory, and functional testing should be done frequently. As the nerve regenerates, orthoses may be changed or eliminated. Exercises and activities should be revised to reflect the client's new gains, and adapted equipment should be discarded as soon as possible.

As motor function begins to return to the paralyzed muscles, a careful program of specific exercises should be devised to facilitate the return. Proprioceptive neuromuscular facilitation (PNF) techniques (e.g., hold-relax, contract-relax, quick stretch, and icing) may assist a muscle with fair strength and increase ROM. Neuromuscular electrical stimulation (NMES) can also provide an external stimulus to help strengthen the newly innervated muscle. When the muscle has reached a good rating, functional activities should be used to complete the return to normal strength.

Sensory reeducation.

The assessment of sensibility is described in some detail earlier in this chapter. This information should be used to prepare a program of sensory reeducation after nerve repair.

When a nerve has been repaired, regeneration is not perfect and results in fewer and smaller nerve fibers and receptors distal to the repair. The goal of sensory reeducation is to maximize the functional level of sensation, or tactile gnosis.

Dellon et al. reported a highly structured sensory reeducation program in 1974.[34] They divided their program into early- and late-phase training, based on vibratory sensation for early phase retraining and perception of moving and constant touch sensation for late-phase reeducation. The researchers also used localization of stimuli and recognition of objects. Higher cortical integration was achieved by focusing attention on the stimuli through visual clues and by using memory when vision was occluded. The clients were taught to compensate for sensory deficits by improving specific skills and generalizing them to other sensory stimuli. Daily repetition appears to be a necessary component of reeducation.

Callahan outlined a program of protective sensory reeducation and discriminative sensory reeducation for clients in whom protective sensation is present and touch sensation has returned to the fingertips.[16a] Waylett-Rendall described a sensory reeducation program using crafts and functional activities, in addition to desensitization techniques. All these programs emphasize a variety of stimuli used in a repetitive manner to bombard the sensory receptors. A sequence of eyes-closed, eyes-open, eyes-closed is used to provide feedback during the training process. Sessions are limited in length to prevent fatigue and frustration. To prevent further trauma, objects must not be potentially harmful to the insensate areas. A home program should be provided to reinforce learning that occurs in the clinical setting.

Researchers have found that sensory reeducation can result in improved functional sensibility in motivated clients.[36,43] Sensation after reeducation must be measured objectively and the findings compared accurately with the initial testing results to assess the success of the program.

Graded Motor Imagery, as described by Moseley and Butler,[80] consists of three sequential exercise phases that are used to retrain the brain for clients who have pain, difficulty moving or initiating movement, or a fear of moving. The three stages involve left/right discrimination (also called laterality recognition), motor imagery, and mirror therapy.[80] The clinical approach of Graded Motor Imagery reduces threatening input, reduces or decreases the pain neuromatrix, targets activation of specific components of the neuromatrix without activating the unwanted parts, and upgrades physical and functional tolerance by graded exposure to threatening inputs across sensory and nonsensory domains.[80]

The exercises in stage I, Left/Right discrimination, consist of identifying right and left positions by showing the individual pictures of hands in various positions, either with flashcards or photographs. "Research has shown that people in pain often lose the ability to identify left or right images of their painful body parts. This ability appears to be important for normal recovery from pain."[81] Stage II, Explicit Motor Imagery, involves thinking about movement without actually moving. It is thought that these imagined movements start firing the "mirror neurons" in the brain, which can be affected by pain. Stage III, Mirror Therapy, involves looking into a mirror and viewing the reflection of the uninvolved extremity in the mirror, which gives the appearance of being the involved hand[86] and creates the illusion that the injured extremity is moving without pain. Mirror therapy is thought to work by providing false, but congruent, visual feedback for the unaffected limb, restoring the normal pain-free relationship between sensory feedback and motor intention.[94] The three treatment techniques are delivered sequentially, starting with activation of the cortical areas involved in thinking about movement and progressing to movement.

Tendon transfers.

If a motor nerve has not reinnervated its muscle after a minimum period of 1 year after nerve repair, the surgeon may consider tendon transfers to restore a needed motion. The rules of tendon transfer are to evaluate what is absent, what is needed for function, and what is available to be transferred.[87]

Some muscles, such as the extensor carpi radialis longus and the flexor digitorum sublimis (FDS) to the ring finger, are commonly used for transfers because their motions are easily substituted by the extensor carpi radialis brevis (ECRB) and flexor digitorum profundus (FDP), respectively, to the ring finger. An example in a high radial nerve injury, multiple tendon transfers may be needed to substitute for lost motor function. As median and ulnar nerve innervated-muscles are intact, common transfers may include pronator teres (PT) for wrist extension (ECRB), palmaris longus (PL) to EPL for thumb extension and flexor carpi radialis (FCR) to EDC for finger extension.[42]

Choices for transfers are variable, and a surgeon may request assistance from the therapist in evaluating motor status to determine the best motor transfer. Therapy before tendon transfer is essential if the motor to be used is not of normal strength. A muscle loses a grade of strength when transferred; therefore, a strengthening program of progressive resistive exercises, NMES, and isolated motion will help ensure the success of the transfer. All joints must have full passive ROM before tendon transfer can be attempted.

After transfer an initial period of immobilization of 3 to 5 weeks is required to protect the surgical repairs. This may be achieved with casting (for those who are not reliable in protecting these repairs) or with fabrication of a thermoplastic orthosis. Once cleared with the surgeon, the client begins activation of the tendon transfers through instruction to perceive the correct muscle during active use. Use of surface electromyography (EMG), biofeedback, muscle reeducation, and supervised activity (to note any substitution patterns during active use) can help the client use the transfer correctly. Therapy must be initiated before the client has time to develop incorrect use patterns. NMES may be used to isolate the muscle and strengthen it postoperatively.

Tendon Injuries

Flexor Tendons

Tendon injuries may be isolated or may occur in conjunction with other injuries, especially fractures or crushes. Flexor tendons injured in the area between the distal palmar crease and the insertion of the flexor digitorum superficialis are considered the most difficult to treat because in this area the tendons lie in their sheaths beneath the fibrous pulley system, and any scarring causes adhesions. This area is often referred to as zone 2, or "no-man's-land."[14]

Primary repair of the flexor tendons in zone 2 is most frequently performed after a clean laceration. Improvements in surgical techniques have been accompanied by advances in the postoperative management of tendon repairs. Choices for treatment will vary, based on the strength of the surgical repair, quality of the tendon, tension of the repair, or whether the tendon sheath or pulleys also were restored. Working closely with the surgeon is vital to understanding the delicacy of these repairs.

Other factors to consider are the client's age, cognition level (i.e., ability to follow instructions), financial or family supports, motivation, and compliance with the therapy program.

With the ongoing research and improvements in flexor tendon surgeries,[96] postoperative management continues to evolve[85]; the common goals of all approaches are to protect the repaired structures, restore strength, promote gliding of the tendons, and minimize the formation of scar adhesions.

Immobilization.

Although early mobilization is preferable, immobilization after tendon repairs may be necessary if the conditions and circumstances are not optimal to allow safe, early controlled movement. Young children, noncompliant clients, and those with cognitive dysfunction may require cast immobilization or a thermoplastic orthosis initially for 3 to 4 weeks. The wrist is positioned at 10 to 30 degrees of flexion, the MP joints at 40 to 60 degrees of flexion, and the PIP/DIP joints in extension. No exercises for the fingers are done by the client alone. Passive range of motion (PROM) and protected active extension may be done in therapy. AROM and tendon gliding exercises may begin after the immobilization period.[25]

Good results have not been consistently achieved with immobilization, and this technique may increase the risk of tendon rupture after repair because a tendon gains tensile strength when submitted to gentle tension at the repair site.[95]

Early passive mobilization.

Early passive motion may be considered when the conditions of a tendon repair are not optimal. For example, an injury may involve other structures that require additional surgical repairs, as can happen with fractures and soft tissue injuries. This may prolong inflammation and edema during the healing phase. Other factors may include a delay in repair, a frayed repair or one that is under tension, or a client who is unable to begin treatment early, resulting in a treatment delay of longer than 1 week. The tensile strength of the tendon is diminished for 5 to 21 days during the fibroblastic collagen-producing phase and may be at risk with tension or rupture from early motion.

Duran et al. suggested the use of controlled passive motion to achieve optimal results after a primary repair, allowing 3 to 5 mm of tendon excursion.[44] They found this amount sufficient to prevent adherence of the repaired tendons. On a client's first visit for therapy, a dorsal blocking orthosis is made with the wrist positioned at 20 degrees of flexion, the MP joint in relaxed flexion, and the PIP and DIP joints in extension.

On the third postoperative day, the client begins a twice-daily exercise regimen of passive flexion and extension of 6 to 8 motions for each tendon. The wrist is kept flexed and the MPs in 70 degrees of flexion during passive exercise. Between exercise periods the hand is wrapped in stockinette. At 4.5 weeks the protective orthosis is removed and rubber band traction is attached to a wristband. Active extension and passive flexion are performed for an additional week and gradually increased over the next several weeks.[44]

In a modified Duran approach, the position of the dorsal blocking orthosis changes to wrist extension between 0 and 20 degrees of flexion, 40 to 50 degrees of MP joint flexion, and the IPs in extension (Fig. 39.8). Additional exercises of passive flexion and active extension into the dorsal blocking orthosis are performed. A strap is applied to keep the fingers in the orthosis at all times except during exercises, and the rubber band traction wristband is eliminated. Another approach, less often used, is the Kleinert technique, which uses dynamic traction after flexor tendon repairs in zone 2.[65a,69] Rubber band traction is applied, bringing the fingers into flexion passively and then allowing the client to bring the IP joints actively into full extension within a dorsal blocking orthosis. The client wears the orthosis 24 hours a day for 3 weeks and performs these exercises hourly. This movement of the tendon through the tendon sheath and pulley system helps minimize scar adhesions while enhancing tendon nutrition and blood flow.

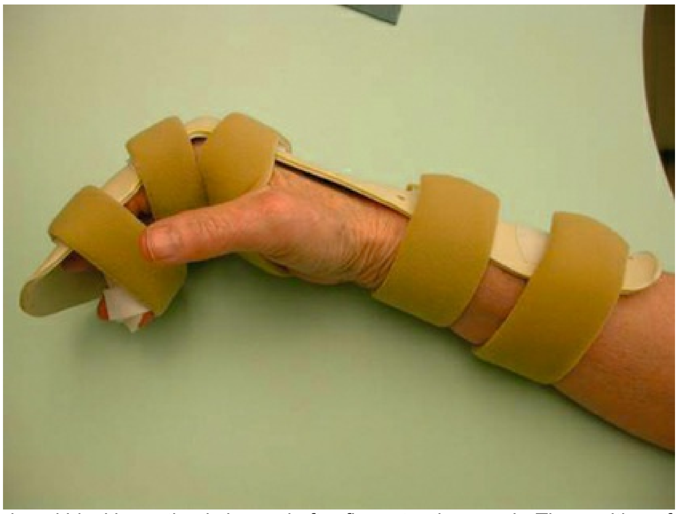

FIG 39.8 A dorsal blocking orthosis is used after flexor tendon repair. The position of the wrist and fingers in the orthosis is determined by the postoperative approach chosen by the surgeon and therapist.

The dorsal blocking orthosis is removed at 3 weeks; the rubber band is attached to a wristband, and this is worn for several more weeks, depending on the return of finger motion. The primary disadvantage of this technique is that contractures of the PIP joints frequently occur as a result of excessive tension on the rubber band traction or incomplete IP extension in the orthosis.

Early active mobilization.

As methods of tendon suturing and the suture materials themselves have evolved, many clinicians have begun to initiate active movement of the repaired tendon within days of surgery. These techniques should be used only when an experienced surgeon and therapist work closely together. The condition of the tendon and the repair technique must be communicated to the therapist, and the client must be closely monitored. With stronger and more sophisticated repairs, the rate of rupture decreases and improved results are increased after tendon injury.

Several early active motion protocols have been well documented, but all the protocols share important common factors. First, the tendon repair must be strong enough to withstand the forces of active mobilization. A strong core suture repair should be performed, with a minimum of four strands crossing the repair[96] and addition of a peripheral suture.[39,93] Second, the timing and the initiation of therapy must be considered. Some have suggested that the therapist start early active motion between 2 and 4 days after repair, to allow inflammation to subside, and that the therapist also reduce the amount of force on the tendon during active flexion. Third, the client must be able to comprehend the exercise program and must be compliant with it for the tendon rehabilitation to be successful; this also prevents rupture of the tendon caused by overstressing of the repair site.

An early passive place and active hold approach using two orthoses has been described by Cannon.[20] A dorsal-based blocking orthosis is made and worn at all times except during exercises. An exercise orthosis is fabricated with a hinged wrist and the MP joints blocked at 50 degrees. Exercises in this orthosis allow for full flexion of the wrist with simultaneous extension of the IP joints, followed by protected wrist extension limited by a dorsal block to 30 degrees (a tenodesis movement). As the wrist is moved into extension, the fingers are passively placed into flexion and the client is asked to actively hold this flexed position by contracting the muscles gently. Silfverskiöld and May[93] adapted this approach by changing the wrist position to neutral.

An active mobilization approach by Gratton[54] applies a dorsal blocking orthosis with the wrist at 20 degrees of flexion and the MP joints in more extreme flexion (between 80 and 90 degrees). In this protective orthosis, clients perform exercises every 4 hours, 2 repetitions each, of the following: (1) full passive flexion of the IP joints, (2) full active extension in the blocking orthosis, and (3) active flexion of the PIP joint to 30 degrees and DIP flexion to 5 to 10 degrees in the first week. Active flexion in this protective position is increased gradually in subsequent weeks to optimally achieve flexion of the PIP joint to 80 to 90 degrees and the DIP to 50 to 60 degrees.

Because early active mobilization of newly repaired flexor tendons involves a higher risk of rupture, close monitoring and practice with the client, especially those with poor compliance, is required. It is strongly recommended that all these early mobilization approaches be used in close collaboration with the surgeon and that they be used with caution by less experienced therapists.

Post-acute flexor tendon rehabilitation.

When active flexion is begun out of the orthosis, after any of the postoperative management techniques described previously, the client should be instructed in exercises to facilitate differential tendon gliding.[108] Wehbe has recommended three positions – hook, straight fist, and fist – to maximize isolated gliding of the flexor digitorum superficialis and the flexor digitorum profundus tendons, in addition to stretching of the intrinsic musculature and gliding of the extensor mechanism.[107] Tendon gliding exercises should be done for 10 repetitions of each position, 2 or 3 times a day.

Isolated exercises to assist tendon gliding may also be performed using a blocking orthosis (Fig. 39.9) or the opposite hand (Fig. 39.10). The MP joints should be held in extension during blocking so that the intrinsic muscles that act on it cannot overcome the power of the repaired flexor tendons. Care should be taken not to hyperextend the PIP joints and overstretch the repaired tendons.

FIG 39.9 A blocking orthosis can be used to isolate tendon pull-through and joint range of motion by blocking out proximal joints. This orthosis is being used to facilitate motion at the distal interphalangeal joint after repair of the flexor digitorum profundus tendon.

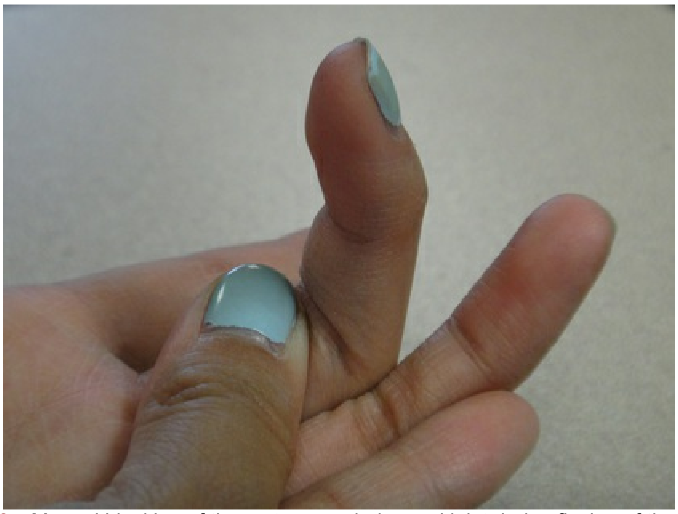

FIG 39.10 Manual blocking of the metacarpophalangeal joint during flexion of the proximal interphalangeal joint.

After 6 to 8 weeks, passive extension may be started, and the use of orthoses may be necessary to correct limitations in PIP joint motion.[27] A cylindrical plaster cast may be fabricated to apply constant static pressure for a flexion contracture, as described by Bell-Krotoski (Fig. 39.11A).[6] Serially casting into extension requires that the client be able to attend treatment every 2 to 3 days initially so that skin tolerance to casting can be checked and the cast changed as the client makes gains. A serial static PIP extension orthosis may be fabricated; when used according to the proper instructions, this orthosis allows the client to make adjustments gradually and independently[27] (Fig 39.11B). A finger gutter extension orthosis may be made using $\frac{1}{16}$-inch (0.16 cm) thermoplastic material and worn at night to help maintain extension gains made during the day. Gentle dynamic traction also may be considered using a commercial orthosis such as a spring finger extension assist (Fig. 39.12) or one fabricated by the therapist (Fig. 39.13). Use of a dynamic flexion orthosis may be necessary if the client has difficulty regaining passive flexion.

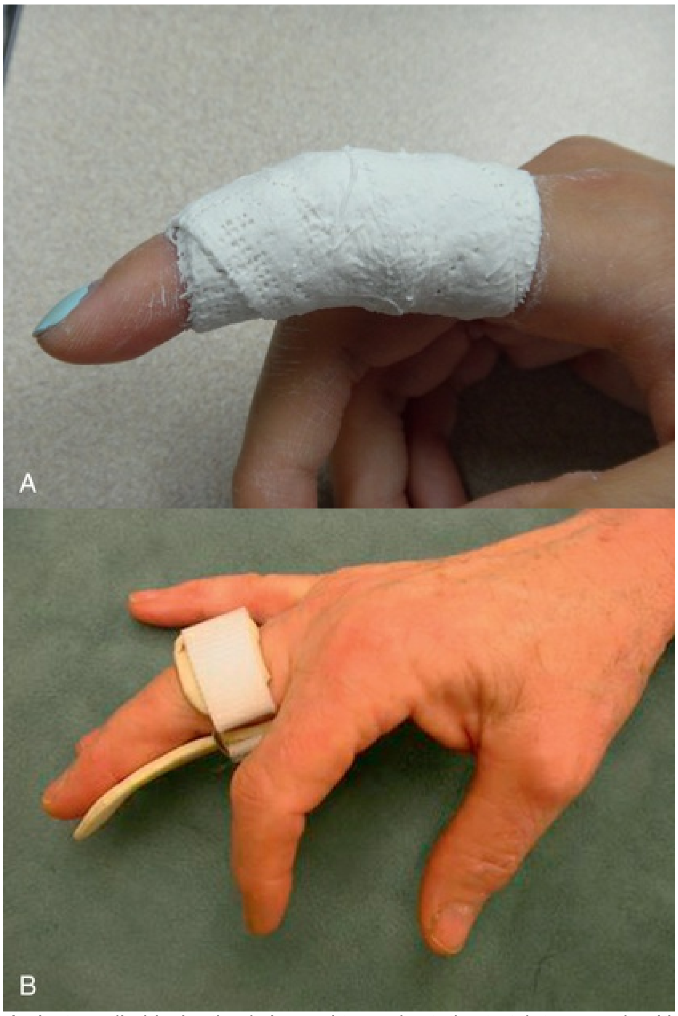

FIG 39.11 A, A plaster cylindrical orthosis is used to apply static stretch to a proximal interphalangeal (PIP) joint contracture. It is not removed by the client and must be replaced frequently by the therapist, with careful monitoring of the skin's condition. B, A static progressive extension orthosis may be fabricated to correct a flexion contracture, allowing the client to make gradual adjustments into PIP joint extension.

FIG 39.12 A finger orthosis with dynamic tension is used to increase the extension of the proximal interphalangeal joint. (Finger orthosis manufactured by DeRoyal Industries, Inc. www.deroyal.com.)

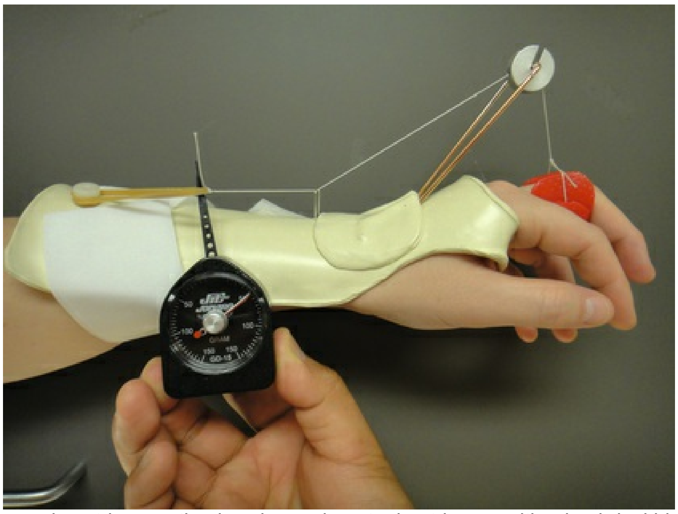

FIG 39.13 A dynamic outrigger orthosis using spring-steel outriggers with a lumbrical block can be used to assist proximal interphalangeal (PIP) joint extension, stretch against scar adhesions of extrinsic flexors, or reduce PIP joint contractures. The therapist must frequently assess the orthosis for proper fit and for tension of the rubber bands.

At 6 weeks after surgery the hand may be used for light ADLs, such as hygiene, grooming, feeding, and tabletop activities such as writing and using a computer. The client should continue to avoid heavy lifting with the affected hand or excessive resistance. At about 8 weeks the client may begin light resistive exercises and progress toward normal activities. Activities such as clay work, woodworking, and macramé are excellent for encouraging return of motion, strength, and coordination. Full resistance and normal work activities can be started 3 months after surgery. Sports activities should be discouraged until cleared with the surgeon.

After a hand has sustained a tendon injury, passive versus active limitations of joint motion must be evaluated. Limitations in active motion may indicate joint stiffness, muscle weakness, or scar adhesions.[83] If passive motion is greater than active motion, the therapist should consider that tendons may be caught in the scar tissue. The therapist should be able to determine whether a tendon is adhering and causing a flexion contracture or the tendon is free but the joint itself is stiff. Intervention should be based on this type of evaluation.

ROM, strength, function, and sensibility testing (if digital nerves were also injured) should be performed frequently, with orthoses and activities geared toward progressing the client. Performance of ADLs should continually be assessed and addressed to help maximize a client's return to his or her occupations. Assessments may include use of an ADL checklist or through simulations and observations during treatment. An example of disuse or neglect of an index finger may occur as a client becomes protective of the injured finger. This should be addressed early and prevented.

Gains in flexion and extension may continue to be recorded for 6 months postoperatively. A finger with limber joints and minimal scarring preoperatively will function better after repair than one that is stiff and scarred and has trophic skin changes. Therefore, it is important that all joints, skin, and scars be supple and movable before reconstructive surgery is attempted. A functional to excellent result is obtained if the combined loss of extension is less than 40 degrees in the PIP and DIP joints of the index and middle fingers and less than 60 degrees in the ring and small fingers[95] and if the finger can flex to the palm.

Flexor tendon reconstruction.

If the tendon is damaged as a result of a crush injury or if the laceration cannot be cleaned up enough to allow for a primary repair, delayed or staged reconstruction may be needed to provide return of tendon function. Repairs by the surgeon may include tendon transfers, lengthening, or grafting.[10,38] In severe tendon loss a staged flexor tendon reconstruction may be performed. At the first operation a Silastic rod is inserted beneath the pulley system and attached to the distal phalanx. Other reconstructive procedures (e.g., pulley reconstruction) are performed at the same time. In the postoperative recovery phase, a pseudosheath lined with mesothelial cells forms around the rod, and a fluid similar to synovial fluid forms.[66] The second stage of the repair is performed about 4 months later, when the digit can be moved passively to the palm. A tendon graft is inserted and the Silastic rod removed. The postoperative program is carried out in the same manner as for a primary tendon repair.[38]

After a two-stage tendon reconstruction or a primary repair, a tenolysis may be performed if the client's progress appears to have plateaued and if a substantial difference is noted between active and passive motion. Surgery may also be considered if motion is equal but strength is not sufficient for function. Tenolysis may be considered as early as 3 months after tendon repair, depending on the degree of limitation of the client's progress.

At the time of tenolysis surgery scar adhesions are removed from the tendon and gliding of the tendons is assessed. If local anesthesia has been used, the client is asked to move the fingers in the operating room at the time of lysis to determine the extent of scar removal.[32] If general anesthesia has been used, a proximal incision at the wrist is made and the tendon is pulled there to determine mobility from adhesions. Active motion is begun within the first 24 hours with tendon gliding exercises[108] and passive flexion of the finger, followed by active holds.[53] Gentle blocking exercises of specific joints may also be performed to help improve excursion of the tendon.[21] Transcutaneous electrical nerve stimulation (TENS)[19] and medications may be used to control pain.

LaSalle and Strickland have recommended a system for evaluating the results of tenolysis surgery by comparing the preoperative passive IP joint motion with the postoperative IP joint motion.[66] Using this comparison these researchers found that in one group of clients undergoing tenolysis, 40% had an improvement in motion of 50% or better compared with their preoperative status.

Extensor Tendons

Treatment of extensor tendon injuries requires a thorough knowledge of the extensor anatomy and biomechanics of the hand. The extensor mechanism of the hand is a highly sophisticated and complicated system. It is divided into seven zones for the fingers and five for the thumb. The level of injury dictates the intervention regimen. Timelines for immobilization, initiation of motion, and resistive exercise depend on the level of injury and the unique healing time frames for the structures in the different zones.

Four zones are distal to the MP joint, and three zones are proximal to it. Zones I and II consist of the structures at the DIP joint and middle phalanx, and injuries to this area are treated similarly. Zones III and IV are the areas over the PIP joint and proximal phalanx; injuries in these zones, too, are treated similarly, depending on the structures repaired. Zone V is the area over the MP joint; zone VI is the area over the dorsal hand; and zone VII is the area over the wrist.

In the thumb, zone T1 is the area over the DIP joint, T2 the middle phalanx, T3 the MP joint, T4 the proximal phalanx, and T5 the area over the carpometacarpal (CMC) joint and wrist.

Dorsal scar adherence is the most difficult problem after injury to the extensor tendons because of the tendency of the dorsal extensor hood to adhere to the underlying structures, thus limiting its normal excursion during flexion and extension. Overstretching of the extensor tendon, another common problem, can result in an extensor lag, or lack of full active extension.

Extensor tendon injuries distal to the MP joint (zones I to IV) generally require a longer period of immobilization, usually 6 weeks. As with flexor tendon injuries, controlled mobilization is being used with increasing frequency for zones III and IV. A protocol developed by Evans, called the short arc motion protocol (SAM protocol),[48a] allows for immediate active flexion of the PIP joint to 30 degrees, followed by full passive extension. Complete immobilization for 6 weeks or longer is necessary for injuries in zones I and II.

Several abnormal changes in the finger joint are associated with injuries distal to the MP joints. An injury to zone I or zone II, when a traumatic disruption of the terminal extensor tendon occurs, is called a mallet finger. This joint change is characterized by flexion of the DIP joint and inability to actively extend the joint. A swan neck posture is seen with dorsal displacement of the lateral bands (part of the extensor mechanism) in zone III; this results in hyperextension of the PIP joint and flexion of the DIP joint. Another abnormal joint position originating from zone III is known as the boutonnière deformity. This deformity results when the common extensor tendon is ruptured and the lateral bands sublux volarly; volar subluxation of the lateral bands results in flexion of the PIP joint and hyperextension of the DIP joint.

Extensor tendons in zones V, VI, and VII (proximal to the MP joints) become adherent because they are encased in paratenon and synovial sheaths; they respond to injury in a way similar to flexor tendons, resulting in either incomplete extension (extensor lag) or incomplete flexion caused by loss of gliding of the extensor tendon.

Evans studied the normal excursion of the EDC in zones V, VI, and VII to formulate guidelines for early passive motion of extensor tendons.[48,48a] She concluded that 5 mm of tendon glide after repair was safe and effective in limiting tendon adhesions, and she designed a postoperative orthosis that allows slight active flexion while providing passive extension.[48,48a] The orthosis is worn for 3 weeks, with initiation of active motion between the third and fourth weeks. A removable volar orthosis is used between exercise periods to protect the tendon for 2 additional weeks. If needed, use of dynamic flexion orthoses may be started at 6 weeks after surgery to regain flexion.

Injuries to extensor tendons proximal to the MP joint may be immobilized for 3 weeks. After this period the finger may be placed in a removable volar orthosis that is worn between exercise periods for an additional 2 weeks. Progressive ROM is begun at 3 weeks, and if full flexion is not regained rapidly, dynamic flexion may be started at 6 weeks.

Dynamic flexion orthoses may include an orthosis with rubber band traction individualized for the affected fingers, or a traction glove that provides tension to all fingers. For isolated fingers PIP-DIP strapping may be used (Fig. 39.14). This orthosis is made from 1 inch–wide pajama elastic, and tension is applied and adjusted by repositioning a safety pin.

FIG 39.14 A proximal interphalangeal (PIP)–distal interphalangeal (DIP) orthosis may be used to increase flexion of both the PIP and DIP joints. Made with pajama elastic tension, the orthosis can be adjusted by changing the position of a safety pin. The therapist should determine the tension and wearing

time.

Early motion may also be used in an immediate controlled active mobilization (ICAM) program for zones IV through VII. This requires at least one uninjured extensor tendon that can provide support to the injured tendons. A yoke orthosis is fabricated, and the repaired digit is placed in 15 to 20 degrees more extension than the adjacent fingers, thus taking tension off the repair. An additional wrist orthosis is fabricated that holds the wrist at 20 to 25 degrees of extension. Initially the client must wear both orthoses at all times.

In phase 1 after surgery (postoperative days 1 to 21) both passive and active motion are performed, with the client wearing both orthoses. The client is encouraged to perform light activities using the affected hand and must still wear both orthoses. In phase 2 (postoperative days 22 to 35) the client continues to wear the yoke orthosis at all times but can take the wrist orthosis off for light hand function. However, both orthoses must be worn for heavier gripping and lifting activities. During phase 3 (postoperative days 36 to 49) the client may be discharged from the wrist orthosis. The yoke orthosis may be gradually weaned or replaced with a less restrictive buddy strap as the client returns to increasing his or her normal hand function.[58]

Total active motion and total passive motion.

Total active motion (TAM) and total passive motion (TPM) are methods of recording joint ROM that are used to compare tendon excursion (active) and joint mobility (passive). They represent the measure of flexion minus extensor lag in three joints. The American Society for Surgery of the Hand has recommended that TAM and TPM be used to report joint motion.[4]

TAM is computed by adding the sum of the angles formed by the MP, PIP, and DIP joints in flexion, minus incomplete active extension at each of the three joints. For example: MP joint flexion is 85 degrees with full extension, PIP joint flexion is 100 degrees and lacks 15 degrees of extension, and DIP joint flexion is 65 degrees with full extension; therefore:

$$\text{TAM} = (85 + 100 + 65) - 15 = 235 \text{ degrees}$$

TAM should be measured while the client makes a fist. It is used for a single digit and should be compared with the same digit of the opposite hand or subsequent measurements of the same digit. It should not be used to compute a percentage of loss or impairment. TPM is calculated in the same manner but measures only passive motion.

Complex Injuries

Complex injuries of the hand, or injuries to multiple anatomic structures of the hand, are some of the most challenging injuries for therapists to treat. Complex injuries to the hand differ from other types of hand injuries because they involve trauma to multiple anatomic systems of the hand, resulting in a varied clinical picture. Injuries to these anatomic systems include skin, nerve, tendon, skeletal, and vascular injuries. Because of the complex nature of these injuries and because each injured structure has a unique healing time frame, precautions, and treatment approach, no set protocol has been determined for treating these injuries.

Many of the treatment precautions established for any one of the aforementioned injuries contradict one another; therefore, the therapist's challenge is to determine when the client can safely move forward with treatment without risking injury to healing structures. “The therapist must have a thorough knowledge of anatomy, wound healing, biomechanics, and treatment guidelines of various traumatic injuries,”[23] in addition to a “thorough understanding of the injuries and types of repairs performed. That understanding should include location and quality of repair, types of sutures used, associated injuries, and any structures that were injured but not repaired.”[23] Consequently the therapist must maintain close communication with the treating surgeon.

Types of complex hand injuries include crush injuries, amputations with or without replantation, and avulsion injuries; these may be caused by motor vehicle accidents, explosions, gunshots, and machinery accidents. Gerry, the client in the case study, had a complex injury to his hand. All the anatomic structures of his hand were affected by the saw injury; therefore, as noted earlier, his intervention plan needed to take into account the unique healing time frames and precautions for each of these anatomic structures.

Generally (and in Gerry's case) the rehabilitation process for these types of injuries is divided into three stages: the early, or protective, stage (first 5 to 10 days); the intermediate, or mobilization, stage (postoperative weeks 1 to 6); and the late, or strengthening, stage (postoperative weeks 6 to 8). The therapist and surgeon must be skilled and experienced in the rehabilitation of these injuries.

Ethical Considerations

Inexperienced therapists should not treat these clients without the supervision of a more experienced therapist or without additional training in and familiarization with treatment protocols for the various injured structures. Explore further reading for treating these types of injuries.

Edema

Although edema is a normal consequence of trauma, it must be quickly and aggressively treated to prevent permanent stiffness and disability. Within hours of trauma, vasodilation and local edema occur, with an increase in white blood cells in the damaged area. The inflammatory response to the injury results in a decrease in bacteria to control infection.

Edema should be controlled early through elevation, massage, compression, and AROM. The client is instructed at the time of injury to keep the hand elevated, and a compressive dressing is used to reduce early swelling. Pitting edema appears early and can be recognized as a bloated swelling that creates a pitted appearance when pressed. Pitting may be more pronounced on the dorsal surface, where the venous and lymphatic systems provide return of fluid to the heart. Active motion is especially important to produce retrograde venous and lymphatic flow.

If the swelling continues, a serofibrinous exudate invades the area. Fibrin is deposited in the spaces surrounding the joints, tendons, and ligaments, resulting in reduced mobility, flattening of the arches of the hand, tissue atrophy, and further disuse.[41] Normal gliding of the tissues is eliminated, and a stiff, often painful hand is the result. Scar adhesions form and further limit tissue mobility. If left untreated, these losses may become permanent.

Early recognition of persistent edema through observation and volume and circumference measurement is important. Several of the following edema control techniques may need to be used.

Elevation

Early elevation with the hand above the heart is essential. Slings tend to position the hand below the heart and may reduce blood flow. Resting the hand on pillows while seated or lying down is effective. Resting the hand on top of the head or using devices that elevate the hand with the elbow in extension has been suggested.

The client should use the hand for ADLs within the limitations of resistance prescribed by the physician. Light ADLs that can be accomplished while the hand is in a dressing are permitted.

Manual Edema Mobilization

Manual edema mobilization (MEM) is a method of edema reduction based on activation of the lymphatic system. These methods include the principles of manual lymphedema treatment (MLT) massage, medical compression bandaging, exercise, and external compression adapted to meet the specific needs of subacute and chronic postsurgical and post-stroke UE edema. The goals are to stimulate the initial lymphatics to absorb excessive fluid and large molecules from the interstitium and to move this lymph centrally. “MEM is not indicated for all hand clients but can be highly effective in cases of recalcitrant subacute or chronic edema. MEM is used to prevent or reduce subacute or chronic high-protein edema as seen in postsurgical, trauma, or post-cerebrovascular accident (CVA) hand edema.”[5]

MEM is an advanced skill that requires specialized training of the practitioner. The following overview will acquaint the reader with the techniques involved in MEM.[5]

- Provide light, stroking massage of the involved area. Keep in mind that pressure greater than 40 mm Hg will cause collapse of the lymphatic pathways.
- Incorporate exercise before and after massage in a specific sequence, following the recommended guidelines.

- Massage is done in segments, proximal to distal and then distal to proximal, always following movement of the therapist's hand in the proximal direction.
- Massage follows the flow of lymphatic pathways.
- Massage reroutes around the incision area.
- Recognize that this method does not cause additional inflammation.
- Provide the client with a home self-massage program.
- Guide intervention to prevent increased edema from other intervention techniques.
- Incorporate low-stretch compression bandaging and warmth to soften hardened tissues, especially at night.

Active Range of Motion

Normal blood flow depends on muscle activity. AROM does not mean wiggling the fingers; rather, it means maximal available ROM, performed firmly. Casts and orthoses must allow mobility of uninjured parts while protecting newly injured structures. The shoulder and elbow should be moved through full available ROM several times a day. The importance of AROM for edema control, tendon gliding, and tissue nutrition cannot be overemphasized.

Compression

Light compression using Coban wraps (available from North Coast Medical) of the affected area (Figure 39.15) or light compressive garments such as Isotoner (Isotoner gloves [available from North Coast Medical]) or Jobst[60] (Figure 39.16) will help to control swelling, especially at night.

FIG 39.15 One-inch 3M™ Coban™ LF Latex Free Self-Adherent Wrap with Hand Tear is wrapped, with minimal stretch, from the distal end to the proximal crease of the digit. The client is instructed to be alert for the development of swelling, discoloration, pain, numbness, tingling, or other changes in sensation. Coban™ LF Latex Free Self-Adherent Wrap with Hand Tear may be worn several hours a day to provide compression to reduce edema.

FIG 39.16 A custom-fitted Jobst garment may be used to reduce edema and to decrease and prevent hypertrophic scar formation after burns or trauma. Inserts may be used with the garment to increase pressure over natural curves, such as the dorsum of the wrist.

Wound Healing and Scar Remodeling

The basis of hand therapy is the histology of wound healing. Acute intervention must be planned using the foundation of tissue healing as a guide. Bones, tendons, nerves, and skin follow a progression of healing phases. Intervention must respect healing tissue to promote recovery and prevent further damage. The therapist must take care to do no harm, and that can be accomplished only with a thorough understanding of the physiology of healing.

The first phase of wound healing, the acute inflammatory phase, is initiated within hours, when the tissues are disrupted through injury or surgery, causing vasodilation, local edema, and migration of white blood cells and phagocytic cells to the area. The phagocytes remove tissue fragments and foreign bodies and are critical to healing. The inflammatory process can subside or persist indefinitely, depending on the degree of bacterial contamination.[103]

Fibroblasts, in combination with associated capillaries, begin to invade the wound within the first 72 hours and gradually replace the phagocytes, leading to the second phase – the collagen, or granulation, phase – between the fifth and fourteenth days. The formation of collagen fiber follows the invasion by fibroblasts, so that by the end of the second week, the wound is rich with fibroblasts, a capillary network, and early collagen fibers. This increased vascularization results in the erythema (redness) of the new scar.

During the third to sixth weeks fibroblasts are slowly replaced with scar collagen fibers and the wound becomes stronger and better able to withstand progressive stresses, leading to the last phase of scar maturation. Tissue strength continues to increase for 3 months or longer. The collagen metabolizes and synthesizes during this period so that new collagen replaces old while the wound remains relatively stable. Covalent bonding between collagen molecules leads to dense scar adhesions and the formation of whorl-like patterns of collagen deposits, which may be altered as the scar architecture and collagen fiber organization within the wound change over time.[41]

Myofibroblasts, which are fibroblasts with properties similar to smooth muscle cells, are contractile and cause shortening of the wound.

Tissues in which gliding has been restored have a different scar architecture from those that do not develop the ability to glide. With gliding the scar resembles the state of the tissues before injury, whereas a nongliding scar remains fixed on surrounding structures. Controlled tension on the scar has been shown to facilitate remodeling. Scar formation is also influenced by age and the quantity of scar deposited.

Wound Care and Dressings

Wounds may be described using a three-color concept: red, yellow, or black wounds.[103] This system simplifies wound description and intervention. Guidelines for treating the three wound types help the therapist choose the proper method of cleansing and dressing wounds. The reader is encouraged to review this material and obtain advanced education before treating wounds.

Topical intervention (e.g., antimicrobials) may be used to control bacteria. A variety of dressings can be placed on a wound, including gauze that has been impregnated with petrolatum (e.g., Xeroform gauze or Adaptic). Ointments (e.g., Polysporin or Neosporin) are also commonly applied. N-Terface (Winfield Laboratories; available from North Coast Medical & Rehabilitation Products) is a dry mesh fabric that looks and feels like the interfacing used in sewing. Because it is nonadherent, it can be used directly over wounds. Sterile dressings can be applied directly over the N-Terface without ointments or gels. The selection of materials depends on the amount of exudate and the goal of the dressing (which may include removing debris, absorbing exudate, or protecting new cells).

The wound can be cleaned with sterile saline, and dead tissue then is gently removed with sterile swabs. Sterile saline solution can be used to soak off adherent bandages, rather than pulling them off. The therapist should pour a small amount of saline on the area that is sticking, wait a few moments, and then gently pry off the dressing. Dead skin can be debrided using iris scissors and pickups. Soft surgical scrub sponges may be used to clean and desensitize the wound once it has healed and the stitches have been removed. The client may resume normal hand washing with running water and soap once this has been cleared with the physician.

Pressure

A hypertrophic scar or a scar that is randomly laid down and thickened is reduced by the application of pressure, often by means of pressure garments (available from Bio Concepts) or the application of Cica-Care silicone gel sheets (available from Smith & Nephew).[60] The conformity of the pressure garment can be increased if a neoprene fabric insert (available from Benik Corp.) or silicone gel sheets or molds made from Silastic elastomer (available from Smith & Nephew)[74] are used under the garment. Pressure should be applied for most of the 24-hour period; with a hypertrophic burn scar, this intervention should continue for 6 months to 1 year after the injury. Silicone gel sheets (e.g., Cica-Care) have been found to reduce hypertrophic scarring when worn on a regular basis for 12 to 24 hours a day.

Massage

Gentle to firm massage of the scarred area using a thick ointment rapidly softens scar tissue and should be followed immediately with active hand use so that tendons glide against the softened scar.[33] Vibration applied to the area with a small, low-intensity vibrator will have a similar effect.[33,61] Active exercise, using facilitation techniques and against resistance, or functional activity should follow vibration. Massage and vibration may be started 4 weeks after injury.

Thermal heat, in the form of paraffin dips, hot packs, or fluidotherapy, immediately followed by stretching while the tissue cools, provides stretch to the scar tissue. Wrapping the scarred or stiff digit into flexion with Coban during the application of heat often increases mobility in the area. Heat should not be used on insensate areas or if swelling persists.

Active Range of Motion and Electrical Stimulation

AROM provides an internal stretch against resistant scar, and the benefits of its use cannot be overemphasized. If the client is unable to achieve active motion because of scar adhesions or weakness, use of a battery-operated NMES may augment the motion.[18] Stimulation may be performed by the client for several hours at home and has been shown to increase ROM and tendon excursion.[78]

Some hand therapists use high-voltage direct current as an intervention to increase motor activity of denervated muscles. Ultrasound interventions are often prescribed but may be more effective if done within the first few months after trauma. A continuous passive motion (CPM) device may be used at home to maintain PROM and does not promote too much tendon gliding. It should be used for several hours a day for maximal benefit.

Pain Syndromes

Pain is the subjective manifestation of trauma transmitted by the sympathetic nervous system, and it may interfere with normal functioning. Because pain leads to overprotection of the affected part and disuse of the extremity, it should be treated early.

Desensitization

Stimulation of the large afferent A nerve fibers leads to a reduction of pain by reducing summation in the slowly adapting, small, unmyelinated C fibers, which carry pain sensation. The A axons can be stimulated mechanically with pressure, rubbing, vibration, TENS, percussion, and active motion. Desensitization techniques are based on the amplification of inhibitory mechanisms.

Yerxa et al. have described a desensitization program that "employs short periods of contact with three sensory modalities: dowel textures, immersion or contact particles, and vibration."[110] This program allows the client to rank 10 dowel textures and 10 immersion textures according to the degree of irritation produced by the stimulus. Intervention begins with a stimulus that is irritating but tolerable. The stimulus is applied for 10 minutes, 3 or 4 times a day. The vibration hierarchy is predetermined and based on cycles per second of vibration, the placement of the vibrator, and the duration of the intervention. Complete instructions for assembling the Downey Hand Center desensitization kit can be found in the literature in the References. The Downey Hand Center Hand Sensitivity Test can be used to establish a desensitization intervention program and to measure progress in reducing hypersensitivity.[5a,110]

Neuromas

Neuromas are a complication of nerve suture or amputation. A traumatic neuroma is an unorganized mass of nerve fibers that results from accidental or surgical cutting of a nerve. A neuroma in continuity occurs on a nerve that is intact. Neuromas may be clinically identified by a specific, sharp pain. Stimulation of a neuroma usually causes the client to pull the hand away quickly; many clients report a burning pain that radiates up the forearm. Neuromas are disabling because any stimulation causes intense pain and the client avoids the sensitive area.

A generalized desensitization program may not work because the client never develops a tolerance for stimulation of the neuroma. Injection of cortisone acetate may help break up the neuroma, making desensitization techniques more effective. Surgically excising the neuroma or burying the nerve endings deeper may be necessary.

Complex Regional Pain Syndrome

Complex regional pain syndrome (CRPS) (formerly known as reflex sympathetic dystrophy [RSD]) is a group of disorders that "involve pain and dysfunction of severity or duration out of proportion to those expected from the initiating event."[109]

"Complex" denotes the complex nature of the pain response, which may include inflammation and autonomic, cutaneous, motor, and dystrophic changes. "Regional" refers to the wide distribution of symptoms beyond the area of the original lesion. Pain is the primary characteristic of this syndrome, which includes spontaneous pain, thermal changes, and at times burning pain. CRPS type I corresponds to RSD; CRPS type II corresponds to causalgia, a severe, burning pain first described during the Civil War.[65]

Diagnostic criteria for CRPS must include spontaneous pain beyond the territory of a single peripheral nerve and disproportionate to the inciting event. Generally, edema, an abnormality in skin blood flow, or abnormal sudomotor activity is present in the area of the pain. The diagnosis is excluded by the existence of conditions that otherwise would account for the pain. The hallmarks of CRPS are pain; edema; blotchy, shiny skin; and coolness of the extremity. Sensory changes may occur. Excessive sweating or dryness may occur in clients with associated sympathetic dysfunction. The degree of trauma does not correlate with the severity of the pain, which may occur after any injury. CRPS type I may be triggered by a cycle of vasospasm and vasodilation after an injury. Abnormal edema and constrictive dressings or casts may be a factor in initiating the vasospasm. Vasospasm causes tissue anoxia and edema, and thus more pain, which continues the abnormal cycle.[105] Circulation is reduced, which causes the extremity to become cool and pale.

Fibrosis after tissue anoxia and the presence of protein-rich exudates result in joint stiffness. The client may cradle the hand and prefer to keep it wrapped. He or she may have an exaggerated reaction to touch, especially light touch. By 8 weeks after trauma, osteoporosis may be apparent on x-ray films after active use of the hand. The symptom of burning pain associated with causalgia (CRPS type II) may be alleviated by interruption of the sympathetic nerve pathways.

CRPS progresses through three stages. Stage I (traumatic stage) may last up to 3 months; it is characterized by pain, pitting edema, and discoloration. Stage II (dystrophic stage) may last an additional 6 to 9 months. Pain, brawny edema, stiffness, redness, heat, and bony demineralization are usually found in this stage, and the hand usually has a glossy appearance. Stage III (atrophic stage) may last several years or indefinitely. Pain usually peaks in stage II and decreases in stage III. Thickening around the joints occurs, and fixed contractures may be present. Swelling, if present, is hard and not responsive to techniques such as elevation. The hand may be pale, dry, and cool, and substantial dysfunction of the limb may be seen.

CRPS is treated by reducing sympathetic stimulation. It is most responsive in stage I. The first goal of intervention is reduction of the pain and hypersensitivity to light touch. This goal may be accomplished with application of warm (not hot), moist heat; fluidotherapy; gentle handling of the hand; acupressure; desensitization; and TENS before AROM. Any intervention that increases pain (e.g., PROM) should be avoided. Many clients respond well to gentle manual edema mobilization,[5] which reduces the edema and reintroduces touching of the hand. Stellate ganglion blocks to eliminate the pain are effective early; they should be coordinated with therapy so that the client can perform AROM and functional activities during the pain-free period after the blocks. AROM is crucial. Gravity-eliminated exercise, either in water or on a tabletop, may be better tolerated.

A variety of drugs may be used in the treatment of CRPS, including sympatholytic drugs that reduce the vasoconstrictive action of the peripheral vessels. Neurontin often is effective in reducing pain and increasing temperature in the extremity. Calcium channel blockers are also effective. Narcotics, carefully monitored, may interrupt the pain cycle and allow active use of the hand. A stress-loading program that has been used effectively to reduce symptoms of CRPS type I (RSD) has been described.[106] It can easily be adapted for home use.

Edema control techniques should be started immediately. Elevation, manual edema mobilization, contrast baths, and high-voltage direct current in water have proved effective. Surface electromyography (EMG) biofeedback training for relaxation may help muscle spasms and increase blood flow, in addition to reducing anxiety.

CRPS frequently triggers shoulder pain and stiffness, resulting in shoulder-hand syndrome or adhesive capsulitis of the shoulder ("frozen shoulder"); therefore, AROM and functional activities should include the entire upper quadrant. Skateboard exercises are helpful in the early stages for active-assisted exercise of the shoulder. Orthoses that reduce joint stiffness should be used as tolerated. Orthoses must not cause pain or increase swelling. Reliance on immobilization orthoses should be avoided because clients with CRPS prefer not to move the affected part, which ultimately makes their symptoms worse.

A tendency to develop CRPS should be suspected in any client who seems to complain excessively about pain, appears anxious, and complains of profuse sweating and temperature changes in the hand. Some clients report nausea associated with touching of the hand. Clients tend to overprotect the hand. Early intervention with a structured therapy program of functional activities, group interaction, and exercises that include the hand and shoulder may prevent the occurrence of a fully developed CRPS. This problem is best recognized early and treated with tempered aggressiveness and empathy.

Transcutaneous Electrical Nerve Stimulation

The intervention technique TENS is thought to stimulate both the afferent A nerve fibers in the high-frequency mode and the release of morphine-like neural hormones (enkephalins) in the low-frequency mode. Its efficacy as an intervention for pain control is well documented in medical literature. As with other electrical modalities that may be used by occupational therapists, TENS should be correlated with functional use of the hand.

To achieve pain control TENS should not be used for longer than 60 minutes at a time.[78]A TENS diary should be kept for recording the level of pain on a scale of 1 to 10 before and after intervention, in addition to activities that exacerbate the pain. To prevent overuse, TENS applications may be tapered as the pain-free periods increase. The intervention can be continued as long as necessary to provide pain control.

Joint Stiffness

Joint stiffness has been discussed in other sections of this chapter because it is seen after almost any hand trauma or disease. In the acute phase it may also result from "internal splinting," done unconsciously by the client to avoid pain. It may be prevented by early mobilization, pain control, reduction of edema, AROM and PROM, use of a CPM device, and appropriate orthotic techniques.

Grades I and II joint mobilization are especially helpful in preparing for passive and active motion and providing pain relief.

The treatment of established joint stiffness is more difficult. Thermal modalities, joint mobilization, ultrasound and electrical stimulation, dynamic orthoses, serial casting, and active and passive motion in preparation for functional use should all be included in the intervention regimen.

Cumulative Trauma Disorders

A number of terms are used to describe injuries to the musculoskeletal system, including overuse syndromes, repetitive strain injuries, cervical-brachial disorders, repetitive motion injuries, and **cumulative trauma disorders** (CTDs).[13,104] However, the term cumulative trauma disorder should be viewed as a description of the mechanism of injury, not a diagnosis. Even when the presenting symptoms are confusing, attempts to define a specific diagnosis are necessary because "each disorder has a different cause, intervention, and prognosis."[88] Diagnoses associated with cumulative trauma usually fall into one of three categories: tendinitis (e.g., lateral epicondylitis [tennis elbow] or de Quervain's tenosynovitis), nerve compression syndromes (e.g., carpal tunnel syndrome or cubital tunnel syndrome), and myofascial pain.

Cumulative trauma occurs when force is applied to the same muscle or muscle group, causing an inflammatory response in the tendon or muscle.[88] Muscle fatigue is an important aspect of cumulative trauma. Excessive use of a muscle or body system (overuse or overexertion) is experienced as a muscle cramp. Acute overuse is relieved by rest, but chronic fatigue is not relieved by rest. The degree of fatigue is related to the amount of force and the duration of force application.

The greater the force, the more quickly fatigue occurs. If force is maintained, repetitions must be reduced to allow recovery; therefore, if the force is reduced but the repetitions are maintained and recovery time is adequate, harm is less likely to occur. The combination of repetitions without adequate recovery time and high force establishes an environment that is likely to lead to injury. Byl found that repetitive hand opening and closing may lead to motor control problems and the development of focal hand dystonias by means of degradation of the cortical representation.[16] Applying this research may help therapists develop more effective intervention programs for cumulative trauma and chronic pain.

Intervention for CTDs may be divided into three phases. In the acute phase, intervention is geared toward reducing the inflammation through dynamic rest. Orthoses are used for immobilization to relieve symptoms, and cortisone injections also may be used to reduce symptoms. Icing, ultrasound, iontophoresis (the movement of ions through biologic material under the influence of an electric current), and interferential and high-voltage electrical stimulation have all proved effective in reducing pain and inflammation. Nonsteroidal anti-inflammatory drugs also are used frequently. When orthoses are used, they should be removed often during the day to allow stretching of the affected musculature (e.g., the extensor group in lateral epicondylitis); this maintains or increases muscle length and prevents joint stiffness. Painful activities should be avoided during the dynamic rest phase. Vibration is contraindicated because it may contribute to inflammatory problems.

As the acute symptoms diminish, the client begins the exercise phase of intervention. After slow stretching has warmed up the muscles, the client begins controlled progressive exercise. Resistance should be increased slowly, and the frequency, intensity, and duration of exercises should be monitored and adjusted in response to pain and fatigue levels.

Clients are instructed to continue stretching 3 times a day, especially before activity, for an indefinite time. Proper body mechanics are critical to the long-term control of inflammatory problems, so clients must become aware of what triggers their symptoms and learn early intervention if symptoms reappear. Icing, orthoses, stretching, and modified activities, combined with correct body mechanics, are usually effective. The key is to ensure that the client learns self-management techniques and takes an active role in the interventions.

Work-related risk factors for CTDs include:

- Repetition
- High force
- Awkward joint posture
- Direct pressure
- Vibration

- Prolonged static positioning

An assessment of the job site, tools used, and hand position during work activities may be indicated for a client whose symptoms are related to job demands. Modification of the equipment used and strengthening of the dominant muscle groups and their antagonist muscles may permit continued employment and control the inflammatory problem.

Tendinitis (inflammation of the tendon), tenosynovitis (inflammation of the tendon sheath), and tendinosis (chronic tendon injury with damage to the tendon on a cellular level) are frequently seen in cumulative trauma. The cycle of overuse that leads to microtrauma, swelling, pain, and limitations in movement is followed by rest, disuse, and weakness. Then normal activity is resumed, and the cycle begins again.[68]

Clients usually have a combination of localized pain, swelling, pain with resisted motion of the affected musculotendinous unit, limitations in motion, weakness, and crepitation of the tendons. The symptoms are reproduced with activity or work simulation. Using functional grades to describe the associated symptoms assists in the evaluation and monitoring of improvement (Table 39.5). Although isometric grip strength may be normal, wrist and forearm strength are often decreased and out of balance. Dynamic grip strength may be more limited because tendon gliding is more likely to increase inflammation and pain. Muscle imbalance leads to positioning and substitution patterns that may result in worsening or spread of the symptoms.

TABLE 39.5

Functional Grading of Cumulative Trauma Disorders

Grade	Description
Grade I	• Pain after activity; resolves quickly with rest • No decrease in amount or speed of work • Objective findings usually absent
Grade II	• Pain in one site while working • Pain consistent while working but resolves when activity stops • Productivity sometimes mildly affected • May have objective findings
Grade III	• Pain in one or more sites while working • Persistent pain after cessation of activity • Productivity affected and multiple breaks sometimes necessary to continue working • May affect other activities away from work • May have weakness, loss of control and dexterity, tingling, numbness, and other objective findings • May have latent or active trigger points
Grade IV	• All common uses of hand and upper extremity result in pain, which is present 50% to 75% of the time • May be unable to work or works in limited capacity • May have weakness, loss of control and dexterity, tingling, numbness, trigger points, and other objective findings
Grade V	• Loss of capacity to use upper extremities because of chronic, unrelenting pain • Usually unable to work • Symptoms sometimes of indefinite duration

From Kasch MC: Therapist's evaluation and treatment of upper extremity trauma disorders. In Mackin EJ, et al, editors: *Rehabilitation of the hand and upper extremity*, ed 5, St Louis, 2002, Mosby.

Nerve compression syndromes, especially carpal tunnel syndrome, are frequently seen. Carpal tunnel syndrome is caused by pressure on the median nerve as it travels beneath the transverse carpal ligament at the volar surface of the wrist.[52] The syndrome is associated with increased pressure in the carpal canal because of trauma, edema, or retention of fluids as a result of pregnancy, flexor tenosynovitis, repetitive wrist motions, or static loading of the wrist.

The symptoms are night pain severe enough to waken the client; tingling in the thumb and index and middle fingers; and, if the condition is advanced, wasting of the thenar musculature caused by pressure on the motor branch of the nerve. Early carpal tunnel syndrome may be recognized during a thorough nerve evaluation.

Conservative intervention usually is attempted first and includes orthotics for the wrist in no more than 20 degrees of extension, contrast baths to reduce edema, wearing of Isotoner gloves, and activity analysis. In carpal tunnel syndrome a semiflexible or neoprene orthosis, rather than a completely rigid one, may be used to provide support while allowing a small amount of flexion and extension for greater functional use.

Ultrasound and iontophoresis may be used to reduce inflammation, and icing techniques are beneficial. Specific strengthening exercises of the wrist, fingers, and thumb should be given after the pain and inflammation have been controlled.

Myofascial pain and fibrositis are common pain conditions elicited by activation of trigger points in the muscles, resulting in pain referred to a distal area. Travell and Simons studied myofascial pain and mapped out the traditional trigger points and their referral patterns.[99] Poor posture and positioning of the body out of normal alignment are often the mechanisms of injury in myofascial pain, so careful examination of the client and his or her normal daily activities is indicated. The therapist should observe the client performing the activity rather than rely on a verbal description.

Myofascial pain should be considered if direct intervention applied to the painful area does not relieve the pain. Evaluation for trigger points must be done meticulously, and mapping of the trigger points and the referral areas must be documented. Because the pain is referred, the trigger point must be treated, not the referral area. The interventions used for other inflammatory problems (e.g., ice and ultrasound) can be used, and specific interventions for the trigger points (e.g., friction massage and TENS) also may relieve the pain. Activity analysis is an essential part of intervention because it enables the therapist to identify stresses on the affected tissues caused by functional activities.

Elastic Therapeutic Taping

Kinesio Tape (available from North Coast Medical & Rehabilitation Products) was developed in Japan in the 1970s, Since its introduction in the United States in 1994, it has become increasingly popular with therapists for use in CTD interventions.[62] The technique of elastic therapeutic taping uses tapes such as Kinesio Tape or other elastic or kinesiology tapes (e.g., SpiderTech tape and KT Tape). Unlike athletic taping, which is restrictive and is used to provide stability and restrict joint motion, elastic therapeutic tape is designed to "mimic the elastic properties of muscle, skin, and fascia."[29,30] When elastic tape is properly applied, its elasticity does not restrict the movement of soft tissue, yet it supports weakened muscles and allows for full movement of the joints by reducing abnormal muscle tension or spasms.

A variety of clinical applications for elastic taping techniques have been described. Depending on the problem, the tape is anchored at either the origin or the insertion of a muscle and then gently stretched and taped over or around either a shortened or an elongated muscle; this puts the muscle back into a neutral position. The tape is believed to affect the peripheral somatosensory receptors in the superficial skin, which in turn affects the skin and lymphatic systems (in addition to muscle and joint function) as they relate to pain, proprioception, and motor control. The goals and concepts of elastic taping include[29,30]:

- Reducing pain by increasing the somatosensory system
- Reducing inflammation and edema by stimulating the lymphatic system
- Normalizing muscle tone by reducing overstretching and overcontraction of muscles
- Reducing muscle fatigue by supporting and enhancing the contraction of weakened muscles
- Improving ROM by relieving pain
- Providing support and alignment to joints by supporting weakened ligaments
- Preventing injuries during ADLs by providing support to muscles and ligaments

Strengthening Activities

Acute care is followed by a gradual return of motion and sensibility and by preparation to return the client to his or her normal ADL and instrumental ADL (IADL) routines.

Fear of further injury and pain usually prevent the client from strengthening the injured and neglected extremity at home. Because every hand clinic has its own armamentarium of strengthening exercises and media, only a few suggestions are provided here.

Computerized Evaluation and Exercise Equipment

The BTE Work Simulator (Baltimore Therapeutic Equipment [BTE]) (Fig. 39.17) is an electromechanical device with more than 20 interchangeable tool handles that can be used for both work evaluation and UE strengthening. The resistance level can be adjusted from no resistance to complete static resistance, and tool height and angle also are adjustable. When the device is used for strengthening, the resistance usually is set low and gradually increased. The duration of exercise is increased when a base level of strength has been achieved. The BTE Work Simulator allows for close simulations of real-world tasks that are easily translatable into the physical demands common to manual work.

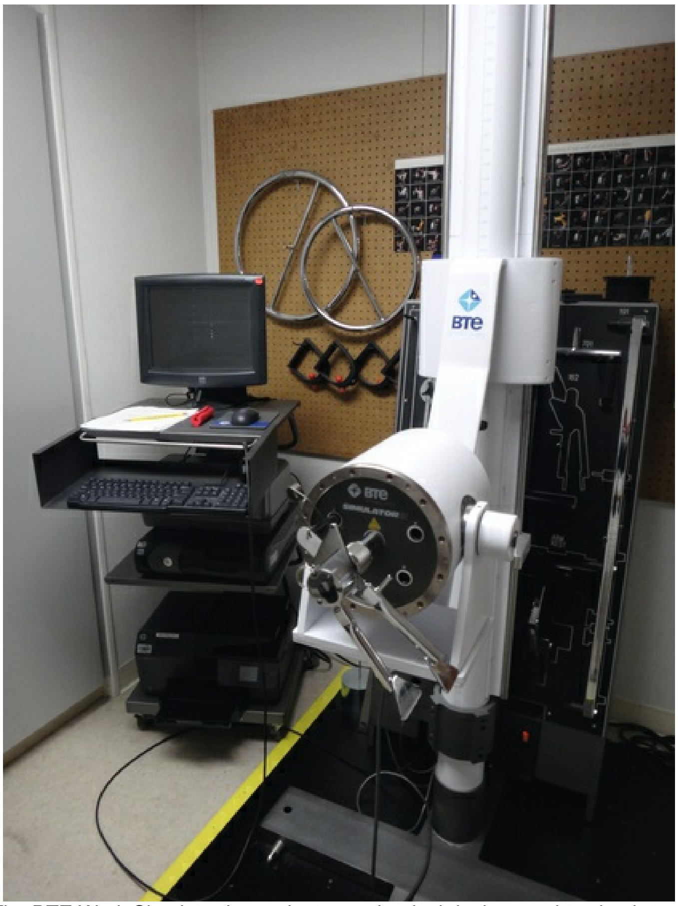

FIG 39.17 The BTE Work Simulator is an electromechanical device used to simulate real-life tasks, thereby allowing evaluation and strengthening of the upper extremity. The client's progress is monitored through a computerized printout, and the program can be modified to increase resistance and endurance. (Courtesy of BTE Tech. http://www.btetech.com.)

Other types of computerized evaluation equipment allow the therapist to record the assessment results and print a report. The percentage of impairment also can be determined electronically. Portable systems are being developed that allow the therapist to record daily interventions and download the information into a computerized network, so that outcome data from many sources can be compared. Technologic advances in rehabilitation are helping therapists to become more efficient and to capture important information not available by traditional means.

Many practitioners use occupation-based interventions, either in the clinic or at the work site, that simulate the actual work done by the client. These methods assist the client toward a return to his or her occupation and are in keeping with the Occupational Therapy Practice Framework.

Weight Well

The Weight Well (Fig. 39.18) was developed at the Downey Community Hospital Hand Center in Downey, California, and is available commercially (Upper Extremity Technology Weight Well [available from North Coast Medical & Rehabilitation Products]). Rods with a variety of handle shapes are inserted through holes in a box, and weights are suspended from them. The rods are turned against resistance throughout the ROM to encourage full grasp and release of the injured hand, wrist flexion and extension, pinch, and pronation and supination patterns. The Weight Well can be graded for resistance and repetitions and is an excellent tool for progressive resistive exercise.

FIG 39.18 The Weight Well is used to strengthen the upper extremity by applying progressive resistance to weakened musculature. It also is useful in retraining prehension of pinch and grip.

TheraBand

TheraBand (available from Patterson Medical) is a 6-inch (15.2-cm) wide rubber sheet that is available by the yard and is color coded according to degrees of resistance. It can be cut into any length required and used for resistive exercise for the UE. The uses for TheraBand are limited only by the therapist's imagination; it can be adapted to diagonal patterns of motion, wrist exercises, follow-up intervention of tennis elbow, and other uses. TheraBand can be combined with dowel rods and other equipment to provide resistance throughout the ROM. It is inexpensive and easy to incorporate into a home intervention program.

Hand-Strengthening Equipment

Handgrips of graded resistance are available from rehabilitation supply companies and sporting goods stores. They can be purchased with various resistance levels and can be used for progressive resistive hand exercises.

Therapists must be especially careful not to use the overly resistive, spring-loaded grippers often sold in sporting goods stores. These devices may be beneficial to the seasoned athlete but are usually too resistive for the recently injured.

Therapy putty can be purchased in bulk; the amount given to the client depends on his or her hand size and strength. This medium also is available in grades of resistance, and some types provide chips that can be added to progressively increase resistance. Therapy putty can be adapted to most finger motions, and it is easily incorporated into a home program.

Household items (e.g., spring-type clothespins) have been used to increase the strength of grasp and pinch. Imaginative use of common objects should present a challenge to the hand therapist.

Purposeful and Occupation-Based Activity

Purposeful and occupation-based activities are an integral part of rehabilitation of the hand. Such activities include crafts, games, dexterity activities, ADLs, and work samples. Several studies have shown that clients are more likely to choose occupationally embedded exercise and that they performed better using this type of exercise than with rote exercise.[26a] Many of the intervention techniques described previously are used to prepare the hand for purposeful activity.

Activities should be started as soon as possible at whatever level the client can perform them, with adaptations to compensate for limited ROM and strength. They should be used in conjunction with other interventions. The occupational therapist must continually assess the client's functional capacities and initiate changes in the intervention plan to incorporate activities as soon as possible in the restorative phase.

Vocational and leisure goals should be established during the initial evaluation and taken into account when the intervention plan is devised. The needs of a brick mason may be quite different from those of a mother with small children, and the environmental needs of the client must not be neglected.

Crafts should be graded from light resistance to heavy resistance and from gross dexterity to fine dexterity. Crafts that have been found to work extremely well with hand injuries include macramé, Turkish knot weaving, clay molding, leather tooling, and woodworking. All these crafts can be adapted and graded to the client's capabilities, and they have been found to have a high level of client acceptance. When integrated into a program of total hand rehabilitation, they are viewed as another milestone of achievement, not as a diversion to fill up empty hours. For example, the pride of accomplishment for Gerry, who was able to complete his first simple woodworking project, is evidence that the purposeful activity of crafts belongs in hand rehabilitation.

Activities that do not have an end product but provide practice in dexterity and ADL skills also fit into the category of purposeful activities. Developmental games and activities that require pinch or grasp and release may be graded and timed to increase difficulty. ADL boards with a variety of opening and closing devices provide practice for use of the hand at home and increase self-confidence. String and finger games are challenging but fun coordination activities that can be done in pairs.

A hobby can often be adapted for use in the clinic. Fly-tying is a difficult dexterity activity, but one frequently enjoyed by an avid fisherman. Golf clubs and fishing poles can be adapted in the clinic; in Gerry's case, therapy with these tools allowed early return to a favorite form of relaxation.

Humor and interaction with other therapists and clients are vital but intangible benefits of hand therapy intervention. The intervention should be planned to promote both.

Functional Capacity Evaluation

The ultimate goal of therapy for an injured worker is to return to full employment. Many weeks or months may elapse between the time of injury and the point at which the physician believes a return to work is appropriate medically. Even though x-ray examinations may show full healing and restored ROM, many clients do not feel that they have the strength, dexterity, or endurance to return to their former jobs. Pain may continue to be a limiting factor, especially with heavy activities. Light duty or part-time positions may not be available, and the physician, therapist, industrial insurance carrier, and especially the client are frustrated by the lack of an objective method of evaluating an individual's physical capacity for work. Occupational therapists with training in evaluation, kinesiology, and adaptation of environmental factors, coupled with a functional approach to the client, may play a key role in the **functional capacity evaluation**.

A renewed interest in evaluation of prevocational factors has brought the OT profession full circle (see Chapter 14). Although regarded as a cornerstone of the profession in its early years, prevocational evaluation was neglected in many centers during the 1960s and 1970s. Since the early 1980s, however, occupational therapists have rediscovered a need that their profession is in a unique position to provide. The term prevocational evaluation ambiguously implied that occupational therapists were involved in assessing the vocational needs of clients they treated. The terms functional capacity evaluation (FCE) and work tolerance screening (WTS) more clearly describe the process of measuring an individual's ability to perform the physical demands of work.

The results of the FCE allow the therapist, worker, physician, and vocational counselor to establish a specific, attainable employment goal using reliable data. This approach relieves the physician of the responsibility of returning the client to work without objective information about the client's ability to do a job. It also allows the client to test his or her own abilities, which may result in increased self-confidence about returning to work.

Many techniques have been proposed for performing an FCE.[91] Some basic steps may be followed regardless of the specific technique adopted. The client should be evaluated for grip and pinch strength, sensation, and ROM. Edema and pain must also be assessed and reassessed during the course of the evaluation.

Job analysis may also be provided by a rehabilitation counselor and through information provided by the client. The therapist should consult the *Dictionary of Occupational Titles* (DOT)[100] to obtain information about the worker traits required for the expected job. This dictionary contains 12,900 job descriptions and 20,000 job titles. If sufficient information about the job is not available through these methods, an onsite job analysis by the therapist may be necessary. Once the physical demand characteristics of work have been documented, the client's ability to perform them can be evaluated. The U.S. Department of Labor sponsors the Occupational Information Network online (http://online.onetcenter.org), which includes job titles and job accommodations and allows the user to search for job information using several criteria.

Schultz-Johnson described an FCE adapted for UE injuries based on the physical demands established by the U.S. Department of Labor.[91] After the evaluation the therapist may recommend a work therapy program,[91] which can include simulated job tasks, to improve job performance.

Matheson has written several manuals and articles describing the work capacity evaluation (WCE).[75] This 8- to 10-day work assessment includes evaluation of the client's feasibility for employment (worker characteristics, such as safety and dependability), employability, work tolerances (e.g., strength, endurance, and the effect of pain on work performance), the physical demand characteristics of the job, and the worker's ability to "dependably sustain performance in response to broadly defined work demands."

Tests with well-accepted reliability (e.g., the Purdue Pegboard Test, the Minnesota Manual Dexterity Test, and the Jebsen Hand Dexterity Test) may be administered as a screening process.[28–90] These tests will give the therapist valuable information through observation, whether the normal tables are used or the test is adapted to an individual worker.

Many assessments and job simulation devices are available, and these should be reviewed before a physical capacity evaluation program is established. To choose appropriate work samples, the therapist should determine the job market in a specific area. This can be done by consulting rehabilitation counselors and representatives from vocational schools and employment agencies in the area.

Work samples (e.g., Valpar work systems) may be used to test specific skills. The therapist may also develop job samples by using information about jobs in the local area. Discarded electronic assembly boards, a lawn mower motor, an automobile engine, or other items from the local hardware store may provide valuable information about the worker's abilities.

Work simulation using job samples or the BTE Work Simulator assess the worker's specific physical capacities, in addition to endurance and symptoms that become cumulative with prolonged use of the injured part (called symptom response to activity [SRA]). Monitoring the client's SRA may prevent loss of time and money spent on training a client for an inappropriate vocational goal. A combination of normed tests, job samples, job simulation, and WCE devices may provide the therapist with the best information about a worker's physical capacity.

Work Hardening

Work hardening is the progressive use of simulated work samples to increase endurance, strength, productivity, and often feasibility. Work hardening may be performed for a period of weeks, and the progressive, ongoing nature of the work usually improves physical capacity. A work hardening program is an important contribution to return to work.

Because an FCE also is performed over time, identifying the difference between an FCE and work hardening may be difficult. An FCE generally is done when the client has stopped improving with traditional therapy methods and may have been released from acute medical care. The client may be unable to return to his or her former employment, or the client's ability to do the former work may be in doubt. A physician, rehabilitation counselor, insurance adjustor, or attorney may initiate an FCE.

Work hardening or work conditioning may be started earlier in the rehabilitation process, perhaps by the treating physician or a therapist who recognizes that an individual may have difficulty returning to his or her former employment. These services are performed before the end of medical care, and the evaluation results may serve as a final checkout before intervention is discontinued.

Standards for work hardening services have been developed by the Commission on Accreditation of Rehabilitation Facilities (CARF)[28] to ensure that injured workers are offered high-quality programs that are maximally effective in returning them to gainful employment. Roy Matheson and Associates[75] offers many publications and resources for therapists interested in establishing WCE, work tolerance screening, or work hardening services.

FCE and work hardening are adjuncts to the vocational rehabilitation process. Occupational therapists are trained to observe behavior, and they have the skills necessary to translate that observation into useful data. FCE and work hardening should not compete with the work of rehabilitation or vocational counselors; instead, they should provide critical information about a worker's physical functioning and foster reentry into the job market.

Consultation With Industry

Occupational therapists may be asked to visit the job site to make recommendations for **ergonomic** adaptations, including tool modification, ergonomic furniture and accessories, and training of workers in proper positioning to reduce the incidence of CTDs. Because prevention substantially reduces the costs to industry, occupational therapists have a unique opportunity to apply their training in activity analysis and adaptation of the environment in a new setting. The Americans with Disabilities Act (ADA) mandates reasonable accommodations for workers with disabilities. Many occupational therapists have become active in helping companies comply with the requirements of the ADA. The American Occupational Therapy Association is an excellent resource for information about the ways therapists can be involved in these efforts in their communities (also see Chapter 15).

Psychosocial Effects of Hand Injuries

After a hand injury a number of psychosocial reactions may occur. To name but a few, these may include a change in body image and self-image, depression, anxiety, and a decrease in self-worth (as experienced by Gerry, the cabinetmaker in the case study whose fingers had been amputated and then surgically replanted). With traumatic hand injuries acute stress disorder and post-traumatic stress disorder are not uncommon and can be problematic for the client, especially if they are not addressed promptly. The hand therapist often is the primary contact for a client after injury and may see the client several times a week on a one-to-one basis. Therefore, the hand therapist plays a very important role in helping the client return to preinjury physical and emotional functioning. Occupational therapists who specialize in hand therapy provide the client with an important source of emotional support. However, they also play a critical role in recognizing psychosocial issues the client may be having; they are educated in evaluating and providing intervention for these issues; and, when necessary because of the severity of the problem, they are capable of facilitating referral to an appropriate mental health professional.

Summary

This chapter has provided an overview of interventions for UE disorders. Evaluation procedures were discussed, in addition to the basic intervention techniques. Management of both acute injuries and cumulative trauma was included, as was information on strengthening and programs for industrial injuries. Most occupational therapists working with physical disabilities should be familiar with the basic UE intervention approaches described because they work with clients who have some limitation in those parts of the body. Specialization in hand therapy requires both advanced academic study and clinical experience. A therapist who specializes in this area of practice and who meets minimum requirements may choose to take the Hand Therapy Certification Examination and become a Certified Hand Therapist (CHT). More information is available from the Hand Therapy Certification Commission (http://www.htcc.org)[55]; and links to educational resources also are available on this website. Another valuable resource is membership in the American Society of Hand Therapists ((http://www.asht.org).

Much of UE rehabilitation involves the use of preparatory methods, such as exercise, orthotics, and physical agent modalities, and these interventions should be used to prepare the client for purposeful or occupation-based activities. The goals always are to help the client become as independent as possible and to use these preparatory methods to achieve the client's occupation-based performance goals. Purposeful activity is used whenever possible in the hand clinic, according to space and time constraints, and clients are encouraged to use their new skills in their own home or work contexts and to bring back to the clinic information about the obstacles they have experienced in achieving their performance goals.

Threaded Case Study

Gerry, Part 2

The case study presented at the beginning of this chapter described Gerry, a 32-year-old cabinetmaker with an acute, complex hand injury involving amputation and surgical replantation of three digits. Gerry progressed through all phases of rehabilitation over the course of 15 months, from the acute hospital stay to return to work and play activities. Based on the case presented, how would the intervention plan change over the course of Gerry's recovery, and what specific intervention approaches could his occupational therapist use?

During the acute phase, one of the therapist's goals was to promote and maintain the health of the client's unaffected joints, which were vulnerable to becoming stiff from protective posturing. Another goal during the acute phase was to prevent further injury or abnormal joint changes to the left hand. ROM exercises were administered to maintain the healthy function of the client's unaffected joints (e.g., the shoulder and the elbow), and a protective orthosis was fabricated to place Gerry's hand in a protective and functional position of mild wrist flexion, MP flexion, and IP extension. During this phase of recovery, education was an important component of Gerry's intervention plan. He was taught appropriate postoperative precautions and orthosis wear and care; his family members were educated in wound care, dressing changes, and signs of infection. Gerry also was given written material about this home program.

During the intermediate phase of Gerry's recovery the intervention approach was to restore AROM and PROM, strength, and coordination to his hand so that he could return to his previous occupations (specifically, cabinetry, golf, and softball). The ROM activities were graded, and motion was progressively added as the tendons, nerves, and vessels healed. Strengthening exercises were added during the late phase of recovery, and at this point Gerry could safely attempt to return to his previous activities. Also at this time purposeful and occupation-based activities were added to Gerry's therapy regimen; Gerry's areas of occupation had to be modified to account for the loss of mobility, strength, and coordination in his hand. He was taught one-handed ADLs during the acute phase of recovery so that he could be self-sufficient until he regained the use of his left hand. Modifications to his activity demands were also implemented, such as enlarging the handles of his golf clubs to compensate for the lack of full finger ROM during the intermediate to late phases of recovery. Gerry was taught to prevent further injury to his hand through visual compensation techniques for loss of sensation, to monitor for signs of infection, and to follow postsurgical precautions during the acute phase of his injury.

Throughout Gerry's rehabilitation a variety of assessment tools were used to review his performance skills so as to identify barriers to performance. A grip dynamometer, pinch meter, and manual muscle tests were used to assess grip, pinch, and muscle strength. A goniometer was used to assess ROM, and Semmes-Weinstein monofilaments were used to assess sensation. A volumeter and circumferential measurements were used to assess edema, and the Jebson Hand Function Test was administered to assess the functional use of Gerry's hand in a standardized format. The evaluation data were then interpreted and the intervention plan modified to achieve the targeted outcomes.

Once the intervention plan had been established, various preparatory methods and purposeful activities were chosen to achieve Gerry's occupational goals. For the occupational performance goal of golfing, orthoses were used as a preparatory method during the intermediate phase of recovery to help Gerry gain PROM in stiff joints and increase overall flexion of the replanted digits, so that he could eventually hold a golf club. Physical agent modalities (e.g., paraffin and ultrasound) were applied before performance of purposeful activity during the intermediate and late phases of recovery. Gerry performed purposeful activities, such as swinging a golf club in the clinic and simulating a golf swing on the BTE Work Simulator, and the physical resistive demands of this golf swing were increased gradually. Gerry also practiced putting in the clinic, using special flexion gloves early on so that he could hold the golf club; later he progressed to wearing no gloves, but instead enlarging the handle of the golf club to facilitate a secure grip.

To address Gerry's occupational goal of returning to work as a cabinetmaker, a volunteer opportunity was arranged for him to participate in the purposeful activity of making wooden sliding/transfer boards and other assistive devices for clients in acute rehabilitation. Not only was this activity goal directed and directly related to his work occupation, but it also fulfilled Gerry's desire to use his talents in carpentry to help other clients in the hospital; this contributed to improving his feelings of self-worth. During the late phase of Gerry's recovery additional occupation-based activity was initiated to address his avocational interests. Outside the clinic, when Gerry actually played golf and softball, he was found to be hypersensitive in his palm over the scars. Desensitization techniques were added to his home program, and he purchased gloves with gel inserts to absorb the shock of hitting the ball.

Review Questions

1. A client is seen for a hand problem and is found to have limited or painful ROM of the shoulder. List three tests that should be performed.
2. Discuss three approaches to postoperative care of flexor tendon injuries and describe how the differences among the methods would influence the initiation of OT.
3. To what does "joint dysfunction" refer? What are its causes?
4. Discuss the three classifications of nerve injury.
5. Define the area referred to as "no-man's-land." What distinguishes injury to this area?
6. What techniques are used to evaluate the physical demand characteristics of work?
7. List three methods of applying pressure to a hypertrophic scar.
8. Which functional activities could be used to restore hand function after laceration and repair of the extrinsic finger flexors?
9. Which assessments should be included in a functional capacity evaluation?
10. List five tests used to assess joint integrity in the hand.
11. List three objectives of the use of orthotics for an injury of the radial, median, and ulnar nerves.
12. What are the characteristics of complex regional pain syndrome type I? What are the intervention goals?
13. Define work hardening. How can work hardening be incorporated into OT?
14. How is the presence of edema evaluated? List three methods used to reduce edema.
15. What are the primary work-related risk factors associated with cumulative trauma? How can the occupational therapist intervene to prevent the development of cumulative trauma?

Orthopedic Conditions

Hip Fractures and Hip, Knee, and Shoulder Replacements

Lynne F. Murphy, Sonia Lawson

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, the student or practitioner will be able to do the following:

1. Describe the etiology and medical management of hip fractures and hip, knee, and shoulder joint replacements and their effect on participation in occupations.
2. Identify precautions associated with hip fractures and joint replacements and their effects on intervention plans and occupational performance.
3. Outline client factors, performance patterns, and performance skills that are appropriate to include in the occupational therapy evaluation.
4. Develop occupational therapy goals that promote occupational engagement, utilizing information gained from the occupational profile and evaluation results.
5. Explain intervention procedures that incorporate precautions, ensure safety, and promote occupational performance in daily tasks.
6. Discuss the emotional and social impact of hip fractures and joint replacements on occupational performance and performance patterns.

KEY TERMS

Anterolateral approach

Arthroplasty

Codman's pendulum exercises
Degenerative joint disease
Hip precautions
Knee immobilizer
Minimally invasive technique
Open reduction and internal fixation
Osteoarthritis
Osteoporosis
Posterolateral approach
Shoulder sling and swathe
Weight-bearing restrictions

Introduction to Orthopedic Conditions

Hip fractures and lower extremity (LE) joint replacements are two orthopedic conditions that occur with a relatively high frequency. The Centers for Disease Control and Prevention (CDC) reported that more than 300 million hip fractures occurred in 2010, with the majority in older adults.[41] According to the American Academy of Orthopaedic Surgeons (2014), more than 1 million joint replacements were performed in 2011, with hip and knee replacements making up the majority.[23] Shoulder replacements total approximately 53,000 per year in the United States.[62] Age-related changes in older adults contribute most to falls resulting in hip fractures or the need to have a joint replaced. Persons who have been involved in activities or occupations that put great amounts of stress on their joints, over time, may experience pain and degeneration as they get older. In addition, older individuals are more likely to have orthopedic problems such as **osteoporosis** and arthritic joint changes as a part of the aging process. When joint problems occur at the hip, knee, or shoulder, in particular, temporary or more long-lasting disability may result. When individuals need to have these joints repaired, there is a period of time in which the joint is unstable, which limits an individual's participation in meaningful daily occupations. However, medical and rehabilitative advances continue to make orthopedic conditions easier to manage with less of an impact on occupational performance.

The elderly population is most at risk for hip fractures, primarily due to age-related changes in muscle strength, bone density, postural alignment, sensory function (eg, vision impairment, decreased proprioceptive awareness), and nervous system function.[32] Reduced balance, coordination, and mobility are potential risk factors for falls.[3] Postmenopausal women, in particular, develop osteoporosis to a greater degree than men and thus tend to have more hip fractures when they fall.[20]

Mobility is compromised in the elderly population because of decreased flexibility, diminished strength, reduced vision, decreased proprioceptive awareness, slowed reaction time, and the use of assistive ambulatory aids such as canes and walkers. Many elderly people become more cautious when moving about and are fearful of falling. This fear may contribute to more sedentary behavior, which can lead to further declines in strength and mobility. In some cases, individuals use a cane or walker improperly, which contributes to a fall. Not seeing a step or threshold may also cause a fall, as does tripping over items in the home (eg, throw rugs, cords).[60]

Individuals with a history of **osteoarthritis**, **degenerative joint disease**, or other rheumatic diseases that limit occupational performance are primary candidates for joint replacement. Individuals who elect to undergo these surgical procedures usually have been living with increasing pain in their joints for many months or years, and their ability to perform daily tasks is limited. By having the painful joint replaced, they hope to return to a more active and satisfying lifestyle. Occupational therapy (OT) plays a key role in identifying the many functional problems imposed by these acute and chronic orthopedic conditions and promoting compensatory or remediation approaches to facilitate the return of the orthopedic client to optimal performance of safe, independent, and meaningful occupations.

This chapter is divided into sections that include a discussion of hip fractures; hip, knee, and shoulder joint replacements; the associated medical and surgical management; and occupational therapy evaluation and intervention for these conditions. The *Occupational Therapy Practice*

Framework, Third Edition, is used to discuss the role of occupational therapy for persons with these conditions. Specific areas addressed in the chapter are occupational therapy evaluation of performance skills, occupational therapy interventions addressing specified occupations, the social and emotional implications of hospitalization and decreased functional abilities, and the interprofessional healthcare team approach in both the acute hospital and rehabilitation settings.

Emotional and Social Factors for the Orthopedic Patient

Attention to emotional and social issues is critical in the overall rehabilitation for the orthopedic client. Many clients in this population are faced with a chronic disability (eg, rheumatoid arthritis), a life-threatening disease (eg, cancer), chronic pain, or consequences of the aging process. The loss or potential loss of mobility and physical ability that limits participation in areas of occupation is a major concern for most of these clients. Adjusting to loss is stressful and requires an enormous amount of physical and emotional energy.[35] An awareness of and a sensitivity toward the psychosocial challenges of the person with an orthopedic problem are critical for the delivery of optimal client care.[48]

Clients with a chronic orthopedic disability often experience one or all of the following challenges: disease of a body part, fear, anxiety, change in body image, decreased functional ability, joint deformity, and pain. Interventions for a client with a chronic orthopedic condition must address these issues, especially in a preoperative phase or if a person chooses to decline surgery. The occupational therapy practitioner should be alert for signs of depression, guilt, anxiety, or fear that may impede participation in valued occupations. These emotions inhibit the client's progress and further damage the client's self-image. In a postoperative phase, clients may also experience pain, fear of operated extremity use, fear of falling, or unexpected delays in recovery that can also have detrimental effects on emotional health.[48]

Occupational therapists can help clients acknowledge and express emotional factors related to their condition, which can ultimately enhance the intervention process. One way to ease anxiety and fear is to make sure the client understands procedures and interventions, as well as the likelihood of a positive outcome. Taking time to answer questions and provide additional information can be crucial for successful adjustment. In addition, communication with the entire healthcare team is important to ensure that these emotional needs are considered in all aspects of healthcare management.

The elderly client experiencing disability deals with additional issues specific to the aging process, such as fear of dependence and relocation trauma. With the onset of a disability late in life, the client may be forced to let go of independence and self-sufficiency.[35] This can be a devastating experience for some clients, and prolonged grieving may be necessary before adjustment. Others may use dependence for secondary gain, remaining in the hospital for extra attention or manipulating their support systems to avoid taking responsibility for themselves and others. When individuals are removed from their familiar environment, confusion, disorientation, and emotional lability may result. Practitioners must take these factors into consideration when implementing an intervention plan and provide supports as needed.

Learning to cope and adjust to the changes resulting from chronic disability or the aging process is a critical aspect of recovery. Practitioners must realize that the client has relinquished a great deal of functional independence as a result of disease or disability. The occupational therapist must address the emotional and social issues resulting from this loss while focusing on maximizing the client's ability to participate in areas of occupation that are meaningful.[35]

OT Practice Notes

It is important for the occupational therapist working with clients who have orthopedic impairments or conditions to have a good understanding of the site, type, cause of the condition, any surgical procedures performed, and treatment precautions before starting the evaluation and intervention processes. A basic understanding of fracture healing and medical management procedures or protocols is also necessary to appreciate the risks, cautions, and implications to occupational performance. The occupational therapist is advised to review additional medical resources if more specific information is needed regarding surgical techniques and healing concerns.

Rehabilitation Team

Optimal rehabilitation for the orthopedic conditions discussed in this chapter requires coordination among the interprofessional team. Collaboration, communication, and clear role delineation among members of the interprofessional team are essential for an effective and efficient therapy program. In addition to the client, the team usually consists of a primary physician or surgeon, nursing staff, an occupational therapist or assistant, a physical therapist or assistant, a dietician, a pharmacist, caregiver, and a social worker or case coordinator. Many facilities have a protocol or critical pathway that outlines each team member's responsibilities and a time frame for accomplishing assigned tasks and goals related to the client's rehabilitation. Regular team meetings to discuss each client's ongoing progress and discharge plans are necessary for coordinating individual intervention programs. Members from each service usually attend each meeting to provide information and consultation. Clients are the most important members of the team. They are involved in goal setting and establishing a plan of care, and they must be able to engage in the interventions specified by other team members. Informal caregivers (eg, spouses, partners, significant others) should be considered part of the healthcare team, as they provide a good deal of care at home once the patient is discharged. Oftentimes restrictions and protocols must be followed weeks after joint repair, and the caregiver is responsible for ensuring those directions are followed in the home setting.

The role of the physician or surgeon is to manage medical needs and inform the team of the client's medical status. This includes information regarding medical history, diagnosis and treatment of the present problem, and information regarding the surgical procedure performed. The physician specifies any precautions or contraindications that all members of the team must enforce. Information provided may include the type of fixation or prosthesis inserted, the anatomic approach used in the surgery, weight bearing or other types of precautions, and contraindications such as movements that could endanger the client or impede healing. The physician is also responsible for ordering specific medications, overseeing the client's medication regimen, and directing pain-management approaches. The physician orders specific therapies and approves any change in the therapy program resulting from a change in the client's medical status.

The nursing staff is responsible for the physical care of the client during hospitalization, including care and monitoring of the surgical incision and administering prescribed pain medication according to the established pain management protocol. The orthopedic nurse must have a thorough understanding of the surgical procedures and movement precautions for each client. The nurse takes care of proper positioning using pillows and wedges, especially in the first few days after surgery. As the client's therapy program progresses, the client starts to take more responsibility for proper positioning and physical care. The nurse works closely with occupational and physical therapists and caregivers to carry through self-care and mobility skills that the client is learning in therapy.

The physical therapist is responsible for evaluation and intervention in the areas of musculoskeletal status, sensation, pain, skin integrity, and mobility (especially gait and bed mobility). In most cases involving joint replacement and surgical repair of hip fracture, physical therapy is initiated on the first day after surgery along with occupational therapy. Adhering to the prescribed precautions of the protocol, the physical therapist obtains baseline information, including range of motion (ROM), strength of all extremities, muscle tone, and mobility. A treatment program that includes therapeutic exercises, ROM activities, transfer training, and progressive gait activities is established. The physical therapist is responsible for recommending the appropriate assistive device to be used during ambulation. As the client's ambulation status advances, instruction in stair climbing, managing curbs, and outside ambulation is given.[25,38] In the case of shoulder replacements, the physical therapist implements mobility training that allows the client to protect the shoulder, works with occupational therapy to prevent movement that is not permitted, and may progress the client through the postsurgery protocol gradually increasing ROM and strength of the shoulder.

The dietician consults with each client to ensure that adequate and appropriate nutrition is received to aid the healing process. The pharmacist monitors the client's pain management and medication routine and provides information and assistance to clients and their caregivers regarding any medications to be continued at home after discharge.

The role of the case coordinator is to ensure that each client is being discharged to the appropriate living situation or facility and the availability of durable medical equipment as recommended by physical and occupational therapy practitioners. The case coordinator is usually a registered nurse or social worker with a thorough knowledge of available community resources and nursing care facilities. With input from the healthcare team, the case coordinator works with caregivers to make arrangements for ongoing therapy after acute hospitalization, for admission to a rehabilitation facility or skilled nursing facility for further intensive therapy if needed, or for home healthcare as appropriate. The case coordinator works closely with the interprofessional team and is instrumental in coordinating discharge plans.

The occupational therapist is concerned primarily with improving performance in daily activities and meaningful occupations but may also create exercise programs to address limitations in specific neuromusculoskeletal body functions/client factors as a basis for occupational performance. Focus is placed on safe execution of functional mobility, performance of activities of daily living, and performance of instrumental activities of daily living. The specific role of the occupational therapist will be discussed in detail in each of the following sections.

Section 1 Hip Fractures and Replacement

Threaded Case Study

Mrs. Hernandez, Part 1

Mrs. Hernandez, a 70-year-old Latina grandmother to three small children, fell outside of the senior center that she attends three times a week for exercise. She sustained a femoral neck fracture of her right hip. Prior to the fall, she had been experiencing increasing right hip pain due to osteoarthritis and degenerative joint disease, and she was concerned about increasing weakness in the right leg. She remembers not lifting her right leg high enough to clear the entrance step to the center where she tripped up the steps, and she was unable to catch herself and fell on her right hip. The fracture was repaired with a total hip replacement that was performed using an anterior approach, minimally invasive procedure. Movement precautions include no hip extension or crossing the legs and weight bearing as tolerated on the right lower extremity. Mrs. Hernandez is usually very active; she attends swimming classes twice a week, helps her daughter care for her three children, and heads two committees at her church. These activities became important to her after her husband died 5 years ago. They give her a sense of purpose and help her feel connected with others. Mrs. Hernandez lives alone in an apartment with elevator access. Her daughter and grandchildren live 15 minutes away and often visit and involve her in many of their family activities.

Mrs. Hernandez was referred for occupational therapy because of her difficulty with functional mobility and completing her daily activities. When asked about what bothered her most about her fall and subsequent hip replacement, she said that she was worried that she would no longer be able to participate in the swimming classes she enjoys so much, nor would she be able to drive herself to all of her appointments and church-related activities. This would make her dependent on her children and church friends. She was afraid of losing her independence, which she valued greatly. She is hoping that the occupational therapy she receives will help her drive again as soon as possible and allow her to remain as independent as possible so that she is not a burden to anyone.

Critical Thinking Questions

1. When completing the occupational profile, what additional information would the occupational therapist need to gather during the evaluation to supplement the information already provided in the case scenario?

2. Identify important areas of occupation and performance skills to address first when educating Mrs. Hernandez to safely perform her daily activities.

3. What prerequisite performance skills should be addressed with Mrs. Hernandez before the occupational therapist directly addresses her ability to drive again?

General Medical Management of Fractures

In general, a fracture occurs when the bone's ability to absorb tension, compression, or shearing forces is exceeded.[22] The healing process begins after the fracture. Osteoblasts, cells that form bone, multiply to mend the fractured area. Adequate blood supply is necessary to supply the cells with oxygen for proper healing. The fracture site may be protected during the postsurgical healing process by internal fixation, such as pins, plates, screws, or wires. In rare cases in which extra protection is needed, an external abduction brace may be used for the hip. This metal brace extends around the pelvis and down the thigh of the fractured hip and prevents movement, especially hip abduction, according to settings determined by the orthopedic surgeon. Other types of braces or casts may be used for fractures of other parts of the lower extremity (eg, a **knee immobilizer**). It may take several months for a bone fracture to heal completely. The time needed varies with the age, health, and nutrition of the client; the site and configuration of the fracture; the initial displacement of the bone; and the blood supply to the fragments.

Etiology of Fractures

Trauma is the major cause of fractures. In most cases, the trauma occurs as a result of falling. Poor lighting, throw rugs, and unmarked steps are environmental hazards that can lead to a fall. Osteoporosis is a bone disease that typically results in decreased bone density, most commonly in the vertebral bodies, the neck of the femur, the humerus, and the distal end of the radius. Because the bone becomes porous and therefore fragile, the affected bones are prone to fracture as a result of a fall or other traumatic event. A pathologic fracture can occur in a bone weakened by disease or tumor, as with osteomyelitis and cancers that have metastasized to the bone.[22]

Medical and Surgical Management

The goals of fracture management are to relieve pain, maintain good position of the bone, allow fracture healing, and restore optimal function to the client. Reduction of a fracture refers to restoring the bone fragments to normal alignment.[22] This can be done by a closed procedure (manipulation) or by an open procedure (surgery). The physician performs a closed reduction by applying force to the displaced bone to realign the bone. Depending on the nature of the fracture, the reduction or realignment is maintained by a cast, brace, traction, or skeletal fixation. With open reduction, the fracture site is exposed surgically so that the bone fragments can be aligned. The fragments are held in place with internal fixation such as pins, screws, a plate, nails, or a rod. Further immobilization by a cast or a brace may be deemed necessary by the orthopedic surgeon. Closed reductions and **open reduction and internal fixation** (ORIF) must be protected from excessive forces during bone healing. Therefore **weight-bearing restrictions** may be indicated.[22]

There are several levels of weight-bearing restrictions. The physician indicates at which level the client should be placed based on the surgical technique selected and the stability of the surgical repair. Elderly clients may not have the upper extremity strength to support their body during non-weight-bearing precautions. The surgeon may take this into account and use a more stable procedure to allow the client to bear weight at tolerance (WBAT) through the operated leg, thereby sparing overexertion of the upper extremities. Restrictions are reduced as the fracture site heals and becomes stronger.[15] The levels of weight-bearing restrictions are listed in Box 40.1.

Box 40.1

Weight-Bearing Restrictions

NWB (non–weight bearing) indicates that no weight at all can be placed on the extremity involved.

TTWB (toe-touch weight bearing) indicates that only the toe can be placed on the ground to provide some balance while standing—90% of the weight is still on the unaffected leg. In toe-touch weight bearing, clients may be instructed to imagine that an egg is under their foot.

PWB (partial weight bearing) indicates that only 50% of the person's body weight can be placed on the affected leg.

WBAT (weight bearing at tolerance) indicates that clients are allowed to judge how much weight they are able to put on the affected leg without causing pain that may limit function.

FWB (full weight bearing) indicates that clients are able to put 100% of their weight on the affected leg.[30]

Types of Hip Fractures and Medical Management

Knowledge of hip anatomy is necessary for understanding the medical management of hip fractures. An anatomy and physiology reference text should be consulted for details. Figs. 40.1 and 40.2 illustrate a normal hip joint and the common locations and directions of fractures (fracture lines). The names of the fractures generally reflect the site and severity of injury and may signal the form of medical treatment that will be used. For example, a femoral neck fracture will typically be treated with femoral neck stabilization.[50]

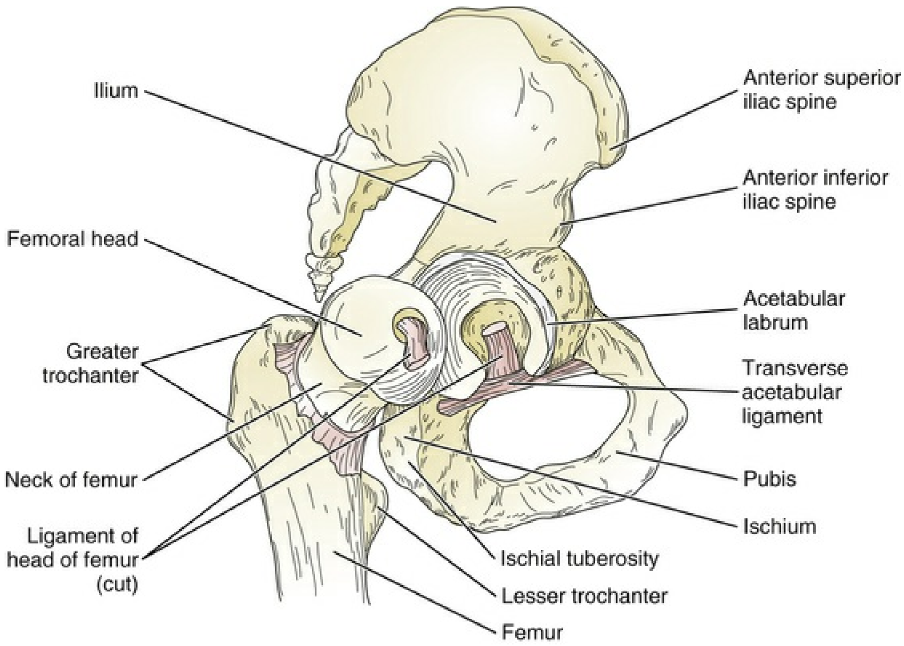

FIG 40.1 Normal hip anatomy. (From Reese NB, Bandy WD: *Joint range of motion and muscle length testing,* ed 3, St. Louis, 2017, Elsevier.)

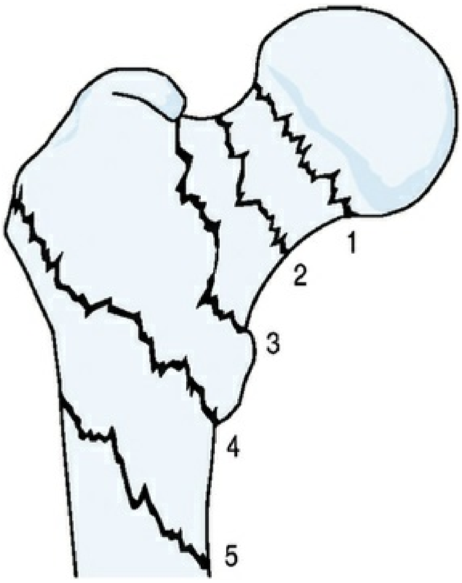

FIG 40.2 Levels of femoral fracture. 1, Subcapital. 2, Transcervical. 3, Basilar. 4, Intertrochanteric. 5, Subtrochanteric. (From Porter S, editor: *Tidy's physiotherapy,* ed 15. 2013, Churchill Livingstone, Elsevier.)

Femoral Neck Fractures

Femoral neck fractures, which include subcapital, transcervical, and basilar fractures, are common in adults over 60 years old and occur more frequently in women. If the bone is osteoporotic, fracture may result from even a slight trauma or rotational force.[35] Treatment of a displaced fracture in this area is complicated by poor blood supply, osteoporotic bone that is not suited to hold metallic fixation, and a thin periosteum covering the bone. The type of surgical treatment used is based on the amount of displacement and the vascular supply in the femoral head as well as the age, health, and activity level of the client.

Internal fixation or hip pinning (application of a compression screw and plate) is generally used when displacement is minimal to moderate and blood supply is intact. With a physician's approval, a client is usually able to begin limited out-of-bed activities 1 day after surgery. Per physician's orders, weight-bearing restrictions may be necessary, with the aid of a walker or crutches for at least 6 to 8 weeks while the fracture is healing. Weight bearing may be limited beyond this time if precautions are not observed or if delayed union occurs.[50]

With severe displacement or in the case of a femoral head with poor blood supply (avascular), nonunion (a poorly healing fracture site where new bone does not form), and degenerative joint disease, the femoral head is surgically removed and replaced by an endoprosthesis (referred to more simply as prosthesis). This joint replacement is called a hemipolar **arthroplasty**, often referred to as a hemiarthroplasty.[38,50] Several types of metal prostheses can be used for a hemiarthroplasty; each has its own shape and advantages to best fit the client's size. Weight-bearing restrictions are sometimes indicated. Surgeons may also choose to perform a total joint replacement depending on the integrity of the joint and anticipated activity level of the client. A total hip replacement may offer better patient satisfaction and functional outcomes for people who are very active.[12] Depending on the surgical procedure used with a hemiarthroplasty or total hip arthroplasty (replacement), posterolateral or anterolateral approach, specific precautions for positioning the hip must be observed to prevent dislocation. These precautions are the same as those advised for a total hip replacement, which will be outlined later in this chapter. Clients with a hemiarthroplasty or total hip replacement can usually begin limited out-of-bed activity, with a physician's approval, about 1 day after surgery.[38,50,56]

Intertrochanteric Fractures

Fractures between the greater and lesser trochanter are extracapsular, or outside the articular capsule of the hip joint, and the blood supply is not affected. Like femoral neck fractures, intertrochanteric fractures occur mostly in women but in a slightly older age group. The fracture is usually caused by direct trauma or force over the trochanter, as in a fall. The preferred treatment for these fractures is an ORIF. A nail or compression screw with a side plate is used. Weight-bearing restrictions must be observed according to the surgeon's orders for up to 6 to 8 weeks during ambulation, with gradual increases in the amount of weight taken through the affected leg over this time.[15] The client is allowed out of bed 1 day after surgery, pending the physician's approval.[50]

Subtrochanteric Fractures

Subtrochanteric fractures 1 to 2 inches below the lesser trochanter usually occur because of direct trauma, as in falls, motor vehicle accidents, or any other situation in which there is a direct blow to the hip area. These fractures make up 10% to 30% of hip fractures and are most often seen in persons younger than 60 years old or in older clients with severe osteopenia (significant bone loss) who have a low velocity fall.[43] These fractures can be the most challenging to repair due to the muscle attachments in this area that can cause forces on the fracture site, impairing proper fracture healing.[17] An ORIF is the usual treatment. A nail with a long side plate or an intramedullary rod is used. An intramedullary rod is inserted through the central part of the shaft of bone to help maintain proper alignment for bone healing.[22]

In all types of hip fractures, the practitioner should observe for and address any subsequent issues from the hip fracture that can impact the rehabilitation process and the client's ability to regain the skills needed to complete daily activities. Such issues can be reactions of the body to the surgery such as soft-tissue trauma, edema, and bruising that occur around the fracture or surgical site.[22,38,50] These issues can greatly affect the amount of pain and discomfort that a client may experience.

Fall Prevention

Another issue that frequently occurs for older adults after hip fracture due to a fall is fear of falling. Frequent falls in older adults can signal to the client and family members that there is a decline in function, which could lead to changes in independence and performance of desired and valued occupations. Psychologically, the client with frequent falls may fear the loss of independence and hide falls from others or under-report the number of falls that have occurred over time. A fear of falling may also lead older adults to reduce their activity level so as not to put themselves in a position to fall in the community. They stay in places that are familiar and risk social isolation and further decreases in strength and mobility. These functional decreases can lead to more falls.[60] It is important for the interprofessional team to be attuned to clues related to fall history for the client and potential negative psychosocial reactions to the fall.

Occupational therapists can work with other team members to provide fall prevention education and training. Occupational therapists can teach adaptive strategies, make environmental recommendations, explore community resources, and teach exercises that address strength, mobility, and balance. Physical therapists can also address fall prevention through therapeutic exercise and teaching correct use of an appropriate assistive device for ambulation. Information regarding local community-based fall prevention programs can be provided to the client and family. These programs, typically held at area senior centers, include education and exercise classes specifically geared to improving the body structures and functions that help reduce the risk of falling.[16] The Stopping Elderly Accidents, Deaths and Injuries (STEADI) Program obtained through the CDC is one example of a comprehensive fall prevention program. Materials and resources for professionals and the community can be accessed from the CDC website.[16]

Hip Joint Replacement

Etiology and Medical Management

Restoration of joint motion and management of pain by total hip replacement, also called arthroplasty or bipolar arthroplasty, is sometimes indicated when a person experiences decreased occupational performance often due to chronic disease processes. Common examples are osteoarthritis, degenerative joint disease, or rheumatoid arthritis, although other rheumatic and systemic diseases may also be present. Osteoarthritis and degenerative joint disease may develop spontaneously in middle age and progress as the normal aging process of joints accelerates. Degenerative changes may also develop as the result of trauma, congenital deformity, or a disease that damages articular cartilage. Weight-bearing joints such as the hip, knee, and lumbar spine are usually affected. In the hip, there is a loss of cartilage centrally on the joint surface and formation of osteophytes on the periphery of the acetabulum, producing joint incongruity. Pain originates from the bone, synovial membrane, or fibrous capsule and from muscle spasm. When movement of the hip causes pain and limited mobility, the muscles shorten, which can result in a hip position of flexion, adduction, and internal rotation that causes a painful limp.[45]

Rheumatoid arthritis (RA) (see Chapter 38) may involve the hip joint but because RA affects smaller joints before larger joints in the body, the hip is typically not affected until later stages of RA. Arthroscopic surgery can be performed early in the disease process to limit fibrotic damage to the joint and tendon structures.[22] However, once there is significant joint damage, a hip replacement may be the only alternative. Other disease processes (eg, lupus and cancer) and some medications (eg, corticosteroids such as prednisone) can compromise the blood flow to the hip joint and lead to avascular necrosis (AVN, a condition in which bone cells die because of poor blood supply) or osteoporosis; either condition results in a painful hip.[45]

When conservative forms of management for the pain and decreased mobility (eg, cortisone injections, modified activity, pain medication) are no longer successful, a total joint replacement is considered to restore an individual's ability to more fully participate in daily occupations. Consideration of the total joint replacement relies on a client's ability to comply with a rehabilitation program, the probability of a positive outcome given other medical issues the client may be facing, and the probability of a significant improvement in functional ability.[38,39] There are two mechanical components to this type of prosthesis. A high-density polyethylene socket is fitted into the acetabulum, and a metallic or ceramic prosthesis replaces the femoral head and neck. Methylmethacrylate or acrylic cement fixes the components to the bone (Fig. 40.3). Hip replacements can last for 15 to 20 years or more before a revision is needed to insert a new prosthesis. Wear and tear on the hip prosthesis is greater for more active people, who may then require a revision sooner than for those who are more sedentary. Those who have their hip replaced at a young age will likely have to undergo a revision in later years.[37]

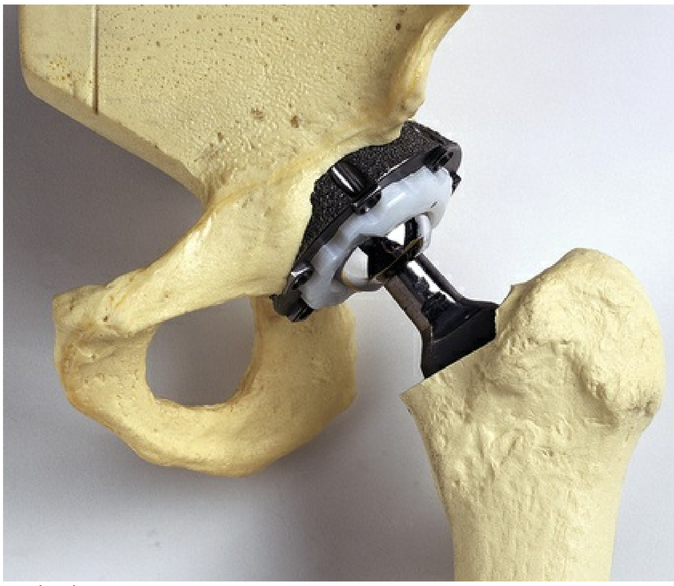

FIG 40.3 Hip prosthesis. (From Black J, Hawks J: *Medical surgical nursing: clinical management for positive outcomes*, ed 8, St. Louis, 2009, Elsevier.)

Various surgical approaches are used with the goal of choosing a technique that will provide the best stability for the client and reduces the occurrence of complications. The specific approach is selected based on the surgical skill or technique of the orthopedic surgeon, severity of the joint involvement, anatomic and biomechanical structure of the client's hip, and history of past surgery to the hip.[13,50] There are two main approaches, anterior and posterior, that indicate from which direction the surgeon opened the hip for the replacement. Both of these techniques have variations that involve the surrounding muscles of the hip to a greater or lesser degree. Muscles that must be displaced during the surgery are not able to support the joint postsurgery. This results in instability in certain directions of movement. With an **anterolateral approach**, the client will be unstable in external rotation, adduction, and extension of the operated hip and usually must typically observe precautions to prevent these movements for 6 to 8 weeks. Hip abduction may be prohibited as well with this surgical approach. It is important for the occupational therapist to carefully read the surgeon's postoperative orders. If a **posterolateral approach** is used, the client will be unstable primarily with hip flexion and must be cautioned not to move the operated hip past specific ranges of flexion (usually 90 degrees) and not to internally rotate or adduct the leg for 6 to 8 weeks. Failure to maintain these **hip precautions** during muscle and soft-tissue healing may result in hip dislocation (Box 40.2).

Box 40.2

Hip Precautions

Posterolateral Approach

- No hip flexion greater than 90 degrees
- No internal rotation
- No adduction (crossing legs or feet)

Anterolateral Approach

- No external rotation
- No adduction (crossing legs or feet)
- No extension

From Early MB: *Physical dysfunction: practical skills for the occupational therapy assistant*, St. Louis, 1998, Mosby.

In younger people, some surgeons may choose to replace the hip using a hybrid technique in which the acetabular socket is not cemented but the femoral component is cemented. In this case,[17] the use of biologic fixation (bony in-growth instead of cement) secures the prosthesis. This can increase the strength of the fixation at the prosthesis interface and can also decrease the possibility of loosening the prosthesis. In other words, new bone grows into openings in the prosthesis, and this secures the prosthesis to the bone. This noncemented approach can be used for both components of the prosthesis. The precautions following the surgery are identical to those of the anterior or posterior hip replacements, but they may involve an additional restriction on weight bearing.[38]

Many orthopedic surgeons use a **minimally invasive technique** to perform the posterolateral and anterior approaches for hip replacement. This technique reduces the amount of trauma to the muscle and soft tissue structures and allows for faster recovery. The traditional posterolateral surgical technique requires that a long (about 10 inches) incision be made and muscles detached to get to the hip joint. In the minimally invasive technique, two incisions of approximately 2 inches are needed and no detachment of muscles is required. Because no muscles are detached, the hip is more likely to remain in a stable position during the healing process. Similarly, for an anterior approach, a small vertical incision is made on the anterior surface of the hip joint with the hip placed in hyperextension. In addition to a faster recovery, this particular technique minimizes the risk of dislocation and postoperative limp.[46,50] The minimally invasive techniques are not appropriate for all total hip replacements or arthroplasties. Persons with severe damage to the hip joint or who have anatomic or biomechanical contraindications will require the traditional surgical method. Hip precautions that are identified for the posterolateral and anterolateral approaches are indicated for persons receiving a minimally invasive technique.[55]

To reinforce use of proper hip precautions during occupational performance and to guide intervention and discharge planning, the occupational therapist must know the type of surgical procedure that was performed. For example, someone with a hip replacement in which the minimally invasive technique was used may tolerate more activity after surgery than someone who underwent the traditional surgical technique. Clients with total hip replacements usually begin out-of-bed activity the same day of the surgery or the day after.

Hip resurfacing is another method of repairing a damaged and painful hip. This technique, less commonly used and with mixed evidence for efficacy over a total hip replacement, is a variation of the total hip replacement.[45] Designed for younger clients, the resurfacing technique preserves more of the bone of the femur should a total hip replacement be needed in later years. The surface of the femoral head is reshaped and then capped by a metallic shell. The acetabular cavity also receives a metallic cup or socket. Both are held in place by methylmethacrylate (acrylic cement). This technique preserves the femoral head and neck. With this technique, no weight-bearing restrictions apply.[18,45]

In summary, the occupational therapist must be informed of the surgical technique, movement precautions, and weight-bearing restrictions before beginning the evaluation and intervention of clients recovering from hip replacement surgery. Restrictions on weight bearing for any of the techniques vary in terms of amount of pressure and length of time, and the orthopedic surgeon will specify these limits. A walking aid, usually a walker or crutches, is necessary for at least the first month while the hip is healing and muscles are becoming stronger.[38] The occupational therapist has the responsibility of working with the inter-professional team to educate clients about their hip precautions and restrictions to allow the surgery to heal optimally without adverse effects such as dislocation. A joint that becomes dislocated may need additional surgery for repair. Strategies for completing daily tasks during the recovery process are implemented that allow the client to retain as much independence as possible while maintaining hip precautions and weight-bearing restrictions.

Special Considerations for Hip Replacements

Individuals with joint changes that increase pain may have multiple joint involvement (ie, both knees or hips, shoulders). With less frequency than for knee replacements, some clients opt to have two hip joints replaced during the same hospitalization, with procedures spaced apart by a few days. This can complicate the rehabilitation process because the client will not be able to rely on the nonoperated leg when walking, transitioning between seated and standing positions, and performing daily occupations.

It is important for the occupational therapy practitioner to be aware of complications or special procedures that occurred during a client's surgery and to verify precautions or risks with the physician. Surgeons will make specific recommendations based on the client's particular situation, surgical procedures used, or postoperative concerns. Common complications that can occur days or months after the surgery include dislocation of the hip joint, degeneration of the components of the prosthesis, fracture of bone next to implanted parts, loosening of prosthetic parts, and infection of the joint after surgery. A special procedure for individuals at high risk for a hip dislocation after surgery involves using an abduction brace to immobilize the hip joint.[22] This brace adds extra movement restrictions to the performance of daily tasks. Worn component parts, bone fractures, and sometimes dislocations must be repaired surgically. Additionally, clients with hip replacements are required to take prophylactic antibiotics for any future dental work or surgery to prevent infection at the joint replacement site.[47] The implantation of metal and plastic parts makes that area more susceptible to infection. Individuals living with a hip replacement must manage this chronic situation for the rest of their lives.

Postsurgical pain is often managed with a regimen of medications, such as epidural or periarticular anesthetics, patient-controlled analgesia, oral analgesics or opioids, or peripheral nerve blocks, although side effects and effectiveness are variable with individual clients. The pain may be caused by the trauma to soft tissues, edema surrounding the hip joint that places pressure on the incision, or improper positioning. Many hospitals that have a coordinated joint replacement program implement a pain management program in which clients receive regular and timely pain medication to allow optimum recovery and participation in their rehabilitation program. Other methods of pain control amenable to use by rehabilitation professionals include the use of superficial cold modalities, proper positioning during transitional movements, and a balance of rest and activity.

Medical Equipment

The OT practitioner should be familiar with the following equipment that is commonly used in the treatment of hip fracture and total hip replacement:

Hemovac. During surgery, a plastic drainage tube is inserted at the surgical site to assist with postoperative drainage of blood. It has an area for collection of drainage and may be connected to a portable suction machine. The unit should not be disconnected for any activity because this may create a blockage in the system. The Hemovac is usually left in place for 1 to 2 days after surgery.

Abduction wedge. Large and small triangular foam wedges (Fig. 40.4) are used when the client is supine to maintain the lower extremities in the abducted position.

FIG 40.4 Abduction wedge. (Courtesy Performance Health, Warrenville, IL.)

Balanced suspension. This is fabricated and set up by an orthopedic technician and can be used for about 3 days after surgery. It balances the weight of the elevated leg by weights placed at the opposite end of the pulley system. Its purpose is to support the affected lower extremity in the first few postoperative days. The client's leg can be taken out of the device for exercise only.[50]

Reclining wheelchair. A wheelchair with an adjustable backrest that allows a reclining position is used for clients who have hip flexion precautions while sitting.

Commode chairs. The use of a commode chair instead of the regular toilet aids in safe transfers and allows the client to observe necessary hip flexion precautions.

Sequential compression devices (SCDs). SCDs are used postoperatively to reduce the risk of deep vein thrombosis. They are inflatable, external leggings that provide intermittent pneumatic compression of the legs.[22]

Antiembolus hose. These are thigh-high elastic hosiery items that are worn 24 hours a day and removed only during bathing. Their purpose is to assist circulation, prevent edema, and thus reduce the risk of deep-vein thrombosis.[22]

Patient-controlled administration IV. Patient-controlled analgesia (PCA) is delivered through an IV; patient-controlled epidural analgesia (PCEA) is delivered through an epidural line. A prescribed amount of medication is programmed by the physician and nursing staff to allow the client to self-administer pain medication by pushing a button to inject a safe amount. When dosages have reached a limit, the machine will not administer medication even if the button is pushed.

Incentive spirometer. This portable breathing apparatus is used to encourage deep breathing and prevent the development of postoperative pneumonia.

Role of Occupational Therapy for Clients With Hip Fracture or Hip Replacement

After a hip replacement or surgical repair of a fractured hip, OT typically begins when the client is ready to start getting out of bed, usually the day of surgery or the following day. The actual time varies, depending on the age and general health of the client and on surgical events or medical complications involved. Before any physical assessment, it is important to introduce and explain the role of OT and complete an occupational profile. This profile involves gathering information regarding the client's occupational history, prior functional status in activities of daily living (ADLs) and instrumental activities of daily living (IADLs), descriptions of performance contexts (eg, home environment and social support available), and the client's goals. The goal of OT is for the client to maximize performance skills in daily occupations, with all movement precautions observed during activities. The role of the occupational therapist and assistant is to teach the client ways and means of performing daily occupations safely.[35]

Evaluation and Intervention

The occupational therapist's role is to assume responsibility for performing any assessments necessary for a complete evaluation. In addition to an occupational profile, an assessment of the psychosocial issues related to the surgery and the surgery's impact on the client's lifestyle is completed via interview. A baseline physical evaluation is necessary for determining whether any physical limitations not related to surgery might prevent functional independence. Performance skills and client factors such as upper extremity (UE) ROM, muscle strength, sensation, and coordination and status of cognitive skills are assessed before a functional evaluation is made, as these can impact the client's ability to fully participate in the rehabilitation program. Evaluation of activities of daily living, instrumental activities of daily living, and functional mobility is necessary for clinical reasoning and holistic intervention planning. During evaluation, it is also important to observe and document any signs of pain and fear at rest or during movement.

Based on evaluation results and a thorough clinical reasoning process, the occupational therapist creates an intervention program of functional activities that gradually enables the client to regain the abilities and skills necessary to participate in identified areas of meaningful occupation. The therapist introduces and trains clients in the use of assistive devices, proper transfer techniques, and ADL and IADL techniques while maintaining hip and weight-bearing precautions. An occupational therapy assistant may play a large role in this training. Both the occupational therapist and the occupational therapy assistant are involved in treatment planning, documentation, and discharge planning (including the recommendation of equipment and home exercise programs).

Client Education

Although hip fractures are never a planned occurrence, hip replacements are usually planned and scheduled to be performed on a specific date. Occupational therapists often provide education classes for individuals at risk for fractures and those planning joint replacement. As mentioned earlier in the chapter, for the person who may be at risk for falling, attending a class on fall prevention is a wise recommendation. Topics may include home modifications (eg, removal of throw rugs, telephone cords, and clutter), safe transfer techniques, use of public transportation, and community mobility tips. The person who is having an elective total joint replacement may benefit from a class offered before surgery that explains the surgical procedures and precautions, introduces assistive devices, describes the therapy process, and describes the typical recovery period so that the client can be best prepared.

Specific Training Techniques for Participation in Occupations

Some common assistive devices are useful for many people with hip fractures or hip replacements (Fig. 40.5). Helpful assistive devices or adaptive aids include a dressing stick, sock aid, long-handled sponge, long-handled shoehorn, reacher, elastic shoelaces, leg lifter, elevated toilet or commode seat, three-in-one commode, and shower chair or bench. Walker bags are helpful for people using walkers who need to carry small items from one place to another. The OT clinic should have samples of these devices that are available for client use during the intervention process.

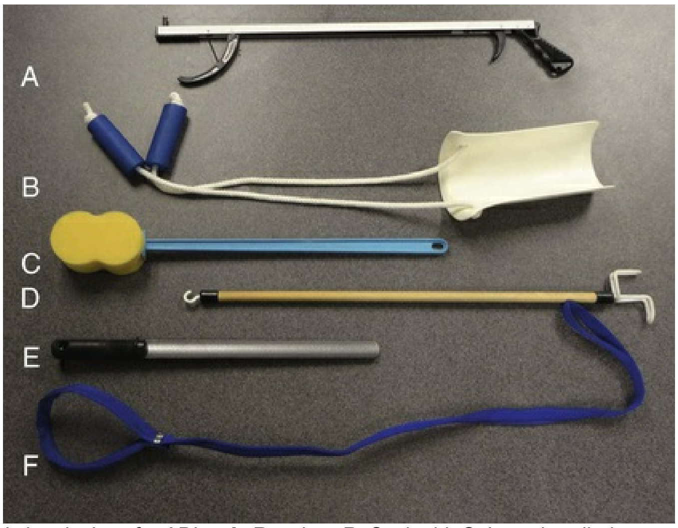

FIG 40.5 Assistive devices for ADLs. **A,** Reacher. **B,** Sock aid. **C,** Long-handled sponge. **D,** Dressing stick. **E,** Long-handled shoehorn. **F,** Leg lifter.

The training procedures outlined in the following sections apply to hip fractures and the different types of hip joint replacement. The positions of hip instability for the specific types of surgical procedures for hip replacement are important to remember. For the posterolateral approach (traditional or minimally invasive), positions of instability include adduction, internal rotation, and flexion greater than 90 degrees. For the anterolateral approach (traditional or minimally invasive), positions of instability include adduction, external rotation, and excessive hyperextension.

Bed Mobility

The supine position with an abduction wedge (see Fig. 40.4) or pillow in place is recommended in bed. If a client sleeps in the side-lying position, sleeping on the operated side is recommended if tolerable. When sleeping on the nonoperated side, the client must keep the legs abducted with the abduction wedge or large pillows supporting the operated leg to prevent hip adduction and rotation. The client is instructed in getting out of bed on both sides, although initially it may be easier to observe precautions by moving toward the nonoperated leg. Careful instruction is given to avoid adduction past midline. It is important to determine the type and height of the client's bed at home. When getting in and out of bed initially, the client may use a leg lifter to help the operated leg move from one surface to another. Some clients have an overhead trapeze bar placed on the bed to assist with bed mobility. It is important to wean the client away from using this device because he or she will most likely not have one at home.

The best procedure for moving from the supine position to sitting on the edge of the bed is to have clients support the upper body by propping up on their elbows, then moving the lower extremities toward the side of the bed in small increments, and following with the trunk and upper extremities (Fig. 40.6). The client should gradually turn in this manner until he or she can lower the legs out of the bed and push the trunk into the sitting position. Following a posterior approach hip replacement, the occupational therapist should observe the client when sitting to ensure that the client is not flexing the hip more than 90 degrees. If so, the client can extend the knee, which will cause the hip to be less flexed and widen the hip angle so that precautions are maintained.

FIG 40.6 Bed mobility.

Transfers

It is always helpful for the client to observe the proper technique for transfers before attempting the movement.

OT Practice Notes

One way to help therapists understand the impact of maintaining the proper hip position during the healing process is for the therapist to tape a goniometer to his or her own hip when positioned at 90 degrees and attempt to do the transfers listed next. Therapists will soon discover the difficulty of maintaining the proper hip position during functional activities!

Chair.

A firmly based chair with armrests is recommended. To move from standing to sitting, the client is instructed to back up to the chair, extend the operated leg forward, reach back for the armrests, and slowly lower to the sitting position. For the person with a posterolateral approach, care should be taken not to lean forward when sitting down (Fig. 40.7). To stand, the client extends the operated leg and pushes up from the armrests. Once standing, the client can reach for an ambulatory aid, such as a walker if it is being used. Because of the hip flexion precaution for the posterolateral approach, the client should sit on the front part of the chair and lean back (see Fig. 40.7). Firm cushions or blankets may be used to increase the height of chair seats and may be especially helpful if the client is tall. Low chairs, soft chairs, reclining chairs, and rocking chairs should be avoided.[1]

FIG 40.7 Chair/commode transfer technique. Client's right hip has the hip replacement. The nonoperated leg is used for weight bearing during sitting and standing from the chair/commode.

Commode chair.

Three-in-one commode chairs with armrests can be used in the hospital and at home (see Fig. 40.7). For the person with a posterolateral approach, the height and angle can be adjusted so that the front legs are one notch lower than the back legs; thus with the client seated, the precautionary hip angle of flexion is not exceeded. A person with an anterolateral approach may have enough hip mobility to use a standard toilet seat safely at the time of discharge. All clients should wipe between the legs in a sitting position or from behind in a standing position and use caution to avoid forward flexion of the hip greater than 90 degrees, or rotation of the hip. The client is to stand up and step to turn to face the toilet when flushing so as to avoid hip rotation.[1] Comfort height toilets (17-inch seat height) can be considered for installation at home as a permanent modification that eases transfers to the toilet.

Shower stall.

Nonskid strips or stickers are recommended in all shower stalls and tubs. When the client is entering the shower stall, the walker or crutches go first, then the operated leg (taking care to avoid active hip abduction if the client is not allowed to perform this motion), and then the nonoperated leg. Installation of a shower chair with adjustable legs or a stool and grab bars is strongly encouraged to prevent the client from losing balance and to maintain weight-bearing precautions. An alternate method to enter the shower stall is to back up to the edge or rim of the shower while using the walker for balance, then stepping into the shower while looking down at the feet and shower rim for safety.

Tub shower (without shower doors).

The client is prohibited from taking a bath sitting on the floor of the tub. This action puts the client at severe risk of causing damage to the impaired joint as well as other types of injuries. A tub chair or tub transfer bench is strongly recommended to preserve hip precautions. The client is instructed to back up to the tub chair or bench using the walker or crutches for support. Then the client should reach for the backrest, extend the operated leg, and slowly lower to a seated position. The legs can then be lifted into the tub as the client leans back, using a leg lifter or bath towel if needed to support the operated leg. A handheld shower is helpful in directing the water for an effective and comfortable bath. Sponge bathing at the sink is an alternative activity,[1] although use of a long-handled sponge or reacher is recommended to avoid hip flexion when bathing the lower extremities.

Car.

Bucket seats in small cars should be avoided. The client is instructed to have a helper move the front passenger seat back as far as it will go and recline the back support in order to observe the hip flexion precaution. Then the client is instructed to back up to the seat, hold onto a stable part of the car, extend the operated leg, and slowly sit in the car. Remembering to lean back, the client then slides the buttocks toward the driver's seat. The upper body and LEs move as one unit to turn to face the forward direction. Firm pillows in the seat may be necessary to increase the height of the seat. Prolonged sitting in the car should be avoided. If transferring to the front passenger seat is a problem, transferring to the back seat of a four-door car is an alternative. The client backs to the seat, extends the operated leg, and slowly sits in the car. Then he or she slides back so that the operated leg is resting on the seat fully supported. Clients should not return to driving until given permission by their surgeon, even if the operated leg is not the leg used for operating the controls. Certain pain medications may cause driving to be unsafe.

Lower-Body Dressing

The client is instructed to sit in a chair with arms or on the edge of the bed for dressing activities. The client is instructed to avoid hip flexion, adduction and rotation, or crossing the legs to dress. The client must refrain from crossing the operated extremity over the nonoperated extremity at either the ankles or the knees. Assistive devices may be necessary for observing precautions (see Fig. 40.5). To maintain hip precautions, the client uses a reacher or dressing stick to put on and remove pants and shoes. For pants and underwear, the operated leg is dressed first by using the reacher or dressing stick to bring the pants over the foot and up to the knee. A sock aid is used to don socks or knee-high stockings, and a reacher or dressing stick is used to doff them. A reacher, elastic laces, and a long-handled shoehorn can also be provided.[1] It is also prudent for the occupational therapist or occupational therapy assistant to discuss clothing choices with the client for ease of dressing. Slip-on shoes with a nonslip sole, for example, may be easier to put on with appropriate adaptive equipment than sneakers with elastic laces.

Lower-Body Bathing

The section on transfers describes the proper method of getting in and out of the shower or tub. Sponge bathing at the sink is indicated until the physician designates that it is safe for the client to shower. Many surgeons use a waterproof bandage over the incision, which protects the site from infection thereby allowing the client to shower before the incision is healed. Care must be taken for clients who are given permission to shower early on in the recovery process. Pain medication and effects from anesthesia may make the patient dizzy when standing or sitting for long periods. The client must be monitored closely. A sponge bath may still be the safest alternative. A long-handled bath sponge or back brush is used to reach the lower legs and feet safely. Soap-on-a-rope is used to prevent the soap from dropping, and a towel is wrapped on a reacher to dry the lower legs.[1] Once showering is approved, a handheld shower head is recommended to direct the water and provide a more comfortable shower.

Hair Shampoo

Until able to shower, the client is instructed to obtain assistance for shampooing hair. The client can have a helper wash the hair while the client is supine, using pillows for back support and a bucket or bowl to catch the water poured from a pitcher to rinse the hair. Another method involves having the client sit in a chair with the back to the sink. The client leans backward to position the head over the sink while the helper washes the hair. The client can also visit a hair salon until he or she is able to perform hair washing independently. If unable to obtain any assistance, the client may shampoo the hair while standing at the kitchen sink with a handheld sprayer, observing hip precautions at all times. Because bending forward at the kitchen sink can be performed with less than 90 degrees of hip flexion, most clients can observe the proper hip precautions using this method.

Homemaking

The client should initially refrain from heavy housework, such as vacuuming, lifting, and bed making. Kitchen activities can be initiated in therapy, with suggestions made to keep commonly used items at countertop level or within easy reach. The client can carry items by using an apron with large pockets, sliding items along the countertop, using a utility cart, attaching a small basket or bag to a walker, or wearing a fanny pack around the waist. Reachers are provided to grasp items in low cupboards or retrieve items from the floor (Fig. 40.8). Items in the refrigerator should be kept on the higher shelves, with only light items that can be obtained with the reacher on lower shelves. For cooking activities, it is recommended that the client use the stovetop or microwave oven rather than placing items in the oven, as it is difficult to maintain hip precautions when reaching in or out of the oven. Washing dishes should be done at the sink or using the top level only of an automatic dishwasher. The occupational therapy practitioner should also instruct the client in relevant energy conservation techniques for instrumental activities of daily living.

FIG 40.8 Functional activities.

Sexual Activity

Persons with a hip fracture or hip replacement will have difficulty performing sexual activities in their usual manner. It is recommended that such persons refrain from sexual activity for a few weeks as specified by their physician so that they maintain the movement precautions applicable to their condition.[38] However, the occupational therapist must create an environment in which the client feels comfortable enough to ask personal questions. The therapist can do this by being open-minded and realizing that sexual activity is an important and meaningful activity of daily living. For clients with a hip replacement, the therapist can suggest participating in sexual activity while side-lying on the nonoperated side when they are allowed to resume this activity. Hip abduction precautions can be maintained by placing pillows between the knees. To prevent excessive external rotation at the hips while in the supine position, the client can place pillows under the knees.[38] Written information with diagrams can be helpful when addressing such a personal issue. The client can read this information privately or with his or her partner.

Caregiver Training

A family member, friend, or caregiver should be present for OT intervention sessions so that any questions may be answered. Appropriate supervision recommendations and instruction regarding activity precautions are given at this time. So that they fully understand the impact of following the hip precautions, caregivers should be encouraged to practice doing the adapted activities as well. Instructional booklets on hip fractures and total hip surgery may be purchased from the American Occupational Therapy Association to supplement training.[1]

Evidence Regarding Occupational Therapy Intervention

A limited number of studies have examined OT intervention for hip joint replacements and hip fractures. Mikkelsen and colleagues examined the effects of reduced (less strict) posterior hip precautions along with the use of assistive devices on patient outcomes versus outcomes for patients who followed strict movement precautions but also used assistive devices.[40] They found that initially there were better outcomes for those patients following the strict movement precautions, but after 6 weeks there was no difference. However, patients with the reduced restrictions returned to work at a higher rate than those who followed the strict movement precautions. It was important for both groups in this study to have been trained properly to use assistive devices for daily activities. Therapists should still be sure to follow the surgeon's directions regarding hip precautions.[40]

Sirkka and Branholm examined life satisfaction in 29 Swedish older adults who suffered a hip fracture. Participants reported a significant decline in their ability to perform hobbies and social activities after their hip fracture and that these activities were more important than self-care activities.[57] Elinge and colleagues also found that social interaction was affected more than other areas of occupation for older adults who have had a hip fracture. Therapists can use the results of these studies to support addressing all areas of occupation and not just ADL.[26] By designing an intervention that targets the client's prior performance patterns and emotional and social needs, the occupational therapist can play a key role in the client's psychosocial adjustment to physical limitations and in maximizing the client's return to participation in meaningful activities.

Threaded Case Study

Mrs. Hernandez, Part 2

1. When completing the occupational profile, what additional information would the occupational therapist need to gather during the evaluation to supplement the information already provided in the case scenario?

Mrs. Hernandez's occupational profile revealed that she has many roles that she finds meaningful: grandmother, church member, and swimmer. She also seems to value being independent. She not only does things with her daughter and her family but also has interests and activities in which she participates on her own. Supporting contextual factors include an accessible home, a daughter nearby who involves her in many activities with her children, and church friends who can offer some assistance. Nonsupportive contextual factors include an inaccessible swimming pool and the fact that she lives alone. Additional information that would be useful to obtain from Mrs. Hernandez for the occupational profile includes but is not limited to specific information about the arrangement of furniture and other items in her home, how willing her daughter is to assist Mrs. Hernandez with her needs or whether the daughter is already assisting with some IADLs, prior surgeries or conditions that would impact the current plan of care or lead to additional falls, history of falls, and equipment or home modifications already established. This information will aid the occupational therapist in planning for discharge and specific equipment recommendations.

2. Identify important areas of occupation and performance skills to address first when educating Mrs. Hernandez to safely perform her daily activities.

Client factors that must be assessed before training Mrs. Hernandez to perform her daily activities safely, including driving, are strength, ROM, sensation, cognition, coordination, and pain. These factors will impact the extent to which she will be able to engage in and learn the prerequisite performance skills needed to optimize her independence in ADLs and IADLs. The occupational therapist must first be sure that Mrs. Hernandez understands the hip precautions and is able to recall them. Then the occupational therapist must address her ability to move herself in and out of bed and perform toileting functions while observing the hip precautions. These prerequisite skills will prepare her for more advanced skills like dressing, bathing, driving, and home management activities. Because she lives alone, she needs to be able to complete all of her ADLs and IADLs independently. The therapist should be sure to address the prerequisite skills first and progress Mrs. Hernandez to more complex ADL tasks that increase her confidence to return home and resume her typical occupations and performance patterns.

3. What prerequisite performance skills should be addressed with Mrs. Hernandez before the occupational therapist directly addresses her ability to drive again?

Because driving allows Mrs. Hernandez to get to her swimming classes, church meetings, and her daughter's home, this is placed as a priority in the list of problems, and she verbalizes that this issue is most important. Mrs. Hernandez should have demonstrated relative independence in different types of transfers, especially car transfers, before she considers driving again. It is important that she obtain medical clearance from her physician or surgeon before resuming driving activities. The occupational therapist can assist her in identifying other community mobility resources available to her until she resumes driving and can complete other assessments directly related to driving, such as an off-road driving assessment.

Section 2 Knee Joint Replacements

Etiology and Medical Management

Knee pain affects the mobility and functional performance of many adults, often due to osteoarthritis in people aged 50 and older. In fact, this knee pain and loss of function are the primary reasons that some people elect to have knee joint replacements.[42] Knee pain is often due to osteoarthritis or degenerative joint disease, trauma or injury to the knee, or other rheumatic conditions and may be compounded by obesity or aging. Surgical knee replacement may be chosen by individuals to alleviate pain, increase motion, and maintain alignment and stability of the knee joint when conservative treatment has failed. Performance in occupations increases the likelihood of the intended result.

The process of knee replacement involves cutting away the damaged bone (as little bone as possible) and attaching prosthetic components of a new joint.[61] Various types of prostheses are used, depending on the severity and region of knee damage (Figs. 40.9 and 40.10). A partial or unicompartmental knee arthroplasty (UKA) is indicated if there is medial or lateral compartmental damage between the femur and tibia. The UKA is often placed with a minimally invasive technique, which allows greater knee flexion (up to 90 degrees) more quickly after surgery.[51] Because limited ligaments and structures of the joint are disrupted, increased stability is obtained immediately.[44]

FIG 40.9 Knee prosthesis. (From Black J, Hawks J: *Medical surgical nursing: clinical management for positive outcomes,* ed 8, St. Louis, 2009, Elsevier.)

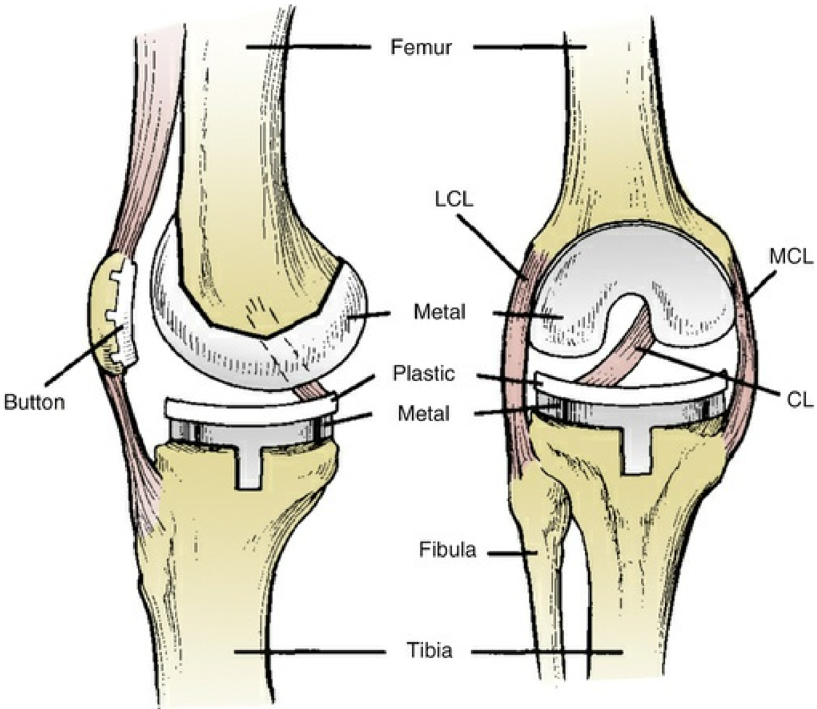

FIG 40.10 Total knee replacement. The metal aspects of the prosthesis cover the distal portion of the femur and the end of the tibia. There is a polyethylene plastic-bearing surface (plastic) between the metallic aspects of the two surfaces. The patella is replaced by a polyethylene button. The medial collateral ligament (MCL), lateral collateral ligament (LCL), and cruciate ligaments (CL) are retained. (From Early MB: *Physical dysfunction: practical skills for the occupational therapy assistant,* ed 3, St. Louis, 2013, Mosby; modified from Calliet R: *Knee pain and instability,* ed 3, Philadelphia, 1992, FA Davis.)

Total knee replacement, or total knee arthroplasty (TKA), is indicated when two or more compartments of the knee are damaged. Various prosthetic devices are chosen based on the medical condition and activities performed by the client.[36] A fixed weight-bearing prosthesis allows only flexion and extension of the knee, as the polyethylene tibia insert is locked into the tibial tray.[54] A rotating platform prosthesis, or mobile weight-bearing prosthesis, allows the slight rotation normally available at the knee, as the tibial component is not locked. This allows for more normal function at the knee, but it has a slightly higher risk of mechanical failure.[54] The rotating platform is typically used for younger, more active people, or for women, as they typically have more rotation available at the knee than men.[31] Both types of prostheses typically decrease pain, improve functional mobility, and enhance quality of life for individuals with degenerative knee conditions. They can be put in place with various surgical techniques, including minimally invasive approaches, in which there is less damage to the quadriceps tendon and the medial collateral ligament, which may improve range of motion at the knee and lead to faster postoperative recovery.[59] The prosthesis can be cemented to the bone with acrylic cement or not cemented. With a cemented prosthesis, clients are usually able to bear weight as tolerated on the operated leg. With a noncemented prosthesis, initial weight bearing is usually avoided or restricted. The choice to use cement to hold the prosthesis in place is typically based on the preference of the surgeon. However, the noncemented procedure requires that the client does not have any other health issues that would slow bone growth, which would extend the time frame for restricted weight bearing.

Clients typically start out-of-bed activities on the first day after surgery, pending the physician's approval and with appropriate assistance or supervision. An ambulatory device, such as a walker or crutches, may also be used for greater stability. If the knee joint is unstable following surgery for any reason, the physician may indicate that a knee immobilizer or other brace should be used to preserve knee joint alignment (Fig. 40.11). The client should avoid excessive rotation at the knee for up to 12 weeks after surgery. There is usually no restriction on flexion and extension of the knee. In fact, maintaining the mobility of the knee is important to ensure adequate mobility during healing, and to regain normal motion and function.[14,25,38,50] Some surgeons recommend the use of a continuous passive motion (CPM) device to provide slow, controlled movement with the intent of improving functional range of motion and reducing postsurgical edema, although there is limited evidence of the long-term effectiveness of the CPM machines.[7,10,25]

FIG 40.11 A knee immobilizer is used to support and stabilize the knee joint during mobility. (From Ignatavicius D, Workman ML: *Medical-surgical nursing: patient-centered collaborative care,* ed 8, St. Louis, 2016, Elsevier.)

Special Considerations for Knee Replacements

As with hip replacements, individuals with joint changes that result in increasing pain may have multiple joint involvement (ie, both knees). Some clients opt to have two joints replaced during the same hospitalization, either during the same surgery or with procedures 3 to 7 days apart. This can complicate the rehabilitation process because the client will not be able to rely on the nonoperated leg when walking, transitioning between seated and standing positions, and performing daily occupations. However, it eliminates the need for an additional hospitalization if both knees are affected. The orthopedic surgeon should discuss these options with the client to determine the most appropriate course of action.

It is important for the occupational therapy practitioner to be aware of complications or special procedures that occurred during a client's surgery and to verify precautions or risks with the physician. Surgeons will make specific recommendations based on the client's particular situation, surgical procedures used, or postoperative concerns. Common complications include dislocation of the prosthesis, degeneration of parts, fracture of bone next to implanted parts, loosening of prosthetic parts, and infection of the joint after surgery.[22]

Some clients describe postsurgical pain that is more significant following total knee replacement as compared to total hip replacement. This is often managed with medications, such as epidural or periarticular anesthetics, patient-controlled analgesia, oral analgesics or opioids, or peripheral nerve blocks, although side effects and effectiveness vary with individual clients.[27] Other methods of pain control amenable to use by rehabilitation professionals include the use of superficial cold modalities, proper positioning during transitional movements, use of CPM machines after therapy if approved by the physician, and balance of rest and activity.

As with hip replacement, the emphasis in rehabilitation is on maintaining or increasing joint motion, slowly increasing the strength of surrounding musculature, decreasing swelling, and increasing the client's independence and participation in areas of occupation, particularly ADLs. The occupational therapist's role in this process is primarily to educate the client who has undergone joint replacement about applying adaptive techniques for ADLs and IADLs with limited mobility while maintaining any joint precautions for movement or weight bearing.

Medical Equipment

The OT practitioner should be familiar with the following equipment that is commonly used in the treatment of knee replacement:

- *Hemovac.* During surgery, a plastic drainage tube is inserted at the surgical site to assist with postoperative drainage of blood. It has an area for collection of drainage and may be connected to a portable suction machine. The unit should not be disconnected for any activity because this may create a blockage in the system. The Hemovac is usually left in place for 1-2 days after surgery.
- *Commode chairs.* The use of a commode chair instead of the regular toilet aids in safe transfers and allows the client to limit flexion of the knee during toileting.
- *Sequential compression devices (SCDs).* SCDs are used postoperatively to reduce the risk of deep vein thrombosis. They are inflatable, external leggings that provide intermittent pneumatic compression of the legs.[22]
- *Antiembolus hose.* This elastic hosiery may be extended up to the knee or over the knee and on the thigh, depending on physician preference They are worn 24 hours a day and removed only during bathing. Their purpose is to assist circulation, prevent edema, and thus reduce the risk of deep-vein thrombosis.[22]
- *Patient-controlled administration IV.* Patient-controlled analgesia (PCA) is delivered through an IV; patient controlled epidural analgesia (PCEA) is delivered through an epidural line. A prescribed amount of medication is programmed by the physician and nursing staff to allow the client to self-administer pain medication by pushing a button to inject a safe amount. When dosages have reached a limit, the machine will not administer medication even if the button is pushed.
- *Incentive spirometer.* This portable breathing apparatus is used to encourage deep breathing and prevent the development of postoperative pneumonia.
- *Continuous passive motion (CPM) machine.* This mechanical device supports a joint and can be set to move slowly through a designated range of motion to promote controlled movement in the operated joint.

Role of Occupational Therapy for Clients With Knee Joint Replacement

After a knee replacement, OT typically begins on the first post-operative day, but there may be some variation depending on the general health of the client and on the physiologic response to surgery. Before any physical assessment, it is important to introduce and explain the role of OT and complete an occupational profile. This profile involves gathering information regarding the client's occupational history, prior functional status in ADLs and IADLs, descriptions of performance contexts (eg, home environment and social support available), and the client's goals. The goal of OT is for the client to maximize performance of daily occupations, with all movement precautions observed during activities. This often involves improving activity tolerance, addressing functional mobility, and providing education in the use of adaptive equipment.[21] The role of the occupational therapist and assistant is to teach the client ways and means of performing daily occupations safely.[35]

Evaluation and Intervention

Following the occupational profile, an assessment of the motor, cognitive, social, and emotional factors is recommended, specifically as they relate to occupational performance. Performance of motor skills such as upper extremity (UE) ROM, muscle strength, sensation, and coordination must be assessed to determine if any adaptations should be made to functional mobility or use of adaptive equipment. Mental functions such as memory, problem solving, and sequencing must be considered in light of potential precautions, safety awareness, and performance of occupations. Activities of daily living and other relevant occupations should be evaluated through standardized assessments, direct observation, or interview as the context and client condition allow. The skilled occupational therapist should be able to identify if social or emotional concerns are present, including pain, fear of falling, hesitation to resume normal activities, or concerns about surgical healing.

OT intervention planning requires careful consideration of evaluation data and clinical reasoning skills to determine how the specific client's needs and concerns can be addressed through a program of functional activities that gradually enables a person to resume meaningful occupations. The therapist introduces and trains clients in the use of assistive devices, proper transfer techniques, and ADL and IADL techniques while ensuring safe positioning of the knee and prosthetic components. Discharge planning should be considered early, as many clients are able to return home within a few days if ADL and IADL function can be restored. Clients who need additional rehabilitation to regain occupational performance, who have limited community support, and with inhibitory contexts may be recommended for inpatient rehabilitation after the acute hospital stay.

Specific Training Techniques for Participation in Occupations

Following any type of knee replacement, the occupational therapist should encourage weight bearing as specified by the surgeon, and knee flexion and extension as allowed by pain level and surgical outcomes. It is encouraged that the leg be supported by the occupational therapist when a client is moved from sitting with the legs elevated—for example, in a recliner or geri-chair—to seated with feet on the floor in preparation for transfers or standing. Clients may also be encouraged to participate in deep breathing and relaxation as methods of pain control.

Bed Mobility

The supine position is recommended when the client is resting in bed, with the knee fully extended. Although it is acceptable for a small towel or bolster to be placed under the knee to allow slight flexion for pain control periodically, the client is encouraged to keep the knee extended and the hip in a neutral position when sleeping. This encourages full extension that will be needed for ambulation. A knee immobilizer or other supportive brace can be used if indicated by the physician. As in hip replacement, a pillow or wedge can be placed between the legs if this is necessary for side-lying and if the person lies on the nonoperated side. A CPM machine may be used for several hours a day following surgery to facilitate recovery and increased range of motion,[33] and the client must use this in a supine position. However, use of the CPM machine is often discontinued prior to returning home, when more activities are resumed. To enter or exit the bed, clients can move freely and specific techniques can be identified according to client preferences. There are no restrictions that dictate bed mobility procedures.

Transfers

Typically, the client can bend freely at the hips if only the knee has been replaced, and this motion may compensate for the more painful knee ROM, often in flexion. Armrests are generally helpful and allow better upper extremity support for the transitions between sitting and standing on a postoperative knee.

Chair or commode chair.

To move from standing to sitting, the client is instructed to back up to the chair, extend the operated leg forward, reach back for the armrests, and slowly lower to the sitting position. To stand, the client extends the operated leg and pushes up from the armrests. Once standing, the client can reach for an ambulatory aid, such as a walker if it is being used. As in hip replacement procedures, low chairs, soft chairs, reclining chairs, and rocking chairs should be avoided.[1] If a client has bilateral knee replacements, it may be uncomfortable to flex either knee to promote the sit-to-stand transitions. In this case, to move from standing to sitting, the client again backs up until he or she feels the back of the chair, then takes a small step forward with both feet. Then the client reaches back for the armrests and gently lowers the body onto the chair, slowly advancing the feet forward if necessary until a seated position is achieved. To move from seated to standing, both feet are placed slightly forward and the arms are used to raise the buttocks off the chair. Then the client can flex forward at the hips and slowly move the feet back toward the chair until the lower extremities are fully supporting the body. Only then should the client release the armrests and reach for a walker or other ambulatory device placed in front of him or her. Three-in-one chairs are often recommended for use, as they can be placed over a toilet in order to raise the height and provide armrests, thereby improving safety during transfers. In addition, the three-in-one can be used as a stand-alone commode if necessary when the home environment does not support easy access to a bathroom on all levels of the home. Comfort height toilets (17-inch seat height) can be considered for a permanent modification at home that can allow for easier transfers to the toilet.

Shower stall.

Nonskid strips or stickers are recommended in all shower stalls and tubs. Several methods are possible for movement in shower stalls, and the occupational therapist should problem-solve with the client to determine which method is safest. As in the hip replacement methods, the walker or crutches may go first, then the operated leg, and then the nonoperated leg. An alternate method to enter the shower stall is to back up to the edge or rim of the shower while using the walker for balance, then stepping into the shower while looking down at the feet and shower rim for safety. Installation of a shower chair with adjustable legs or a stool and grab bars is strongly encouraged to help the client maintain balance and preserve endurance.

Tub shower (without shower doors).

As in the method for hip replacements, the client is prohibited from taking a bath sitting on the floor of the tub, as this action puts the client at severe risk of causing damage to the knee when transitioning to or from the tub floor. Although a tub seat can be used as in the hip replacement techniques, it is not necessary, as hip flexion is permitted after a knee replacement. To maintain balance during the transfer, it is recommended that the client stand next to the tub, with the hands placed on the short wall of the head or foot of the tub. Then by flexing the hip and knee, or alternately by extending the hip and knee, the client can side-step into the tub while using the upper extremities to maintain balance (Fig. 40.12). A grab bar may be added for safety as needed.

FIG 40.12 Tub transfers following knee replacement.

Car.

Bucket seats in small cars should be avoided. Bench-type seats are recommended. The client is instructed to have a helper move the front passenger seat back as far as it will go. Then the client is instructed to back up to the seat, hold onto a stable part of the car, extend the operated leg, and slowly sit in the car. The client is able to lean forward at the hip for clearance of the upper body and head as they move into the car. The upper body and LEs move as one unit to turn to face the forward direction. Prolonged sitting in the car should be avoided. If transferring to the front passenger seat is a problem, transferring to the back seat of a four-door car is an alternative. The client backs to the seat, extends the operated leg, and slowly sits in the car. Then he or she slides back so that the operated leg is resting on the seat, fully supported. Clients should not return to driving until given permission by their surgeon, even if the operated leg is not the leg used for operating the controls. Sports utility vehicles, vans, or trucks typically have higher seats and may make the transfers easier for some clients.

Lower-Body Dressing and Bathing

The dressing of lower extremities presents a problem only if the client is unable to reach his or her toes, which is usually done by leaning forward at the hips or raising the feet onto a footstool. If necessary, the techniques described for hip replacement can be used, including the use of adaptive equipment. The client should also be instructed in donning and doffing the knee immobilizer or other brace, if used. The client should be cautioned to prevent torque or rotation at the knee joint when dressing by not twisting the body or leg while bearing weight on the operated leg. Clients can take a sponge bath in the initial stages of recovery and typically are not approved to shower until the margins of the incision have healed,[2] approximately 7 to 10 days after the surgery. Showering may be permitted if a waterproof dressing covers the incision.

Homemaking

Homemaking and caregiver training follow the same procedures as for hip replacement techniques, although hip movement is not restricted. Care should be taken when standing or sitting for extended periods of time, to avoid prolonged static positioning of the knee and for pain management.

Sexual Activity

Much like those with hip replacements, persons with a knee replacement will have difficulty performing sexual activities in their usual manner. It is recommended that they refrain from sexual activity for a few weeks so that they maintain the movement precautions applicable to their condition.[38] For clients who have questions about the level of sexual activity allowed during the healing process, the therapist may need to suggest ways for the client to position the operated leg during sexual activity to maintain precautions or to minimize discomfort. Side-lying on the nonoperated side is one option. Clients with knee replacements or weight-bearing precautions should refrain from kneeling.[38] Written information with diagrams can be helpful when addressing such a personal issue.

Evidence Regarding Occupational Therapy Intervention

Occupational and physical therapies are typically initiated in inpatient settings as soon as permitted by surgeons following knee replacements. In fact, a greater intensity of post-op rehabilitation has been proved to enhance patient outcomes, including improved scores on standardized ADL assessments (ie, Functional Independence Measure) in the areas of self-care, transfers, locomotion, and cognition.[5] Home care and outpatient rehabilitation are also important for the client who needs continued support during recovery. Fewer days between discharge from the inpatient setting and the initiation of outpatient services are associated with greater return of function and lower pain levels.[10]

Section 3 Shoulder Joint Replacements

Threaded Case Study

Mrs. Green, Part 1

Mrs. Green is an 80-year-old with degenerative joint disease that is affecting many of the joints in her body. She's already had bilateral knee replacements, and now her orthopedic surgeon says she would benefit from a reverse shoulder replacement of her dominant right arm. Mrs. Green lives alone and manages her self-care and most housekeeping tasks independently. She has a housekeeper to do the heavy cleaning once a month. She has made some modifications to her home so that she does not need to reach very far—for example, she has moved the microwave oven and most frequently used dishes and glasses to the countertop. Additionally she moved her hanging clothes to the doorknobs in her bedroom and has a handheld showerhead. She uses a reacher and long shoehorn when dressing. Mrs. Green drives and just recently stopped working part-time. She keeps herself busy by visiting with friends and knitting. She is an avid knitter, known to make beautiful scarves and Christmas stockings for family members. This is the activity that is most meaningful to her and the reason she has decided to go ahead with the surgery.

The reverse shoulder replacement technique was chosen because the muscles supporting the shoulder girdle were weak due to prior rotator cuff problems. Mrs. Green received home-based therapy 2 days after the surgery when she was discharged home. She had to rely on her adult children to help care for her as well as her sister who came to live with her for 2 weeks. Because of the postsurgery pain and movement precautions, Mrs. Green had great difficulty completing self-care tasks, bed mobility, and transfers. This frustrated her greatly, especially her inability to perform toilet hygiene with her nondominant hand. The majority of the therapy sessions were spent figuring out compensatory strategies for Mrs. Green.

Eventually, Mrs. Green became stronger, and after 6 weeks the movement precautions were lifted and she was able to progress faster in her physical rehabilitation. After about 4 months Mrs. Green was able to resume all of her prior occupations, including knitting and driving. She reports a lot less pain during activity but still has some range-of-motion limitation, which she had been informed prior to surgery might not improve to normal limits.

Critical Thinking Questions

1. What could Mrs. Green have done to better prepare for the surgery knowing that her dominant hand/arm would be immobilized for 6 weeks?

2. How could the therapist utilize caregiver training in this case?

3. Identify self-care tasks that would pose a particular problem due to her movement and weight-bearing precautions (no passive or active shoulder extension or external rotation; no active movement in any direction; only passive shoulder flexion and abduction to about 80 degrees allowed, non–weight bearing)

4. Mrs. Green did not have any movement precautions with her right hand, wrist, or forearm. How could you enable Mrs. Green to use her right hand as an assist (while it was still in the sling) during daily activities without breaking her movement precautions at the shoulder?

The shoulder complex is not a single joint, as functional upper extremity use relies on consideration of the glenohumeral, acromioclavicular, sternoclavicular, and scapulothoracic joints (Fig. 40.13). Musculature acts upon the joints to allow complex movements of the shoulder in elevation and depression, retraction and protraction, and rotation of the scapula, as well as flexion, extension, rotation, and horizontal movements typically measured at the glenohumeral joint. The occupational therapist must carefully analyze shoulder dysfunction to determine the potential deficits, to develop interventions, to protect the joints, and ultimately to promote and facilitate upper extremity function during occupations.

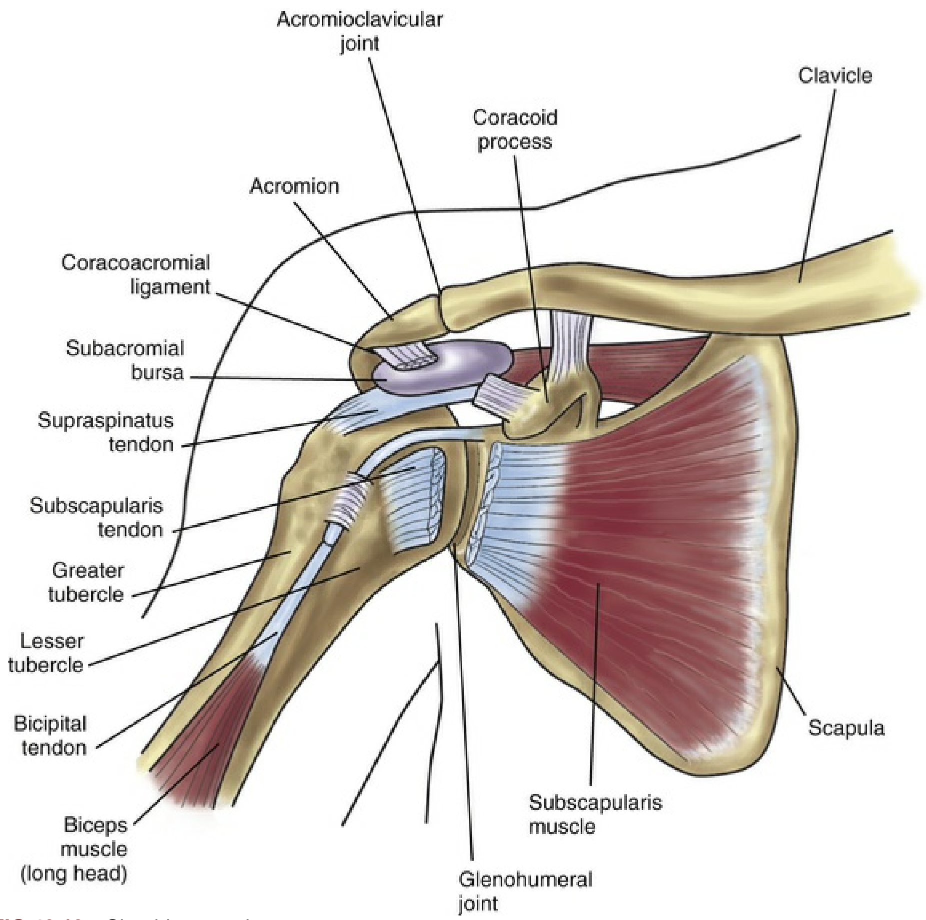

FIG 40.13 Shoulder complex. (From Miller MD, Hart J, MacKnight JM: *Essential orthopaedics.* Philadelphia, 2010, Saunders. Adapted with permission from Anna Francesca Valerio, MD.)

Just as osteoarthritis has been described as a contributor to pain that often leads to hip or knee replacement, this orthopedic condition can also contribute to shoulder pain and dysfunction. Other inflammatory or anatomic conditions, biomechanical forces that may cause damage to the shoulder complex, or proximal humerus fractures are often sources of shoulder pain and dysfunction.[11,28] Conservative medical treatments may include oral or injected drugs designed to decrease pain and inflammation.[34] In addition, therapeutic exercise and activity modifications may be used to control pain and promote function. In this chapter, only conditions that may result in various types of shoulder replacements will be considered due to the need for rehabilitation following these surgical interventions.

Etiology and Medical Management

The type of damage to the shoulder complex typically dictates the type of medical intervention by the orthopedic physician. People who suffer a humeral fracture typically undergo a hemiarthroplasty or humeral head replacement. In this procedure, the humeral head and fractured area are removed and replaced with an endoprosthesis. A total shoulder arthroplasty (TSA), also referred to as a total shoulder replacement (TSR), is more often performed for a person with degenerative or inflammatory conditions such as osteoarthritis (Fig. 40.14). In this procedure, the humeral head is replaced by a ball-shaped prosthesis and the glenoid is resurfaced or replaced with a prosthetic component.[34] A reverse total shoulder arthroplasty (RTSA), also referred to as a reverse total shoulder replacement (RTSR), is indicated for patients with a degenerative or inflammatory condition present in the shoulder complex, but also with some involvement or deficiency of the rotator cuff. In some cases, this procedure is also used when a revision of a traditional TSA is required. When the rotator cuff is extremely weak or damaged, the muscles are unable to effectively support the newly repaired joint so a reverse technique is indicated. In the RTSA, the ball and socket of the glenohumeral joint are reversed; the semicircular ball is placed in the glenoid and a polyethylene cap is implanted into the humerus. In this procedure, good deltoid function is needed to stabilize the joint without as much reliance on rotator cuff muscles for support.[6,34,53]

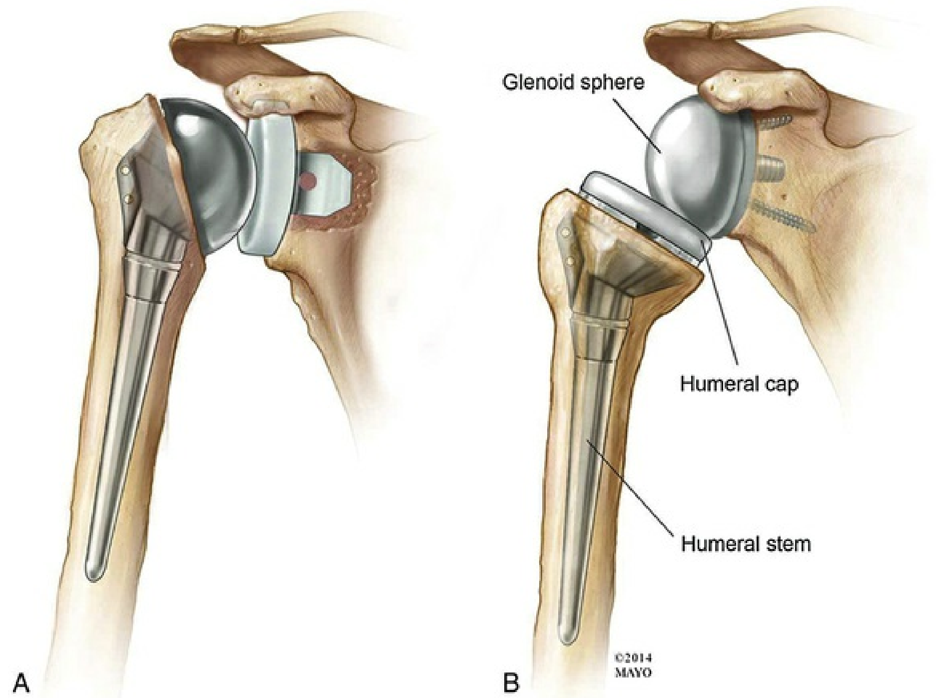

FIG 40.14 **A,** Total shoulder arthroplasty. **B,** Reverse shoulder arthroplasty. (By permission of Mayo Foundation for Medical Education and Research. All rights reserved. Copyright The Mayo Clinic, 2014.)

All of these procedures are expected to eventually decrease the patient's pain, improve functional use of the shoulder over time, and enhance quality of life.[34] However, when compared with the hemiarthroplasty or replacement of the humeral head, the TSA typically has greater range of motion results and higher patient satisfaction ratings as well as a decreased need for revisions, as further glenoid wear is not a factor.[49] The most common postoperative complications for any of the shoulder surgeries is loosening of the glenoid component, loosening of the humeral component, glenohumeral joint instability, or rotator cuff tears. These complications have an incidence of only about 10% to 16% in the 3 to 5 years after surgery and approximately 22% in the 10 to 15 years after surgery.[29,58] Full shoulder ROM is not typically achieved with shoulder replacements, but the pain relief and moderate increases in ROM make the surgery worthwhile for many individuals. A typical prosthesis will last 15 to 20 years in the majority of patients, depending on the particular conditions of the patient and how the joint is used or protected.[34]

Special Considerations for Shoulder Joint Replacements

Because orthopedic concerns and surgical techniques may vary among surgeons, so also will the particular postoperative precautions. The occupational therapist should be familiar with the procedures and should communicate openly with the surgeon to ensure movements of the shoulder that promote patient safety, prevent complications, and progress function as efficiently as possible.

In the initial postoperative phase, soft tissues that surround and support the joint must be preserved for healing, and the glenohumeral joint must be maintained in the appropriate anatomic position. Pain and inflammation are controlled as prescribed by the physician. As with those who have had total hip and knee replacements, the client is provided with a pain medication regimen that provides a consistent level of pain relief to allow full participation in the rehabilitation program. Although active range of motion is encouraged in the joints of the elbow, wrist, and hand, only passive range of motion is permitted in the shoulder joint and only for motions specified by the surgeon. Activities of daily living should be restored, but typically in compensatory or adaptive patterns as the operative shoulder should not have undue resistance placed on it. A **shoulder sling** is typically used for 3 to 4 weeks following shoulder surgery, which is worn when the patient is moving or sleeping (Fig. 40.15). A **swathe** (a long, wide strap that encircles the arm in the sling and the trunk) may also be prescribed to provide extra support and protection for the arm and to prevent prohibited movement. These may be removed for therapeutic activities and when seated with the upper extremity in a supported position (with the humeral head approximated in the glenoid fossa). The sling (and swathe) should be worn during functional activities, during ambulation, and when sleeping to preserve the shoulder joint position. For approximately 6 to 8 weeks, patients may not bear weight on the operated upper extremity, may not lift items weighing more than 1 to 2 pounds with the operated upper extremity, and should avoid the following motions: shoulder extension past neutral, shoulder abduction past 45 degrees, external rotation past approximately 30 degrees, and internal rotation past approximately 60 degrees. They may not participate in any resistive activities in internal or external rotation. When sleeping, a pillow or towel roll should be placed under the scapula or elbow as needed for comfort to ensure that the shoulder in supported in the front of the body and in adherence to the precautions (Box 40.3).

FIG 40.15 Sling with the swathe. (Courtesy North Coast Medical, Inc., Gilroy, CA.)

Box 40.3

Total Shoulder Replacement Precautions

No weight bearing through surgical upper extremity

No lifting more than 1 to 2 lbs with surgical upper extremity

Avoid shoulder extension past neutral

Avoid shoulder abduction past 45 degrees

Avoid shoulder external rotation past 30 degrees

Avoid internal rotation past 60 degrees

Limit shoulder PROM in flexion to approximately 90 to 100 degrees

Pain management is usually achieved in the postoperative phase with patient-controlled anesthesia, which can be administered through an epidural line or a pump with a line inserted into the surgical site. This can be supplemented with superficial cold therapies, movement restrictions and sling wear, and activity modification. After a few days, the anesthesia lines are replaced with oral analgesics or anti-inflammatory medications.

Role of Occupational Therapy for Clients With Shoulder Joint Replacement

As in the other types of joint replacement, occupational therapy typically begins on the first postoperative day if there is no adverse response to the surgery. Introduction of the role of OT and expected types of interventions should precede the gathering of data for the occupational profile. In shoulder replacements, it is vital to understand hand dominance and how this may influence occupational performance, especially if the dominant hand is on the side of the surgical intervention. The goal of OT is for the client to maximize performance of daily occupations, but therapeutic exercise and activities must be advanced carefully in consideration of movement precautions and typical patterns of upper extremity use in occupations. Shoulder use is carefully advanced in the 12 weeks following surgery, but full recovery of function may take up to 9 months.[4,9,19,63]

Evaluation and Intervention

Following the occupational profile, an assessment of the motor, cognitive, social, and emotional factors is recommended, specifically as they relate to occupational performance. Upper extremity assistive range of motion (AROM) and muscle strength can be tested in joints of the elbow, wrist, and hand. However, movement, weight bearing, and resistance precautions must be observed in the shoulder in the postoperative phase. Only gentle, controlled passive range of motion (PROM) should be conducted in all shoulder movements. Sensory function and coordination are assessed distally as well, although analgesics inserted through joint or epidural catheters may mask sensory abilities for a few days after surgery. Mental functions such as memory, problem solving, and sequencing must be considered in light of precautions, safety awareness, and performance of occupations. Activities of daily living and other relevant occupations should be evaluated through standardized assessments, direct observation, or interview as the context and client condition allow. Social or emotional concerns may include fear of participation in appropriate therapeutic exercise, hesitation to resume normal activities, or concerns about surgical healing.

OT intervention planning will focus on the following two primary areas: (1) appropriate therapeutic exercise and resuming normal occupations and (2) primarily routines involving activities of daily living and instrumental activities of daily living. Therapeutic exercise must be designed to promote controlled movement within precautions so that eventual return of full upper extremity function is possible, avoiding long-term complications of adhesive capsulitis, soft tissue contractures, or bony abnormalities such as heterotopic ossification. Occupations may need to be modified during healing to promote the client's active participation while advancing shoulder use appropriately. Performance in both of these areas will be used to determine discharge planning and consideration of inpatient rehabilitation or home and outpatient care.

Therapeutic Exercise Considerations

Total Shoulder Replacement

In the immediate postoperative phase, patients are permitted to perform active assistive range of motion (AAROM) and PROM only of the shoulder in protected ranges. Passive range of motion is typically limited to 90 degrees of shoulder flexion, 45 degrees of shoulder abduction, and extension only to neutral. Specific surgical precautions should be followed related to internal and external rotation, but clients are typically permitted to lay the hand across the abdomen in internal rotation, to about 30 degrees of external rotation. **Codman's pendulum exercises** may be initiated on the first postoperative day. After removal of the sling, the client is instructed to bend forward by flexing at the hips, allowing up to 90 degrees of passive shoulder flexion, with the arm hanging perpendicular to the floor. The nonoperated upper extremity should rest on a counter or tabletop surface, and a wide base of support with the feet should be maintained to avoid a risk of falls. By shifting the body weight, the arm may passively move in anterior-posterior motions, lateral motions, small clockwise circles, and small counter-clockwise circles (Fig. 40.16).[52] Depending on the surgeon's preference, distal AROM should also be performed several times daily to avoid distal edema and to promote functional hand use. Over the next 2 to 4 weeks, larger PROM ranges may be initiated at the shoulder. These may include table slides, in which the client sits next to a table with the operated UE supported on the table, and he or she slowly leans forward and allows the shoulder to passively flex. Some physicians allow dowel exercises (the client holds a wooden dowel with both hands) so that the nonoperated UE can be used to assist movement of the operated UE.

FIG 40.16 Codman's (pendulum) exercises.

Approximately 4 to 6 weeks following the surgery, and if PROM is gradually increasing and normal movement patterns are observed, precautions related to movement may be relaxed. Greater PROM is expected, but weight bearing and lifting are still restricted. Active-assisted therapeutic exercise and carefully executed overhead pulley exercises may be initiated. The therapist should assess glenohumeral and scapula-thoracic mobility to ensure normal movement patterns. Light strengthening can be initiated in the elbow, wrist, and hand joints in preparation for greater functional use. Some physicians will allow for a light weight to be added to Codman's pendulum exercises. Shoulder strengthening and full movement through all planes is typically initiated 6 weeks postoperative. Monitored therapeutic exercise to ensure return to full AROM and strength may continue from the 6 weeks through several months as indicated.[4,63]

Reverse Total Shoulder Replacement

As for patients with a traditional total shoulder replacement, these patients are permitted to perform AAROM and PROM only of the shoulder in protected ranges in the immediate postoperative period. Passive range of motion is typically limited to 90 degrees of shoulder flexion, 45 degrees of shoulder abduction, and extension only to neutral (see Box 40.3). Because there is limited support of the rotator cuff, there should be no actions that require reaching behind the back, which consists of combined shoulder adduction, extension, and internal rotation.[6] Specific surgical precautions should be followed related to internal and external rotation, but it is typically permitted for the client to lay the hand across the abdomen in internal rotation, to about 30 degrees of external rotation if the shoulder is slightly flexed. Although therapy begins post-op day 1, Codman's pendulum exercises (see Fig. 40.16) may only be performed with the permission of the surgeon due to rotator cuff instability. PROM only may be performed for the first 5 to 7 days post-op. Active movement of the distal extremity should be delayed until all anesthesia or nerve blocks that may have been used during surgery for pain control have cleared the patient's system and good motor control returns. Approximately 5 to 7 days after surgery, the patient may begin isometric exercise in the scapula and shoulder and AAROM, up to 90 degrees of flexion and abduction and up to 30 degrees of external rotation. AROM may be initiated approximately 2 weeks post-op, as long as the glenohumeral joint remains stable and pain is managed. Table slides, dowel exercises, and pushing items up an incline board may assist in moving from AAROM to AROM. From weeks 2 to 6, gains are expected in AROM, isometric control, and shoulder stability. Light strengthening may begin in about week 6, although the occupational therapist should carefully monitor progression, and moderate strengthening may begin around week 12.[9]

Specific Training Techniques for Participation in Occupations

Regardless of the type of surgical procedure performed, the occupational therapist must ensure that the client is able to safely and effectively participate in occupations. Basic activities of daily living are typically addressed first within the parameters of precautions and allowed movements. Ambulation is generally not affected by the shoulder replacement if balance is functional and there are no other lower extremity problems; however, significant adaptations may be needed for bed mobility, ADLs, and other areas of occupation. The occupational therapist can encourage the patient to use the hand on the side of the operated shoulder as a stabilizer or assist for light activities that do not require weight bearing or strength (eg, holding toothpaste, buttoning lower buttons, stabilizing paper for writing, or holding a washcloth while soaping it up with the other hand).

Sleeping Positions and Bed Mobility

The sling (and swathe) is worn during sleeping, usually for the first 4 to 6 weeks following the shoulder replacement. A pillow or towel roll should be placed under the scapula or elbow as needed for comfort to ensure that the shoulder is supported in the front of the body, in slight flexion, and in adherence to the precautions. When entering or exiting the bed or when changing positions in bed, the client may roll over the nonoperated shoulder only. The client may need to adjust sleep arrangements to allow for optimal bed mobility that protects the operated shoulder. Core and lower extremity strength and positioning may support movement to and from the bed, but for clients who do not have this level of strength, care must be taken that clients do not use the operated arm to push themselves up. Bed ladders or pulls, bed rails, or leg lifters may be needed to assist with bed mobility. Bed mobility routines including those associated with going to the bathroom at night should be addressed to anticipate problems that might arise around providing a safe path to the bathroom, managing clothing and hygiene at the toilet, getting back into bed, and adjusting the aforementioned pillows or towel rolls. (See Chapter 10 for additional ADL and IADL suggestions.)

Functional Mobility

If a cane was required prior to the surgery, it should be used with the nonoperated UE only. Physical therapy practitioners typically address balance, ambulation, and gait with the client. If a cane is needed, the occupational therapist should ensure its safe use during homemaking tasks or other instrumental activities of daily living. Use of the operated UE should also be avoided during transfers to avoid weight bearing.

Upper-Body Dressing and Bathing

Clothing should be chosen for ease of dressing and with consideration of sling wear. Button front shirts will be easiest to use for dressing, though oversized tops made of stretchy material may also be suitable. The client should sit while dressing and bend forward at the waist to promote passive flexion of the shoulder while extending the elbow to put the operated arm in the sleeve first. Once this sleeve is pulled onto the upper extremity and the client returns to sitting upright, he or she can reach around the back to pull the shirt to the other side and to reach to slide the nonoperated arm into the other sleeve. The client can use the hand of the operated shoulder to stabilize and assist in buttoning the shirt. Women should use a bra with the closure in the front so it can be managed like the button-front shirt. The occupational therapist should also ensure that the client is aware of how to put the sling on and off over the clothing. Additional adaptations to clothing or technique may be needed for the client who also has limited shoulder motion on the nonoperated side, as there typically is bilateral joint involvement with osteoarthritis.

For bathing, the sling is removed and a sponge bath can be completed when the client is seated. A rolled towel can be used to support the arm when bathing while seated. A waterproof dressing should be placed over the surgical site if the client will shower during the first week after the surgery. Once sutures or staples are removed, the client can shower normally. Precautions should be maintained during bathing, no matter what method is used. A long-handled sponge may help the client reach the back using the nonoperated arm.

Lower-Body Dressing and Bathing

It is recommended that the client sit to pull on pants and underclothes in order to maintain balance and avoid the need to use the operated arm to brace the body during a potential fall. Leaning forward in the seated position will also ensure that precautions are maintained. Again, clothes should be chosen for ease of dressing; for example, slip-on shoes will prevent the necessity of tying shoes.

Homemaking

Following shoulder replacements, ambulation is typically unaffected. However, homemaking will need to be done with the shoulder in the sling for the first few weeks. The nonoperated arm can be used primarily for cooking and homemaking, and lifting should be limited in accordance with precautions. A few pieces of adaptive equipment may be helpful, such as a rocker knife or pan stabilizer. The occupational therapist should analyze how the client typically performs household activities to determine if adaptive equipment or compensatory techniques should be used to protect the operated shoulder.

Evidence Regarding Occupational Therapy Intervention

Limited evidence exists that examines specific occupational therapy interventions for people with a shoulder replacement. However, researchers have examined the quality-of-life and return-to-prior-activity levels for this population. Zarkadas and colleagues collected data from patients on their activity level after having their shoulder replaced with a total replacement technique or a hemiarthroplasty. Patients reported having the most difficulty with overhead activities, combing/curling their own hair, washing/drying the back, sleeping on the operated side, and dressing/undressing, as well as other leisure activities.[64]

Boardman and colleagues evaluated the effectiveness of a home-based exercise program for 77 individuals after shoulder replacement.[8] Because most patients return to the home setting within a few days of the surgery, much of the rehabilitation occurs either at home or in an outpatient therapy program. The researchers found that a sequence of exercises, progressing from active hand, forearm, elbow motion, and passive shoulder motion to using a pulley, then a wand or cane exercises, isometric exercises, and ending with Thera-Band exercises, produced good outcomes, with 70% of patients maintaining motion gained during the surgical procedure without causing soft-tissue healing complications.[8]

These studies support intervention priorities that address participation in daily activities, especially self-care tasks, and provide thorough training in home exercises that will help the patient maintain movement precautions and prevent soft-tissue complications while allowing for the maximum functional ability during the healing process.

Threaded Case Study

Mrs. Green, Part 2

1. What could Mrs. Green have done to better prepare for the surgery knowing that her dominant hand/arm would be immobilized for 6 weeks?

It is likely that Mrs. Green was seeing either an occupational therapist or a physical therapist before deciding to have her shoulder replaced. The therapist was aware of her prior knee replacements and the assistive devices she already used. Mrs. Green could be directed to practice using the assistive devices she already had with her nondominant arm for completing ADL and IADL tasks. Additionally, the therapist could have provided her with information or suggested she attend a preoperative class to learn tips for postsurgery activity.

2. How could the therapist utilize caregiver training in this case?

Unlike lower extremity joint replacements, when an individual's arm is immobilized, especially the dominant arm, the ability to perform daily activities can become impossible and a caregiver is needed. It is important to prepare clients for shoulder replacement surgery so that a caregiver can be identified before the surgical procedure in order to best prepare him or her for assisting the client. Caregivers can be taught the movement and weight-bearing precautions as well as any home exercises that should be performed daily. Caregivers need to learn ways to assist the client during mobility (eg, bed mobility, transfers, and ambulation) so that he or she uses proper body mechanics and ensures movement precautions are maintained. If the caregiver cannot be trained prior to the surgery, it is important to incorporate this training during postsurgery rehabilitation.

3. Identify self-care tasks that would pose a particular problem due to her movement and weight-bearing precautions (no passive or active shoulder extension or external rotation; no active movement in any direction; only passive shoulder flexion and abduction to about 80 degrees allowed, non–weight bearing).

Mrs. Green would have problems with upper body dressing/bathing because she might be tempted to actively move her arm to manage clothing or to wash under her arms. Pulling up her pants/underwear might be difficult if she is unable to pull up both sides evenly without rotating her trunk and potentially extending her operated shoulder. Because Mrs. Green is unable to use her dominant arm for self-care tasks, she would likely use many compensatory movements with her nondominant arm in her efforts to complete tasks that she did in a more coordinated way with her dominant arm. This increases the potential of performing active movement or passively moving the shoulder in directions that are not permitted.

4. Mrs. Green did not have any movement precautions with her right hand, wrist, or forearm. How could you enable Mrs. Green to use her right hand as an assist (while it was still in the sling) during daily activities without breaking her movement precautions at the shoulder?

Mrs. Green could use her right hand to stabilize objects (eg, small food packages) while using her left hand to open the package and perform some fine motor tasks (eg, screwing on the toothpaste top, buttoning lower buttons). She could hold very lightweight objects (eg, pen, paper, toothbrush) during transport.

Summary

Hip fractures and hip, knee, and shoulder replacements are orthopedic conditions in which OT intervention may speed the client's return to optimal participation in daily activities safely and comfortably. OT evaluation and intervention begin with obtaining the client's occupational profile and an assessment of the emotional and social issues related to the surgery and the surgery's potential impact on the client's lifestyle. Awareness of and a sensitivity to the psychosocial challenges of the person with an orthopedic problem are critical for the delivery of optimal occupational therapy.

The protocol for other areas of OT intervention is determined by the surgical procedure performed and by the precautions prescribed by the physician. Clients who have weight-bearing precautions must be trained to observe these safety measures during all ADL and IADL routines. A simulation of the home environment or a home assessment will prepare the client for potential problems that may arise after discharge. Areas to assess include the entry, stairs, bathroom, bedroom, sitting surfaces, and kitchen. Recommendations to remove throw rugs and slippery floor coverings and obstacles are made because the client will most likely be using an assistive device for ambulation. A kitchen stool or utility cart may be indicated. It is important to assess and instruct the client and caregiver regarding ADLs and IADLs with adaptive equipment, as well as any movement precautions. Home therapy may be indicated after a hospital stay to ensure safety and independence in daily occupations if these goals were not met during hospitalization.

In addition to the ADL and IADL strategies previously specified, the occupational therapist should be sure to address all areas of occupation that may be difficult for the client, as well as those that may pose a safety risk. Occupations such as caring for a pet, navigating through a cafeteria for meals, traveling in vehicles other than cars, and attending religious or other community activities that require specific transfers (ie, to a church pew) are all examples of activities that may be part of a client's typical performance pattern and should be addressed by occupational therapy. The occupational therapist can assist the client in approaching meaningful occupations safely, observing any movement precautions that are required, and suggesting and demonstrating alternative methods and assistive devices.

Preoperative teaching programs are invaluable in aiding client adjustment. These classes familiarize clients with the hospital, nursing, physical therapy, occupational therapy, and discharge planning. Procedures and equipment, concerns regarding hospitalization, discharge, and therapy are addressed. Participation in this type of class has been shown to relieve anxiety and fear, empower the client during the hospitalization, and decrease the hospital length of stay.

Review Questions

1. Explain the difference in precautions for the anterolateral and posterolateral approaches for a hip replacement.
2. When a client is transferring from one surface to another, what is the general procedure to follow to ensure the safety and protection of the involved side?
3. List the most common types of adaptive equipment used during rehabilitation of hip fractures and LE joint replacements, and describe their purpose.
4. Describe how the case coordinator and occupational therapist can work together to ensure a safe discharge for the client.
5. List two specific suggestions for performing sexual activities for someone with a hip replacement.
6. What information should be obtained when completing the occupational profile?
7. Identify two factors that affect fracture healing.
8. Identify two ways an occupational therapist can address the psychosocial adjustment to LE joint replacement and hip fracture.
9. Why are weight-bearing precautions observed with an ORIF?
10. Compare the rehabilitation techniques of clients with a hip replacement to those of clients with a knee replacement.
11. What are the benefits of conducting client education preoperative classes for persons who are at risk for falls or who are planning a joint replacement?
12. How might a person's rehabilitation program be affected by bilateral joint replacements?
13. How do shoulder precautions limit daily activities?
14. During what activities would the occupational therapist suggest that a client wear a sling or swathe following a shoulder replacement?
15. During what activities would the occupational therapist suggest that a client opt not to utilize a sling following a shoulder replacement?
16. Identify one key exercise that a person should perform multiple times daily following a shoulder replacement. How will you ensure client safety during this exercise?

Low Back Pain*

Ashley Uyeshiro Simon

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, the student or practitioner will be able to do the following:

1. Identify how low back pain can impact occupational engagement and daily life, physically and emotionally.
2. Identify the most common causes of low back pain.
3. Define neutral spine.
4. Identify the basic concepts of body mechanics and how this relates to anatomy.
5. Apply general body mechanics techniques during basic activities of daily living and instrumental activities of daily living.
6. Identify the occupational therapist's role in evaluation and intervention.
7. Recognize the psychosocial effect of low back pain.
8. Identify adaptive equipment that may improve function.
9. Identify other multidisciplinary pain team members.

KEY TERMS

Activity pacing
Body mechanics
Energy conservation
Ergonomics
Lifestyle modifications
Neutral spine

Self-regulation

Threaded Case Study

Maria, Part 1 (Evaluation)

Maria, a 47-year-old homemaker, lives with her husband and adult son in their one-story home. She worked in a retail store prior to her low back injury, which was caused by a motor vehicle accident (MVA) 3 years ago. Maria has bilateral myofascial (muscular) low back pain, and also has herniated disks at L4 and L5. She primarily complains of intense muscle soreness and often compares this to how muscles feel after rigorous exercise. Maria also reports sometimes feeling a sharp shooting pain down the buttock and back of the thigh when she bends over, which only lasts for short periods of time. She is currently also receiving physical therapy (PT).

Maria has been referred to occupational therapy because she is having difficulty completing activities of daily living (ADLs) (dressing, getting in and out of bed, and meal preparation), difficulty doing home management tasks (laundry, dishes), and was diagnosed with depression. Maria's goals are to decrease her pain, to improve her ability to complete home tasks independently, and to be able to go to a movie with friends.

During the evaluation, the Canadian Occupational Performance Measure (COPM) is used to assess functional limitations and occupational engagement difficulties.[2] Maria reports any activities involving bending or twisting are difficult and painful, including doing laundry, picking items up off the floor, making the bed, and completing her morning hygiene routine. She also reports she is not going out of the house (except for doctor's appointments), has significantly decreased her social activities, and has low energy levels. Maria's baseline level of pain is 5/10 on the numeric rating scale. During self-care and home management activities, her pain increases to 8/10, and after staying in one position for too long, her pain increases to 7/10, which makes it difficult for her to sleep well. Due to difficulty with meal prep and because her husband and son are at work during the day, Maria has also been eating only one morning snack and one large meal per day.

Maria experiences a lot of guilt about not being a good mother and wife, and she often pushes herself to do tasks despite significant pain increases. She demonstrates little awareness of how her mood affects her pain levels, and vice versa.

Maria's occupational therapy intervention plan will involve education about body mechanics, positioning techniques, and depression management strategies. Problem-solving with Maria and her family about how she can incorporate this education into her daily life to decrease pain and increase engagement in occupations will be a large part of treatment. She will also receive training in relaxation techniques and use of adaptive equipment if necessary.

Critical Thinking Questions

1. What other occupations (not listed in the case study) do you think would be impacted by Maria's low back pain?

2. How do you think Maria's depression contributes or relates to her low back pain?

3. What barriers and supports to occupational engagement exist for Maria?

4. What is anatomically happening to the spinal column as Maria bends or twists that is causing pain?

Introduction

Low back pain (LBP) can impact almost every area of functioning, from self-care activities, to childcare and relationships, to emotional functioning. Low back pain is the most common type of pain in the United States (27%) and the leading cause of disability in Americans younger than 45 years old.[3] It is also the number one cause of years lived with disability in the world and in the United States.[4]

Nearly 1 in every 12 people experience frequent back pain of varying degrees.[4] For some, this pain will resolve on its own; for others, it can be minimized or eliminated with exercise, core strengthening, and rehabilitation. As for the rest, back pain can become chronic, and these people will have to function with back pain for the rest of their lives.

Have you ever thrown out your back, had a low back injury, sat in an uncomfortable chair for too long, or just lifted something in the wrong way that caused LBP or muscle strain? Even if you have never personally experienced LBP, perhaps you know someone who has, or you can imagine what it is like. Think of the daily occupations this pain may impact. If prolonged sitting is painful, then driving, working at a desk job, studying, or even eating a meal can be difficult. If standing still or leaning forward is painful, then cooking a meal, washing your face, showering, or applying makeup can be impacted. For many people with low back pain, even lying down can be painful, which can limit restorative sleep routines.

Mentally walk through your day from beginning to end, and think about all of the activities *you* do that involve movement, strength, and flexibility from the low back. Think of how having LBP may influence these activities. What if you want to pick up your child? How will you exercise so you do not gain weight? Would you be able to concentrate to study? How will you do the laundry if you live alone? Would you be as social if you were in pain? Even something as simple as picking up a dropped pen can be difficult, depending on the severity of low back pain. Thinking about the breadth of the impact of LBP will help you to better understand how to help your patients.

Common Causes of Low Back Pain

Understanding the anatomy of the back is essential to help a client with LBP. The occupational therapist must understand both normal anatomy as well as the pathology underlying numerous back problems, and must be able to convey this information to patients of varying backgrounds and levels of understanding. To educate the patient regarding the rationale for proper **body mechanics**, the occupational therapist must also understand how the anatomy and pathology are related to movement and daily occupations. Patients who understand the causes of their pain are often capable of applying strategies in multiple contexts and more motivated to make changes to manage their pain.

Vertebral Column and Musculature Review

The vertebral column is composed of the vertebrae and intervertebral disks. Each vertebra contains the vertebral body, which is the weight-bearing component, and the vertebral arch, which arises from the back of the vertebral body (Fig. 41.1). The vertebral arch is composed of two pedicles (one on each side) that extend into the lamina. The laminae join to form the vertebral foramina, which make up the vertebral canal in which the spinal cord resides. From the pedicle and joining of laminae are three bony projections called processes. These lateral processes join to form joints with adjacent vertebrae superiorly and inferiorly (Fig. 41.2). Between the joint of these adjacent vertebrae is the intervertebral foramen, from which the spinal nerves enter and exit. At the back of the spinal arch is the spinous process, where muscles attach. The low back region is composed of five lumbar vertebrae.

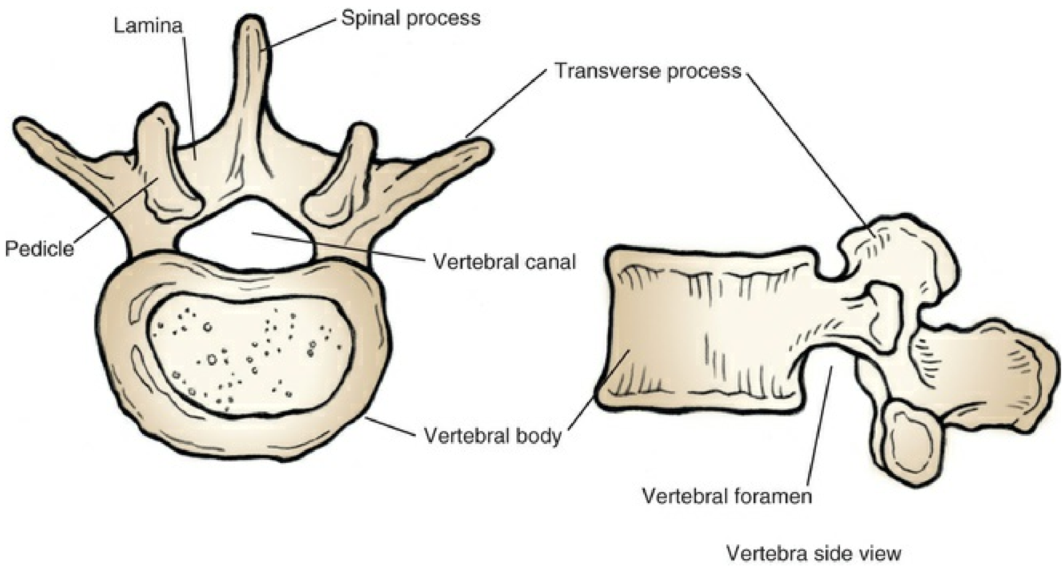

FIG 41.1 Vertebra from above and side view.

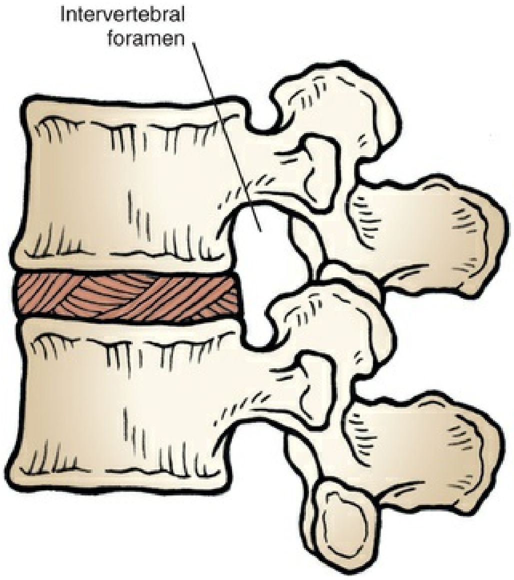

FIG 41.2 Two vertebrae in articulation. The spinal nerve exits via the intervertebral foramen.

Between the vertebrae are intervertebral disks, which are composed of fibrocartilage, a harder outer shell, and the nucleus pulposus, a softer gelatinous tissue (Fig. 41.3). The disks work as shock absorbers and are relieved of pressure only when the body is supine. As the nonrigid parts of the vertebral column, they provide spinal flexibility for movement. When a person is standing with a **neutral spine**—the most comfortable spinal posture and pelvic tilt, yielding equal pressure on all the vertebrae and disks—the pressure on all sides of the disk is equal. Movements such as bending, leaning, and reaching result in disk pressure and bulging on the side that the person is bending toward and stretching of the disk on the opposite side (Fig. 41.4).

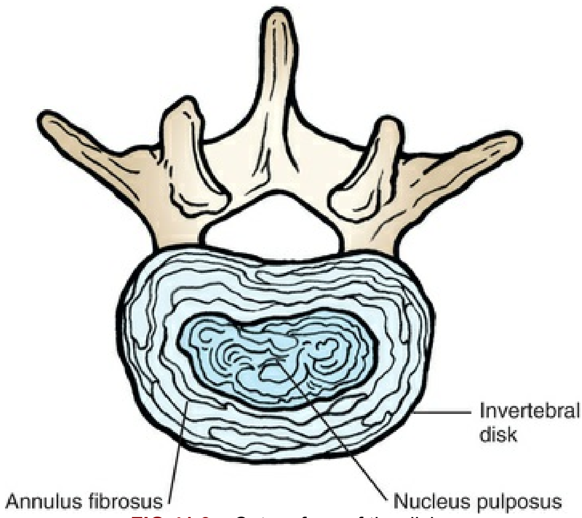

FIG 41.3 Cut surface of the disk.

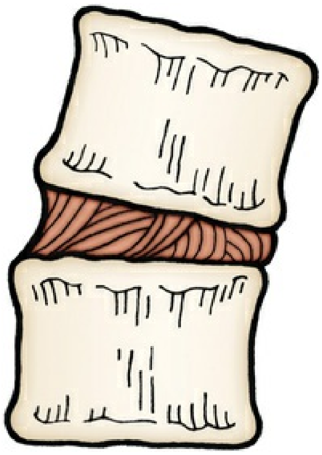

FIG 41.4 The same disk may be under compression and extension at the same time.

Anterior and posterior longitudinal ligaments extend the length of the vertebral column and are attached to the vertebral bodies and intervertebral disks. These ligaments prevent excessive movement of the column. The sacrum is the lower fused portion of the vertebral column and is attached to the pelvis. Movement of the pelvis changes the lordosis, or curve of the lumbar spine: anterior tilt of the pelvis results in more lordosis (arching of the low back), and posterior tilt of the pelvis flattens the low back.

Muscles of the lumbar spine include the intertransversarii and interspinales, which are small intersegmental muscles that connect the transverse process to the spinous process of adjacent vertebrae (Fig. 41.5). The lumbar multifidus, lumbar longissimus, and iliocostalis make up the lumbar muscles. These muscles are primarily extensors for the spine, but the lumbar longissimus and iliocostalis can also assist in lateral flexion. In addition, muscles of the abdominal wall, including the transversus abdominis and obliquus internus abdominis, help to stabilize the spine by providing a corseting effect. For further information on interaction of the back and abdominal muscles during specific movements, the reader is advised to do additional reading in this area.

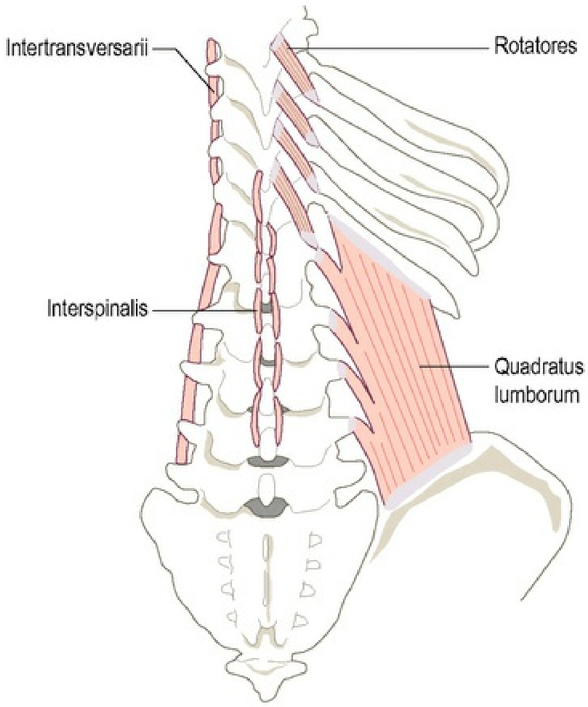

FIG 41.5 Intertransversarii and interspinales muscles. (From Palastanga N, Soames RW: *Anatomy and human movement: structure and function*, ed 6, Edinburgh, 2012, Churchill Livingstone.)

Common Low Back Pain Diagnoses

Typically, back pain is a result of poor physical fitness, obesity, reduced muscle strength and endurance, or poor body mechanics. For 90% of clients, LBP resolves within 6 weeks; for another 5%, it resolves in 12 weeks. "Less than 1% of back pain is due to 'serious' spinal disease (eg, tumor, infection). Less than 1% of back pain stems from inflammatory disease, and less than 5% is true nerve root pain."[1] Changes in the structure or mechanics of the lower part of the back may lead to problems, including the following:

- Sciatic (nerve root) pain: the nerve is entrapped by a herniated disk.
- Spinal stenosis: narrowing of the intervertebral foramen decreases the space where the spinal nerve exits or enters the spine.
- Facet joint pain: inflammation or changes in the spinal joints cause facet joint pain.
- Spondylosis: this is a stress fracture of the dorsal to the transverse process.
- Spondylolisthesis: one vertebra slips on another.
- Herniated nucleus pulposus: stress may tear fibers of the disk and result in an outward bulge of the enclosed nucleus pulposus. This bulge may press on spinal nerves and cause various symptoms, including nerve entrapment.
- Compression/stress fractures: these fractures are usually a result of osteoporosis and occur in the vertebrae.[5]

As noted later in the chapter, behavioral health has a significant impact on pain, and a mental health diagnosis such as anxiety or depression can often worsen, or in some cases cause, LBP as well.

Occupational Therapy Evaluation

The occupational therapist's primary goals during the evaluation are to determine which occupations are impacted by LBP and how the person's actions influence pain. This can be done by using self-report questionnaires, assessment tools, patient/caregiver interviews, or patient demonstration, depending on the treatment setting. Box 41.1 lists some common LBP assessment tools. Educating the patient about the role of occupational therapy and how occupational therapists can help improve function is vital in the evaluation so the patient can correctly identify areas of functional difficulty.

Box 41.1

Common Low Back Pain Assessment Tools

- Canadian Occupational Performance Measure (COPM)[2]
- Brief Pain Inventory[8]
- Pain Self-Efficacy Questionnaire[6]
- Beck Depression Inventory-II[10]
- Activity of daily living checklists
- Numeric rating scale
- Wong-Baker Faces[11]

The patient's current understanding and knowledge of LBP and pain-relieving strategies can be assessed by asking if patients know any activities that decrease or increase their pain or by listening for action-oriented statements that describe the patient's experimentation with various techniques to find strategies for pain management. The occupational therapist's evaluation should not be limited to physical problematic areas but should include an assessment of how the LBP impacts the person's emotional, spiritual, and social functioning.

When creating a plan of care, outcomes can include reduction of pain, use of back stabilization techniques, use of adaptive equipment, and incorporation of body mechanics and **ergonomics** into client-specific areas of occupation, as well as the ability to adapt this information to new occupations to prevent future problems. Depending on the payer, goals can also be written about stress and mood management, lifestyle and habit changes like losing weight or managing blood sugar levels, work/school abilities, and socialization.

Postoperative Occupational Therapy Evaluation

Surgical treatment of back problems has undergone many advances. Interventions include laminectomy, fusion, nerve decompression, disk dissection, vertebroplasty, and kyphoplasty. Surgical interventions are divided into two basic types: surgery that decompresses the nerve and surgery that stabilizes the spine to reduce pain. Surgeries that decompress the nerve open the transverse foramen and increase the space for exit of the spinal nerve and entrance to the spinal cord. Some surgeries may remove a structure, such as part of a disk or an osteophyte that is putting pressure on the nerve root. Stabilization can include the use of various pieces of hardware, such as screws, wires, rods, and bone grafts, to stabilize the bony structures of the spine. In addition, both vertebroplasty and kyphoplasty use a cement-like substance to stabilize compression/stress fractures. Kyphoplasty involves the use of a balloon that is placed in the fracture and, when inflated, helps restore height and reduce deformity before the cement is injected.[5]

Client precautions must be identified. Therapists should work with the physician to develop protocols or standards of care for specific surgeries. It is also important to identify the types of braces and other equipment that may be used for a specific surgery by a specific physician so that the occupational therapist can provide the expected instructions and precautions for use of the equipment in daily occupations. For example, one physician may allow a client to put a brace on while sitting at the bedside, whereas another physician may require the client to logroll into the brace and completely don it before coming to a seated position. Frequently, braces are ordered and fitted before surgery so that they are available to patients upon admission.

When seeing a client for the first time postoperatively, the occupational therapist should obtain the client's history and occupational profile, as well as a description of his or her home environment to ascertain the types of modifications required for safety. During the occupational profile, ADL and instrumental activity of daily living (IADL) issues should be identified. As part of the home assessment, education in work simplification techniques, in conjunction with directive questions, helps the client identify further needs. For example, when explaining how storing frequently used items within easy reach and infrequently used items in lower or higher places can save energy, the therapist can then ask the client how meal prep and eating items are stored in the home. This return demonstration helps clients to process the training and to independently identify other areas of the home where this concept may apply. Home modifications may include picking up rugs to prevent falls, increasing awareness of pets, and selecting a type of chair that is easy to get in and out of and that provides good support and fits the client well. The therapist should also determine whether the home contains a standard toilet and shower and whether modifications for safety and comfort are required.

Occupational Therapy Interventions

Based on the occupational therapy evaluation, the therapist may implement any of the following intervention areas, depending on the needs and personal goals of the client. Factors to consider when implementing interventions include the client's willingness to change old behaviors, educational level, financial abilities, social support, cognition, and self-awareness.

Client Education

Education is the key to success for a client with LBP. Knowledge of basic anatomy and physiology helps the client understand what is occurring while engaging in an occupation. Understanding how lifestyle factors and stress levels can affect pain helps motivate the client to make behavior changes. This knowledge is the foundation on which to build the rest of the intervention plan and ultimately select the appropriate interventions.

Information individualized to each client's needs is ideal. Many books, videos, card systems, and computerized educational systems are available. In addition, charts and models of anatomy can help the client to understand anatomy and physiology. Education can be provided in both group and individual settings.

Body Mechanics

To incorporate body mechanics, the person must first find his or her own "neutral" spinal position by standing with the knees slightly bent and the weight distributed evenly. Using the abdominal muscles to tilt the pelvis, the client should flex and extend the lumbar spine until he or she attains the balanced position of optimal function and stability (Fig. 41.6). The abdominal muscles should be contracted to maintain this position, much as a corset would. This position or stabilization should be maintained and integrated into performance of the client's occupations. Some individuals experience no pain while in a greater degree of extension or with a greater curve in the lower back region, whereas others prefer a neutral position of flexion and have more of a flattened abdomen.

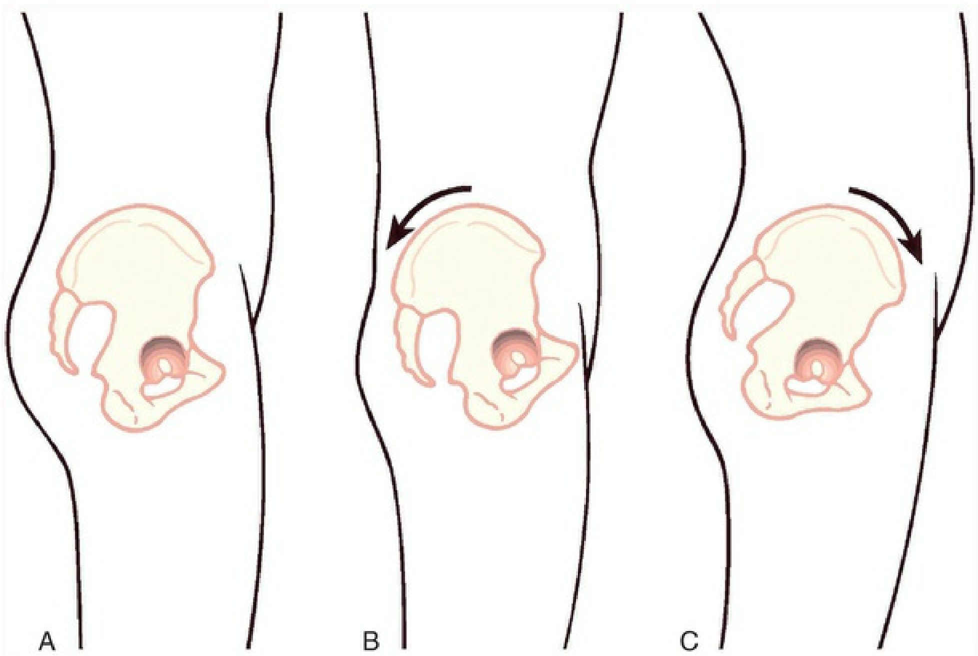

FIG 41.6 Sagittal plane movements of the pelvis. A demonstrates a pelvis in neutral position. B demonstrates a posteriorly tilted pelvis (pelvis tilted to a flattened back). C demonstrates an anteriorly tilted pelvis (pelvis tilted to an arched back). To obtain a neutral spinal position, a person must find a comfortable position between arched and flattened. (From Muscolino JE, Cipriana S: Pilates and the "powerhouse," *J Body Work Movement Ther* 8:15-24, 2004, Figure 6, page 20.)

In addition to developing a neutral spine, the client will need to learn and integrate different techniques into activities to help in lifting and movement. These positions include the squat, diagonal lift, and golfer's lift. Performing a squat requires the absence of any knee or hip pathology; the client keeps the back straight while maintaining a neutral spine (Fig. 41.7, A). A diagonal lift requires the lift to be performed with one foot in front of the other and the legs shoulder length apart (Fig. 41.7, B). A golfer's lift requires bending at the hips while raising one leg behind (Fig. 41.7, C).

FIG 41.7 **A,** Squat. Squat and lift with both arms held against the upper part of the trunk. Tighten the stomach muscles without holding your breath. Use smooth movements to avoid jerking. **B,** Diagonal lift. Squat down and bring the item close for lifting. **C,** Golfer's lift. When reaching into the cart, lift the opposite leg to keep the back straight.

It is important that clients thoroughly understand how to use body mechanics to stabilize their backs. This includes maintaining a straight back, bending from the hip, avoiding twisting, maintaining good posture, carrying objects close to the body, lifting with the legs to promote safe performance, and using a wide base of support. To reduce back stress for activities done in standing, the client can use a small stool or open a cabinet door and rest the foot inside the cabinet base. Instruction in avoiding any twisting of the back during activities is also essential, as will be noted in many habitual activities such as flushing the toilet. In these instances the client must be instructed to turn the body as a unit while maintaining a neutral spine.

Ergonomics at Work

Many LBP injuries are caused or exacerbated by working. Whether the person sits at a computer all day or works on an assembly line, the spine is involved with every movement. For labor-intensive jobs, principles of body mechanics are applied to encourage posture and limit strain on the back. For desk jobs, ergonomic principles are applied to ensure a neutrally positioned spine and to minimize muscle strain during periods of extended sitting.

Equipment that allows employees to work while both sitting and standing (Fig. 41.8) can benefit those with LBP, as frequently changing positions reduces muscle strain and promotes more neutral alignment of the spine. Ideally, the person should change positions at least every 30 minutes to alleviate prolonged pressure on disks, pressing of nerves, and muscle strain.

FIG 41.8 Sit/stand equipment example. (Courtesy Ergotron, Inc., St. Paul, MN.)

Ergonomic task chairs that permit seat height, seat depth, back angle, and back height or lumbar placement adjustments allow users to fit the chair to their bodies. A chair for desktop work must provide back support (ideally all the way up to the shoulders) and maintain the hips and knees at 90 degrees with the feet flat on the floor or a footrest. Tilt on a chair can also provide desk decompression periodically throughout the day. Often clients place their chairs too high, resulting in pelvic anterior tilt and putting strain on the low back.

The occupational therapist assesses the client's work tasks and helps the client to modify his or her workspace, equipment, and behaviors. The client is taught to take frequent breaks (again once every 30 minutes), change positions and tasks frequently, and move objects closer to prevent repetitive reaching or leaning. Apps, phone and calendar reminders, and computer software programs can be used to cue clients to take more frequent breaks at work.

Occupational therapists are prime candidates for ergonomic consulting given their anatomic training, occupational analysis, and creative problem-solving skills. Ergonomic equipment manufacturers can help a therapist identify specific products that fit a client's needs, and therapists should make contacts with these vendors.

Chapter 14 discusses ergonomic principles in more detail.

Energy Conservation

Clients may not realize the toll that normal daily activities can take when they have back pain. For instance, a man who usually runs all of his errands in one day may not be aware of how taxing this is on his back and how this pattern is contributing to a pain increase, as opposed to doing one or two errands each day. Teaching clients the principles of **energy conservation** can alleviate or minimize problems in this area. These principles include planning ahead, setting priorities, learning one's activity tolerance, eliminating or delegating unnecessary tasks, and expending less energy for tasks that are performed (Box 41.2).

Box 41.2

Energy Conservation Strategies for Hosting Dinner With Friends

- Planning ahead: shop for food 2 days prior; do all chopping and food prep one day prior.
- Prioritize: do not schedule other events that day to save energy for dinner that night.
- Eliminate tasks: go out to eat to eliminate the need for cooking, cleaning before, and cleaning after the dinner.
- Delegate: make the signature dish, and let others bring side dishes.
- Learning activity tolerance: limit the dinner to a certain amount of time.
- Decreasing required energy for a task: sit while preparing food instead of standing; use a fan in the kitchen to decrease heat exhaustion.

Energy conservation analogies are helpful when educating clients about how this concept can be applied to their lives. One analogy is that of a pitcher of water. Imagine the pitcher represents how much *potential* energy a person has, and the amount of water in it is the *actual* amount of energy the person wakes up with at the beginning of the day. Energy levels may differ based on sleep quality, pain levels, or general fatigue.

Now imagine each occupation is a cup, and depending on the activity, the cups may be of varying sizes. The person must prioritize and plan ahead for which cups he or she is going to pour water into, as sometimes the most important tasks come toward the end of the day when energy has already been expended (meal prep, time with family, sex, etc.). The person must also choose how much water is going to be poured into each glass, as some glasses do not have to be filled completely (instead of cleaning the whole house, a person can choose to dust, decreasing the amount of required energy).

This analogy often helps clients visualize the concepts of energy conservation as well as convey the idea that energy is finite and must be spent wisely. A person can dig into his or her “reserves” for more energy if needed, but this will result in less energy to start with the next day and often can cause a pain flare-up, decreasing that person's level of functioning. The key to success in incorporating energy conservation into one's daily occupational life is for the client to be aware of his or her individual activity tolerance, including specific knowledge regarding triggers of fatigue and the amount of rest necessary for recovery.

For Maria, implementing energy conservation techniques during laundry tasks may be as simple as sitting while she folds laundry or using an ironing board as a raised table if folding laundry when standing. This technique would decrease the size of the “cup,” or required energy, and thus would require less “water” or energy to complete the task, leaving more water for other activities.

Activity Pacing

Activity pacing is a simple concept in theory, but it can be one of the most difficult concepts to help a person implement into daily life. Activity pacing is applied both on a large scale (daily or weekly) and on a small scale (moment to moment). In its simplest form, activity pacing calls for always alternating between periods of activity and periods of rest in order to prevent overexertion.

On a large scale, people can use time management skills and good planning to make sure they pace themselves with activity. For example, if Maria wants to have her friends over to her home, she may choose to cook foods that can be prepped the day before, go food shopping several days beforehand, and schedule a period of rest just before the event. This would help her to avoid overexertion, which would minimize fatigue and limit pain exacerbation.

On a smaller scale, activity pacing can also happen from moment to moment, as people listen and respond to their changing pain and fatigue levels (Fig. 41.9). Often people with pain will push themselves to finish tasks despite significantly increased pain, as they fear the unpredictability of pain may prevent them from being functional later. However, when people push themselves to their body's limit, they are further sensitizing and damaging the painful area, as well as putting themselves at risk for a subsequent period of decreased function (usually people report this as being "out of commission" for a few hours to a few days) while their bodies recover. This becomes a vicious cycle, as people push themselves, have a pain flare, then have an abnormally long period of decreased function, causing them to believe they only have small windows of opportunity in which to accomplish tasks. This then leads back to overexertion.

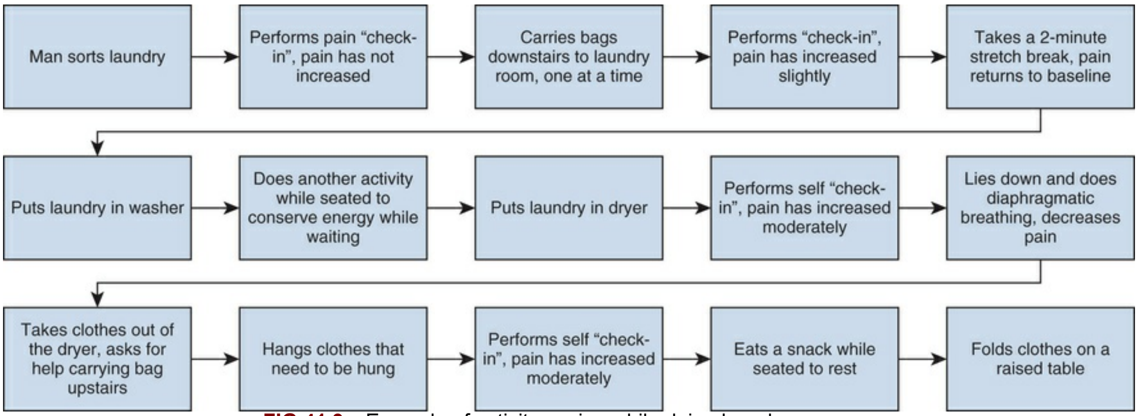

FIG 41.9 Example of activity pacing while doing laundry.

Poor activity pacing can include scheduling too many activities in one day (or one week) without enough rest breaks, having unrealistic expectations of what can be accomplished in a given amount of time, or periods of overexertion followed by a pain flare that lasts for an abnormal period of time.[7]

Occupational Strength and Endurance Building

Once the principles of energy conservation have been taught and incorporated into several of the client's occupations, it is important to build on that knowledge and enable the client to increase strength and endurance for more occupational engagement. Gentle and slow-paced activity grading is the primary strategy for building tolerance when treating someone with pain, as the body's response to increased activity can vary. For example, given the opportunity to prepare a meal nightly, the client can soon develop the endurance to prepare a meal for guests. Likewise, sitting at a computer to write a letter while maintaining a neutral spine strengthens the abdominal muscles and sitting tolerance, which can increase the ability to sit in the car for a moderate to long car ride.

Self-Regulation Training and Coping Skills

LBP can also be influenced by a person's behavioral health status. Stress, anxiety, depression, and sometimes other behavioral health issues can have a significant impact on pain level and the person's perceived control over pain. Likewise, being in pain (especially chronic pain) can influence emotions and mood (Fig. 41.10). According to the Centers for Disease Control and Prevention, adults who report LBP are more than four times as likely to experience serious psychological distress as people without LBP.[3]

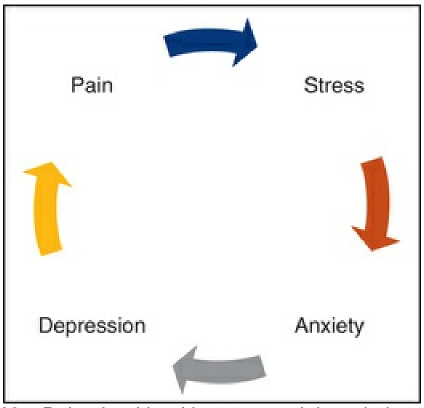

FIG 41.10 Behavioral health status and the relation to pain.

Stress and Anxiety

Pain causes stress on the body, simply because pain is a signal to the body that something is wrong, and this triggers automatic responses to encourage the body to remove or address the painful stimulus (eg, moving your foot away from a fire). In addition, feeling stress or anxiety stimulates the sympathetic nervous system, which adds to an already overly excited nervous system, causing a cycle of stress, anxiety, and pain that is difficult to control, as one usually feeds the other.

Depression

Depression and LBP are often comorbid and are the two leading causes of years lived with disability in the United States and globally.[4] Depression can cause physical symptoms that include painful responses, and it is also believed that depression influences pain through neurotransmitter dysregulation.[9] For Maria, not only do her pain and depression influence one another, but she also reports feelings of guilt due to not being able to accomplish the tasks that she feels contribute to her family's needs. She also is dealing with the loss and change of former occupations, which she is both grieving and learning to accept.

Behavioral Health Interventions

Box 41.3 provides basic strategies to encourage patients to self-manage their stress and mood. Several interventions listed encourage parasympathetic nervous system activation, thereby decreasing the sympathetic nervous system response, and are deemed **self-regulation** techniques as they seek to regulate and calm an overstimulated nervous system. These strategies not only target the behavioral health of the patient, but often they can directly affect pain levels as well by dampening the sympathetic response. Also see the section in Chapter 7, Section 2, on mindfulness strategies.

Box 41.3

Behavioral Health Strategies for Pain

- Getting 20 minutes of direct or indirect sunlight exposure each day
- Getting dressed each day
- Performing good self-hygiene
- Exercising, as tolerated
- Getting out of the house each day
- Taking medications on time
- Using diaphragmatic breathing

- Employing progressive muscle relaxation (passive or active)
- Incorporating guided visualization/imagery
- Socializing regularly

Lifestyle Modifications

Eating

Making **lifestyle modifications** and behavioral changes to keep blood sugar stable, so as to prevent episodes of very low blood sugar, can help people avoid episodes of increased achiness and low energy. Identifying an eating schedule, educating a person about general blood sugar management strategies, and problem-solving when the person is going to go food shopping and how he or she is going to prep meals without increasing pain are all areas occupational therapists can address.

Sleep

Lack of quality and amount of sleep can cause dysregulation in the body and thereby increase pain levels. However, pain can often limit a person's ability to get enough quality sleep due to difficulty falling asleep, frequent waking, anxiety, or discomfort. This creates a problematic cycle for some people with LBP, as pain interferes with restorative sleep, leading to more pain the following day. See Chapter 13 for more information.

Occupational therapists can educate clients about sleep hygiene strategies to help people fall asleep and stay asleep, or fall back asleep if frequent waking at night is an issue. Activities performed prior to bedtime can greatly impact one's ability to fall asleep and the quality of that sleep. Avoiding stimulating activities that will alert the mind or body for at least 30 minutes (ideally 60 minutes) before bed is important. This includes using electronic devices with bright screens, exercise, housework, answering emails, and sometimes looking at social media. Alcohol and nicotine should also be avoided, as these can interfere with sleep cycles.

Instead, people should be encouraged to engage in calming and relaxing activities before they plan to fall asleep. Reading, listening to music, light stretching, aromatherapy, and hot showers are often used to relax the body and mind before bed. Refocusing thoughts on breathing exercises, guided muscle relaxation, meditation, or even just using white noise can often help people fall asleep more easily by taking their minds off stressful thoughts. Sleep hygiene plans should be individualized to fit the client's preferences and opinions to optimize relaxation before bed (Fig. 41.11).

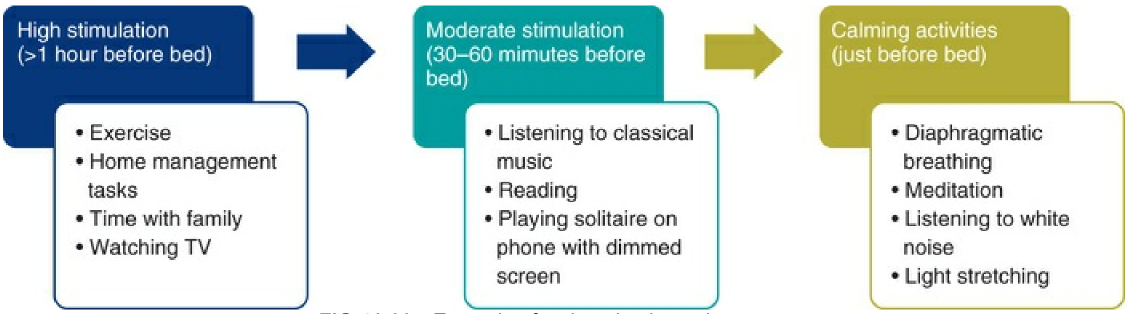

FIG 41.11 Example of a sleep hygiene plan.

Exercise

Maintaining muscle tone is important for those with LBP. Improving muscle strength in the areas surrounding the damaged site can reduce painful symptoms for conditions such as herniated disks or arthritis. Yoga, Pilates, and other strength-building activities can be helpful in these situations and can be slow, controlled, and easily graded if the person fears exercise. In addition, people with LBP often find the right forms of exercise can alleviate pain. Movement of joints releases synovial fluid and can reduce pain and improve mobility for those with arthritis or degenerative diseases.

Pool exercises can be extremely useful for those with LBP, as water decreases gravity's pull, which will decrease strain on muscles and lessen the compression of vertebral disks. Water also provides resistance, which is helpful when trying to build strength over time.

Medication Management and Cognition

Some patients may have difficulty managing their medications, possibly due to cognitive deficits, medication side effects, or being overwhelmed. These difficulties can include the following:

- Frequently forgetting to take medications
- Not taking medications on time
- Not using medication appropriately (addressed with the guidance of a physician)
- Difficulty remembering body mechanic techniques
- Forgetting where adaptive equipment is placed
- Poor attendance at healthcare appointments

Occupational therapists can help people improve medication management skills by providing organization, tracking, and cueing strategies to increase the accuracy of dosages and promote patient safety.

Adaptive Equipment

Adaptive equipment is often useful for patients with LBP. The most frequently recommended pieces of equipment for persons with LBP are used primarily to prevent the client from excessive spinal movement and include long-handled sponges or brushes, reachers, long-handled shoehorns, sock aids, elevated commodes or toilet seats, wiping wands for toileting, handheld shower sprayers, and footstools.

Postoperative Interventions

After surgery, it is the therapist's responsibility to educate the client in the required performance precautions for daily occupations. This should take place before even attempting to have the client get out of bed. Contrary to customary practice in occupational therapy wherein the therapist observes occupations and makes corrections afterward, in this situation the therapist does not want to observe performance before the intervention. Instead, the primary focus is to educate then cue the client through the process to avoid any improper positions or posture that creates stress on the surgical area. The goal of occupational therapy intervention is to train the patient to perform necessary ADLs while maintaining a straight back, avoiding twisting, incorporating back safety techniques, and using adaptive equipment.

The most basic ADLs must be addressed initially while the client is in the hospital. It is important to educate clients on proper positions for sleeping and have them return-demonstrate the positions correctly. The client will need to use the logroll technique for functional mobility in the bed. Proper methods are also taught for getting in and out of bed, in and out of a chair, and on and off a toilet; brushing teeth; washing the face; shaving; and dressing using the back protection techniques discussed earlier. Clients are instructed to use adaptive equipment to prevent back stress during daily activities, including getting in and out of an automobile.

Because hospital stays are often short and because most people will be discharged home, it is good to provide them with resources should specific occupations be overlooked during the hospital stay. Some facilities develop educational materials that include basic body mechanics information, hints on ADLs, and anatomic and surgical information. Various publications include postsurgical back dos and don'ts. Many hospitals have computerized education programs that allow the provider to issue information on the surgical procedure and the resulting back precautions. Although most insurance plans do not cover adaptive equipment such as reachers, raised commodes, shower chairs, and long-handled sponges, this equipment is necessary to ensure a successful postoperative outcome, and many clients purchase these items and have them delivered to their homes before discharge. To prepare the client for home and occupation modifications, many hospitals provide preoperative classes.

Client-Centered Occupational Therapy Analysis

Consider the following questions when providing occupational therapy services for a client with LBP:

Evaluation

- What are the client's goals?
- What is the occupational goal?
- What is the context in which the occupation is performed?
- What supports and barriers to engagement exist?
- How does the patient perform the necessary occupations currently?

Intervention

- What movements during activity increase pain?
- What anatomic structures are involved during occupational performance?
- What can the patient do or use to decrease pain?
- How can the environment or task be modified to fit the patient's needs?

Reassessment

- Did the intervention improve the patient's function?
- Is the patient able to manage pain during and after activity?
- Does the patient have the education needed to problem-solve through occupational engagement barriers independently after discharge?

In addition, it is important to always consider how the person, occupation, and environment interact when deciding on treatment interventions (Fig. 41.12). Thinking of the complex way in which these three areas support and contradict each other (especially with the help of the patients themselves) is what leads to effective, individualized care plans.

Threaded Case Study

Maria, Part 2 (Occupational Analysis)

Maria states her primary goal is to do the family's laundry independently, as this would give her a sense of productivity and fulfillment. The occupational therapist observes Maria attempt to load and unload the top-load washer and observes that Maria often folds at the hips and uses her back to lift the basket of clothing, reporting increased pain. When unloading the washer and placing clothes in the front-load dryer, the therapist also notes Maria bends forward again to retrieve the clothes, then twists and leans back and to the right to toss the clothing into the dryer.

Person

Maria states laundry is very important for her to do independently, as this will give her a sense of fulfillment. This means delegating part or all of the activity may not be the first option for her. Maria is willing to make changes to the way she goes about doing the laundry, but sometimes her depression makes it difficult to initiate tasks. Maria also states she tends to push herself despite pain increases during activity, as she believes her pain flare-ups are unpredictable and wants to finish things “while she still can.”

To increase motivation, the occupational therapist uses a motivational interviewing approach to help Maria identify why it is important to her that she be able to do the family's laundry. The therapist also has Maria place cue cards around the home to remind her that even small accomplishments are victories (for example, placing clothes in the hamper instead of in a pile).

The anatomic causes of Maria's LBP (herniated disks, myofascial pain) are mostly fixed, so treatment will focus on managing and minimizing her pain, not necessarily eliminating pain.

Occupation

As Maria bends forward, she is straining the posterior portion of the lumbar disks and causing the anterior portion of the disk to bulge outward. She is also placing strain on the spinal musculature in the lumbar area, especially when she picks up the basket of laundry and when bending to retrieve items from the washer.

These tasks may be modified using good body mechanics to lift a heavy laundry basket, such as using a golf lift for item retrieval and to ensure the hips and shoulders are always facing the same way to prevent twisting. The speed and intensity of the task can also be modified because Maria tends to push herself; if unloading the washer is the most painful part of this activity, Maria can do it in two parts with a break in between to prevent her pain from increasing significantly.

Environment

Barriers to Maria doing laundry independently are lack of assistance during the day, not owning any adaptive equipment, and having laundry equipment that encourages bending forward (top-load washer).

Maria can change to a front-load machine, then put the washer and dryer (also front-loading) on risers to limit the amount of bending she has to do. This will allow her to squat or kneel with a neutral spine next to the open machine door and reach in without twisting or leaning. If this is not possible, Maria can use a long-handled reacher or dressing stick to retrieve the clothes from the washer. If Maria spends a lot of time doing laundry, she can acquire an antifatigue mat to limit disk compression when standing. Maria can also place a small table near her laundry machines, so she can prevent bending and never has to place the laundry basket on the floor. She may also be able to use this table to fold clothing afterward.

If Maria is willing, she can ask her son and husband to carry the laundry baskets to the laundry room before they leave for work, then carry them back when the clothes are washed. This will help her to conserve energy. If Maria is unsure about asking for help, the occupational therapist can suggest this task modification be a temporary solution until Maria is able to tolerate more activity.

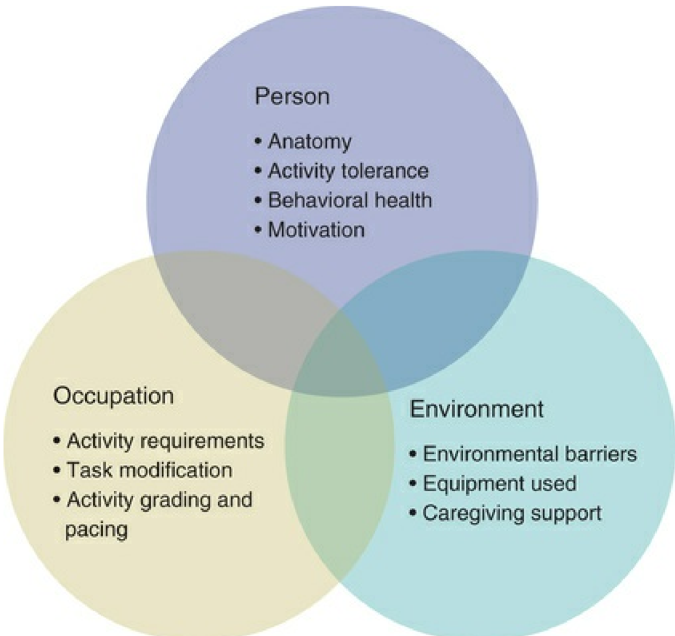

FIG 41.12 Person, environment, and occupation influences.

Intervention Strategies for Frequently Impacted Occupations

Showering

To promote energy conservation and limit bending, clients can keep all items on a shower rack or ledge that stands between chest and eye height. Use of a shower chair or bench can help if balance and bending when washing lower extremities is difficult while standing. Use of long-handled scrub brushes or sponges allows clients to wash their back, legs, and feet without bending and twisting. A handheld shower attachment controls water flow and decreases unnecessary movements. For safety, the client should always use a bath mat to reduce the chance of slipping and drain the water before attempting to get out.

Dressing

Keeping the back in a neutral position is the main goal when dressing. The client can sit in a chair or lie flat on the bed while using mostly hip flexion to get clothing onto the lower extremities, as opposed to spinal flexion (Fig. 41.13). To don and doff socks and shoes, the client should sit and bring the foot to rest on the knee using external rotation at the hip, or place the foot on a stool using mostly hip flexion. Maria preferred to use slip-on shoes as a compensatory strategy to minimize and avoid bending. A long-handled shoehorn and elastic shoelaces are useful for donning shoes that require tying. Back protection techniques should be used for both dressing and undressing.

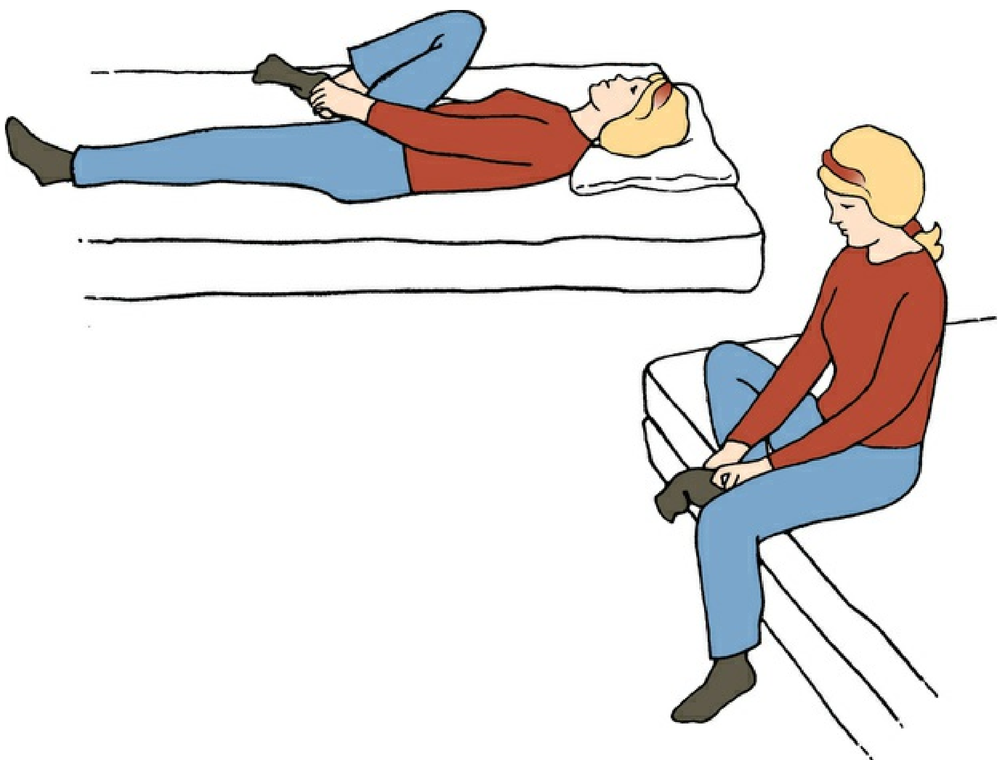

FIG 41.13 Dressing. Lie on your back to place socks or slacks over your feet, or bend your leg up while keeping your back straight.

Functional Mobility

Use of the *logroll* technique to maneuver in bed requires moving the body as a whole unit (Fig. 41.14, A). To sit up, the client lies on one side, bends the knees over the side of the bed, and pushes up with the arms while coming to a sitting position, using the weight of the legs as leverage (Fig. 41.14, B). To lie down, the client brings the legs up and uses the arms to lower the body to the bedside. During both movements, the client must keep the back straight and tighten the abdominal muscles to support the back.

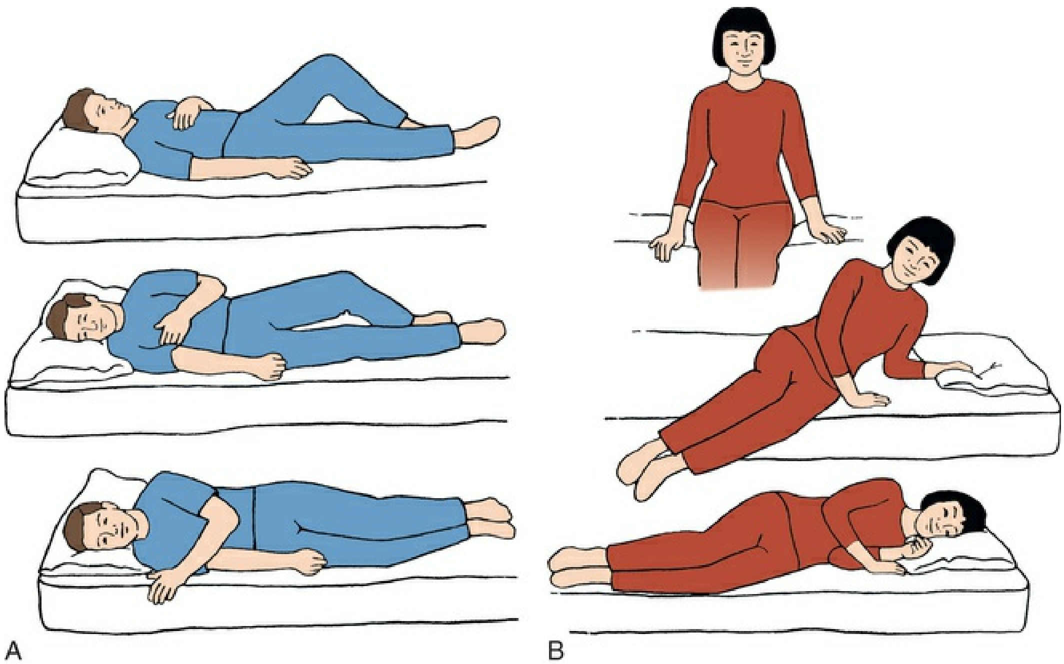

FIG 41.14 **A,** Logroll. Lying on your back, bend your left knee and place your left arm across your chest. Roll all in one movement to the right. Reverse for rolling to the left. Always move as one unit. **B,** Movement in and out of bed. Lower your body to lie down on one side by raising your legs and lowering your head at the same time. Use your arms to assist in moving without twisting. Bend both knees to roll onto your back if desired. To sit up, start by lying on your side, and use the same movements in reverse. Keep your trunk aligned with your legs.

When getting on and off the toilet, the client must maintain a straight back and neutral spine, and she or he should move slowly if pain levels are high. Supporting the hands on the thighs is helpful, or, if needed, a toilet frame or grab bars at the side of the toilet can be used. Occupational therapists must teach clients to differentiate between a weight-bearing grab bar that is bolted into the wall and towel bars or shelves that are not meant to bear weight. Clients also need to receive education regarding the safe use of other surfaces for stability, as people often use countertops, tubs, and walls for bracing during transfer, which can jeopardize safety and cause twisting. For some clients, a raised toilet seat can be helpful.

It is recommended that clients use an armed chair with firm cushions that is supportive and not too low, as compared to an oversized plush couch. The client can use the chair arms to push up to a standing position (Fig. 41.15), and the firm pillows will better support the back while seated. To reduce stiffness, the client should stand and walk or stretch frequently (about every 15-20 minutes).

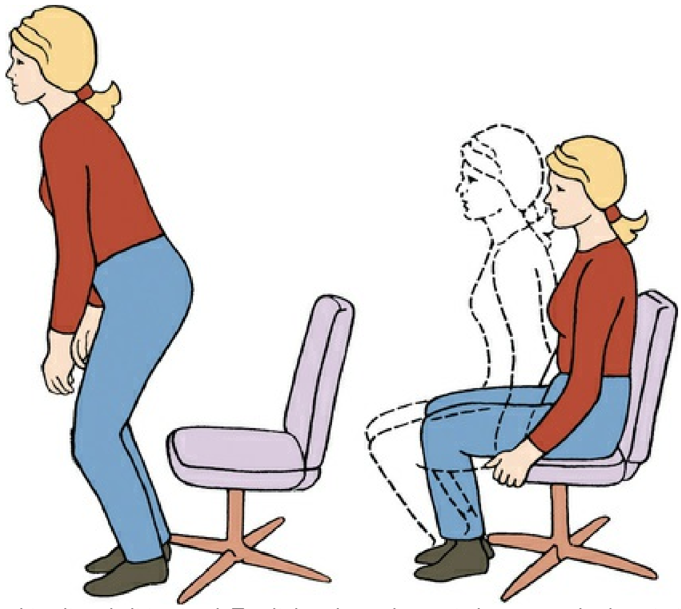

FIG 41.15 Stand to sit and sit to stand. To sit, bend your knees to lower your body onto the front edge of the chair and then scoot back on the seat. To stand, reverse the sequence by placing one foot forward and scoot to the front of the seat. Use a rocking motion to stand up.

Personal Hygiene

Activities at the bathroom sink can be difficult, as most sinks are hip or waist height, requiring most adults to bend forward, increasing stress and strain on the low back. While brushing the teeth, shaving, or washing the face, the client should place one foot inside the base cabinet to reduce strain on the lower part of the back and bend from the hips while keeping the back as straight as possible (Fig. 41.16). Alternatively, the client may bend forward and bear weight through one knee while extending a straight leg back for balance and support and maintaining a neutral spine position. Maria prefers to lean against the countertop with one hand to relieve some of the compression on her low back when rinsing after brushing her teeth, or she uses a cup to rinse her mouth instead of leaning over the sink. To apply her cosmetics, Maria uses a handheld mirror or a mirror attached to the wall at face height to limit bending.

FIG 41.16 Shaving. Stay upright with one foot on the ledge of the cabinet under the sink. (Courtesy Visual Health Information, Tacoma, WA.)

Sexual Activity

Sexual activities require positions and movements that keep the low back in the neutral position and prevent excessive twisting or repetitive flexion and extension of the spine. Clients whose pain increases with spinal extension may be most comfortable lying on their back with pillows under the buttocks or upper part of the back to minimize extension. For those whose pain increases with spinal flexion, a rolled towel under the low back may also help maintain a neutral back position (Fig. 41.17). If the client prefers positions that require being on hands and knees, large wedge pillows can assist the client in keeping a neutral spine. For men, standing during sexual activity and placing one foot in front of the other can promote good alignment.

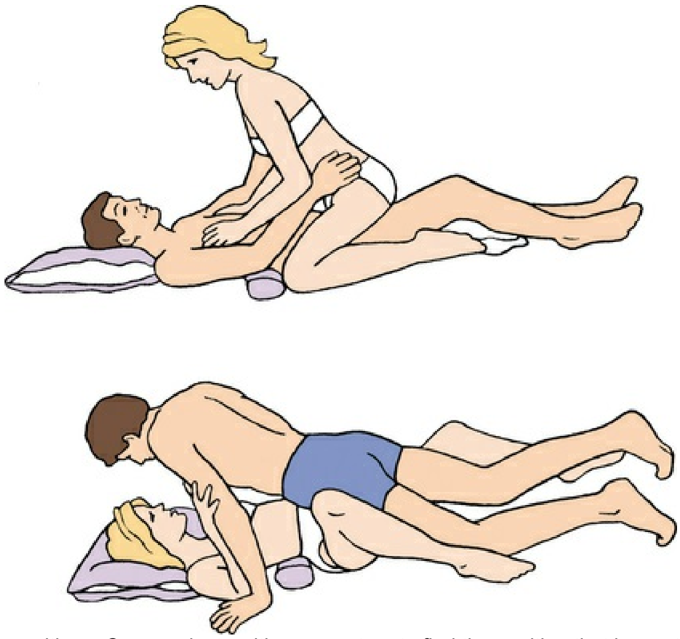

FIG 41.17 Sex positions. Communicate with your partner to find the position that is most comfortable for you. Plan ahead, and use pillows and rolls for support as needed.

Activity grading and pacing are especially important with sexual activity, and the client is advised to start slowly and gradually work up to more vigorous movements depending on tolerance. Before sexual activity, stretching and warming up muscles or taking a warm shower may enable greater activity through muscle relaxation.

Communication with a partner is also a key component of engaging in sexual activity. Often clients are too embarrassed, shy, or excited to talk about tolerance levels and speak up during activity when a movement becomes painful. Teaching clients about assertive communication strategies and helping them create an individualized plan for sexual activity can prevent injury and increase a patient's confidence.

Sleep

We spend almost a third of our lives in bed, so it is important to consider the effects that sleep positioning has on our backs. A firm, supportive mattress is important, as mattresses that are too soft or plush will not maintain neutral alignment. The pillow should support the neck and head without causing the neck to flex forward or laterally. Many types of contoured cervical pillows are helpful for this purpose.

While sleeping on the back, the client should place a pillow under the knees to reduce strain on the lower part of the back and help maintain a balanced lower back position (Fig. 41.18, A).

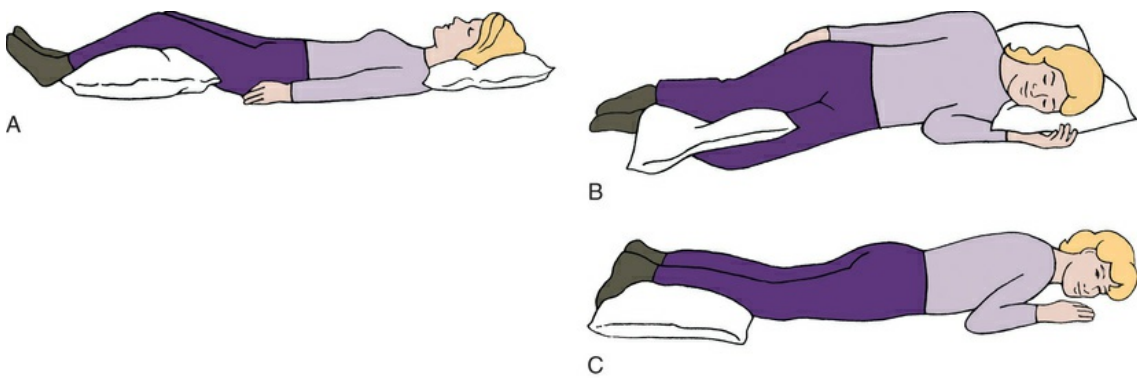

FIG 41.18 **A,** Sleeping on the back. Place a pillow under your knees. A pillow with cervical support and a roll around the waist are also helpful. **B,** Sleeping on the side. Place a pillow between your knees. Use cervical support under your neck and a roll around your waist as needed. **C,** Sleeping on the stomach. If

this is your only desirable sleep position, place a pillow under the lower part of your legs and under your stomach or chest as needed.

While lying on the side, the client should place a pillow between the knees to prevent the hips from collapsing in toward the bed and twisting the lower part of the back (Fig. 41.18, B). It is also sometimes helpful for people to hold a pillow at chest height when side-lying, as sometimes the shoulders collapse in toward the bed as well. A long body pillow can be used instead of two smaller pillows if desired.

It is not recommended that individuals sleep on their stomachs, but individuals who prefer this position should place a small pillow under the ankles to bend the knees and take stress off the lower back region (Fig. 41.18, C). If back extension is painful, a flat pillow can be placed under the hips. For additional information on sleep and rest, please refer to Chapter 13.

Toileting

When cleaning after toileting, the client should reach between the legs to avoid twisting the back, using a long-handled tissue holder if needed. When turning to flush the toilet, the client should stand first, then turn all the way around and face the toilet rather than twisting and reaching. During an acute episode of back pain, the client can straddle the toilet seat and face the back of the toilet. This affords a wider base of support and allows one to use the toilet tank when coming to a standing position.

Child Care

Handling children requires special precautions for individuals with back pain. Sudden movements can increase the client's pain and interfere with the ability to handle the child safely. Clients should use a changing table or elevated surface when dressing the child. Bathing can be performed in a kitchen sink or in a portable tub on an elevated surface. Many contemporary cribs have drop-down rails so that the client does not need to extend his or her arms to lift the child over the crib.

Always remind the client to bend at the hips and knees while keeping the back straight during these tasks. To lift a child from the ground, the client should squat down and bring the child close before using the legs and buttock muscles to stand up, all while engaging the abdominals. To place a child in a car seat, the client should stand close to the car seat and keep the back straight, minimizing any twisting movements (Fig. 41.19). Therapists should also encourage their clients to think of bonding activities that require less strain on the back, such as reading, doing tabletop puzzles, or snuggling in bed.

FIG 41.19 Child care, in and out of a car. Stand close and keep your back straight. Bend your knees to put the baby in or take the baby out of the car seat.

Pet Care

Depending on the size and type of the pet, a client may need different strategies to protect the low back. Use of proper body mechanics strategies such as squatting or kneeling with a neutral spine to serve food, water, or to pick up the pet itself is advised. Long-handled pet waste scoopers and self-cleaning litter boxes can minimize bending as well. Self-dispensing food and water containers can eliminate the need to bend multiple times per day. Clients with larger dogs need to be cautious when walking or playing with the pet to avoid any sudden twists or jerks.

Computer Use

It is important to remind people to fit the environment and equipment to the body, instead of using the body to compensate for environmental shortcomings. Clients should first position themselves in a seated neutral position by adjusting the chair and their own posture, then place items in close proximity to prevent reaching, bending, or twisting. The keyboard and mouse should be easily reached without the elbows leaving the sides of the body, which allows the chair to support the back from sacrum to scapulae. Frequently used items should be within arm's length, accessible without the scapulae coming off the back of the chair to prevent repetitive reaching.

The monitor should be placed at a height that encourages sitting up in the chair, rather than slouching. Clients should be taught to use their eyes to look down at the screen, as opposed to using neck and spinal flexion. Document holders can assist in proper placement of papers and books to prevent the need for repetitive or sustained twisting or bending. Tall users may need a different desk height compared to shorter users, and the keyboard (usually placed below the elbows) may need to be a different height than a writing surface (usually above the elbows).

Maria used a laptop computer while seated on the couch, which created much discomfort. To limit spinal flexion, Maria now uses an external keyboard, external mouse, and a laptop stand (or a stack of books) to prevent reaching or slouching. She also now uses the laptop at a desk instead of on the couch to provide herself with more back support. Most important, clients like Maria are encouraged to stretch, take breaks, and change positions at least every 20 to 30 minutes. (See Chapter 14 for additional information on ergonomics and seating.)

Driving

When transferring in and out of a car, the client should sit on the seat while facing the door and turn the body as a unit to keep from twisting. In some cars, and depending on the person's height, this may require adjusting the seat forward and backward to get in and out. The client should also increase the height of the seat to decrease the effort needed to sit and stand, as well as sit with the knees no higher than the hips to reduce strain on the low back. Most cars now allow adjustments in seat height, seat angle, seat position, and steering wheel angle, and some even come with adjustable lumbar support. A small, rolled-up towel positioned in the lumbar area will suffice as well. When riding for extended periods, the client should schedule rest breaks to change positions and use the recline feature of the seat to alleviate any spinal compression from sitting upright for prolonged periods of time. For drivers with back pain, use of cruise control allows more frequent changes in position, and taking frequent rest stops to stand, walk, and stretch is vital.

Home Management

Organization

The client should organize all work spaces so the equipment and materials needed for specific tasks are within easy reach and the work area is at an optimal height (usually around elbow height). For example, if the client is planning to bake cookies, flour, sugar, baking spices, bowls, measuring cups, and maybe a mixer should all be within reach. Routinely used items should be stored on the countertop, in the lowest cabinets, or in the highest drawers to limit back extension, reaching, and bending. Items in lower cabinets can be accessed with a partial or full squat. This same technique is used to reach items on the lower shelf of the refrigerator (Fig. 41.20), and items above the head can be accessed using a footstool. Cabinets can be modified with slide-out shelves/drawers that eliminate the need to reach far back into the cabinet. Items that are used less frequently can be stored in less accessible cabinets.

A B

FIG 41.20 **A,** Incorrect way to reach into a refrigerator. **B,** Squat with the knees apart to reach the lower shelves and drawers.

Laundry

To remove clothing from a top-load washer, the client should use a golfer's lift to reach inside the machine (Fig. 41.21). To place clothes in a front-load washer or dryer, the client is instructed to use a squat or to use an underhand toss without any spinal twisting or bending. To retrieve clothes from a front-load machine, the client repeats the squat, removes the clothes, and places them in a basket that is positioned nearby. When carrying the basket, the client should hold it close to the body and use the body mechanics for lifting that were discussed earlier in this chapter. It is highly recommended that the client fold clothes on an appropriate elbow-height table while standing or seated, to minimize the need for prolonged bending.

FIG 41.21 Laundry: unloading the wash. To unload small items at the bottom of the washer, lift your leg opposite the arm used for reaching.

For ironing, it is recommended that the client raise the ironing board to elbow height, and to use mostly shoulder flexion and elbow extension to maneuver the iron instead of twisting the lower back. While ironing, the client is instructed to rest one foot on a low stool to help reduce low back strain. Ironing can also be completed while sitting if the ironing board is lowered beforehand. Because of the adjustability of an ironing board, this surface can be used for many other activities, such as folding clothes and wrapping packages.

Dishes

Similar to standing at the sink for bathroom activities, washing dishes sometimes causes people to stand for prolonged periods of time in spinal flexion. Clients should open the cabinets below the sink and use the lowest shelf as a footrest, alternating one foot at a time. In addition, over-the-sink dish racks or countertop tubs can be used to elevate dishes while washing and avoid the need to bend forward to retrieve items repetitively.

Cleaning

A long-handled brush, sponge, or Swiffer mop is recommended to clean low surfaces such as the floor or bottom of a tub. Using a handheld spray cleaner is easier than scrubbing and rinsing the surfaces. While vacuuming, clients should move their feet and legs rather than reach or bend forward. They are also cautioned to avoid twisting; when vacuuming under a table or chair, they should bend at the hips and knees to keep the back in a balanced position.

Yard Work

When mowing the lawn, the client should face forward and align the hips with the mower. The client should keep the back straight, the spine in a neutral position, and the abdominal muscles tight; take frequent breaks; and refrain from twisting or using the back to move the mower. When using a shovel, the client should bend at the hips and knees rather than at the waist and keep the shovel and its load close to the body. The preferred method for emptying the shovel is to turn the entire body and keep the hips and shoulders in alignment while maintaining the load close to the body and facing the location to unload the shovel. None of these yard activities should be attempted when the client is in an unstable condition with acute pain.

Gardening can be challenging for clients with back problems. Raised garden beds, potted plants on windowsills, and light-weight hoses are good options to reduce back strain. Many carts or moving seats can be purchased that allow safer back positioning when working at ground level. Knee pads make gardening in a kneeling position more comfortable. The gardener is cautioned to work only within his or her immediate reach to avoid bending forward or twisting.

Shopping

When retrieving items from a lower shelf, the client should squat or kneel while keeping the back straight. The thigh can be used as support when returning to a standing position; clients are not advised to use the shelf for support, as these are not meant to be weight bearing and may tip. To use a shopping cart, the client should find his or her neutral spine position, keep the abdominals activated, stand up straight, and push the cart with the elbows at the side, using the legs and gluteals for pushing force instead of the back. Use of a cart is preferable to carrying a basket even for small loads, as baskets cause uneven strain on the back. Clients can also place items in the upper portion of the cart, decreasing the need for bending. When unloading the cart, the client should use the golfer's lift to retrieve items. Heavier items should be placed in the tray below the cart if possible, as a squat or kneel can be used to get the item closer to the body.

Work

Job demands vary considerably. Many employers now have health and safety staff to assess workstations, educate employees about body mechanics, and determine whether modifications can be made (see Chapter 14). In many cases, however, it is up to the individual to modify his or her work situation. Many improvements can be made by simply using correct lifting techniques, using the proper equipment for the job, pacing the activity, and asking for help.

Leisure

When reading, clients should sit in a supported chair, not curl up on a sofa. Tabletop hobbies such as sewing and building models require attention to table height, chair comfort, and positioning of the work items. These positioning recommendations resemble those for computer use and will reduce uneven pulling and twisting of the body.

When traveling, the client should use a wheeled suitcase that can be pushed or pulled, which is easier on the back. When wheeling the suitcase, clients should be mindful of pulling the suitcase without twisting at the shoulders or waist. Backpacks and fanny packs with light loads can also be used. Travelers are encouraged to pack lightly and take only what is needed for the trip. Checking luggage and asking for help with placing luggage in overhead bins is also recommended. If needed, the client can also bring a seat or back cushion to promote proper positioning during longer flights. Similar to working at a computer, the person is encouraged to take frequent breaks from sitting (see Chapter 16).

Many clients, male or female, carry briefcases, purses, or bags throughout their daily routines. Decreasing the weight of the bag and frequently switching shoulders can decrease the uneven strain on the back, but using a rolling laptop case or purse is optimal for alleviating back strain.

When using a cell phone, tablet, or other small electronic device, it is important to remember the positioning principles discussed throughout this chapter. Instead of holding a cell phone at a low level and using extreme neck and back flexion to look down, clients should be instructed to hold the device just below eye height, similar to that of a computer monitor. If using the device for prolonged periods of time, the client can use pillows (if seated) to prop the elbows up without tensing the shoulders. Again, frequent breaks are recommended to avoid prolonged spinal column discomfort.

For Maria, socializing is very important to her well-being. She requires help with problem-solving different social situations, including how to best communicate her health needs to her friends and family. Analyzing different types of social gatherings to identify factors that may influence successful pain management (eg, ability to sit, stand, or stretch when needed; the ability to bring a lumbar cushion for use when seated) is key in Maria's successful social engagement.

Only a few of the many possible interventions have been described here. Each occupation must be analyzed, and an individualized intervention should be developed for each client. ADL body mechanics cards from Visual Health Information can be used to customize recommendations. This is a card file system from which cards can be selected and copied to develop interventions for each client according to his or her individual needs. Also available are many preprinted booklets and computer programs that may assist in client instruction. It is important to remember that most insurance companies do not cover adaptive equipment, and hospitals typically have large markups on vended equipment. Consequently, many clinics offer sample equipment for clients to try and provide community resources for equipment or consumer catalogs from vendors such as Sammons/Preston and North Coast Medical. Consumers should be made aware that many products once considered adaptive therapy equipment or ergonomic items are frequently available at a lower cost in discount stores.

Other Multidisciplinary Pain Team Members

The best intervention strategy for managing LBP is a team approach with the patient as the central and most important team member. Occupational therapists should validate their patients' opinions and goals and remind patients to advocate for themselves. It is important for all team members to remember that the client is the expert on his or her own life, and despite what healthcare providers objectively think and observe, in the end the person's subjective experience is what is real to himself or herself.

Box 41.4 lists common multidisciplinary team members who can play a role in LBP management for patients. Complementary and alternative therapists, although not always part of the immediate medical team, can contribute to the pain management plan for certain patients and should be considered referral resources for the appropriate clients.

Threaded Case Study

Maria, Part 3 (Multidisciplinary Care)

The occupational therapist communicates with the other members of the pain team to create the best possible collective healthcare plan for Maria. The physical therapist plans to work on massaging the low back, as well as core exercises to strengthen the spinal column muscles, in the hope that this will lessen the herniated disk pain.

Due to the lack of motivation to initiate daily activities as a result of depression, the occupational therapist refers Maria to a pain psychologist to help Maria manage her depression. The pain psychologist uses cognitive behavioral therapy to help Maria change her thought patterns and learn how to use positive self-talk and objective reasoning to feel less guilty about not being able to do certain tasks that she previously performed for her family.

As Maria progresses through her therapies, she shows improvement in strength and motivation, and the occupational therapist uses these improvements to gradually grade and increase Maria's occupational goals.

Box 41.4

Multidisciplinary and Complementary Pain Team Members

Multidisciplinary

- Physician
- Occupational therapist
- Physical therapist
- Pain psychologist
- Psychiatrist
- Case worker
- Nurse

Other Pain Team Members

- Surgeon (if needed)
- Pharmacist

- Nutritionist
- Vocational counselor
- Discharge planner
- Social worker

Complementary and Alternative Therapies

- Acupuncture
- Chiropractic
- Reiki
- Animal-assisted therapy
- Gentle yoga
- Massage

Physician

The physician is responsible for the client's initial evaluation, usually including a thorough medical history, current symptoms and complaints, functional limitations, posture, gait, strength, reflexes and sensation, and past interventions for this problem. A diagnosis is usually made at this time, or the physician may order additional tests, such as nerve conduction tests, computed tomography scans, magnetic resonance imaging, and blood work. After arriving at a diagnosis, the physician often prescribes medication, determines restrictions in activity and exercise guidelines, and may refer the patient to physical therapy, occupational therapy, or counseling. To reevaluate progress or lack thereof, the physician will see the patient for follow-up visits at whatever frequency he or she deems necessary.

Physical Therapist

The client is usually referred to PT to address pain, spasms, limited flexibility, limited strength, and posture. The PT evaluation generally includes a review of the mechanism of injury, date of injury, progression of symptoms, medical history, recent tests and procedures, medications, past treatment history, previous level of functioning, and the client's goal for therapy. A subjective history of ADLs is reviewed. An objective examination will include analysis of posture, gait, active ROM of the spine, active ROM of the extremities, pelvic symmetry, signs of nerve tension, strength, reflexes and sensation, leg length, and palpation of soft tissue. On the basis of the data collected, the physical therapist develops a treatment plan that includes pain and spasm control, increased core stability and strength, exercises, improved joint mobility, and patient education. The goals of PT are to reduce symptoms and increase strength and flexibility to achieve a functional pain-free outcome for the client.

Physical therapists use dynamic lumbar stabilization (DLS) as a treatment technique that involves integration of the muscle groups that control movement of the spine and the abdominal muscles that support the back. The abdominal muscles act as a corset to support the lumbar area, and the client must learn to balance muscular function and flexibility to control the stresses that are placed on the spinal column during movement.

Pain Psychologist

We have addressed how pain and emotional health are integrally connected. Some clients, especially those with chronic pain, may require the support of a pain psychologist who can assess the person's coping skills and mental health status. Psychologists use cognitive behavioral therapy to help the patient cope with unhelpful thought processes, teach the client self-regulation techniques similar to those discussed earlier, and help the person process any anger, disbelief, or sadness surrounding pain. Psychologists can also help people better manage anxiety, depression, and other behavioral health diagnoses that may be impacting the client's pain levels and self-management capabilities.

Summary

Providing effective occupational therapy for a client with low back pain requires a good understanding of how anatomy, physiology, behavioral health, and lifestyle can impact pain. The ability to analyze daily occupations and keep the client at the center of treatment is crucial to attain successful outcomes. Good communication between the patient and the team and among all team members is important for reducing symptoms, integrating knowledge, and supporting the performance of meaningful occupations for a person living with low back pain.

Review Questions

1. Identify five ways low back pain can impact occupational engagement and daily life, physically and emotionally.
2. Identify three common causes of low back pain.
3. Define *neutral spine.*
4. Identify three body mechanic techniques and how they relate to anatomy.
5. Identify the occupational therapist's role in evaluation and intervention.
6. Identify five occupational therapy interventions used for patients with LBP.
7. Identify other multidisciplinary pain team members.
8. Identify the interventions used for postsurgical patients.

Burns and Burn Rehabilitation*,**

Dawn Kurakazu, Agnes Haruko Hirai †

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, the student or practitioner will be able to do the following:

1. Define and identify the characteristics of the different burn depths.
2. Identify the anatomy of skin and its importance to individuals' health and well being.
3. Understand and describe the different phases of recovery and the role of occupational therapy in each phase.
4. Understand implications of scar formation on the individual and his or her occupational roles.
5. Understand the importance of early mobilization with therapy and its implications on recovery of the client's ability to perform activities of daily living.
6. Understand the complications of a severe burn injury and its implications on function in occupational roles.
7. Understand and appreciate the impact large or severe burn injuries have on an individual's performance patterns, occupational roles, and self-image.

KEY TERMS

Allograft
Autograft
Compartment syndrome
Deep partial-thickness burn
Dermis
Epidermis
Eschar
Escharotomy
Full-thickness burn
Heterotopic ossification
Hypertrophic scar
Ischemia
Keloid scar
Scar maturation
Subdermal burn
Superficial burn
Superficial partial-thickness burn
Total body surface area
Xenograft

Threaded Case Study

Tonio, Nora, and Lee, Part 1

Three case studies were developed to represent the array or gamut of circumstances the occupational therapy practitioner might encounter when treating clients with burns. Tonio's case is an example of a large total body surface area burn that required extensive rehabilitation. The injury impacted all aspects of his occupational role of a young man. Nora is an example of the impact burn injury has on a child. Although she suffered a small burn, it put her at risk for fine motor delays and body image problems. It also showcased the importance of family participation in her recovery. Finally, Lee's case represents the ideal functional outcomes when the patient is motivated and supported by the medical/rehabilitation team and family.

Case Study: Tonio

Tonio is a 27-year-old right hand–dominant (RHD) man who was involved in a house fire. He sustained 70% total body surface area (TBSA; to be described in more detail later in the chapter) deep partial- and full-thickness flame burns to his face, chest, back, abdomen, (B) upper extremity (UE), and (B) lower extremity (LE). He was noted to be obese, but his medical history was otherwise unremarkable. Tonio had a history of ethyl alcohol and hash oil use. He had a support system consisting of his girlfriend of 2 years, his brother, both of his parents, and friends. Tonio had been employed as an exterminator for several years. At the time of his injuries, he was initially evaluated and treated at an acute hospital without a burn center where he was intubated, sedated, and placed on a ventilator for suspected inhalation injury due to singed nasal hairs and suspected airway edema. He also underwent fluid resuscitation. He was later transferred to a large metropolitan burn center for higher level of care. Upon arrival, Tonio was assessed thoroughly by the burn medical team. He underwent a bronchoscopy, which confirmed the presence of an inhalation injury. Also on the day of admission, he required (B) UE and (B) LE escharotomies (surgical removal of scar tissue) due to increased concern for compartment syndrome. Despite the (B) LE escharotomies, Tonio required (B) LE fasciotomies (surgical release of the fascia to relieve tension and prevent the loss of circulation to an area of tissue or muscle) a few hours later as the LEs became pulseless and mottled. After the fasciotomies, he regained pulses detected by ultrasound Doppler studies. Over the next 8 weeks, Tonio underwent multiple surgeries to débride and cover his burn injuries with grafting. Because of the large surface area of burn, the patient had Integra (biosynthetic wound dressing) placed on his chest, abdomen, and right hand. During this time, he went into oliguric renal failure due to volume depletion with electrolyte imbalance. Tonio's kidneys recovered with resuscitation of fluids and electrolytes. He remained in the intensive care unit (ICU) during this time but was able to be weaned from the ventilator to oxygen via a tracheal mask and eventually to room air. Once he was weaned from the ventilator, after a month-long stay, he was transferred out of the ICU to the burn ward. Tonio required no further surgical interventions but remained in the burn center for complex wound care, pain management, and rehabilitation. His injuries continued to be treated for 3 months until his wounds were healed enough for him to be referred to inpatient rehabilitation where he could demonstrate the ability to tolerate 3 hours of therapy per day. Tonio continued inpatient rehabilitation for 1 month and was discharged home to his family.

Tonio continued to improve with the help of his home exercise program and outpatient physical and occupational therapy. He regained full independence with his basic activities of daily living (ADLs) and is working toward independence with instrumental activities of daily living (IADLs). Surgery is pending to remove the abnormal bone growth in his elbow. Tonio is also preparing to return to his work as an exterminator on a part-time basis with plans to return to full-time work after his elbow is repaired. He is also having discussions with doctors at the regional burn service concerning further reconstruction and scar revisions to the large areas of deformity caused by his burn scars.

Case Study: Nora

Nora is a 3-year-old girl who sustained a 1% TBSA partial-thickness contact burn to her left palm after touching a hot curling iron when she was 10 months old. Nora is a normal, healthy child. She lives with both her parents and two older siblings. Her injury is significant for severe hypertrophic scarring of the left palm resulting in flexion contractures of digits 2 through 5 and adduction contracture of the left thumb. Her burn recovery has been impacted severely by her mother's poor follow-through concerning recommendations and instructions provided by the burn medical staff as well as therapy recommendations. This noncompliance impacted Nora's ability to grasp and manipulate objects, effectively placing her at risk for fine motor developmental delay. Nora was initially treated in the outpatient pediatric occupational therapy department at a large metropolitan hospital but missed several appointments due to transportation issues. The burn occupational therapist (OT) as well as the pediatric OT referred Nora to a state/county-run medical therapy agency to assist in providing therapy services closer to home. The medical therapy agency was able to schedule Nora to be seen in a clinic closer to her home, and she was able to be more consistent in attending therapy appointments. At 13 months it was determined that the deformity to her left hand required surgical intervention. She underwent surgical release of the palmar scar contracture and full-thickness skin grafting. On post-op day (POD) 5, the physicians took down Nora's dressings and observed areas of dehiscence (wound separation or splitting). Nora was placed back in a Xeroform/Bactroban dressing and then in a resting hand splint to protect the skin graft. She was then sent home with referrals for both burn clinic follow-up and outpatient occupational therapy follow-up. Nora continued to receive aggressive outpatient occupational therapy services that consisted of serial splinting, range-of-motion (ROM) treatment, and scar massage, and her mother and father received parent education. Follow-up burn clinic visits consisted of ordering custom pressure garments, assessing hypertrophic scarring, and addressing therapy concerns raised by outpatient occupational therapy.

Despite aggressive management on the part of the burn clinic and the patient's outpatient therapist, Nora's joints once again became contracted at age 3 years. Growth contractures formed, and her mother did not follow up with her outpatient occupational therapy as scheduled. When Nora returned for a scheduled clinic visit, the burn clinic team again discussed with her mother the importance of attending follow-up appointments with her primary occupational therapist to prevent further deformity. Due to the significance of the scar contracture deformity, Nora underwent a second scar revision with local tissue rearrangement surgery to correct her deformity. Nora returned to outpatient occupational therapy, and her mother has been compliant with all therapy appointments, clinic schedules, and schedules with the custom pressure garment maker since her last surgery. Throughout Nora's burn care and recovery, it was found that her mother had significant stressors such as chronic medical issues of family members, denial of the significance of the injury, and educational and language barriers. It took many years for Nora's mother to comprehend the importance of good carryover of Nora's medical and therapeutic care.

Case Study: Lee

Lee is a 25-year-old Korean man who suffered 15% deep partial-thickness hot oil burns to his left hand and (B) LEs while frying fish at home. Lee was a healthy man with no previous injuries or medical conditions prior to his injuries. He is married and attends seminary school. He plans to become a pastor. Lee lives in an apartment with his wife. Both are devoutly religious. His interests were playing soccer and spending time with friends. Lee was admitted to a large burn center for complex wound care, pain management, and therapeutic intervention. The largest portion of his burn injury was to (B) LEs. This impacted Lee's ability to walk, and he required a front wheel walker (FWW) to walk 200 feet on level surfaces. Lee underwent surgical débridement and split-thickness skin grafting to his (B) LEs and left hand. A mesh graft was placed on the (B) LE burns, and a sheet graft was placed on the left hand burn. On POD 2, the surgeon removed the dressings to Lee's left hand to assess for seromas (collections of fluid that build up under the surface of the skin). None were found, and Lee was placed back in dressings and his left hand splint was replaced. After the POD 2 takedown (post-operative day removal of surgical dressings), Lee expressed being upset by the way the skin graft looked. His feelings were relieved after his therapist explained the changes to the skin graft that appear over time and that improvements will be observed over weeks and months. Lee expressed being comforted by having his feelings validated and his concerns addressed.

On POD 5, all of the surgical dressings were removed and, because he was motivated to return home, Lee was willing to work with his physical and occupational therapists to get out of bed, begin to move his extremities, and participate in ADLs. On POD 8, Lee was discharged home using an FWW for ambulation and being modified independent for his ADLs. Lee returned to the outpatient burn clinic for follow-up as instructed. He was observed to be walking independently and no longer required a walker. He continued to progress and became completely independent in his ADLs. When asked, Lee attributed his healing and improved ability to function to prayer and God. He expressed feeling happy about returning home and he was looking forward to returning to seminary school to complete his studies. He also stated that he would like to return to playing soccer as soon as possible.

Critical Thinking Questions

1. When should occupational therapy be initiated for optimal patient results?
2. What were the main factors affecting the pediatric patient's treatment in the preceding case study?
3. How were the occupational roles of the two adult patients affected by their burn injuries? How will their scars continue to affect their occupational roles in the future?
4. As you read and learn more about burn injuries and the role of occupational therapy, consider the effect of occupational therapy intervention on each of these patient's/client's lives. How were their performance skills and patterns affected? What were the long-term effects on occupational performance for each patient/client?

Increasing numbers of individuals are surviving burn injuries that in the past would have proved fatal. Since the 1970s, advances in burn management, such as in resuscitation, early excision and grafting, and surgical critical care, have dramatically improved the percentage of survivors of severe burn injuries.[14] With this improvement in survival comes an increased need for comprehensive burn rehabilitation so that when a life is saved, the quality of life and participation in meaningful occupation are also preserved.

Incidence of Burn Injuries and Burn-Related Deaths

It has been estimated that more than 0.5 million burn injuries requiring medical treatment occur each year in the United States.[3] This represents a significant decline in the incidence of burn injuries since the early 1960s, when an estimated 2 million injuries occurred annually.[4] Total fire- and burn-related deaths are currently estimated at 4000 per year. This total includes an estimated 3500 deaths from residential fires and 500 from motor vehicle and aircraft crashes; contact with electricity, chemicals, and hot liquids or objects; and other sources of burn injury.[3] Fire- and burn-related deaths in the United States continue to decline. Conversely, hospitalizations for burn injury have increased steadily because of improved emergency care helping victims survive. Burn prevention and fire safety measures have reduced the incidence of severe burn injury to the extent that burn centers are now admitting greater numbers of patients with less severe burns and fewer large, deep burns.[5]

Since the early 1970s, advances in the medical, surgical, and rehabilitative management of individuals who sustain burns have expanded the focus of burn care professionals from simply ensuring patient survival to include regaining quality of life and the previous life context after a burn injury. Although functional recovery may be a long and arduous process, most burn survivors can expect to resume their roles, function at a level that is comparatively close to their preinjury level of independence, and continue to engage in occupation for satisfactory participation in life. However, from the date of injury through the outpatient phase of care, a multidisciplinary team approach is necessary to effectively manage the medical, functional, and psychosocial problems encountered during recovery.

Skin Anatomy

The skin is the largest organ of the body. It varies greatly in thickness, flexibility, presence and amount of hair, degree of pigmentation, vascularity, nerve supply and sensitivity, amount of keratin, and types of glands present in different locations. Keratin is the tough protein substance present in skin and also forms the primary elements of hair, nails, and callused areas of the skin on the hands and feet. Most of the body is covered with thin, hairy skin. However, thicker, tougher, hairless skin, known as glabrous skin, covers the soles of the feet and the palmar surfaces of the hand and fingers.

Anatomically, the skin consists primarily of two layers: the dermis and the epidermis (Figure 42.1). The **dermis**, or corium, is composed of fibrous connective tissue made of collagen and elastin and contains numerous capillaries, lymphatics, and nerve endings. In it are the hair follicles and their smooth muscle fibers, sebaceous glands, and sweat glands and their ducts.[94]

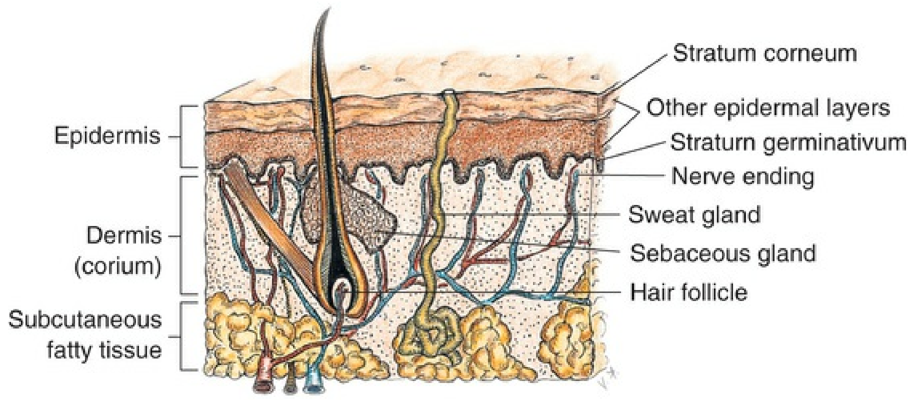

FIG 42.1 Cross section of the skin. (From Potter PA, et al, editors: *Fundamentals of nursing,* ed 9, St. Louis, 2017, Elsevier.)

The **epidermis** is the outermost layer of epithelium, and it also lines the nail beds and the skin appendages, which are pockets of epithelium that extend down into the dermis and contain the hair follicles, sweat glands, and sebaceous glands. The epidermis consists of four or five layers, depending on the location and type of skin. The innermost layer of the epidermis is the stratum germinativum, where the keratinocytes that synthesize keratin are formed. Above this layer lies the stratum spinosum, in which the progressive stages of keratinization occur. The keratinocytes in this layer have a well-developed capacity for phagocytosis, which helps control infection by ingesting and breaking down bacteria and particulate debris. Melanin granules, which give the skin and hair their color, are present in the cytoplasm of certain cells in the stratum spinosum. In the next layer, the stratum granulosum, the cells making their way toward the surface become flattened and accumulate many large keratin granules, termed keratohyalin. In this layer, cells lose their nucleus, change from viable to nonviable, and become a cornified layer composed chiefly of keratin filaments. Above this layer is the stratum lucidum, seen best in glabrous skin, which is thicker. The outermost layer, the stratum corneum, is composed of tightly packed dead keratinocytes known as squames that become the cornified, flattened skin cells that eventually separate from one another and detach from the surface of the epidermis. The time taken by a newly formed keratinocyte to pass from the deepest layer to the surface to be shed is estimated to be 45 to 75 days. This is the natural manner in which the epidermis continually renews itself.[95]

Skin Function

The skin serves as an environmental barrier that protects against ultraviolet rays, chemical contamination, and bacterial invasion. It also serves as a moisture barrier to prevent excessive absorption of moisture or evaporative loss. Temperature regulation is also a function of the skin, with hair to insulate and perspiration to cool the body. The skin perceives injury or infection through tactile sensory receptors located in the dermis layer of the skin. These receptors heighten environmental awareness through perceived touch, pressure, pain, and temperature. When the skin is damaged, various systemic, physiologic, and functional problems can occur. A burn injury causes destruction of the protective environmental barrier, which results in exposed nerve endings, loss of body heat, seepage of body fluids, and exposure to bacterial invasion.

The skin also influences the development of an individual's body image and personal identity and enhances nonverbal social interaction. Along with age, gender, body type, and voice, the skin's scent, texture, and coloration and the appearance of facial features contribute strongly to a person's external context (physical) and self-concept–related internal contexts (e.g., body image, self-regard, and sense of social and cultural acceptance). Because of all these factors, a large burn injury is considered to be one of the most physically and psychologically painful forms of trauma.

After a burn injury, many factors are taken into consideration in determining the severity of injury, potential for functional recovery, and treatment needs. Primary considerations in evaluating burn wounds are the mechanism of injury, the depth and extent of the burn, specific body areas burned, and associated or concurrent injuries such as inhalation injury and fractures. The individual's age, medical history, preinjury health, and previous life context are of equal importance in determining the impact of a serious burn injury on future occupational performance.

Mechanism of Injury and Burn Depth

Burns can be thermal, chemical, or electrical in nature and can be caused by flame, steam, hot liquids, hot surfaces, and radiation. The severity of the injury depends on the area of the body exposed and the duration and intensity of thermal exposure. Thermal burns can be caused by heat in the form of flame, steam, hot liquids, or hot objects. The type of fluid or type of object is important to assess; for example, hot oil boils at a higher temperature than water and retains heat for a longer period of time, resulting in a deeper burn injury, and objects heated for construction or industrial purposes are often hotter than household items. Thermal burns can also be caused by excessive cold such as in dry ice. Electrical burns often have the appearance of being a small burn with an entrance and exit wound, but this burn injury can be deceptive as the electrical current can cause damage beneath the skin through soft tissue, burning the patient from within. Electrical burns can also affect the heart, so these patients often require monitoring with an electrocardiogram to ensure that the current did not damage their hearts. Chemical burns can often be deep, requiring that the patient be washed with a neutralizing agent. Patients suffering from chemical burns are often asked for the name or type of substance they were using. This information assists the burn team, especially the pharmacist, in identifying the correct neutralizing agent.

Burn wounds are classified by depth, which is determined by clinical assessment of the appearance, sensitivity, and pliability of the wound.[99] Burn injuries were traditionally classified as first, second, third, and fourth degree. They are now classified as superficial, superficial partial thickness, deep partial thickness, full thickness, and subdermal.[44] The depth of injury is established by clinical determination of which anatomic layers of the skin are involved.[91]

A **superficial burn**, previously referred to as a first-degree burn, involves only the upper layers of the epidermis. Damage through the epidermis and upper third of the dermis is referred to as a **superficial partial-thickness burn**. The term **deep partial-thickness burn** describes damage to the epidermis and upper two thirds of the dermis, and a **full-thickness burn** describes an injury that extends down through the entire dermis. A **subdermal burn** involves the fatty layer, fascia, muscle, tendon, bone, or other subdermal tissues (e.g., those seen in electrical injuries; Table 42.1).

TABLE 42.1
Burn Wound Characteristics

Burn Depth	Common Causes	Tissue Depth	Clinical Findings	Healing Time	Scar Potential
Superficial	Sunburn, brief flash burns, brief exposure to hot liquids or chemicals	Superficial epidermis	Erythema, dry, no blisters, short-term moderate pain	3–7 days	No potential for hypertrophic scar or contractures
Superficial partial thickness and donor sites	Severe sunburn or radiation burn, prolonged exposure to hot liquids, brief contact with hot metal objects	Epidermis, upper dermis	Erythema, wet, blisters; significant pain	Less than 2 weeks	Minimal potential for hypertrophy or contractures if healing is not delayed by secondary infection or further trauma
Deep partial thickness	Flames; firm or prolonged contact with hot metal objects; prolonged contact with hot, viscous liquids	Epidermis and much of the dermis nonviable, but survival of skin appendages from which skin may regenerate	Erythema; larger, usually broken blisters on skin with hair; on glabrous skin of the palms and soles of the feet; large, possibly intact blisters over beefy red dermis; severe pain to even light touch	Longer than 2 weeks, may convert to full thickness with onset of infection	High potential for hypertrophic scarring and contractures across joints, web spaces, and facial contours; high risk for boutonnière deformities if the dorsal surface of fingers involved
Full thickness	Extreme heat or prolonged exposure to heat, hot objects, or chemicals for extended periods	Epidermis and dermis: nonviable skin appendages and nerve endings	Pale, nonblanching, dry, coagulated capillaries possible; no sensation to light touch except at deep partial-thickness borders	Surgical intervention required for wound closure in larger areas; possible for smaller areas to heal inward from borders over extended period	Extremely high potential for hypertrophic scarring or contractures, depending on the method used for wound closure
Full thickness with complications	Electrical burns and severe long-duration burns (e.g., house fires, entrapment in or under a burning motor vehicle or hot exhaust system, smoking in bed or alcohol-related burns)	Full-thickness burn with damage to underlying tissue	Possible charring of nonviable surface or, with exposed fat, possible presence of small external wounds on tendons, muscles; with electrical injuries, possibility for small external wounds with significant secondary loss of subdermal tissue and peripheral nerve damage	Requires surgical intervention for wound closure; may require amputation or significant reconstruction	Similar to full-thickness burns except when amputation removes the burn site

Superficial burns are usually caused by sun exposure or brief contact with rapidly cooling, nonviscous hot fluids or surfaces (e.g., spilled coffee or a hot pan). Superficial partial-thickness burns are typically caused by prolonged sun exposure, contact with flames, or brief contact with hot viscous liquids (Figure 42.2, A). Deep partial-thickness burns (Figure 42.2, B) are caused by longer exposure to intense heat, such as immersion in hot water or contact of the skin with flaming material. Full-thickness burns usually result from prolonged immersion scalding, contact with flaming or high-temperature viscous material such as hot grease or melted tar, extended exposure to chemical agents, and contact with electrical current (Figure 42.2, C).

FIG 42.2 **A,** Superficial partial-thickness burns are wet and painful with characteristic fluid-filled blisters. **B,** Deep partial-thickness injury. Note the moist open wound. **C,** Full-thickness injury with thick adherent eschar. (*C,* From Song DH, Neligan PC, editors: *Plastic surgery,* ed 3, London, 2013, Saunders.)

Superficial partial-thickness and deep partial-thickness burns generally heal without surgical intervention. However, once healed, they tend to be excessively dry, itchy, and subsequently susceptible to excoriation (i.e., abrasion or tearing of the skin surface) secondary to shear forces caused by rubbing, scratching, and other trauma. These shear forces can give rise to blisters and compromise long-term skin integrity as a result of repetitious reopening of the wound. Partial-thickness and full-thickness burns usually lead to uneven pigmentation of the healed scar. Deep partial- and full-thickness burns have a greater potential for thick, hypertrophic scar and contracture formation because of the prolonged healing period. This is especially true if a burn converts from partial thickness to full thickness because of infection or repeated trauma. Most full-thickness wounds require surgical intervention or skin grafting for wound closure. Skin graft donor sites generally heal in the same manner that superficial partial-thickness burns do, with less scarring but uneven pigmentation. In all three of the case studies, the majority of the patients' burns were deep partial-thickness injuries but with serious scar development after healing.

Percentage of Total Body Surface Area Involved

The extent of a burn is classified as a percentage of the **total body surface area** (%TBSA) burned. The two most common methods for estimating %TBSA are the "rule of nines" and the Lund and Browder chart.[34,57,89] The rule of nines divides the body surface into areas consisting of 9%, or multiples of 9%, with the perineum making up the final 1%. The head and neck area is 9%, each upper extremity is 9%, each lower extremity is 18%, and the front and back of the trunk are each 18%. Body proportions vary in children, depending on their age, especially in the head and legs (Figure 42.3). The Lund and Browder chart[53] provides a more accurate estimate of TBSA[67] and is used in most burn centers. This chart assigns a percentage of surface area to body segments (Figure 42.4), with the calculations adjusted for different age groups. For smaller %TBSA injuries, the therapist can obtain a quick, rough estimate by using the size of the patient's palm (the hand excluding the fingers) to equal approximately 1% of the individual's TBSA.

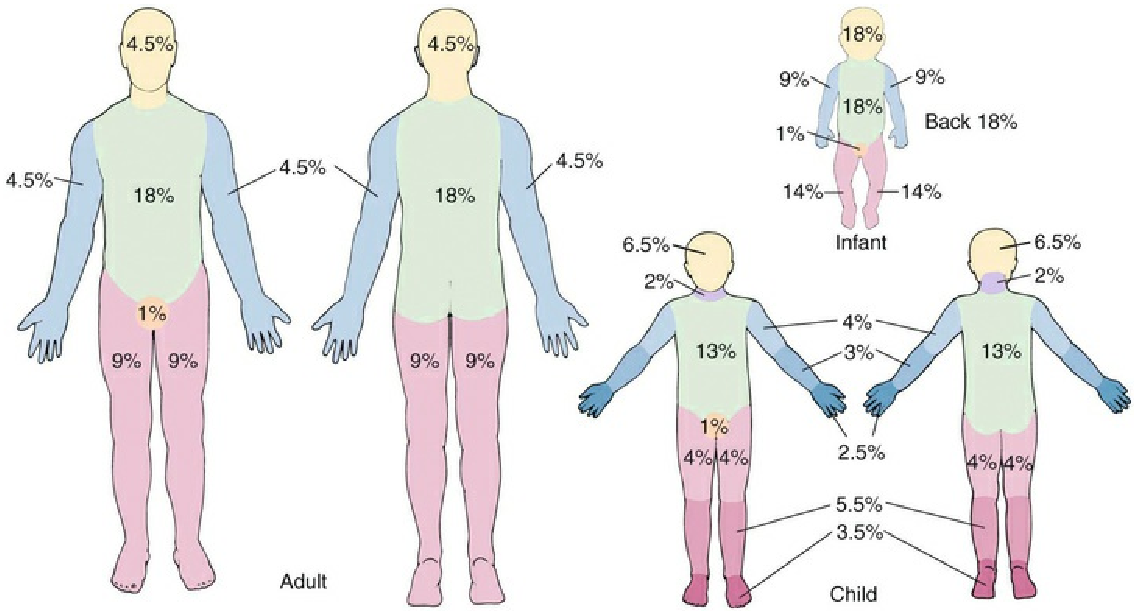

FIG 42.3 Rule of nines. Proportions for adults/adolescents, children, and infants are shown. Note the relatively greater surface area of the head and slightly lesser surface area of the lower extremities in young children than in adults. (From Lovaasen KR: *ICD-10-CM/PCS coding: theory and practice,* St. Louis, 2016, Elsevier.)

Modified Lund and Browder Chart								
Area	Age (Years)					% Partial-thickness	% Full-thickness	% Total
	0-1	1-4	5-9	10-15	Adult			
Head	19	17	13	10	7			
Neck	2	2	2	2	2			
Ant. trunk	13	13	13	13	13

					Total			

FIG 42.4 Modified Lund and Browder chart. Burn size can be determined most accurately in children by using the Lund and Browder chart, which accounts for changes in the size of body parts that occur with growth. (Modified from Lund CC, Browder NC: The estimation of areas of burns, *Surg Gynecol Obstet* 79:352, 1944.)

In the case studies, the %TBSA of the burn injury varied considerably from one individual to another. Tonio's %TBSA burn was 70%. Nora's burn injury was <1% TBSA burn, and Lee's %TBSA was 15%.

It is also important as a clinician to understand that the %TBSA of the burn injury will change as the burn injury evolves and fully declares itself in the first 3 to 5 days. Also to be considered in the case of burn patients that require surgical interventions is that the donor site for surgery then adds to the percentage of open wound even though it is not a part of the actual burn injury. This is important for nutritional optimization, wound dressings, and discharge planning.

Severity of Injury

The severity of a burn injury is determined by many factors. The size, depth, and location of the injury are of primary concern in a burn-injured patient, but other factors such as a patient's age, previous medical history, social support and resources, functional ability, and pain are also important for determination of admission to a burn center and also the individual's ability to recover. Usually a burn of 15% or greater with a superficial partial- to full-thickness injury is cause for admission as it will require fluid resuscitation. However, burn centers will at times admit patients with smaller burns if the patient is nutritionally deficient, the pain of the burn injury is unable to be managed effectively on a home regimen, or the patient's functional ability is severely impaired (i.e., the patient is unable to ambulate due to the LE burn injury).

Burns that are partial-thickness, deep partial-thickness, or full-thickness injuries that are larger than 20% usually require a period of hospitalization that includes complex wound care, pain management, nutritional optimization, and rehabilitation. The burn injury becomes more severe if the person sustains an inhalational injury in addition to the cutaneous burn injury.

Burns of <15% TBSA that are partial-thickness injuries not requiring surgery can be treated on an outpatient basis as long as the patient has adequate resources, social supports to provide optimal wound care, pain management, and functional mobility at home.

A patient's past medical history will also affect his or her ability to recover from a burn injury, even one that is relatively small. A patient's comorbidities will increase mortality in burn-injured patients. Chronic conditions that are cardiovascular, neurologic, renal, or pulmonary in nature will increase the likelihood of death, especially in the presence of a cutaneous injury or inhalation injury.[95]

Phases of Wound Healing

Wound healing takes place in three overlapping phases: the inflammatory phase, the proliferation phase, and the maturation phase.

Inflammatory Phase

The inflammatory phase usually lasts 3 to 10 days after onset. This phase is characterized by a vascular and cellular response, with neutrophils and monocytes migrating to the wound to attack bacteria, débride the wound, and initiate the healing process. The wound is typically painful, warm, and erythematous (red), and edema develops.

Proliferation Phase

The proliferation phase begins by the third day after the injury and lasts until the wound heals. It is during this phase that revascularization, reepithelialization, and contraction of the burn wound take place. Endothelial cells bud at the end of capillaries, and they grow and create a vascular bed for new skin growth. Epithelial cells migrate over the vascular bed to form a new skin layer. Fibroblasts deposit collagen fibers, which contract to reduce wound size. During this phase the wound remains erythemic, and raised, rigid scars may develop. The tensile strength of the newly healed scars is poor and they are easily excoriated or injured.

Maturation Phase

The maturation phase generally begins by the third week after initial healing and may last 2 or more years after the initial burn injury or the date of the last reconstructive surgical procedure. During this phase, the fibroblasts leave and collagen remodeling takes place. The erythema fades, and the scar softens and flattens. The tensile strength of the scars increases but never recovers to more than 80% of the original tensile strength of the unburned skin.[66]

Scar Formation

After initial healing, most burn wounds have an erythematous, flat appearance. As the healing process continues, the wound's appearance may change as a result of scar hypertrophy and contraction. The long-term quality of a mature burn scar can be affected by numerous factors, some of which occur during the early phases of burn care.[40] The amount of time needed to achieve wound closure is a strong determinant. Age, race, and burn depth are other variables.[34] Bacterial infections in the wound increase the inflammatory response, which can delay wound healing and contribute to scar formation. However, any factor that delays healing will increase the potential for scarring.

Hypertrophic scars are thick, rigid, erythematous scars that become apparent 6 to 8 weeks after wound closure.[1] Histologically, these immature scars have increased vascularity, fibroblasts, myofibroblasts, mast cells, and collagen fibers arranged in whorls or nodules that make the scar appear raised and rigid.[10,66] Biochemical investigations have discovered increased synthesis of collagen fibers and connective tissue in hypertrophic scars. As a hypertrophic scar matures, capillaries, fibroblasts, and myofibroblasts decrease significantly, collagen fibers relax into parallel bands, and the scar becomes flatter and more pliable. The time needed for scars to mature differs markedly among individuals and depends on genetics, the age of the patient, the location and depth of the original burn wound, the presence of chronic inflammation, wound contamination, and other factors that have been reported to influence hypertrophic scarring.[26,90] Superficial burns that heal in less than 2 weeks will not generally form a hypertrophic scar. Deeper burns that take longer than 2 weeks to heal have a greater potential to form hypertrophic scars. Although most hypertrophic scars mature in 12 to 24 months,[24] excessive scar formation, including keloid scars, may take up to 3 years to mature (Figure 42.5). All three subjects in the case studies were of different age groups and ethnic/genetic backgrounds and had different occupational therapy interventions. Nevertheless, they all experienced serious scarring as a result of their burns.

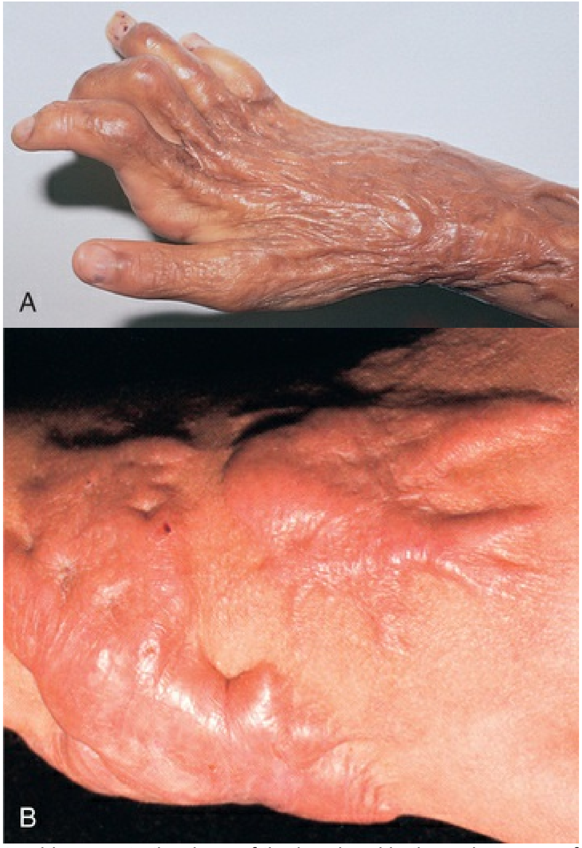

FIG 42.5 **A,** Hypertrophic scars to the dorm of the hand and in the web spaces of the hand result in a limited ability to grasp objects and impairs fine motor function. **B,** Severe keloid scars usually require surgical removal and aggressive compression therapy to help prevent recurrence. (*A,* Courtesy Michael Peck, MD, University of North Carolina Burn Center, Chapel Hill; in Copstead L, Banasik JL: *Pathophysiology,* ed 5, St. Louis, 2013, Saunders. *B,* From Lafleur Brooks M, LaFleur Brooks D: *Exploring medical language: a student-directed approach,* ed 9, St. Louis, 2014, Mosby.)

All scars initially have increased vascularity and a red appearance. Scars that remain erythematous for longer than 2 months are more likely to develop into hypertrophic scars. They become progressively firmer and thicker and rise above the original surface level of the skin. There is a marked increase in the production of fibroblasts, myofibroblasts, collagen, and interstitial material, all with contractile properties that help draw together the borders of a wound but can also result in scar tightness. Pain and skin tightness cause most patients to become less active. These patients prefer to rest in a flexed, adducted position for comfort. This allows the new collagen fibers in the wound to link and fuse together in the contracted position. The fibers become progressively more compact and coil up into the whorls and nodules that give the scar surface the textured appearance that often leads to disfigurement. If the scar extends over one or more joints, the progressive tightness leads to a scar contracture and loss of motion. Fortunately, collagen linkage is less stable in new scars, and restructuring of an immature hypertrophic scar contracture can be influenced by sustained mechanical forces such as proper positioning, exercise, splinting, and compression. Scar hypertrophy and contracture are most active for the initial 4 to 6 months after healing.[24]

Keloid scars are thick and raised scars that extend outside of the boundary of the initial injury. They can be unsightly and may take longer than a hypertrophic scar to mature fully. Some races are more likely to form both keloid and hypertrophic scars. If the patient has a tendency to form keloid-type scars, it is important for the treating therapist to be aware of this possibility, as the scars may disrupt daily functional movement more quickly than non-keloid-forming individuals.

In the case with Lee, who is of Korean background, the patient was observed to begin forming hypertrophic scars early in his healing. The appearance of the scars was shocking to him, especially that of the mesh graft. “It looks like fish skin” was how Lee described seeing his healed skin for the first time. Lee's interests were soccer and socializing with friends. The appearance of his skin made him very self-conscious and reluctant to leave home, significantly affecting his avocation pursuits and friendships.

Many burn survivors express the same apprehension as Lee. Consequently, they tend to be housebound because they want to avoid being seen in public. A significant number of burn survivors describe their regular burn clinic visit as the only time they leave their home during the day. This can foster feelings of isolation and create a barrier to the burn survivor's inclination to reengage in social activities and occupational roles.

The psychological impact of scar formation is long lasting. The patient will bear the scars of the burn for his or her whole life. They are very evident and unmistakable, especially in highly visible areas such as the hands, face, and neck. Occupational therapists working in burn care are uniquely qualified to address these issues because of their background in psychology as well as their understanding of physical disabilities. With care and support the burn survivor can find a sense of self-efficacy, self-worth, and self-sufficiency by reengaging in normal daily occupations. By reconnecting them with their occupational roles, occupational therapists help burn survivors to adjust to their environment and reintegration into society.

Initial Medical Management

Fluid Resuscitation and Edema

Immediately after a burn injury, during the inflammatory phase, the permeability of blood vessels increases. This causes rapid leakage of protein-rich intravascular fluid into the surrounding extravascular tissues.[60] In larger burns, extensive loss of intravascular fluid can result in hypovolemia or burn shock because of decreased plasma and blood volumes and reduced cardiac output.[37] Fluid resuscitation with an intravenous fluid such as lactated Ringer solution is essential for promptly replacing venous fluid and electrolytes. The fluid volume required is determined by various formulas, such as the Parkland and modified Brook formulas,[8] and is based on the extent of the burn and weight of the patient. The rate of fluid infusion is determined by monitoring the pulse rate, central venous pressure, hematocrit, and urinary output.

The lymphatic system, which normally carries excess tissue fluid away, often becomes overloaded, and subcutaneous edema develops. With circumferential full-thickness burns, loss of elasticity of the burned skin combined with increased edema can cause **compartment syndrome**, a condition in which interstitial pressure becomes severe enough to compress blood vessels, tendons, or nerves, which could result in secondary tissue damage. When blood vessels are compressed, **ischemia**, or restriction of circulation, could lead to tissue death in the areas of compromised circulation or even the entire distal end of the extremity. Tight burned tissue can also restrict chest expansion during respiration. **Escharotomy**, or incision through the necrotic burned tissue, is performed to release the binding effect of the tight **eschar** (adherent dead tissue that forms on skin with deep partial- or full-thickness burns), relieve the interstitial pressure, and restore the distal circulation (Figure 42.6, A). In deeper wounds, an incision down to and through the muscle fascia, or fasciotomy, may be required to achieve adequate relief of pressure (Figure 42.6, B).

FIG 42.6 **A,** Escharotomies performed on the dorsal surface of a hand with full-thickness burns. **B,** Electrical injury requiring fasciotomy, which will allow the muscle belly of the forearm to expand and prevent loss of blood flow to the hand. Note the distances between the edges of the incisions. (*A*, From Song DH, Neligan PC, editors: *Plastic surgery*, ed 3, London, 2013, Saunders. *B*, From Herndon DN: *Total burn care*, ed 4, Edinburgh, 2012, Saunders.)

Respiratory Management

A smoke inhalation injury is a common secondary diagnosis with thermal injury and can significantly increase mortality. When the face is burned, and the burn was caused by a fire in an enclosed space, or when other objective evidence of a possible inhalation injury is present, bronchoscopy, arterial blood gas readings, and chest x-ray examinations are used to confirm the diagnosis. Intubation and mechanical ventilatory support may be required in addition to vigorous respiratory therapy. A tracheostomy is performed if the airway is difficult to maintain or if ventilatory support is prolonged.[101] This procedure, which involves surgical incision through the trachea and relocation of the ventilation tube to the neck, is more comfortable for the patient, allows oral care, and helps prevent permanent damage to the larynx or vocal cords, which may occur with extended oral intubation.

Wound Care and Infection Control

After a patent airway and fluid resuscitation have been established, attention is directed to wound care. The burn injury itself can be a complex and dynamic injury that requires specialized wound care. The burn injury will often *convert* or change over time, healing a wound that is deeper or larger than initially thought. The initial burn injury is thought to *declare* itself in the first 72 hours if the patient is a healthy, well-nourished individual and received adequate resuscitation at the time of the initial injury. If the patient was not resuscitated properly, delayed treatment of the burn injury, received inappropriate wound care, or was malnourished, his or her wounds may continue to progress and will fail to heal. This leaves the patient at increased risk of infection, hypertrophic scar formation, and requiring surgery for wound closure.

Wound treatment may involve a combination of surgical and nonsurgical therapy.[45] Nonsurgical treatment involves the use of products to promote healing in a partial-thickness wound. These products are usually in the form of topical antibiotics, biologic dressings, and nonbiologic skin substitute dressings.

Topical Antimicrobial Agents

Topical antimicrobial agents have been shown to decrease wound-related infections and morbidity in burn wounds when used appropriately. The goal of topical antimicrobial therapy is to control microbial colonization, thereby preventing the development of invasive infections.

An ever-increasing variety of topical antimicrobials are used for burn wound care.[98] Neomycin/polymyxin B/bacitracin antibiotic ointments are often used for facial and superficial burns. The ointment is applied, and the burn wound is left open. Silver sulfadiazine (Silvadene cream, Keltman Pharmaceuticals, Inc.) is a commonly used antibacterial cream applied heavily over larger burns and held in place with layers of gauze dressings. Both of these agents are changed on a daily basis. Mafenide acetate (Sulfamylon, UDL laboratories, Inc.) and papain/urea (Accuzyme, DPT Laboratories, Ltd.) topical solution and creams are used to loosen eschar and facilitate débridement through enzymatic digestion.[64] Mafenide hydrochloride cream is hyperosmolar and can be painful when applied to larger areas. However, it is often used on the ears, where it can penetrate eschar to prevent chondritis, or inflammation of the ear cartilage. Mupirocin (Bactroban, GlaxoSmithKline) is an agent used to treat wounds infected with methicillin-resistant *Staphylococcus aureus* and *Staphylococcus pyogenes*.[92] Nystatin (Nilstat, Lederle Laboratories) may be used in combination with other topical agents for fungal infections caused by secondary immunosuppression. These fungal infections are often caused by long-term antibacterial use, usually originate in the gastrointestinal tract, and can be life threatening if they infect burns covering a large surface area or invade the bloodstream.

With the improved resuscitation measures developed for burns in the 1960s, infection became the predominant cause of morbidity and mortality. Silver salts and other chemically active silver compounds have been used in various forms because of their potent antimicrobial properties and ability to reduce burn wound infection. These substances have included silver colloidal solution, which was later replaced by silver nitrate solution, and silver sulfadiazine. Silver sulfadiazine is a water-soluble cream that is usually applied twice a day to the wound surface, as opposed to the continuous soaking required with silver nitrate. Since the 1970s, silver sulfadiazine has become the preferred option for antimicrobial silver therapy for burns.[25]

Major technological advances have resulted in the ability to crystallize silver in a nanocrystal form, which can release pure silver onto a wound surface in large quantities. This silver nanocrystalline delivery system is a three-ply dressing that may consist of an inner rayon/polyester core between two layers of silver-coated mesh.[13,104] Silver-infused dressings are also available in fabric-mesh or foam form. The ionic silver and silver radicals are released in high concentration when exposed to water. A layer between the wound and silver membrane maintains moisture for healing and decreases the formation of exudate.[25] The dressings, applied directly to the wound surface, promote healing by stimulating cellular dedifferentiation, followed by cellular proliferation. The dressings also have antibacterial, antifungal, and analgesic properties. These dressings have been found to be highly microbicidal against aerobic and anaerobic bacteria (including antibiotic-resistant strains), yeasts, and filamentous fungi[13] and can remain active and in place for up to 7 days instead of having to be changed every 12 to 24 hours.

Mepilex (Mölnlycke Health Care) is a silver-infused foam dressing that adheres to the area of the burn injury by a light adhesive. It can stay in place for 7 to 10 days. It provides antimicrobial coverage, and the foam is light and allows for movement of extremities. It is an expensive product, which can affect a burn unit's decision to use it. It is a very good product for children as it is comfortable and does not require a painful dressing change to be done at home. It is provided additional support by using Kerlix wrapping to secure it to the patient and then burn netting to hold the dressing together. It is most effective with superficial partial-thickness injuries.

Another silver-infused dressing is Acticote (Smith & Nephew) and Exalt (Exciton Technologies Inc.) dressing. This product is a silver-infused mesh product that can be secured to the patient with Kerlix wrap and burn net. Because it is a fabric, it is moldable and able to be secured over joints easily. It requires a light irrigation with water to release the silver into the wound and also to prevent the dressing from adhering to the wound bed and causing pain during movement. These products can be used in pre- and postoperative periods as burn dressing. These can be effective for up to 5 to 7 days between dressing changes.

Aquacel AG (ConvaTec Inc.) is a silver product that is different from the others. This product is a silver-infused fabric material that becomes a gel when in contact with a moist wound bed. When the dressing forms the gel, the silver aggregate is activated. It then hardens and forms an artificial "scab" that falls off when the burn injury reepithelializes. It comes as a sheet or as a glove. It is only effective with superficial partial-thickness injuries that do not require surgery. The product will harden and restrict movement in most cases, so this factor should be considered when deciding to use this product.

Biological Dressings

Biological dressings serve as temporary coverings to close a wound, prevent contamination, reduce fluid loss, and alleviate pain.[55] Theoretically, biological products may deliver growth factors to a wound as well. Traditional biological dressings, such as xenografts (porcine skin) and allografts (human cadaver skin), are still widely used in burn care. Xenografts may adhere to the superficial surface film of partial-thickness burns and facilitate débridement of eschar. Human amnion has also been used as a biological burn dressing, especially in developing countries.[87]

Biosynthetic Products

Biosynthetic products have been used widely for burn care. Closure of wounds with these dressings may lead to less pain, faster skin regrowth, and therefore less scarring. They are used until the wound is healed over, typically in 10 to 14 days, and then the dressing peels off.

Biobrane (Bertek Pharmaceuticals), a biosynthetic skin substitute wound-dressing sheet, has been used extensively. It is constructed of an outer silicone film (the epidermal analogue) with a nylon fabric partially embedded into the film collagen. The nylon components bind to the wound surface fibrin and collagen, which results in initial adherence (dermal analogue). Small pores are present in the structure to allow drainage of exudate and increase the permeability to topical antibiotics. However, if used improperly, the dressing can enclose dead tissue in the wound and provide a medium for bacterial overgrowth and invasive wound infection.[87]

Integra (Integra LifeSciences Corporation) is a biosynthetic wound dressing that is made up of an outer semipermeable silicone layer and an inner matrix of bovine collagen and glycosaminoglycan. According to Integra, "the collagen-glycosaminoglycan matrix provides a scaffold for cellular migration and capillary integration." This product is used for partial-thickness and full-thickness burn injuries. Because this product facilitates capillary growth into the wound area of coverage, it is often used for areas of tendon exposure, as the exposed tendon will have no blood supply of its own. This can allow for protection of the exposed tendon, maintaining the health and integrity of the tendon and allowing for eventual autograft placement over the area of exposed tendon, thereby preserving the overall function of the joint. In full-thickness injuries where the entire dermis is lost, Integra can facilitate the creation of a fertile wound bed in preparation for skin grafting, thereby creating the optimal environment for the skin graft to adhere and survive.

Biosynthetic products are becoming more widely used in burn care for wound closure. Some research indicates that use of these dermal substitutes can improve the appearance of the scar. However, there is no biosynthetic product that can substitute and provide all of the functions of real skin. It appears that biosynthetic products are emerging as a necessary part of burn care. However, most researchers agree that more research is needed on the functional outcomes of these products. Additionally, for a burn center careful consideration for the following must be made when using biosynthetic products: cost of the product (some products can be very expensive), its availability, and the skill required (surgical and wound care) for the product to be effective and safe.[18,35,86]

Hydrotherapy

Once the patient's condition is sufficiently stable, hydrotherapy is usually performed at least once a day to remove loose debris and "stale" topical antibiotics. It provides thorough cleansing of both the wound and the uninvolved areas. Hydrotherapy is generally accomplished by placing the patient on a "shower trolley" covered with a sterile plastic sheet and washing and showering the wound for 20 to 30 minutes. This nonsubmersive showering method of hydrotherapy has become the preferred technique of cleansing burn wounds to prevent cross-contamination of wounds among patients and has replaced the traditional whirlpool form of hydrotherapy.[2,29]

In hydrotherapy, the burn injury is cleaned, often with just a plain white soap (Ivory or Dove) and water. The wound bed is cleaned with soft washcloths. Dead skin, eschar, and pseudo eschar are removed from the wound, sometimes on a daily basis, and a new antimicrobial dressing can be placed. Fresh topical agents are then reapplied to delay colonization of organisms and reduce bacterial counts in the burn wounds. During hydrotherapy the patient has usually received some form of analgesics as well as antianxiety medications, as patients often have fear or anxiety surrounding the pain of a dressing change. Therefore the reduced pain and freedom-of-motion characteristic of the hydrotherapy intervention provides an excellent opportunity for the therapist to perform assessments and range-of-motion (ROM) exercises.

Sepsis

Burn wound colonization begins at the moment of injury, with gram-negative organisms replacing normal bacterial flora. Wound cultures and biopsies are performed to monitor such growth when signs of possible serious infection are present.[38] A severe infection can result in sepsis, in which the infection spreads from the original site through the bloodstream, a condition known as septicemia. Septicemia initiates a systemic response that affects the flow of blood to vital organs. Bacterial infections are the most common source of sepsis, but it can also result from fungal, parasitic, and mycobacterial infections, especially if the patient is immunocompromised. Broad-spectrum antibiotic therapy is typically initiated. However, if host defenses continue to be overwhelmed, the bacterial by-products or endotoxins accumulate in the bloodstream, a condition known as toxemia, which eventually leads to septic shock, a cardiovascular response that impedes blood flow to the organ systems, and to generalized circulatory collapse. Septic shock may be characterized by ischemia, diminished urine output, tachycardia, hypotension, tachypnea, hypothermia, disorientation, and coma. Septicemia and septic shock often require multisystem supportive measures for recovery, such as the use of cardiovascular medications, hemodialysis, and mechanical ventilation.

Surgical Intervention

There are different surgical interventions for a burn-injured patient. If a patient is unable to tolerate dressing changes or if the nursing staff is unable to clean the wound sufficiently in hydrotherapy, the burn unit team may decide to take a patient to the operating room for débridement. Some surgeons are certified or have access to conscious sedation in their burn units. In both cases, a surgeon will sedate a patient and then débride the wound down to a clean wound bed. This allows the surgeon to assess the clean wound and determine if the wound will heal on its own or if the patient will require a skin graft.

Although all burn wounds are treated with some type of topical antibacterial agent, when the depth and extent of the wound require more than 2 weeks for healing, surgical intervention is indicated to decrease burn morbidity and mortality. Surgical treatment of burns usually consists of excision of the nonviable burned tissue, or eschar, and placement of biological or synthetic skin grafts.

Essentially three types of biological grafts are available. A **xenograft**, or heterograft, is processed pigskin. A homograft, or **allograft**, is processed human cadaver skin. These grafts are used as biological dressings to provide temporary wound coverage and pain relief. An **autograft** consists of permanent surgical transplantation of the upper layers or a split-thickness skin graft (STSG) of the person's own skin taken from an unburned donor site.[79] The STSG is applied to the clean, excised tissues of the burn wound graft site. Skin grafts placed as a sheet have superior appearance and quality, but to cover large surface areas rapidly, the graft may be "meshed" to allow a single sheet of skin to be expanded for coverage of a larger surface area (Figure 42.7). The meshed graft attaches to the burn surface in the same manner as a sheet graft, but the interstices, or openings in the meshed skin, must heal by reepithelializing over granulation tissue. This leads to more scarring and a permanent mesh pattern on the skin.

FIG 42.7 **A** and **B,** Meshed skin grafts can be expanded to cover a larger surface area but have a higher risk of developing hypertrophic scars as they heal. The skin will also heal with the characteristic mesh pattern. **C,** Sheet grafts cover a smaller surface area but have a lower risk of developing hypertrophic scars as they heal.

Now that the size of a survivable burn has increased, the amount of available donor sites for autografting has conversely decreased. For this reason, alternatives to autografts have been developed. Examples of such alternatives are epidermal cultured skin substitutes,[36] cultured epidermal autografts,[9,87] and dermal analogues such as Integra (Integra LifeSciences Corporation) and AlloDerm (LifeCell Corporation).[87] A wound may be limited in size, but the defect may be so deep that survival of bone or tendon is at risk. In these instances, STSG adherence is difficult to achieve, and a full-thickness skin graft or microvascular skin flap may be indicated.[79]

Vacuum-Assisted Closure

Negative pressure wound therapy, also known as vacuum-assisted closure (VAC), is a treatment in which a sealed dressing and controlled negative pressure are used to evacuate wound fluid, stimulate growth of granulation tissue, and decrease bacterial colonization, especially in deeper wounds.[56] Since their introduction, VAC (VAC Therapy; KCI Concepts) dressings have been used in a number of surgical specialties, including burn care. By assisting in the débridement of necrotic tissue and removal of soluble inflammatory substances, VAC therapy reduces the number of dressing changes required and shortens the time interval between débridement and wound closure. This has been shown to facilitate the growth of granulation tissue even in deep wounds and thus make graft adherence more successful.[83]

Using a VAC device to secure a skin graft prevents fluid collection beneath the graft, ensures full contact between the wound bed and the transplanted skin, and distributes an even amount of pressure over the entire surface, regardless of the irregularity of the recipient bed. However, movement of the recipient surface could compromise the graft if it is not immobilized by proper positioning or splinting.[85] During treatment the therapist must be attentive to the VAC dressings and avoid activities with the patient that could disrupt the seal around the dressing and cause an air leak.

Nutrition

Adequate nutrition is essential during wound healing because the metabolic rate of a patient with a burn injury greatly increases with corresponding increases in protein, vitamin, mineral, and calorie needs.[54,81] Protein is especially important for wound healing and must be provided in substantial amounts. Nutritional requirements are calculated on the basis of the %TBSA and the patient's admission weight. Calorie counts and the patient's weight are closely monitored to ensure adequate nutrition. If the patient is unable to meet individual requirements through the diet, high-protein and high-calorie supplements are given either orally or through a nasogastric or gastric tube. If the gastrointestinal tract is compromised, intravenous hyperalimentation is frequently necessary for severe burns with extensive %TBSA. This solution contains sufficient amino acids, glucose, fatty acids, electrolytes, vitamins, and minerals to sustain life, maintain normal growth and development, and foster needed tissue repair. It is often infused through a central line catheter into the superior vena cava of the heart.

Later, as the wound closes and normal feeding resumes, nutritional demands decrease and the individual's eating habits must be normalized to prevent excessive weight gain. The occupational therapist and dietician will often work together when self-feeding is an issue. The occupational therapist can assist the dietician in understanding a patient's physical ability in the context of self-feeding so that food choices can be better tailored to suit the patient. For example, patients with mouth and face burns may find it painful to eat solid foods but may be willing to drink nutritional shakes to meet their needs as they are waiting to heal.

Associated Problems and Complications

Stress

Traumatic events associated with severe burns include natural and intentional disasters such as tornadoes, lightning, house fires, motor vehicle accidents, acts of war or terrorism, physical or sexual assault, and the sudden death of loved ones or friends. Burn treatment further traumatizes the patient because of associated painful medical procedures (e.g., wound care, limb amputations, multiple surgeries, and therapies). Mental health professionals are increasing their understanding of the factors associated with increased psychiatric risk and the ways in which burn patients, especially children, cope with the stress and pain triggered by traumatic events. Responses to major stress often include reliving the event, avoidance, and hypervigilance; these responses may continue long after the precipitating event. Post-traumatic stress disorder is a common psychiatric condition after traumatic experiences, including physical injuries such as burns.[22,27,28] Mood, anxiety, sleep, conduct, learning, and attention problems are often comorbid conditions, especially in children. Treatment involves pain assessment followed by specific interventions such as pain management, psychiatric consultation, and crisis intervention initiated promptly after the traumatic event. Intervention should also involve the burn survivor's family.[17]

Pain

Pain Assessment

Some of the most commonly used pain assessment tools include visual scales, color scales, word and faces scales, and adjective scales. A 1998 study indicated that patients prefer the faces and color scales over commonly used visual analog and adjective scales.[33] Pain levels should be assessed during a quiet time and again immediately after any painful activity.

Pain Management

Because pain has adverse physiologic and emotional effects, pain management is an important factor to achieve better outcomes. Developmentally appropriate and culturally sensitive pain assessment, pain relief, and reevaluation are essential in treatment. Pain control guidelines should address both background and procedural pain and associated anxiety. The occupational therapist should assist nursing staff in focused surveillance of burn pain and its successful treatment.[58]

Pharmacologic treatment is primary, strengthened by new concepts from neurobiology, clinical science, and the introduction of more effective drugs offering fewer adverse side effects and decreased toxicity. Opiates remain the most common form of analgesic therapy for patients with burns, but because these patients require increased opiate dosages, optimal relief of burn pain can be difficult. Alternative pain control methods include acetaminophen as a useful analgesic for minor burns. Nonsteroidal anti-inflammatory drugs and benzodiazepines are often combined with opiates. Antidepressants appear to enhance opiate-induced analgesia, whereas anticonvulsants are useful in the treatment of sympathetically maintained pain following burns. Ketamine has been used extensively during burn dressing changes, but psychological side effects, such as delirium and hallucinations, have limited its use.[63]

Nonpharmacologic intervention using various hypnotic, cognitive, behavioral, and sensory treatment methods is becoming more accepted. Transcutaneous electrical nerve stimulation, topical and systemic local anesthetics, and psychological techniques are also useful adjuncts.[64] Hypnosis may be a very useful alternative when opioid pain medication proves to be dangerous or ineffective; it has received strong anecdotal support from case reports.[62] The mechanisms behind hypnotic analgesia for burn pain are poorly understood; however, patients with burn injuries are more receptive to hypnosis than the general population, possibly because of increased motivation, dissociation, and regressive behavior.[65] Other methods of nonpharmaceutic pain reduction may be helpful. Relaxation techniques that may be of benefit include progressive relaxation, breathing exercises, guided imagery, aromatherapy, music therapy, and teaching individualized coping strategies.[72] As with hypnosis, distraction and relaxation techniques work best with alert, motivated patients.[59]

Patients with a severe burn injury naturally respond to pain by resisting painful motions or activities. Behavioral regression is also a normal response in most children (and many adults). When regression occurs, the therapist should be supportive and continually explain beforehand what needs to be done and why in terms that the patient can understand.

Most patients are usually more interested in whether the procedure will hurt and how long it will last than in lengthy explanations or technical information. Coordinating treatments with scheduled pain medications is often helpful and highly recommended, especially if active participation is necessary. The therapist should be aware of and use techniques to minimize preventable pain (e.g., applying adequate vascular support to the LEs before standing or ambulation). The therapist must also inform the nursing staff about any noted side effects from pain medication, as well as the observed effectiveness of the currently used pain management regimen. The need for short-term breakthrough pain relief should be coordinated with the nursing staff to reduce discomfort and stress during intensive therapy procedures. If a patient's anxiety or pain is disproportionate to the treatment, antianxiety medication may be indicated both to relieve anxiety and to increase the effectiveness of pain medication. Time limits on painful treatment sessions should be predetermined with all patients who are cognizant and capable of participation. The therapist should consistently adhere to these time limits to foster trust and a sense of control for the patient. By reducing the patient's anxiety, the therapist reduces the fear factor that can exacerbate perceived pain.[71] As the wound heals, the amount of narcotic analgesia is gradually decreased, and patients usually require minimal pain medication by discharge (see Chapter 28).

Psychosocial Factors

After a burn injury there is a potential for psychological reactions, including depression; withdrawal reactions caused by disfigurement; behavioral regression; and anxiety over the ability to resume work, family, community, and leisure roles.[31] The way in which a person copes with burn trauma is strongly influenced by his or her psychological status before the injury and whether the injury was a result of accident, arson, assault, or suicide attempt. The psychological ramifications can include guilt, anxiety, depression, regression, increased hostility, and existential crisis.[59] In the case of permanent loss of function and deformity, the patient may experience severe grief as a result of decreased physical abilities, changes in personal appearance and identity, loss of vocation, or loss of loved ones who were killed in the same accident. In the case of facial disfigurement and amputations, the patient's previous support system may also be reduced or lost as a result of abandonment by friends or significant others who cannot adjust to the physical changes in the patient.

Whether the permanent loss is social or physical, the patient may need to move through stages of grief similar to the five stages of grief in patients with a terminal diagnosis as described by Dr. Kübler-Ross in her book *On Death and Dying*.[49] The stages include the following:

- *Denial.* In this phase a burn-injured patient may express, "Why is this happening to me?" "The doctor said I'm going to have surgery to fix my burn." In this phase, burn patients may have the belief that their problems will be over once they heal the burn injury or have their surgery. They will not take into consideration the need for ongoing wound care, scar management, and therapeutic interventions to return to normal function.
- *Anger.* "Leave me alone!" Or "Stop hurting me!" Patients may express anger at medical staff, themselves, or at family or friends. They may refuse treatments or therapeutic interventions in their state of anger.
- *Bargaining.* In this phase, most burn-injured patients do not understand the length of time required for the burn injury to heal and to return to normal functioning. They may make statements such as "I'll do therapy later."
- *Depression.* When burn-injured patients realize that they are forever altered by their burn injury and that they must endure some amount of pain during their recovery, they will often experience sadness.
- *Acceptance.* The patient accepts the burn injury as part of him or herself. Patients learn to manage their pain without trying to avoid it. They acclimate to the new sensations of movement and touch. In this phase, patients will adapt to the bodily changes and return to work with modifications as needed; they will learn new physical and coping skills to deal with the burn injury and resume their place within their social/family circle, often creating new additional social supports.

If the patient does not reach the stage of acceptance, the rehabilitation process could be severely impaired. Providing emotional support and education and helping the patient develop coping mechanisms and self-direction can promote the psychological adjustment of patients with burn injuries. However, a severe burn injury occasionally results in a reassessment of personal values and relationships or a renewed appreciation of life. The complex interactions among premorbid personality style, extent of injury, and social and environmental contexts should be considered when determining how patients will adjust psychologically to a severe burn injury.[59]

OT Practice Notes

Occupational therapy intervention must address the psychological aspects from the initial assessment and onset of occupational therapy intervention and continue through discharge from occupational therapy services at the end of the rehabilitation phase. Even after discharge from rehabilitation, the client may continue to need psychosocial occupational therapy intervention as he or she attempts to become actively involved in the community, resume social activities and relationships, and return or enter the paid workforce.

Burn Rehabilitation

The Team

Successful care and rehabilitation of burn survivors require a multidisciplinary team approach that begins immediately after the patient's admission to the hospital and continues through and beyond hospitalization.[8,77] Ideally, the burn care team includes physicians, nurses, physical and occupational therapists, respiratory therapists, nutritionists, social workers, psychiatrists and psychologists, speech and language pathologists, orthotists and prosthetists, child care and recreational therapists, pastoral caregivers or clergy, interpreters or cultural support personnel, and vocational counselors. The most important members of the team, however, are the client and the client's family or support system.[82,88]

OT Practice Notes

All healthcare professionals must continue to update their knowledge and professional competencies and keep abreast of the rapidly changing treatments and therapies available for treating burned patients.[83] Recommended ways to continue professional development include the following:

- Review professional journals such as the *Journal of Burn Care and Rehabilitation, Burns, Journal of Wound Care, Journal of Trauma,* and *Journal of Burns.*
- Obtain membership in burn care associations such as the American Burn Association and the International Society of Burn Injuries.
- Attend local, regional, and national association meetings. Visit regional burn centers to confer with other burn therapists.
- Visit online websites of professional burn associations, and participate in online discussions with other burn care professionals.

Goals of Rehabilitation

The entire burn team is involved in some aspect of burn rehabilitation, whether it is providing verbal support, preparing the patient for self-care tasks, reinforcing the importance of active motion, or providing patient education. The long-term goals of occupational therapy are quite similar to the long-term goals of the entire burn team. Although specific goals may be the responsibility of various team members, everyone's efforts are focused on the same outcome. Occupational therapy treatment goals should therefore be compatible with all other treatment regimens and be established in collaboration with the patient, family, and entire rehabilitation team. Inherent in this concept is the need for close communication and cooperation of all burn team members. Occupational therapy should take the lead in helping all team members understand the client as a unique occupational being, along with all the relevant factors and contexts that will come into play. Role delineation between different disciplines, especially occupational therapy and physical therapy, differs among burn care facilities and may be determined by insurance reimbursement rather than by traditional roles or the specialized skills of the individual therapist. Therefore it is especially important that all disciplines work closely together with ongoing communication so that patients benefit from the skills and viewpoints of all areas of specialization. Occupational, physical, and speech therapists who specialize in burn rehabilitation increasingly use co-treatments that promote independence in both mobility and ADLs.

Phases of Recovery

Rehabilitation management of burn survivors can be divided into four overlapping phases to aid in categorizing and determining effective intervention goals. These phases of recovery are the acute care phase, the surgical and postoperative phase, the inpatient and outpatient rehabilitation phase, and the reconstructive phase.

The acute care phase is usually the first 72 hours after a major burn injury. However, if it is a superficial partial-thickness burn and heals spontaneously in less than 2 weeks without surgical intervention, the time from injury until epithelial healing is also considered an acute care phase.[76]

The surgical and postoperative phase follows the acute phase and continues for varying lengths of time, depending on the size of the burn injury and the presence of associated medical complications. During this period, vulnerability to wound infection, sepsis, and septic shock is especially great, and medical treatment is focused on promoting healing and minimizing infection.

The rehabilitation phase covers both inpatient and outpatient care and can extend for an indeterminate length of time. This phase follows the post-grafting period, when the patient is medically stable and most open wounds have healed. The quality of wound healing, scar formation, and need for aggressive rehabilitation make this the most challenging phase for burn patients, their families, and their therapists.

Acute Care Phase

During the acute care phase, medical management is of utmost importance for survival of the patient, and the goal of occupational therapy is primarily preventive. As the patient recovers and wound closure progresses, the nature of occupational therapy also changes, with treatment directed at restoring function. Initially, however, when the wounds are deep partial or full thickness, the acute care rehabilitation goals are as follows:

- Provide cognitive reorientation and psychological support.
- Reduce edema.
- Prevent loss of joint and skin mobility.
- Prevent loss of strength and activity tolerance.
- Promote occupational performance, such as independence in self-care skills.
- Provide patient and caregiver education.

Surgical and Postoperative Phase

Rehabilitation goals during the surgical and postoperative phase are focused on preserving or enhancing performance skills and patterns while supporting surgical objectives. Excision and grafting procedures usually require periods of immobilization of the areas treated to allow graft adherence. The preferred position and length of immobilization will vary by physician prerogative and burn center protocol, with the average period of immobilization being between 2 and 7 days.[16,42,79,84] Full-thickness skin grafts are immobilized for up to 10 days. When the patient requires biosynthetic grafting, the affected areas are immobilized from 10 to 14 days. The most advantageous postoperative position usually maintains the grafted area in the position that maximizes the surface area of the grafted site. For example, a hand with a dorsal burn should be splinted with the wrist in a neutral or slightly extended position, the metacarpophalangeal (MP) joints flexed, and the thumb radially abducted to protect the first web space.

During this phase, the goals of therapy include the following:

- Promote cognitive awareness by providing orientation activities when necessary, and continue psychological support.
- Protect and preserve graft and donor sites by fabricating splints and establishing positioning techniques that support the surgeon's postoperative care orders.
- Prevent muscular atrophy and loss of activity tolerance, and reduce the risk for thrombophlebitis by providing exercise for areas that are not immobilized.
- Increase independence in self-care by teaching alternative techniques and providing adaptive equipment as needed.
- Educate and reassure the patient and family members regarding this phase of recovery.

Rehabilitation Phase

The third phase of recovery is the rehabilitation phase, which begins as wound closure occurs. Individuals with large %TBSA burns frequently enter this phase needing further surgery. However, the majority of their wounds are closed, and scar maturation is commencing. The focus of intervention during this phase is on maximizing function and participation in occupations, promoting physical and emotional independence, and managing scar formation to prevent or correct deformity and contracture formation. Patient and family education is especially important for developing competence in wound/scar care and therapy programs in preparation for discharge.

The rehabilitation phase extends past hospital discharge and continues until maturation of all burn wounds and surgical sites is complete. Before discharge from the hospital, emphasis is placed on independence, self-management, and education. Once the client is home, emotional support and intervention must continue to help sustain the client's confidence, self-esteem, and motivation, qualities that the client needs to cope with the physical, social, and emotional consequences of a severe burn injury.

Intervention goals for this phase can be exhaustive given the potentially disabling effects of burn scars. Therefore it is important for the therapist to incorporate the patient's personal goals from the beginning of the rehabilitation process.

Treatment goals for the rehabilitation phase are expanded to include the following:

- Continue to provide psychological support as the patient progresses toward physical and emotional independence and faces new challenges.
- Improve joint mobility and reduce contractures by using correct positioning, sustained passive stretching exercises, and splinting as needed.
- Restore muscle strength, coordination, and activity tolerance.
- Initiate a compression therapy and scar management program with the use of vascular support garments, custom scar compression garments, and pressure adapters to minimize scar hypertrophy, contractures, and disfigurement.
- Promote independent self-care skills or the ability to direct others to assist when needed, including appropriate positioning, exercise, and skin care. Provide instruction and opportunities to practice IADLs, including vocational and home-care activities.
- Continue to provide instruction on scar development, including potential sensory and cosmetic changes, scar management techniques, and related safety precautions such as sun protection and skin care.
- Guide the implementation of a post-discharge plan that supports resumption of school, work, social, and leisure occupations.

Reconstructive Phase

In this phase of burn survivors' recovery, they have often reintegrated into their daily life and have assumed their occupational roles. They have effectively entered the acceptance phase of the grief process and are able to demonstrate hope for the future by learning new occupational skills and acquiring new occupational roles. These patients often return to the outpatient burn clinic for follow-up once or twice a year to assess their scars and functional ability. These patients are ready to discuss surgery to improve the appearance of scars. In this phase, the patients psychologically understand the limitations of surgery and scar management interventions to improve the burn scar appearance. They are able to have a conversation with the physicians about how they look and the concerns they have. They typically become active participants in the decisions on elective surgeries to improve the appearance of their scars. Though the occupational therapist's role during this phase is limited, he or she can empower the patient to initiate the conversation with the surgeon to discuss reconstruction.

Occupational Therapy Evaluation

Although medical status issues are a primary concern during acute care, whenever possible the occupational therapist should complete an initial evaluation within the first 24 to 48 hours after hospital admission. Burn etiology, medical history, and any secondary diagnoses are obtained from the medical record and team. The wounds are then visually assessed to determine the extent and depth of injury. Any areas affecting future occupational performance and context are noted and documented.

Whenever possible, both the client and family are interviewed to establish rapport and to obtain a history of the client's previous occupational performance. This history should include preinjury body structures and body functions (i.e., hand dominance, previous injuries, and performance-limiting illnesses or conditions) and specific information on past performance skills and patterns, daily routines, and activities (including professional, educational, and domestic responsibilities). Obtaining data concerning preinjury personality traits and psychological status is equally important. With this information, the therapist can monitor for changes in the client's behavior and cognitive functioning and choose the most appropriate interactive approach to encourage the client's involvement in goal setting and the therapy process. In the case of a severe burn requiring intubation and mechanical ventilation, this information must be obtained from family members and significant others to verify and supplement what the patient may relay nonverbally.

OT Practice Notes

Ideally, the client's history of occupational performance would be obtained before assessment of current client factors. However, the acuity of the injury, time constraints, and the need to coordinate physical assessment with pain medications, wound dressing changes, and other medical procedures may supersede completion of a detailed performance history.

Involved and uninvolved areas should be evaluated for joint mobility, strength, sensation, and functional use. However, before beginning this evaluation, the therapist should explain the purpose of occupational therapy and what the client should expect during the assessment, including the potential for discomfort. Preassessment instruction and ongoing encouragement help reassure clients and decrease anxiety so that they can perform at their best. Emphasis is placed on the ultimate long-term goal of resuming engagement in meaningful occupations and participation in life contexts.

The initial clinical evaluation should address all areas of potential occupational therapy intervention, including assessment of wound location and severity, presence and severity of edema, passive range of motion (PROM) and active range of motion (AROM), muscle strength, gross and fine motor coordination, changes in sensation, and level of cognitive awareness. Ideally, these assessments take place during a dressing change or hydrotherapy, when the involved areas are exposed and unencumbered.

During the initial evaluation, distinctions are made among superficial, superficial partial, and deep partial-thickness burns, as well as full-thickness burns, on the basis of appearance and presence of sensation. The therapist must view the wounds as soon as possible after the injury, before the development of burn eschar. Eschar causes deep partial-thickness burns to closely resemble full-thickness burns and makes an accurate evaluation of depth difficult. Attention should also be directed to burned joint surface areas and the presence of any circumferential burns. ROM assessment should be performed to evaluate joint mobility, and general strength should be tested before significant edema develops or restrictive dressings are applied.

Instructing the client regarding the types of movements and the number of repetitions expected while gently guiding the individual through the specific motion can help ensure achievement of full range. When possible, a goniometer should be used for assessing ROM to accurately document baseline deficits and future changes in recorded measurements. If pain, edema, tight eschar, or bulky dressings limit full ROM, such information should also be documented. Preexisting conditions that may alter expected AROM should be investigated during the patient and family interview. Although AROM is preferred, PROM should be measured if a client is unresponsive or unable to move the extremity sufficiently. When using PROM, care must be taken to not apply excessive force, especially with older clients who have degenerative joint disease or small children with hypermobile joints.

With deeper partial- or full-thickness dorsal hand burns, boutonnière precautions should be initiated until the integrity of the hand's extensor hood mechanisms can be verified. Boutonnière precautions involve avoidance of composite active or passive flexion of the fingers. Instead, isolated MP flexion is combined with interphalangeal (IP) joint extension to prevent stress and possible damage to a compromised extensor tendon mechanism. All passive proximal interphalangeal (PIP) flexion is avoided, and protective splinting is promptly initiated to maintain the PIP joints in extension.

A gross sensory screening that includes all sensory distribution areas should be performed. Such screening is especially important in individuals with electrical injury or a history of long-standing diabetes, in whom peripheral neuropathies may be present.

If the client possessed normal functional muscle strength before the injury, an initial test of gross muscle strength may not be needed if the AROM assessment reveals adequate strength to work against gravity. Manual muscle testing of major muscle groups is indicated if the burn resulted from an electrical contact injury, if the presence of severe edema might cause compartment syndrome, or if other musculoskeletal or neurologic injuries are suspected.[103] If the hand is unburned or if it is a superficial partial-thickness burn, a dynamometer and pinch gauge provide objective baseline measurements of grip and pinch strength.

ADL assessment begins by interviewing the client or the family to obtain the client's preinjury level of physical, cognitive, and social performance skills and patterns. When the burn injury is severe, the ADL assessment is postponed until the client is medically stable and able to participate in the pursuit of more advanced occupational goals. Clients with less severe burns and those who are not mechanically ventilated should be assessed for basic ADL skills, such as feeding, basic grooming, and donning and doffing of hospital gowns. Any compensatory actions or awkward movements used to complete the activity should be noted. Any abnormal patterns should be investigated and discussed to determine whether they were present before the burn injury.

After completion of the initial evaluation (Table 42.2), short- and long-term goals should be established with the client's collaboration. The client's previous context and lifestyle, personal long-term goals, and current priorities should be taken into account when establishing occupational therapy intervention goals. All short-term goals should be specific and realistic and have an established time frame for completion. After goals are agreed on, the intervention plan can be formulated. The occupational therapy intervention plan should be practical and should complement and support the goals of the other team members.

TABLE 42.2

Components of Evaluation for Burn Rehabilitation

Initial Evaluation	Inpatient Rehabilitation	Outpatient Rehabilitation
Cause of the burn	Graft adherence	Skin or scar condition
%TBSA	Skin or scar condition	Compression garment fit
Depth of the burn	Contracture concerns	Volumetrics if needed
Area(s) involved	Edema (if present)	ADL performance level
Age, hand dominance	ADL performance level	Work skills
Functional status	Work skills	Active and passive ROM, TAM
Occupation	Active and passive ROM, TAM	Strength and activity tolerance
ROM and strength	Strength and activity tolerance	Developmental level (child)
Mobility and activity tolerance	Developmental level (child)	Psychological status
Developmental level (child)	Psychological status	Social support
Psychological status	Social support	Leisure activities
Social support	Leisure activities	Compression garment needs
Leisure activities	Compression garment needs	Home management
	Home management	Home care understanding
		Return-to-work capacity
		Return-to-school potential and need for reentry program

ADL, activity of daily living; ROM, range of motion; TAM, total active motion; TBSA, total body surface area.

Two fundamental principles must be kept in mind when working in burn rehabilitation: (1) the main factor hindering post-burn functional recovery is the formation of scar contractures and hypertrophic scarring, and (2) severe scars and contractures are often preventable with prompt therapeutic intervention.[73] Therefore most burn rehabilitation intervention techniques and objectives are directed at prevention, as well as restoration.

Occupational Therapy Intervention

Acute Care Phase

Preventive Positioning

The purpose of preventive positioning is to reduce edema and maintain the involved extremities in an antideformity position (Table 42.3). Proper positioning is critical because the position of greatest comfort for the patient is usually the position of contracture.[50] The typical position of comfort consists of adduction and flexion of the UEs, flexion of the hips and knees, and plantar flexion of the ankles. The toes are generally pulled dorsally. Acutely burned hands are held by edema in a dysfunctional position consisting of wrist flexion, MP extension, IP flexion, and thumb adduction. This position, often called the “clawhand” or “intrinsic minus” position, can lead to severe dysfunction if not prevented during active scar formation.

TABLE 42.3

Antideformity Positioning for Specific Areas of the Body Following Burn Injury

Body Area	Antideformity Position	Equipment and Technique
Neck	Neutral to slight extension	No pillow; soft collar, neck conformer, or triple-component neck splint
Chest and abdomen	Trunk extension, shoulder retraction	Lower the top of the bed, towel roll beneath the thoracic spine, clavicle straps
Axilla	Shoulder abduction of 90 to 100 degrees	Arm boards, airplane splint, modified hip abduction pillow, clavicle straps, overhead traction
Elbow and forearm	Elbow extension, forearm neutral	Pillows, conformer splints, dynamic splints (when wounds healed/closed)
Wrist and hand	Wrist extension to 30 degrees, thumb radial abducted and extended, MP flexion of 50 to 70 degrees, IP extension	Elevate with pillows, volar burn hand splint
Hip and thigh	Neutral extension, hips in 10 to 15 degrees of abduction	Trochanter rolls, pillow between the knees, wedges
Knee and lower leg	Knee extension; anterior burn: slight flexion	Knee conformer, casts, elevation when sitting, dynamic splints
Ankle and foot	Neutral to 0 to 5 degrees of dorsiflexion	Custom splint, cast, AFO
Ears, face, mouth, eyes	Prevent pressure; maintain mouth opening, ability to close eyelids	No pillows; headgear, mouth splint

AFO, ankle-foot orthosis; IP, interphalangeal; MP, metacarpophalangeal.

Positioning needs are determined during the initial wound assessment by evaluating the surface areas burned and the presence of edema, considering the posture that the individual tends to assume, and assessing whether that posture would limit function if allowed. For example, if the burn injury involves the shoulder, chest, and axillae, the client's UEs should be elevated and positioned in approximately 90 degrees of shoulder abduction, 45 degrees of external rotation, and 60 degrees of horizontal adduction by using pillow inclines and arm boards or supporting the arms with sheepskin slings suspended from an overhead traction rig (Figure 42.8). Achieving full shoulder flexion and abduction with frequent exercise and activity is critical to prevent axillary contractures and subsequent loss of overhead reach as wound healing progresses. Once positioning needs are determined, illustrated guidelines should be posted at the bedside so that the nursing staff and team can assist in ongoing correct positioning (Figure 42.9).

FIG 42.8 Shoulder positioning postsurgery using a small hip abduction pillow.

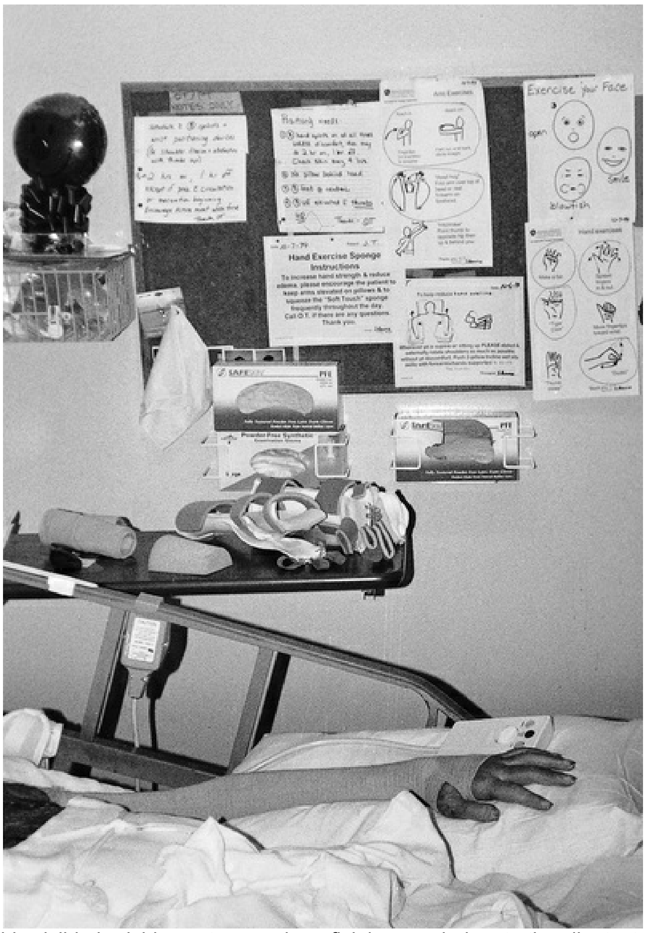

FIG 42.9 Highly visible bedside posters are beneficial as reminders to the client, staff, and visitors regarding positioning, exercises, and splinting instructions.

After admission, positioning is initiated primarily to reduce edema formation.[69] Elevation of the entire extremity above heart level can reduce the severity of distal edema formation, especially when paired with AROM exercises. As edema decreases and wound closure progresses, positioning goals should be directed toward prevention of skin tightness over joint surfaces (see Table 42.3).

Splinting

Splinting is initiated to maintain correct positioning and protect compromised tissues. It is not necessary for splints to be worn at all times to prevent contractures. When a splint is used during the acute phase, it is generally static in design and applied when at rest, with activity and exercise being emphasized during waking hours. Volar hand splints are indicated if a burned hand has chronic edema, active motion is limited, or unsupervised movement is contraindicated because of deep dorsal burns or other traumatic injury. The typical volar hand splint provides approximately 15 to 30 degrees of wrist extension, 50 to 70 degrees of MP joint flexion, full IP joint extension, and combined thumb abduction and extension (Figure 42.10).[24,74] Elbows or knees should be splinted at neutral position and secured with elastic wraps and taped on versus applying metal clips to prevent tears in grafts or surrounding intact skin.

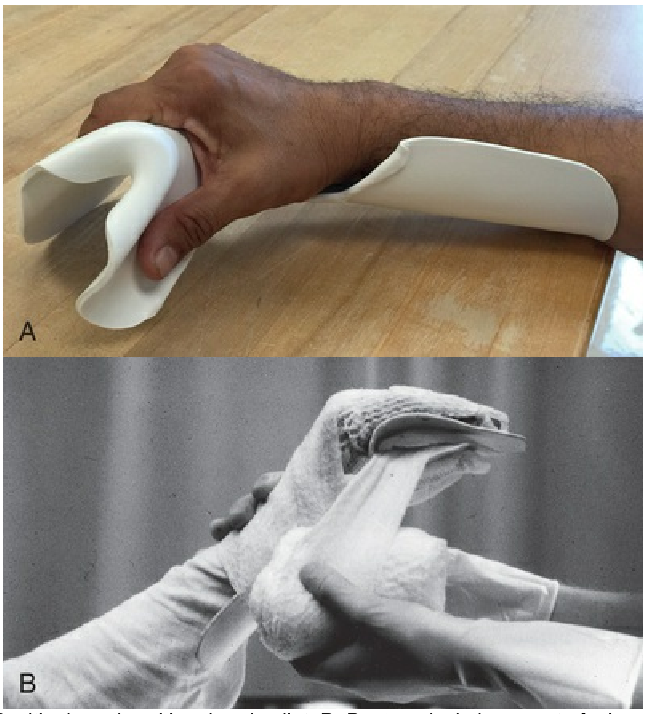

FIG 42.10 **A,** Positioning a hand in a hand splint. **B,** Postsurgical placement of a hand in a burn hand splint secured with elastic bandages.

When checking the fit of any splint, the therapist should consider potential pressure points and ensure correct placement. Splints fabricated shortly after injury require daily assessment and may require alterations to accommodate any significant changes in edema. Hand splints are secured in place with a figure-of-eight wrap of gauze bandage or elastic wraps, with the fingertips being exposed so that circulation can be monitored. Folded 4 × 4–inch gauze sponges are used over the proximal phalanges and under the wrap to keep the fingers extended and secured in the splint. Detachable straps, though convenient for later use, may be inappropriate for use with acute burn splints because of infection control concerns and the potential for constriction during fluctuations in distal edema.

During the course of Tonio's treatment, he was provided with a static-progressive hand splint for use throughout the day. His family was instructed on how to don/doff the splint so that he could continue to use the splint on the weekend to improve his functional ROM of (B) hands. The treatment was effective, and Tonio was able to form a more secure grasp with the right hand.

When the external ear has sustained a partial- or full-thickness burn, protection is desirable to prevent further damage caused by pressure from pillows, dressings, or endotracheal tubing. An ear protection splint should be fitted at the earliest opportunity and worn until the external ear burns have healed. The splint can be fabricated from two thermoplastic ear cups or cushioned oxygen masks secured in place with a dressing or a three-point stabilizing strapping technique.[23,46]

Activities of Daily Living

A client's ability to perform self-care is often limited during the acute care phase because of his or her current medical condition. The need for artificial ventilation, multiple lines, catheters, and other supportive equipment interferes with independence in ADLs, and clients are dependent on nursing staff for self-care.

While the client is maintained on the ventilator and orally intubated, ADL activity may be limited to self-suctioning of the oral cavity and, if no facial burns have occurred, basic facial hygiene. After extubation, oral care is often the next ADL attempted. When the client is medically cleared to take fluid or food by mouth, the occupational therapist should assess self-feeding abilities. Airway damage, accompanied by compromised speech and swallowing ability, often results from an extended period of intubation or direct damage during the burn injury. In these cases, the occupational therapist works in concert with the speech pathologist on common goals that promote effective communication skills and independent self-feeding. Burns involving the UEs and associated pain, dressings, and edema may interfere with self-feeding, hygiene/grooming, and writing motions and make temporary use of adaptive equipment necessary. This equipment may include built-up or extended handles on utensils, a plate guard, or an insulated travel mug with a lid and straw. Hair grooming and shaving are other self-care activities to initiate early, depending on the client's strength and activity tolerance. Adaptive equipment is sparingly used as the ultimate goal is for the patient to have and use the full range of motion of the upper extremities and hands.

In the acute phase, ADL tasks should be selected that are valued by the client and have a high probability of success even though temporary adaptations may be necessary. Modifications in the client's environment, equipment, or previous performance patterns may be necessary to support independence. However, eventual discontinuation of adaptive techniques and devices is a long-term goal of therapy and should be presented to the client as a sign of progress during the course of therapy. A goal shared by both the client and therapist alike should be independence in all ADLs using previous performance patterns, completed within an appropriate length of time and with minimal adaptations.

Therapeutic Exercise and Activity Tolerance

Sitting tolerance, transfers, and ambulation activities are initiated as soon as the client is medically cleared to get out of bed and bear weight on his or her LEs. If the client has burns on the LEs, elastic wraps should be applied before the client sits up and the feet become dependent. A figure-of-eight pattern should be used from the base of the toes, over and including the heel, to at least the knees, and up to the groin as needed. When the client is sitting in a chair, the LEs should be kept elevated. Any time spent dangling the feet or standing statically should be limited to prevent distal venous congestion and unnecessary discomfort.

In addition to functional activities, active exercise is a primary component in every burn treatment plan. The exercise techniques used during acute care are not unique to the injury. Active, active-assisted, or passive exercises are used, depending on the client's condition. The focus of exercise in acute care is to preserve ROM and functional strength, build cardiopulmonary endurance, and decrease edema.

Strengthening activities are introduced into the acute care intervention program as soon as the patient's condition allows. Such activities range from simple active movement to resistive activities, as tolerated, to counteract the deconditioning effects of hospitalization. Exercise after a severe burn injury was once thought to overstress an already hypermetabolic client. However, research and experience have shown that graded, progressive exercise is beneficial when recovering from acute burns.[43,100]

Client Education

Client education should be thought of as ongoing. Newly injured patients are often in a state of shock from the initial trauma. They can feel overwhelmed and have difficulty processing information. Cognitive studies show that stress can negatively impact the patient's frontal lobe or thinking brain. This can make providing education more challenging. The patient should be given multiple opportunities to learn information. Ward and home programs are good ways to begin educating a patient on his or her burn injury, expected ROM exercises, safety precautions, and contracture preventions. When the patient is given an array of modalities and opportunities to learn information in multiple ways such as handouts, verbal instruction, video presentations, and return demonstration, outcomes improve significantly. Exercise programs should be a part of the regular treatment session, as this is how patients learn to make stretching and movement a part of their daily routine upon returning home. Information should be given to patients as they can tolerate to prevent the patient from feeling overwhelmed. The therapist should assess the exercise program on a daily basis to continue to provide the patient with an adequate challenge toward progression in his or her goals.

Although client education is the responsibility of all burn team members, success of the occupational therapy intervention program depends on the client's recognition of long-term activity demands, contextual needs, and role responsibilities. Initial educational objectives should focus on developing an understanding of the stages of burn recovery, the need for and importance of independent activity and motion, and pain and stress management techniques. Meeting these goals promotes motivation, active participation, and engagement in occupation, which are essential for successful treatment outcomes.[32]

Surgical and Postoperative Phase

Positioning and Postoperative Splinting

Excision and grafting procedures usually require a period of postoperative immobilization to allow adherence and vascularization of the grafted skin.[23] It is beneficial for the occupational therapist to discuss postoperative positioning needs with the surgeon before surgery so that splints and positioning devices can be prefabricated and applied in the operating room immediately after the surgical procedure. Various materials and protocols are available. All have the common purposes of immobilizing the grafted area, preventing edema, and assisting in wound healing.[76]

Postoperative positioning may follow standard positioning techniques or may be unique and designed exclusively for the specific surgical procedure. Although standard burn splints position the extremity in the antideformity position, preoperative or postoperative splints should hold the extremity in the position that promotes the greatest surface area for graft placement. For dorsal hand grafts, the wrist is positioned in neutral, the MP joints in flexion, and the thumb in abduction to maximize the dorsal grafted surface area. Another example is that in which an axillary advancement flap is performed; the shoulder is abducted only 45 degrees. Gaining prior knowledge of the surgical procedure and determining potential postoperative complications enable the therapist to establish effective positioning and splinting procedures.

Although postoperative immobilization is often achieved through the use of bulky restrictive dressings and standard positioning equipment, splints are frequently needed to maintain the position. Most splints are typically made with plaster bandages or thermoplastic material (Figure 42.11). If a wet dressing will cover the graft site, a perforated or open-weave splinting material may be preferred to permit continuous drainage and prevent graft maceration.[23] In some instances, movement of adjacent joints may disrupt graft adherence even though the graft does not cover the joint surface. In these cases, the splint design should incorporate immobilization of those joints in a functional position. A postoperative thermoplastic splint can generally be made by using a drape-and-trim technique.[23] Most postoperative splints are molded into position for temporary use and are discontinued once graft adherence is ensured. However, if the splints are made of thermoplastic material, they can later be remolded into the antideformity position.

FIG 42.11 Thermoplastic total-contact ankle dorsiflexion splint to prevent plantar flexion contracture.

Therapeutic Exercise and Activity

Throughout the postoperative phase of care, active and resistive exercise of the uninvolved extremities should be continued when possible to prevent loss of ROM and strength. Immediately after excision and grafting procedures, exercises for adjacent body areas are usually discontinued for a short time. Although the time varies among burn centers, the average period of immobilization is 3 to 5 days for most STSGs and 7 to 10 days for cultured epithelial grafts.[16,32,42,79] Exercises can be resumed as soon as graft adherence is confirmed. Before resuming exercises, the occupational therapist should view the grafts and adjacent areas to determine graft integrity and whether any tendons are exposed or subcutaneous tissues are compromised.

Gentle AROM is the treatment of choice to avoid shearing of the new grafts. If the client exhibited normal ROM before surgery and was immobilized for only 3 to 5 days, baseline ROM should be expected within 3 days after resumption of activity. Active exercise of a body area with a donor site is generally permitted after 2 to 3 days if no active bleeding is present. Donor sites on the LEs are treated similar to burns on the LEs; therefore standard treatment involves elevation and wrapping with elastic bandage.

Ambulation following excision and grafting of the LEs is not usually resumed until 5 to 7 days after surgery. With the physician's written consent, the client is encouraged and assisted to ambulate for short distances and then slowly increase the distance. Before ambulation, double elastic bandage wraps should be applied over a fluff gauze dressing to prevent shearing of the graft or vascular pooling. Use of an elastic bandage, elevation, and a stance that discourages static positioning is particularly important for protecting grafts on the LEs. When the client is able to walk, exercise on a stationary cycle ergometer is beneficial for increasing activity tolerance.

Activities of Daily Living and Client Education

Self-care and leisure-promoting activities should be continued and increased in a way that is commensurate with the demands of the activity, the client's physical abilities, and the client's tolerance of activity. Self-care is often difficult during this phase because of the immobilization positions necessary to ensure graft adherence. If a UE is immobilized, creative ADL adaptations may be needed to allow clients continued involvement in their care and control over their environment. Though only temporary, simple techniques such as universal cuffs strapped over splints or extended-handle utensils help preserve newly reacquired independence and foster confidence and feelings of self-actualization. Continued psychosocial support and burn care education are also essential to ensure understanding of post-surgical precautions and procedures.

Rehabilitation Phase: Inpatient

The rehabilitation phase generally begins when a severely burned patient no longer needs the intensive wound care provided by the burn unit. Most of the wounds are now closed, and the patient may move to a step-down unit or transfer to a rehabilitation setting. Here, patients are expected to assume a more active role in establishing treatment goals, demonstrate more independence in their care, and fully participate in their therapy. An upgraded exercise program, a variety of self-help and rehabilitation equipment, and new techniques are introduced to help increase ROM, strength, activity tolerance, and independence in higher-level ADLs and IADLs. Intervention and patient education focus on work, recreation, and the self-care skills necessary to help prepare clients for returning to normal daily activity routines, including resumption of previous performance patterns and roles. Potential roadblocks to resuming participation in occupation in previous personal contexts, including community reentry concerns and psychological adjustments, are anticipated and addressed during this phase.

Reassessment and Intervention Goals

As the wound closes, scar formation develops, and clients frequently report increased skin tightness that restricts certain functional movements and inhibits completion of ADLs. Intervention techniques to counteract the effects of scar development include skin conditioning, scar massage, compression therapy, therapeutic exercise preceded by slow, gentle sustained stretching, and splinting.

During the inpatient rehabilitation phase, the occupational therapy evaluation should emphasize a thorough ongoing assessment of performance skills. Active and passive goniometric measurements should be taken to document any limitations caused by joint restrictions or scar tightness. Joint-specific measurements can be used to document individual joint restriction, but if skin tightness affects several joints in the same extremity, the total active motion measurements or total passive motion measurements of all the joints in a combined movement pattern should be documented. If the injury is unilateral, measurements taken from the unaffected side can be used to establish normal values for the injured extremity. Muscle strength can be measured by manual muscle testing (MMT). However, if MMT is used, caution is required when the therapist applies resistance to avoid shearing of newly healed skin. Other components of the evaluation should include muscular and cardiopulmonary endurance, performance of self-care and home management activities, skin integrity, presence of edema, and scar development indicating the need for scar compression garments (see Table 42.2).

Treatment goals during inpatient rehabilitation are to increase ROM, strength, and activity tolerance to achieve independence in self-care; begin skin conditioning; aid in psychological adjustment; and provide patient and caregiver education, including familiarizing the client with the care necessary for discharge from the hospital. Although these goals are continued and progressively increased during the outpatient rehabilitation phase, other goals are added as the client prepares for reintegration into the home and community.

Skin Conditioning and Scar Massage

Skin-conditioning techniques are used to improve scar integrity and durability against minor trauma caused by pressure or shearing forces, decrease hypersensitivity, and moisturize dry, newly healed skin. These techniques should be used for any burned areas or surgical sites that took longer than 2 weeks to heal. Lubrication and massage with a water-based cream or lotion should be performed three to four times a day or whenever the skin feels excessively dry, tight, or itchy. This action provides needed lubrication for skin that is dry because of damaged sweat and sebaceous glands. Massage is beneficial for desensitizing well-healed but hypersensitive grafted areas or burn scars and for softening tight scar bands during sustained stretching exercises. When massaging a scar band, the therapist should be sure that the scar is fully stretched and premoisturized to reduce shearing forces and prevent splitting of immature or unstable, problematic scar tissue. Massage should be performed in a circular motion, with more pressure applied gradually as tolerated over time. Because of damaged or lost skin pigment, burn survivors are at a greater risk for sunburn. Precautions, including the use of sun block and avoidance of prolonged sun exposure, are taught before the client is discharged.

Compression Therapy

Compression therapy should be initiated early in the inpatient rehabilitation phase, as soon as most of the larger wounds are closed. Temporary interim pressure bandages or garments assist in general skin desensitization, edema control, and early scar compression. The type of compression chosen and the degree of compression gradient applied depend on how much pressure and shear force that the client's newly healed skin can initially tolerate; both are upgraded as the integrity of the skin improves. Selection of an interim compression bandage or garment is based on the degree and consistency of pressure that it applies, the ease of application, and the potential for damage from shear forces during application.[15] Elastic bandage wraps, self-adherent elastic wraps, tubular elastic support bandages, presized elastic pressure garments, and commercial or custom-made elastic garments are all commonly used (Figure 42.12).[7,24] Approximately 5 to 7 days after removal of the postoperative dressings, temporary compression dressings or garments can usually be applied. Tubular elastic bandages, presized or ready-made temporary elastic garments, Spandex "bicycle pants," and Isotoner-style gloves can be worn over light dressings. When patients have small open areas requiring minimal gauze dressings, a standard knee- or thigh-high nylon stocking can be applied over the dressings before the donning of tubular bandages or garments to reduce shearing forces and prevent displacement of the dressings. Temporary compression dressings and garments are taken off only for bathing, dressing changes, skin care, and garment laundering. Independent donning and doffing of interim garments are incorporated into the client's ADL training.

FIG 42.12 Early compression techniques: tubular elastic dressings, ready-made gloves and chin strap, custom-fabricated foam collar, and padded clavicular strap to preserve the neck and axillary contours.

Therapeutic Exercise and Activity

Newly healed skin tends to blister as a result of shearing forces or to split as a result of overstretching, especially when the skin is dry. Every therapy session should therefore begin with massage of the scars with a moisturizing lotion to prepare the dry or tight skin for increased motion. Whenever possible, clients should learn to perform their own skin care independently before their scheduled therapy. Once the scars are moisturized and lubricated, stretching is performed to increase the flexibility and fluidity of movement. Stretches should be slow and sustained, and forceful dynamic stretching should be avoided, with attention given to the position of adjacent joints during the stretching motion.

Massage with additional moisturizers during stretching exercises helps relieve itching and discomfort. Stretching in front of a mirror provides positive visual feedback for the patient and is helpful in correcting abnormal posturing. The therapist and client should see blanching of the scar as confirmation of an effective stretch.

AROM exercises, strengthening, and tasks to increase activity tolerance should follow stretching exercises. During the rehabilitation phase, emphasis is placed on flexibility exercises using complex motions that require the movement of several joints simultaneously. An activity that requires hand manipulation skills while reaching overhead is an example of a complex motion for a burn injury that involves the shoulder, elbow, and hand. Most ADLs require complex motions, and exercise programs should emphasize not just individual joint ROM but also combined joint mobility in functional patterns of movement (Figure 42.13).

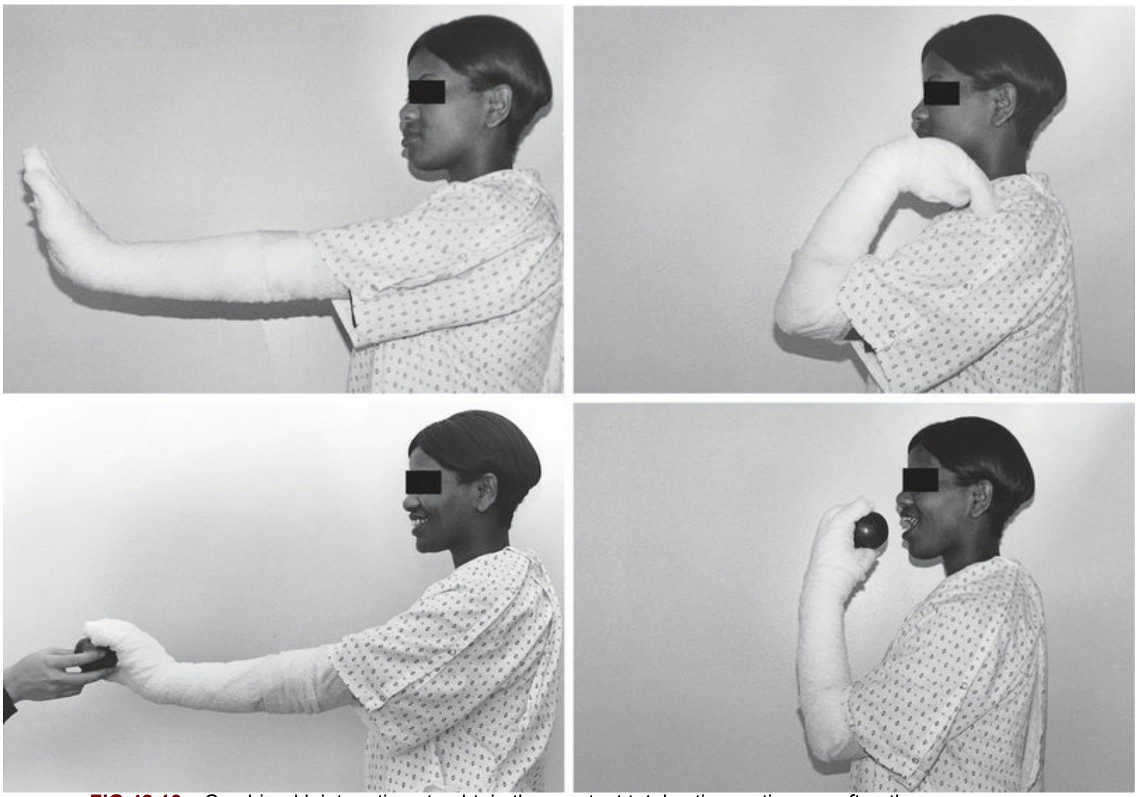

FIG 42.13 Combined joint motions to obtain the greatest total active motion are often the same functional patterns of movement used when performing activities of daily living.

For clients recovering from severe hand and UE burns, intervention activities may include a variety of exercise and activity treatment media. Strengthening activities may involve the use of cuff weights, dumbbells, resistive exercise bands, or work simulation equipment. Activities for hand strengthening and coordination may include using exercise putty, hand manipulation boards, work simulators and work samples, crafts, and meaningful activities such as typing on a computer, dialing a cell phone, and playing cards or board games with visitors.

Edema Management

During the rehabilitation phase, edema often continues because of decreased function, dependent positioning without adequate external compression, or circumferential scarring of the extremity with associated lymphatic damage. When edema is present, motion is limited and painful; if the edema becomes chronic, it may lead to fibrosis.[51] To treat edema of an extremity, elevation, progressive compression, and activity are recommended.

Self-adherent elastic bandage material (Coban or Coflex) is often used as an early form of compression for the digits, hands, and feet. It is applied in a spiral fashion, from distal to proximal, with the previous lap overlapped by a half overlap starting on each digit and continuing in this manner across the hand or foot and onto the wrist or ankle. Strips are also applied to each web space (Figure 42.14). The distal tips of digits are left open to monitor color, which should be rosy and not blanched or bluish. The rest of the extremity is wrapped with an elastic bandage or other form of temporary compression garment. The wrapped hand should be used during ADLs and other functional motions and elevated just above heart level when the client is resting. For edema of the LEs, use of a double layer of elastic wrap when ambulating, elevation when resting, active ankle exercises, and avoidance of static standing are recommended. Intermittent compression pump therapy is often used to treat chronic edema of the distal ends of extremities. Whenever compression therapy is used to treat edema of the hands or feet, before and after circumferential or volumetric measurements are recommended to monitor the effectiveness of the treatment (Figure 42.15).

FIG 42.14 Application of self-adherent elastic wrap to newly healed hands and feet provides external compression for the treatment of edema and early scarring.

FIG 42.15 In the treatment of extremity edema, sequential circumferences and volumetric

measurements are methods to monitor and document treatment efficacy.

Activities of Daily Living

As patients approach discharge from the hospital, the therapist must stress the importance of independent self-care. Eating, dressing, grooming, and bathing skills should be emphasized as part of the normal daily routine to increase independence and activity tolerance. When problems occur, the therapist must determine whether the dysfunction originates from a physical limitation, scar contracture, pain, edema, or an assumed abnormal postural reaction. Early identification of abnormal movements helps patients understand and relearn normal movement patterns before the abnormal patterns become habitual.

Practicing ADLs with personal care items and supplies from home fosters self-confidence in functional performance skills before hospital discharge. Clients with major burn injuries may initially require adaptations to support independence. However, when assessing the need for adaptive self-care, the therapist should differentiate between a physical limitation that can be rehabilitated and permanent loss of function.

In addition to basic ADL and self-care tasks, IADL tasks such as home management responsibilities should be practiced before discharge. Fear of items associated with the injury, such as hot water, the stove, or an electric iron, can hinder functional recovery. For clients injured during a home activity, the therapist should arrange counseling, support, and practice of the skills or activity in the clinic. Prevention techniques taught as part of the inpatient treatment program should also be part of the home program.[105]

Splinting

Splinting in the rehabilitation stage is used to limit or reverse potentially disabling or disfiguring contracture formations, increase ROM, distribute pressure over problem areas, or assist in function (Figure 42.16). Static splints, dynamic splints, and casting may be used,[11,47,77] depending on the location and severity of the contracture. Regardless of the purpose of the splint, every effort should be made to ensure that its purpose and method of application are fully understood. Splinting at nighttime and during rest periods is preferred because it allows functional use of the extremity during waking hours and provides treatment of contractures while the client is unoccupied. However, splints must fit comfortably, and corrective splinting should not cause discomfort that interferes with the client's rest. Although most clinicians agree about the value of splinting based on the strong rationale for splint use to provide counterforce to contracting scars or to lengthen scars when they limit joint motion, decision making on specifically when and how to splint remains controversial because of lack of strong clinical evidence.[75] The therapist must continually weigh the risk-to-benefit ratio and consider timing, design, and duration of splinting relative to each client's functional needs.

FIG 42.16 Static-progressive dynamic hand splints allow for a gradual progression of ROM of the joints of the fingers and wrist during an individual treatment session. Family members or patients can be instructed on how to apply these splints, and they can be incorporated into home exercise programs.

Client Education

Client and caregiver education becomes increasingly important during the predischarge phase to aid the transition from hospital to home. Increased understanding is needed in the areas of wound healing, the importance of preserving independence in ADLs and IADLs, the need for continued activity and exercise, the causes and effects of scar contracture, and scar management techniques and principles. Before discharge from the hospital or transfer to an inpatient rehabilitation facility, the client and family should receive a comprehensive home care education review (Table 42.4).[48] To reinforce learning, information should be presented through a variety of methods, such as verbal instruction, printed handouts, demonstrations, and educational videos. Most important, opportunities should be provided for the client and caregivers to practice wound care, garment and splint application, and all exercises under staff supervision in the weeks preceding discharge. Only with a detailed understanding of home care techniques and potential outcomes can clients be expected to assume responsibility for their own care and recovery.[105]

TABLE 42.4

Home Program Outline

Item	Information Needed
Wound care, positioning	Dressing change technique, precautions, elevation
Skin and scar care	Lubricant frequency, sun protection, trauma precautions such as no scratching
Self-care	Techniques and minimizing use of equipment
Splints and orthotics	Donning techniques, schedule, precautions
Pressure garments*	Purpose, washing, reordering, donning techniques, wearing schedule
Exercises	Frequency, techniques for specific areas, contracture prevention

*Custom-made garments are available from Jobst Institute, http://www.jobstcompressioninstitute.com; Barton-Carey, http://www.bartoncarey.com; Bio-Concepts, Inc., http://www.bio-con.com; Medical-Z, http://www.medicalz.com.

Rehabilitation Phase: Outpatient

Reassessment

Reassessment procedures take on greater significance after discharge. ROM, strength, activity tolerance, ADLs and IADLs, and skin and scar status must be assessed frequently to ensure early identification of specific problem areas. In addition to these rehabilitation components, the effectiveness of compression garments, the fit and need for continuation of certain splints, home care activities, emotional coping skills, and resumption of engagement in preburn occupations to support participation in contexts or life situations should also be closely monitored.

Reassessment of activity tolerance and work skills is indicated to help determine whether clients are ready to return to school or work or be referred for vocational rehabilitation. Driving evaluation and prevocational assessment by using simulated work activities or work sample testing may also be indicated for the more severely injured burn survivor. Vocational counseling and exploration should be undertaken in the later stages of recovery if residual dysfunction necessitates a change in the work environment or vocational role.

Therapeutic Exercise and Activity

Inpatient rehabilitation techniques, equipment, and therapeutic activities continue to be appropriate during outpatient therapy. However, progressive grading of exercise and the frequency, intensity, and duration of activity is necessary to successfully regain or improve the client's strength, activity tolerance, and performance skills and patterns, as well as abilities in performance in areas of occupation. Sequencing the order of intervention activities is necessary to prevent injury, minimize client discomfort, and prevent excessive fatigue. Skin lubrication, massage, and stretching should precede progressive strengthening exercises and activities.[52] Before being discharged, clients should learn how to prepare for exercise and activity by performing their own skin lubrication, massage, and stretching. Doing their own pretreatment skin care and stretching will allow outpatients to maximize actual therapy time and develop habits that promote consistent follow-through with their home activities and independent exercise program.

Scar Management

A primary objective of most burn rehabilitation techniques is prevention or treatment of hypertrophic scars and scar contractures. For effective treatment of scar problems, scar characteristics must be monitored so that one can recognize when maturation occurs. Active scars are erythematous, raised, and rigid. As they mature, scars become less vascular in color, with flatter and more pliable contours and a smoother texture. **Scar maturation** usually takes from 12 to 18 months after injury, depending on the length of time that the original burn takes to heal. However, it is important to remember that each patient heals differently. Some scars mature in less than 1 year, whereas others may take more than 2 years.[77]

A rating scale has been designed that allows serial assessment of scar pigment, vascularity, pliability, and height.[93] Although the ratings are somewhat subjective and time-consuming, the scale is a useful clinical tool. However, use of digital photography is a time-efficient and objective method of documenting changes in scar appearance; copies of the images can easily be inserted into the medical record.

Wearing intermediate-pressure garments prepares the skin for the later fitting of custom-made compression garments. Use of compression garments is indicated for all donor sites, graft sites, and burn wounds that take more than 2 weeks to heal spontaneously.[19,20] The occupational therapist is often responsible for measuring, ordering, and fitting of these garments. The occupational therapist must frequently make special on-the-spot modifications during a clinic visit or fabricate underlying conformers to ensure uniform pressure. All custom-made garments are measured and ordered according to the specific instructions of the manufacturer. Most compression garment manufacturers offer a variety of design options, including special zippers or Velcro closures, silicone lining, custom inserts, and assorted colors.

Ideally, clients should be fitted with custom-made compression garments no later than 3 weeks after wound healing; otherwise, interim garments are worn until custom garments can be applied. It may be necessary to order garments on a piecemeal basis because different areas of the client may be ready for compression treatment at different points in time. Custom-made compression garments are constructed to provide gradient pressure, starting at 35 mm Hg distally (Figure 42.17). They should be worn 23 hours a day and be removed only for bathing, massage, skin care, or sexual activity. Face masks and gloves may also be removed for meals. Compression therapy should be applied to the burned area for approximately 12 to 18 months or until scar maturation is complete. Donor sites may also require compression garments, depending on the thickness of the donor skin taken and whether healing occurred in less than 2 weeks.

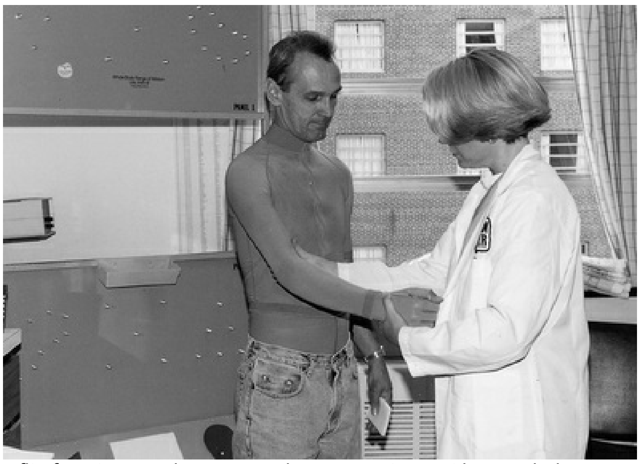

FIG 42.17 The fit of custom-made compression garments must be regularly reassessed to ensure adequate compression for effective scar management.

Once proper fit is established, it is recommended that the client possess a minimum of two sets of garments at any time to allow both around-the-clock compression therapy and laundering. Because of the elastic construction of the fabric, clients should hand-wash the garments with mild soap and allow them to air-dry unless otherwise advised by the manufacturer. To prolong the life of the garments, washing machines, dryers, direct heat, strong detergents, or bleach should not be used. If they are properly cared for, most garments will last approximately 2 to 3 months before replacements are needed. Children may need replacements more frequently as a result of their growth and active lifestyle. Toddlers undergoing toilet training and incontinent adults may need extra garments and design options that make independent toileting easier. Adults employed indoors are usually able to return to work and previous activities without interference from the garments. However, some individuals who work outside in warmer climates may find compression garments to be too hot in the summer months and may need to change their work setting until compression therapy is no longer required.

To be effective, compression garments must exert equal pressure over the entire burned surface area. Because of body contours, bony prominences, and postural adjustments, flexible inserts or pressure-adapting conformers are often needed under the garments to distribute the pressure more evenly. Areas commonly requiring pressure adapters are the supraclavicular region of the upper part of the chest, the areas between and under the breasts of women or obese men, the nasolabial folds, the midface and chin, the areas between the scapulae and over the axillary folds, the gluteal fold, the perineum, and the web spaces of the hands and feet.

Pressure inserts and conformers are now made from a variety of materials; the choice is based on the area to be treated and the need for flexibility when applied. As with compression garments, the fit of a conformer should be monitored at regular intervals for effectiveness and signs of deterioration and be replaced as needed to maintain exact contouring. Silicone gel pads, Silastic elastomer, Otoform-K (Dreve-Otoplastik GmbH), Plastazote (Zotefoams Inc.), and Velfoam (North Coast Medical, Inc.) are useful for hand scars. One-sixteenth-inch Aquaplast and Silastic (Qfix) elastomer work well on face scars; closed-cell foams, prosthetic foam elastomer, silicone gel pads, Plastazote, Otoform-K, and Velfoam are also useful for other body areas. In addition, Velfoam and silicone gel pads are effective at the flexion creases of the knees, elbows, and anterior aspect of the ankle to equalize pressure and prevent discomfort during activities.

It is important to note that although the use of pressure garments and silicone gel is commonplace, their effectiveness is not well established. A 2009 meta-analysis examining the effectiveness of pressure-garment therapy for the prevention of abnormal scarring after burn injury found sparse evidence to support its widespread use.[6] A systematic review of silicone gel sheeting reported weak evidence of its benefits in preventing or treating abnormal scarring.[61]

Activities of Daily Living

In addition to continued exercise, skin care, and scar management, the outpatient intervention plan should be directed at increasing independence in home care while also emphasizing resumption of prior life roles and context, including returning to previous work, school, social, and leisure activities. Scar contracture is often the primary cause of dysfunction (Figure 42.18). Therefore activities performed during therapy should not only promote strength, activity tolerance, and functional ROM to counteract the effects of scarring but also preserve independence in performance of occupations related to clients' personal contexts and interests.

FIG 42.18 **A,** A scar contracture occurs when tight scars limit free motion of a joint. This can be very limiting when the contractures are present in the hand. **B,** Surgical scar revisions can be done to reconstruct the hand and improve hand function.

Community Reentry

Returning to school or work becomes a primary objective during outpatient rehabilitation. However, most recovering burn survivors are capable of resuming normal daily routines and performance patterns long before their scars completely mature.

Returning to previous community settings (e.g., school, work, and social settings) and becoming reacquainted with friends and coworkers can be a difficult process for burn survivors who have cosmetic disfigurement, loss of functional performance, or restrictions in activity. A community reentry program should be implemented before the client returns to school or work. Correspondence sent to the community setting before the client's return helps educate employers, teachers, and peers about burn injuries and what the client has experienced. This correspondence should explain the purpose of compression garments, splints, exercise, and skin care precautions; digital photos are helpful. The goal of a reentry program is to reduce restrictions in the client's activities and ease the transition of returning to previous areas of occupation.[52]

Children may have a more difficult time reintegrating into their previous roles as students and playmates. Many burn centers offer school reentry programs to assist children in the emotional and physical challenges of returning to their school environment.[52] With prior parental permission, predischarge plans are made to send written information to the child's teacher, classmates, and (when available) a community-based therapist working in the school system to acquaint them with the child's changed appearance and special needs. A videotaped message recorded by the child to his or her classmates explaining what happened can be very effective, especially when delivered by a family member or healthcare professional, who can then answer the children's questions. The tape can show the child both with and, if appropriate, without compression garments to help satisfy classmates' curiosity and concerns before the burned child returns to the classroom. Such preparations ease resumption of the student role for the child and can help improve acceptance by other children, who may misunderstand the cause of the disfigurement and the need for splints, adapted equipment, and scar compression garments. Informed classmates often serve as advocates for the burned child by passing information to students in other grades or on the bus and providing support when misinformed students reveal their ignorance or fear by teasing or taunting the burned child. Regional burn summer camps, often sponsored by local firefighter organizations or burn centers, also help children adjust by placing them in settings where they can socialize with peers who have also been burned.

Preparing a burn patient for return to work does not have to be a long-term process. Burn rehabilitation and work skills training have many similarities; therefore it is possible to design treatment activities that simulate not only functional activities but also various work skills. Strength, activity tolerance, and flexibility, often identified as work tolerances, are obvious goals of burn rehabilitation. Physical demands of jobs, as described in the *Dictionary of Occupational Titles*,[96] are also components of functional skills; lifting, stooping, pushing, pulling, handling, and manipulating are a few examples. A job analysis interview, performed as part of the activity needs analysis, provides the type of information needed to integrate activities into the intervention plan, which should not only improve functional ability but also provide reconditioning for returning to work.

Preparing the client for community reentry after a burn injury also requires attention to two other types of tolerance: skin and temperature. Most clients will still need to wear compression garments and inserts, avoid prolonged sun exposure, and perform skin care while they are at school or work. Skin-conditioning activities and exercises performed while wearing garments will improve skin tolerance for friction and shear force demands (Figure 42.19). Education regarding the body's response to variations in temperature and precautions for dealing with extremes of temperature are necessary for the patient to plan for anticipated temperature tolerance problems. A systematic review of the literature reported that an average of 66% of patients returned to work following their burn, with the time taken to return to work ranging from 4.7 to 24 months. The extent and severity of the burn were the most significant barriers; others were longer hospital stays and the number of operative procedures.[70] (See Chapters 14 and 15 for further information.)

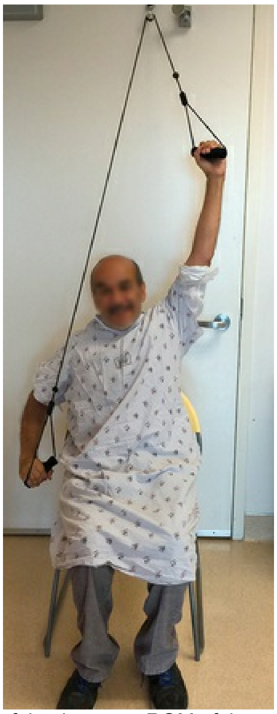

FIG 42.19 Overhead pulleys are useful to increase ROM of the upper extremities. They are also easily issued to patients for setup and use at home as a part of their home exercise program.

Psychological Adjustment

During outpatient rehabilitation, clients may undergo numerous physical and emotional changes. Once discharged from the hospital, they must face the overwhelming task of becoming responsible and self-reliant while dealing with the stress associated with developing scars and a changing self-image. They may not participate fully in therapy or adequately follow through with home care activities because of the physical and emotional effects of the injury. Apathy, avoidance of pain, scar tightness, and hypersensitivity all contribute to noncompliance and subsequent dysfunction after injury. Clients may experience symptoms of post-traumatic stress disorder, nightmares, and changes in appetite with subsequent weight gain or loss. They may become reclusive or disengage from previous relationships. Depression may occur even before discharge.[12,68,73]

In addition to established treatments such as counseling, support, and training in pain management and relaxation techniques, visits from a recovered burn survivor to a new patient are often of great benefit. Attending a burn support group can also help the burn survivor and family members in psychological adjustment. Research has shown that burn survivors at different stages of recovery tend to provide positive support to one another. Group discussions among burn survivors promote acceptance of what they have already experienced and realistic expectations of what they still need to accomplish.[12]

Discharge From Treatment

The outpatient therapy program should be reevaluated periodically to determine whether the frequency of treatment, program progression, or professional or educational status should be changed (e.g., return to work or school).[52] When clients have resumed their preinjury activities, outpatient therapy may be discontinued. Because burn scar maturation may take more than 18 months, a schedule of follow-up care, with appointments every 2 to 3 months, is needed until wearing of compression garments is discontinued. However, for children, annual burn clinic visits are recommended, even after discontinuation of compression garments, until full physical maturity is reached to ensure that growth is not impeded by scar inflexibility (see this chapter's case study).

Burn-Related Complications

Heterotopic Ossification

Heterotopic ossification (HO) is formation of bone in locations that normally do not contain bone tissue.[30,97] The underlying cause of HO is not yet fully understood. It typically develops either in the soft tissue around the joint or in the joint capsule and ligaments, and it often forms a bony bridge across the joint, resulting in a fused joint.[41] Although HO is frequently found in the posterior aspect of the elbow, it may occur in other joint areas such as the shoulder, wrist, hand, hip, knee, and ankle. It may occur in either extremity or bilaterally, even if the extremities were not burned. Signs that HO may be present usually appear during the latter stages of hospitalization, with the patient experiencing increased pain at a certain point in the joint's ROM. The pain is fairly localized and severe, and loss of ROM is usually rapid, with development of a hard, unyielding feel at the joint's end of available ROM. Inflammatory signs, such as redness or swelling, are not easily discernible within healing burn wounds. Once HO has been detected, frequent AROM exercise of the joint should be carried out within the pain-free range to preserve as much joint motion as possible.[21] Use of dynamic splints or forceful passive stretching of the involved joint should be discontinued. If the condition does not resolve with time, surgical intervention may be necessary to resect the limiting bony tissue, followed by therapy to preserve the regained ROM.

Neuromuscular Complications

Peripheral neuropathic conditions are the most common neurologic disorder observed in burn patients. They usually occur with high-voltage electrical burns or burns involving greater than 20% TBSA.[39] Peripheral nerve damage may be caused by infections, metabolic abnormalities, or neurotoxicities. A peripheral neuropathic condition is generally manifested as symmetric distal weakness, with or without sensory symptoms. Most conditions improve with time; however, patients often complain of fatigue and decreased activity tolerance that may last for months.[39]

In addition to peripheral neuropathic conditions, localized compression or stretch injuries of nerves are encountered during burn recovery. Causes of localized nerve injury include improper or prolonged positioning in bed or on the operating room table, tourniquet injury, and extreme edema. Common injury sites are the brachial plexus and ulnar and peroneal nerves. Prolonged frog leg positioning can cause a stretch injury, whereas prolonged side lying can cause a compression injury of the peroneal nerve.[39] The ulnar nerve is subject to a compression injury if the client rests on a firm surface with the elbows flexed and the forearms pronated. The brachial plexus is susceptible to stretch or compression injury if inappropriate shoulder-positioning techniques are used. To implement more effective prevention and intervention techniques, therapists should be aware of the causes and symptoms of various nerve injuries.

Contact with high-voltage electrical current often produces permanent damage to peripheral nerves as a result of thermal damage at the entrance and exit sites of the electrical current. Damage also occurs to peripheral nerves as a result of secondary compression of the blood supply caused by swelling of surrounding tissues. Delayed neurologic complications are caused by direct thermal damage, which results in demyelination and subsequent nerve cell death, or by vascular compromise of the brain or spinal cord. This generalized damage may be manifested as paralysis, cognitive impairment, aphasia, seizures, balance problems, or other neurologic symptoms. The therapist should be attentive to any developing symptoms of sensory or motor dysfunction in a client who was initially neurologically intact.[102]

Facial Disfigurement

Facial scars can be devastating, both functionally and psychologically. Tight or hypertrophic scars not only distort the smooth contours of the cheeks and forehead but can also flatten the nasal contours, evert the eyelids and lips, and constrict the optic and oral commissures. Vision, speech, feeding, and dental hygiene can be adversely affected by oral and eye contractures. Facial disfigurement is also damaging to an individual's self-image and inhibits social reentry. A significant amount of communication and social interaction depends on nonverbal facial expressions and eye contact. Severe facial burn scars not only distort the face and restrict expression but also undermine the patient's self-esteem when he or she is met by social rejection.

Two main compression therapy methods are used to prevent or manage hypertrophic facial scars. An elastic face mask can be worn with underlying flexible thermoplastic conformers. The other option is a rigid, total-contact transparent facial orthosis.[78] Each has advantages and disadvantages.

Because face masks are made of elastic fabric, generally enclose the entire head and neck, and use flexible conformers, they provide uniform multidirectional compression during movement or changes in position. However, because they occlude the face, they are cosmetically and socially less acceptable. The effectiveness of the compression is based on subjective feedback from the patient and observations made by the therapist during outpatient clinic visits. Most underlying conformers are easy to modify or replace to provide effective distribution of pressure over facial concavities and contours.

Conventional fabrication of a transparent, rigid facial orthosis is an involved and often expensive process. First, a cast is made with dental alginate over the surface of the face, and then the alginate is reinforced with a layer of fast-setting plaster strips. The patient must lie still and breathe through straws or small openings left in the alginate, which can be difficult for claustrophobic adults or small children. For this reason, some patients are unable to cooperate with this procedure unless they are under anesthesia. After the cast is removed from the patient, the breathing and neck openings are closed with more plaster strips and the facial cast filled with plaster of Paris. The resulting exact duplicate plaster model is polished smooth of scars and defects by hand. Additional plaster is carved off as needed to increase pressure on specific scarred areas of the face. Clear, high-temperature thermoplastic is then heated, stretched over the model, and either vacuum-molded to the model or manually stretched and molded by hand. The edges are finished, elastic straps are applied, and the orthosis is fitted to the patient. Because the material is clear, the rigid face mask has the advantage of allowing the therapist to view the face and objectively evaluate the amount of pressure exerted on the scars. By noting the presence of scar blanching under the clear mask, precise adjustments can be made as needed. The clear mask allows the face to be seen but has the disadvantage of exerting primarily unilateral compression, which may be compromised by speech, facial expressions, or side-lying positions. The mask does not allow perspiration to evaporate and must be removed and wiped clean regularly, especially in warmer climates.

Computer-aided design and manufacturing systems have been developed to efficiently and economically fabricate transparent face masks.[80] A software system integrates shape capture, mask design, and model fabrication with a linear scan noncontact laser imager for the acquisition of facial topography. The computer then integrates with a milling machine to fabricate a positive model out of urethane foam. The foam model is modified through use of the computer program and lined with a layer of polypropylene to smooth the foam texture. The model is then sprayed with silicone and the mold released and used basically in the same manner as the plaster model described previously. The rest of the fabrication process also works in a similar way. The advantage of computerized imaging and model fabrication is the speed of fabrication of the model and the ability to obtain a model without having to take a direct cast of the patient's face.

With either method, frequent alterations are necessary to achieve and maintain adequate compression of all facial scars (Figure 42.20). The choice of method is based on the preferences of the patient and physician. However, a combination of both types may be advantageous: the patient wears a clear, rigid face mask in social settings and a fabric mask with conformers at home. Appropriate skin care education is also important. Massage with lotion twice a day will aid in scar desensitization and provide the necessary lubrication. Facial massage and exercises are performed at least four times a day to help stretch tight facial skin, maintain eyelid and mouth flexibility, and preserve the nostril openings.

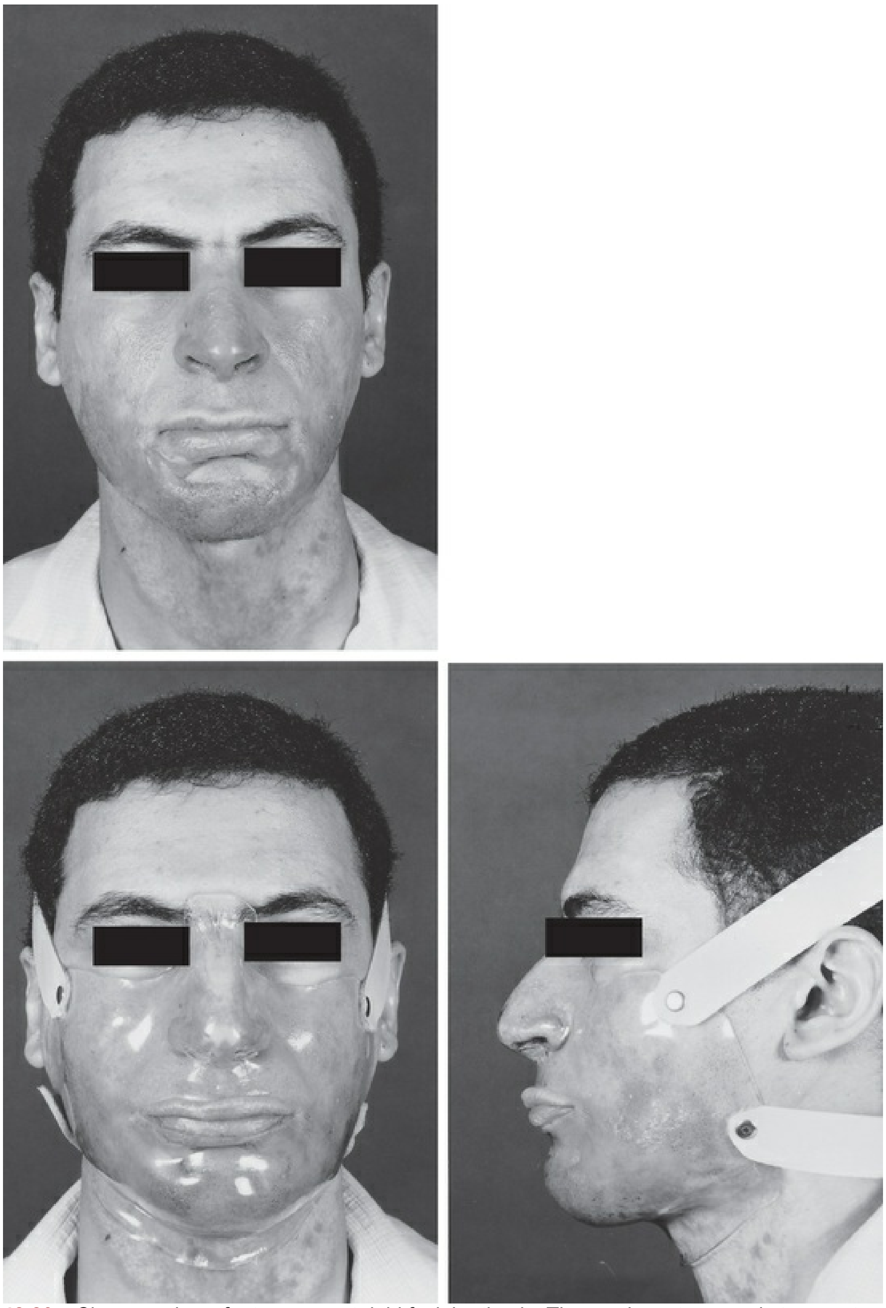

FIG 42.20 Close-up view of a transparent rigid facial orthosis. The mask contours and strap system are modified to adjust the amount of pressure over specific scarred areas (note the blanching of the scars on the lower lip and lateral aspect of the chin).

Just as with any compression therapy technique, patient compliance is essential for effectiveness of the treatment. The patient is instructed to wear the face mask at all times except while eating, bathing, or engaging in sexual activity. The patient should carry written verification from the burn physician verifying the medical necessity for the mask. Regardless, patients should always remove their masks before entering any public facility to avoid provoking suspicion that they are prepared to commit robbery or violence. This is especially important when entering banks, convenience stores, or government facilities, even if the patient is well known to the employees.

Individuals wearing either type of mask initially experience acute feelings of self-consciousness and may avoid going out in public. Parents may have difficulty putting the mask on their children and may experience feelings of guilt if the child rebels. Supportive intervention from family members and therapists is an important way to successfully manage these social and personal issues.

Consistent follow-through is especially critical in preventing or correcting facial scarring and disfigurement. Before applying the mask, the therapist must provide early education, ongoing encouragement, and continual support to ensure that the client wears the facial orthosis. Once the scars are mature and compression therapy is no longer needed, the client should be instructed in the use of special camouflaging cosmetics such as Covermark by Lydia O'Leary, which will cover minor flaws in texture and correct uneven pigmentation.

Threaded Case Study

Tonio, Part 2

Tonio experienced an inhalational injury to his lungs in the house fire and was subsequently placed on mechanical ventilation for several weeks. He eventually received a tracheostomy and was able to be weaned to trach mask oxygen and eventually to room air. The tracheostomy tube was removed (decannulated) one week prior to Tonio's discharge from the hospital and transfer to an inpatient rehab facility. At discharge, Tonio was able to eat a regular diet but still required maximum assistance for all ADLs. He had small, spotty open areas throughout his trunk and lower extremities that amounted to <5% TBSA open areas.

Evaluation and Goals

Tonio's initial evaluation consisted of a wound assessment, edema assessment, and ROM assessment of his (B) UEs. Because he was intubated and sedated, he was dependent for ADLs and mobility. His long-term girlfriend was very involved in his care and was able to provide a thorough occupational, environmental, and social history. Tonio's initial evaluation also included a cognitive component to see if he was able to awaken and to respond to simple commands.

As Tonio improved and was able to participate in occupational therapy sessions, he was observed to have great difficulty staying motivated to participate. This was discussed with both Tonio and his girlfriend. As a result, Tonio's family and friends became more active during his stay to help keep him motivated. Tonio's girlfriend informed visitors on how to encourage Tonio to participate in therapy and to follow through with his ward exercise programs. Tonio then became more motivated and was observed to participate more fully in his own therapy program. He was able to participate in goal setting and make progress in his self-care skills.

During the acute phase, treatment goals included reducing edema in the UEs, preserving and increasing UE ROM, maintaining and improving cognitive awareness, and regaining ADL independence. In the post-operative phase, the goals then included patient and family training in being independent using a continuous passive motion machine (CPM) to improve right hand function.

The following treatment interventions were initiated in the acute phase: To prevent and minimize edema, Tonio's UEs were elevated on pillows or a blanket above the level of his heart at all times. He engaged in cognitive reorientation activities every day with all staff members and his family. ROM exercises were graded based on his cognitive abilities. For example, while he was sedated, PROM exercises were performed to maintain flexible UE and hand joints. When Tonio was more awake and cognizant of his environment and situation, he participated in active assistive range of motion (AAROM) and AROM exercises and other therapeutic activities.

Once Tonio was cleared for out-of-bed activities and a regular diet, he engaged in self-care behaviors such as oral hygiene, self-feeding, and dressing while seated at edge of bed or in a wheelchair. A thin strip of Coban or Coflex was added to his utensils to provide additional grip.

During Tonio's operative phases, BUEs and hands were immobilized multiple times with (B) hand splints and (B) elbow splints. He required three surgeries to the UEs and was immobilized 5 days for each surgery. Tonio's hands were grafted first with STSG sheet grafts to preserve function. He then received meshed skin grafts to (B) UEs (forearm and upper arms). A third surgery was required to cover an area of the LUE where the skin graft had failed, resulting in an additional period of immobilization for that extremity.

Rehabilitation Phase

It was deemed early on that due to the 70% TBSA inhalation injury (a very large and extensive burn injury), multiple surgeries, difficulty with mobility, and associated medical complications Tonio would benefit from being transferred to an inpatient rehab program prior to returning home to improve his functional ability. Two key medical complications that Tonio had developed were heterotopic ossification (HO) in his left elbow and oliguric renal failure while in the ICU. HO in his left elbow limited his ability to perform B UE ADLs such as grooming, bathing, and dressing. The renal failure limited his level of participation in ADLs and ROM exercises, as he easily fatigued from being weak.

After surgery was completed, therapy focused on increasing the amount of time Tonio spent out of the bed and either walking or seated in a chair, wheelchair, or at edge of bed while engaged in a functional activity:

- Recreational activities such as board games and listening to music were incorporated into treatment sessions to improve Tonio's motivation as well as his functional movement.

- Tonio was encouraged to eat a normal diet so that he could sustain himself on PO intake without needing feedings via a nasogastric tube.

- Tonio and his family were educated on inpatient rehabilitation programs, the criteria for admission, and the need for him to participate in such a program in order to return home and function as independently as possible.

- A continuous passive motion machine was incorporated into Tonio's therapy program to improve ROM of the right hand for functional grasp. Tonio and his family were instructed on how to don/doff the machine so that ROM exercises could continue throughout the day and on weekends when the therapist was not available.

Outcomes

Tonio was able to be transferred to an inpatient rehab program after approximately 3 months in the burn center. He was placed at a facility close to his home where family and friends could be more involved in his recovery. He spent 1 month at the rehab facility. Upon discharge, he was referred to outpatient physical and occupational therapy, where he resumed treatment twice a week for both therapies. Tonio could ambulate independently with the use of a cane, and he was able to complete upper body ADLs independently and required only minimal assistance for lower body ADLs. In outpatient therapy, Tonio improved further and was able to ambulate independently without an assistive device. He was able to perform upper and lower body ADLs independently. Lower extremity edema continued to be an issue, causing Tonio occasional discomfort. His occupational therapy sessions transitioned to include strengthening and work-hardening activities to prepare him to return to work as an exterminator. His left elbow had limited ROM (25 to 130 degrees) due to the heterotopic ossification, but there was no functional limitation in the movement. Six months post discharge from inpatient rehab, Tonio was referred to an orthopedic surgeon and was preparing for surgery to remove the heterotopic ossification from the left elbow. His subsequent plan was to return to work. He returned to the outpatient burn clinic at 6 months post discharge from inpatient rehab and 10 months post burn injury. He was observed to be in good spirits and excited to return to work. Custom pressure garments were ordered for (B) UEs, and hands with grippers were added to the palmar surface of the gloves to improve grip in preparation for Tonio to return to work. No garments were ordered for the LEs due to continued edema. Tonio's main area of concern was the defect left in his chest and abdomen area from the tangential excisions and skin grafting. He is currently planning reconstructive procedures with the plastic surgeons of the outpatient burn clinic to correct defects. Reconstruction is planned for after the correction and rehabilitation of the left elbow.

Tonio continues to live with his family. He is planning to resume living on his own with his girlfriend after he is able to return to work and financially support himself.

His pain is well controlled and he reports no issues with pain management. His friends and social support system remain intact, and this support system has improved since his injury. Prior to his injury, Tonio reported being somewhat distant from his mother, but since his injury their relationship has improved; she is present with him during his outpatient burn clinic appointments and supports his choices and decisions.

Tonio reported feeling hopeful for the future and wanting to help other burn survivors. He was given resources to burn-survivor groups and organizations and encouraged to participate in programs that train burn survivors to counsel other survivors. He was also encouraged to attend the World Burn Conference to meet other survivors.

Tonio expressed being thankful to all of his caregivers. He acknowledged having a difficult time beginning the process of recovery but found it helpful to have the burn team of nurses, therapists, doctors, dietitians, and social workers all encouraging him not to give up and to keep moving forward. “I feel like myself again. I feel hopeful for the future. I can't wait to go back to work and get back to my life. Thank you all for everything you've done for me.”

Threaded Case Study

Nora, Part 2

The main focus of this case is to illustrate the importance of both the patient's needs (developmental stages) and the family's involvement in Nora's care and rehabilitation. Although Nora's injury was considered very small (1% TBSA to the palm), it had the potential to create major complications in her fine motor development as a growing 3-year-old.

During the initial stages of evaluation and treatment, focus was on wound status, ROM, and developmental age assessments; parent education on ROM exercises for the affected left hand; and prevention of contracture formation. The treatment plan and intervention included not only the child's participation in occupational therapy but also her mother's participation. Nora's mother was educated on age-appropriate play activities to encourage use of Nora's left hand and to facilitate normal fine motor development such as finger feeding and using crayons. Additionally, Nora's mother was educated on the importance of consistently following through with therapy recommendations such as attending all appointments in the burn clinic and with outpatient occupational therapy as well as actively participating in those therapy sessions.

Final Outcome

Nora is now 2 years post burn injury. She has had two scar revision surgeries for the left palm contractures. She continues to receive outpatient occupational therapy services one to two times per week for scar management, ROM exercises, and fine motor development. Because her family had been negligent in keeping Nora's appointments with the burn clinic and outpatient therapist, Nora developed significant central palm scarring that led to flexion contractors of her MP joints of all digits and a thumb adduction contracture. These deformities interfered with her ability to grasp objects effectively and led to her developing a strong preference for the right hand and diminished use of the left hand. With coordinated care between Nora's outpatient therapist and the outpatient burn clinic therapist, the burn clinic surgeons were made aware of both Nora's and her family's deficits. This allowed the physician to counsel the parents on the importance of following through with therapy and how surgery can be avoided or at least delayed with participation in therapy sessions. Ongoing discussions and education with the parent from the burn clinic staff enabled Nora's mother to better understand that while her daughter's hand wound would never look “normal,” it would be able to function normally if there was better compliance with therapy and outpatient clinic appointments. Once Nora's mother accepted this idea, her compliance with clinic visits, therapy sessions, and consistent use of compression garments improved. As a result, after Nora's last surgery, she regained full functional ROM and has normal fine motor development. At her last clinic assessment, the surgeons determined that Nora would not require surgical intervention at this time but would likely require further surgery to correct growth-related contractures of the left hand.

Threaded Case Study

Lee, Part 2

Lee's case illustrates the rare ideal patient case. His burn injury was considered classic and easy to manage medically. His occupational therapy needs were clear and straightforward because he was motivated and had a good support system. Lee seemed to accept support from all sources: from family, church, and his healthcare providers.

Lee was admitted to the burn center for complex wound care and pain management after his initial injury. He eventually required surgical interventions for skin grafting to the left hand and (B) LEs. After surgery, Lee was placed in (B) LE splints and a left hand splint for 5 days. Lee had been a very active young man and consequently found the 5 days of immobilization and bed rest difficult to tolerate. Given his history as a seminary student, a referral to the hospital Christian chaplain was requested, and he provided Lee with spiritual support at bedside. This helped to relieve Lee's feelings of boredom and inactivity. He had additional support from his friends and his wife in maintaining his spirits. They also provided nutritional assistance. On post-op day (POD) 2, the doctor assessed the surgical site of Lee's left hand. The skin graft was observed to be intact and well adherent for POD 2. However, Lee was discouraged by the way that his hand looked. When Lee vented about his anxiety, both the OT and registered nurse reassured him that his wound looked appropriate and would heal and regain normal function. He took comfort in knowing that the experienced burn team members felt that his skin graft looked very good and that in time the appearance would improve. On POD 5, Lee's dressings were taken down and he was able to be out of bed and resume basic ADL activities to tolerance. Lee was motivated to go home as soon as possible, which inspired him to work through his pain. He was discharged home on POD 8, and he ambulated with an FWW and was independent in all ADLs.

During his first follow-up clinic visit, he continued his ambulation and ADL status but admitted that he was mostly housebound. On his second return visit to the clinic, which was approximately 1 month post burn, Lee was walking without the walker, appeared to be in better spirits, and reported that he was still staying in the house most of the time but was attending church with his wife and was socializing by having friends over to his home. He reported that his school was on break but would resume in 2 months. At that time, he planned to complete his seminary training. He continued to be concerned about the appearance of his skin, especially the mesh graft that he described as looking like “fish skin.” Burn clinic team members reinforced their assertion that healing skin and color changes would occur in time. Lee was shown pictures of healed mesh and sheet grafts to reinforce the many changes that were described as occurring and appeared to be comforted by the information. On his third burn clinic visit, a custom pressure garment was ordered for his left hand. He expressed feeling better after seeing the healing that was occurring in his skin and the improved appearance. He attributed his recovery and improvements to his Christian faith and prayer. He was looking forward to resuming school and playing soccer again.

Summary

Burn injury is one of the most painful and devastating injuries that can be sustained. Advancements in trauma care and in surgical techniques have significantly improved the survival rate of patients with large burn injuries as well as those with accompanying multiple medical problems. Treatment of the burn injury is as traumatic as the injury itself at times and can lead to a negative psychological impact on the patient. The occupational therapist treating in a burn center is a valuable member of the team, not just for the patient's physical rehabilitation but also for his or her psychological rehabilitation. Reengaging in normal, valued daily occupations can improve not only a patient's functional ability and movement but also the feelings of competence in occupational performance. Burn survivors often endure more pain than they previously thought they could and must push themselves past what they believed their strength and ability could tolerate to accomplish their goals. As these patients engage in the therapeutic process and recover their functional abilities, they learn new skills to adapt and problem solve. This gives them a tremendous amount of self-esteem and self-efficacy. The word *survivor* then takes on a new meaning of having not only survived traumatic injuries but having learned new skills and created new occupational roles. They transition from the role of burn patient to that of the burn survivor—as exemplified by the narratives of Tonio, Nora and her parents, and Lee. They move past the negative feelings of denial, anger, and depression and onto the positive feelings of acceptance and hope.

Review Questions

1. Name the two layers of the skin. In which layer are the nerves and sebaceous glands located?
2. Which factors are considered in determining burn severity?
3. What is an escharotomy, and why is it performed? How does it differ from a fasciotomy?
4. Describe two factors that affect the quality of burn wound healing and promote excessive scar formation.
5. During the acute care phase, which factors may limit full ROM?
6. What is a boutonnière deformity, and what are boutonnière precautions?
7. What are the two basic principles underlying most burn rehabilitation treatment techniques?
8. What is the primary objective for positioning during acute care?
9. What are the indications for initiating splints during the acute care phase?
10. When a splint is indicated in the acute phase, what is the preferred wearing schedule and why?
11. When should client education about burn injury and rehabilitation begin?
12. What would cause a patient to require temporary adaptations for self-care during the acute phase?
13. Why are patients immobilized postoperatively? On average, how soon after grafting can gentle AROM exercises be resumed?
14. How soon postoperatively can an intermediate compression dressing or garment be applied?
15. What are the two main compression therapy options for the treatment of facial scars?
16. Why are skin-conditioning activities used in burn rehabilitation? What are examples of skin-conditioning techniques?
17. What is the average length of time required for scar maturation?
18. What are possible causes of limitations in ADLs during the rehabilitation phase?
19. What information should be included in predischarge education and a home program review?
20. What is the primary cause of dysfunction after a burn injury?

*In this chapter, the terms *patient* and *client* are both used, with *client* being used in occupational therapy contexts.

**It is important for the reader to recognize that although the American Occupational Therapy Association, to date, does not have an official burn specialization, the American Burn Association (for the burn center verification-type of accreditation) has indicated recommendations for occupational therapists to have the following experiences in order to work with burn patients: extensive experience in (1) intensive care unit and acute care, (2) hand therapy, (3) pediatrics, and (4) upper and lower extremity splinting.

†The authors would like to acknowledge the significant and outstanding contributions of Sandra Utley Reeves and Lisa Deshaies to this and the previous editions.

Amputations and Prosthetics

Annemarie E. Orr, Jennifer S. Glover, Chelsey L. Cook

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, the student or practitioner will be able to do the following:

Sections 1 and 2

1. Understand the role of the occupational therapist in the evaluation and treatment of upper limb amputations.
2. Identify the upper limb amputation levels and describe the prosthetic systems and componentry associated with each level of amputation.
3. Identify the phases of upper limb prosthetic training and describe key characteristics of each phase of intervention.
4. Name the five types of prosthetic systems and explain the advantages and disadvantages of

each type of system.
5. Identify the outcome measures that are used specifically with upper limb amputations.
6. Recognize the emerging technologies and advances in the area of prosthetics and analyze how these may affect functional outcomes for individuals with upper limb loss.
7. Analyze how upper limb amputation affects an individual's performance skills and patterns as they relate to occupational performance.

Section 3

1. List the types and causes of lower extremity amputation (also known as lower limb amputation).
2. Describe the types of equipment that may be used by a person who has had a lower limb amputation.
3. Describe how lower limb amputation may affect a person's occupational performance.
4. Identify the effects that lower limb amputation may have on client factors, performance skills, and performance patterns.
5. Discuss the potential psychosocial repercussions of lower limb amputation.
6. Describe the role of the occupational therapist in working with a person who has had a lower limb amputation.
7. Explain how context and activity demands can be altered to improve a client's ability to participate in a given occupation.
8. Discuss possible additional concerns for an older person who has had a lower limb amputation.

KEY TERMS

Above-knee amputation

Acquired amputation

Below-knee amputation

Body-powered prosthesis

Disarticulation

Hybrid prosthesis

Interscapular thoracic

Myoelectric prosthesis

Myosite

Neuroma

Phantom limb pain

Phantom limb sensation

Preprosthetic phase

Prosthetic training

Pylon

Residual limb

Residual limb support

Separation of controls

Syme's amputation

Terminal device

Transhumeral

Transradial

Section 1 General Considerations in Upper Limb Amputations[a]

Annemarie E. Orr

Amputation can result from several causes, including disease, trauma, infection, tumor, or congenital limb deficiency. Individuals with congenital limb deficiencies and those whose amputations occur early in life usually develop sensorimotor skills and a self-image without the limb; therefore, these two populations present different problems for the rehabilitation worker.[7,99,100] This chapter discusses adults with **acquired amputations**; that is, surgical removal of a limb as a result of disease or trauma.

Causes and Incidence of Amputation

Approximately 1.6 million persons live with limb loss in the United States.[122] This number is projected to more than double to 3.6 million by 2050.[122] Annually more than 185,000 persons in the United States undergo an amputation. Dysvascular disease and diabetes are the primary reasons for amputation of the lower limb, and trauma is the primary cause of upper limb amputation in adults.[28] Approximately 75% of upper limb amputations are the result of trauma caused by work-related accidents, gunshot wounds, and burns.[59] The ratio of upper limb to lower limb amputation is estimated to be 1 : 3.[36] Limb loss as a result of trauma is increased during times of active warfare.[73] As of June 1, 2015, more than 1600 U.S. military service members had undergone an amputation as a result of the wars in Iraq and Afghanistan; this was the case for Daniel, described in the case study in Section 2.[19]

Classification of Amputation Levels

The classifications for levels of upper extremity amputation are illustrated in Fig. 43.1. The term **interscapular thoracic** (forequarter) describes an amputation of the entire upper extremity, scapula and clavicle; **transhumeral** describes an amputation through the humerus; and **transradial** describes an amputation through the radius and ulna. These levels of amputation are also commonly referred to by their relationship to the elbow joint: above elbow (AE) and below elbow (BE). The term **disarticulation**, at the shoulder, elbow, or wrist level, describes an amputation through the joint. The higher the level of amputation, the more difficult it may be for a person to use a prosthesis because fewer joints and muscles are available to control the prosthesis.

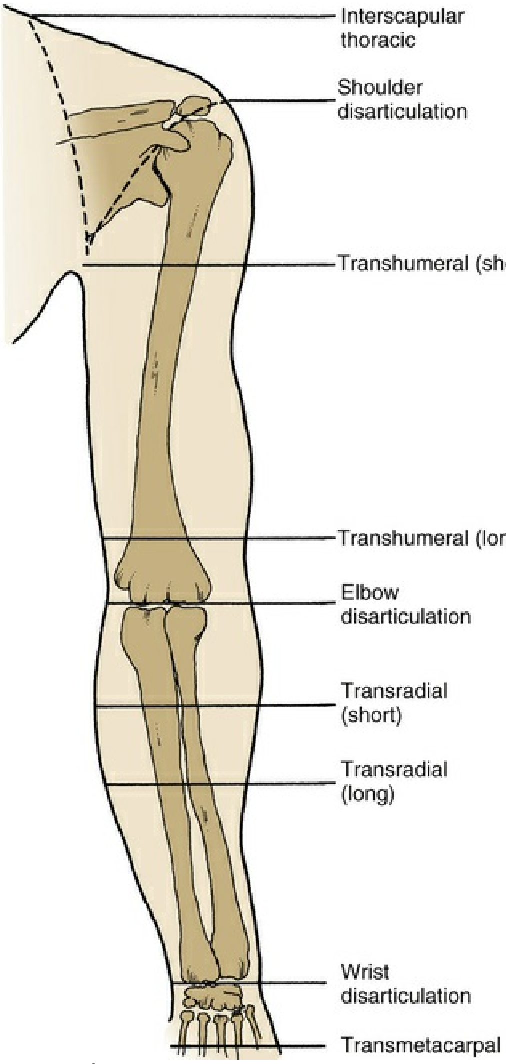

FIG 43.1 Classification levels of upper limb amputation. (From Saunders R, Astifidis R, Burke SL, et al, editors: *Hand and upper extremity rehabilitation: a practical guide,* ed 4, St Louis, 2016, Elsevier.)

Rehabilitation as a Team Approach

Rehabilitation after amputation requires a team approach. Members of the interdisciplinary team include the physician, occupational therapist, physical therapist, prosthetist, social worker, and psychologist. The client is the primary member of this team and should be encouraged to be an active participant in the rehabilitation plan of care. The primary role of the occupational therapist in the rehabilitation of amputations is to facilitate an individual's return to maximum performance of daily occupations and roles that lead to a meaningful life.[52,96]

Surgical Management

Although the mechanism of injury may vary, the primary goal of surgical management of upper limb amputations is the same—to maintain limb length and provide an opportunity for an optimal prosthetic fit that allows for maximal use of the prosthesis.[96,105] A longer residual limb typically leads to improved functional outcomes. Increased limb length and preservation of each progressive joint allows for greater opportunities for the person to position the residual limb in space and to feel, grasp, and manipulate objects in his or her environment. It is important for the surgeon and interdisciplinary team to understand the capabilities of each prosthetic device as they correspond to the amputation level, so as to maximize the functional outcomes and overall satisfaction of the client.[105]

Surgical management of muscles and nerves is critical with upper extremity amputation.

Myodesis, myoplasty, and myofascial closure are surgical techniques used to stabilize the muscle and tendons of the residual limb and to provide adequate soft tissue padding to the distal end of the bone. With myodesis the muscle and fascia of the residual limb are sutured directly to the bone, making it structurally stable. Myoplasty involves suturing the residual opposing muscle groups together over the transected bone end. Myofascial closure, the least stable technique, involves suturing the residual muscle and its fascia together.

Nerve management in the residual limb is also important to limit neuroma development and optimize myosite signals for myoelectric control. Traction neurectomy is a surgical technique that moves the eventual neuroma away from the skin and muscle closure by isolating all the major nerves and allowing them to retract proximal to the closure into the residual muscle.[96,105]

Surgical techniques vary with the level and cause of amputation.[97,99] A closed or open surgical procedure may be performed. The open method allows drainage as the surgical site heals and minimizes the possibility of infection. The closed method reduces the period of hospitalization but also reduces free drainage and increases the risk of infection.[99] The specific type of amputation performed is left to the discretion of the surgeon and is often determined by the status of the limb at the time of amputation. The surgery may be ablative only (removal of devitalized tissues) or reconstructive. In either case the surgeon must remove the part of the limb that has to be eliminated and allow for primary or secondary wound healing. The surgeon reconstructs a **residual limb** (sometimes referred to as a stump) to achieve the optimal prosthetic fit and function.[99]

Section 2 Upper Limb Amputations

Annemarie E. Orr

Threaded Case Study

Daniel, Part 1

Daniel is a 19-year-old combat engineer in the US Army. While on patrol in Afghanistan, his vehicle came under attack by enemy fire. Seated in the passenger side of the vehicle, Daniel was hit by a rocket-propelled grenade, resulting in the traumatic amputation of his nondominant left upper extremity below the elbow. Daniel was medically stabilized in theater and medevaced to a military hospital in the United States for continued medical treatment and rehabilitation. Daniel underwent multiple surgeries, including a myoplasty, to optimize limb closure and healing. He had no postoperative complications. Occupational therapy was consulted for an evaluation after closure of his residual limb.

Daniel is originally from California, where he enlisted in the Army directly after high school. He is engaged to his high school sweetheart and had planned to be married after his deployment. Daniel and his family lived in the desert of California, where he and his father would work together on restoring cars and riding dirt bikes. Before this deployment Daniel was stationed at Fort Stewart in Georgia. He was living in the barracks on base, and his fiancée remained in California. Before his injury Daniel was independent with all activities of daily living (ADLs) and instrumental activities of daily living (IADLs). He has a passion for motocross and expressed concern about his ability to participate in the sport he loves after the amputation. He identifies primarily with his role as a soldier and is unsure whether he will be able to stay on active duty as a combat engineer in the Army after the amputation.

Daniel's parents and fiancée are present for the initial evaluation. A comprehensive occupational therapy evaluation is performed at Daniel's bedside on the inclient unit. Upon arrival the occupational therapist notes that a compressive elastic bandage wrap has been applied to Daniel's left residual limb. Range of motion, strength, and sensory assessments are performed for both upper extremities. Daniel has full range of motion throughout all joints except his left elbow. His left elbow is limited in both flexion and extension as a result of postoperative edema and pain. Daniel is educated on the various forms of pain that occur after amputation. He is able to describe his pain as phantom pain; he reports that his hand feels as if it is in a tight fist position, and he is unable to move it. Daniel has sutures in place along the distal end of the residual limb and no other open wounds. Daniel and his family are educated on the use and application of an elastic shrinker to assist with residual limb volume reduction and shaping.

During the evaluation Daniel reports that he is initiating basic ADL performance (e.g., feeding, hygiene and grooming, and dressing) with his right arm using one-handed techniques. Overall he shows a positive affect throughout the initial meeting with the occupational therapist, and he is motivated to begin his therapy and preprosthetic training.

Critical Thinking Questions

1. For Daniel, how will each area of occupational performance (ADLs, IADLs, work, education, leisure, play, and social participation) be affected as a result of the loss of his left arm?

2. How will Daniel's occupational profile and contexts influence and guide occupational therapy treatment interventions?

3. What is the therapeutic role of the occupational therapist in Daniel's psychological and psychosocial adjustment to life after amputation?

Preprosthetic Training

The **preprosthetic phase** of training begins immediately after amputation and continues through prosthetic fitting. During the period between amputation and fitting of the prosthesis, the client participates in a program designed to prepare the residual limb for a prosthesis, facilitate adjustment to his or her loss, and achieve maximal independence in self-care.[77,114] The primary goals of this phase of rehabilitation are to promote wound healing and closure, pain management, initiation of basic ADL retraining, and client and family education.[95,96]

Evaluation

A comprehensive evaluation is administered to determine baseline information about the client's past medical history, functional status, and rehabilitation goals. An interview with the client and family members is performed to identify occupational roles, the home and work environments, and premorbid interests. The occupational therapist evaluates the client's medical history, upper quadrant range of motion and strength, sensation in the residual and intact limb, wound and skin healing, edema and limb volume measurement, residual limb and phantom limb pain, and psychological and emotional adjustment after amputation.[96] A baseline functional assessment is performed to evaluate the client's level of independence with basic ADL performance in such tasks as self-feeding, dressing, toileting, and bathing, and with IADLs, such as work and leisure.[1,2] The findings from the initial perioperative evaluation and a statement of the client's goals are important for guiding the rehabilitation program toward meeting these functional goals.[7]

Activities of Daily Living

One of the primary goals of occupational therapy is independence in basic self-care after amputation. During this acute phase of recovery, feelings of helplessness for the client are typical. It is important for the occupational therapist to provide the client with control over his or her environment and a sense of independence in basic ADLs. Modifications to the environment, such as adaptive call bells and pain-controlled analgesia (PCA), are a simple first step toward independence. Adaptive equipment, such as universal cuffs, bidets, and hook-and-loop–adapted clothing, can provide initial independence in basic ADLs (Fig. 43.2). The ADLs that should be addressed immediately after amputation are (1) self-feeding, (2) toileting, and (3) oral hygiene.[96] If the client is medically stable and the wounds have healed, training in additional ADLs (e.g., dressing and bathing) may be initiated. It is the role of the occupational therapist to creatively adapt and modify the client's environment to achieve maximum independence.

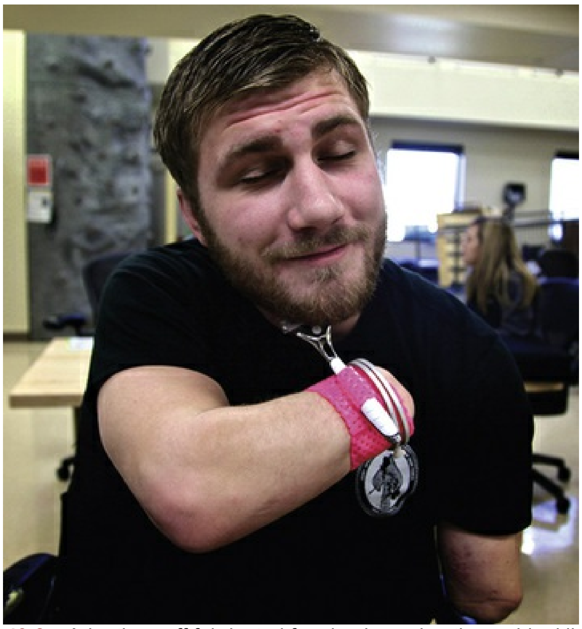

FIG 43.2 Adaptive cuff fabricated for shaving using the residual limb.

The change in hand dominance is introduced during this phase of recovery for persons with amputation of the dominant limb. Because a prosthesis has limited fine motor prehension and dexterity, it is important to transfer hand dominance in handwriting to maintain independence with written communication.[121] Clients learn and adapt quickly to limb loss and often begin to perform ADLs on their own with the nondominant hand. The occupational therapist will also educate the client on one-handed techniques for performing ADLs and will make recommendations for adaptive equipment as necessary. The occupational therapist educated Daniel in the use of adaptive equipment, such as a pump soap dispenser and a rocker knife, to increase his independence in bathing and self-feeding.

Wound Healing and Limb Shaping

During the initial wound healing phase the occupational therapist performs wound care and dressing changes according to the physician's guidelines. Immediately after surgery, limb wrapping is initiated to decrease edema and promote optimal limb shaping for the prosthesis. Figure-eight limb wrapping with an elastic bandage is performed for distal to proximal compression and shaping of the residual limb. The limb must never be wrapped in a circular manner because this restricts circulation and causes a tourniquet effect. Once the wound has stopped draining and clearance has been obtained from a physician, progression to use of an elastic shrinker or a compression garment can be initiated. Shrinkers come in a range of measurements; therefore progression of residual limb volume change can be documented accordingly. Use of a cylindrical tube, or donner, is recommended for ease of application of the shrinker on the residual limb (Fig. 43.3). If the shrinker loosens, a smaller size is indicated. A shrinker should be worn whenever the client is not in a prosthesis to maintain residual limb volume and shaping. The client is educated to remove the shrinker two or three times daily to examine the skin for any redness or pressure. The client and family are instructed in donning and doffing the compression garment with the goal of independence for the client in this technique.

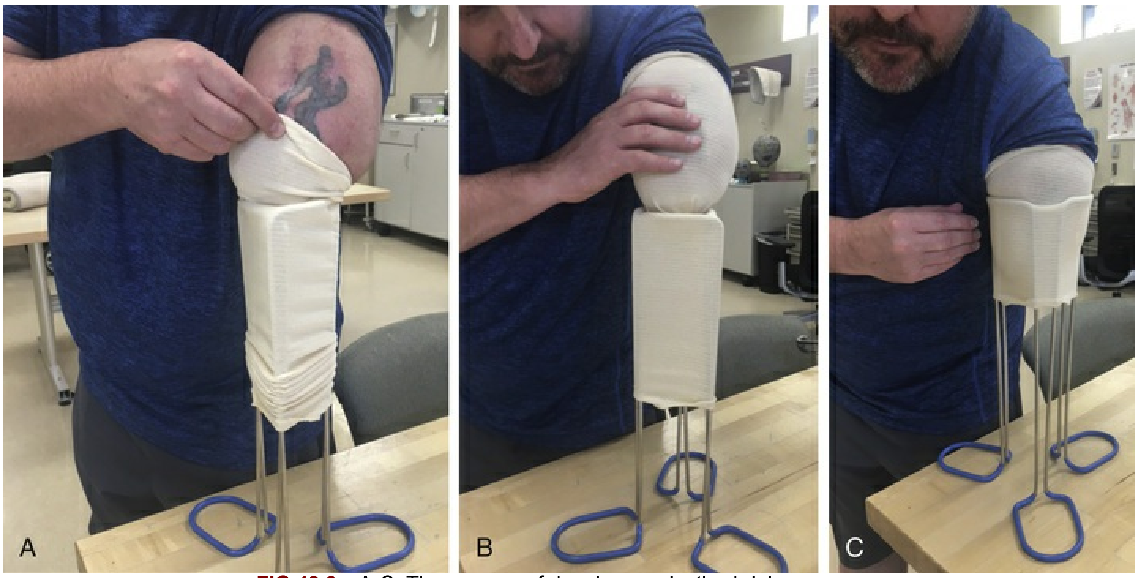

FIG 43.3 A-C, The process of donning an elastic shrinker.

Pain Management

Residual limb hyperesthesia, phantom limb pain, phantom limb sensation, and neuroma are common problems after amputation that can interfere with functional use of the limb with or without the prosthesis.

Desensitization

A residual limb may be hypersensitive after surgery, requiring a technique known as desensitization. Overstimulating a hypersensitive peripheral area with nonharmful stimuli teaches the central nervous system to accept these stimuli as nonharmful and to minimize aversive responses to them. Residual limb hyperesthesia, or an overly sensitive limb, limits functional use and causes discomfort. Reduction in hypersensitivity of the residual limb improves the client's tolerance to wearing of the prosthesis. Desensitization techniques are implemented after wound closure. Methods include tapping, vibration, constant pressure, and rubbing of various textures on the limb. The therapist introduces the tissue to soft, lightweight, smooth textures and progresses to rough, hard, uneven, heavier textures as the client is able to tolerate them. As the techniques are performed, the therapist teaches them to the client, family members, or caregivers to facilitate use of the techniques at home.[7,45,84] Desensitization is used to prepare the residual limb to tolerate the initial socket.

Phantom Limb Pain

Approximately 90% of individuals who have had an amputation experience **phantom limb pain**.[17] Phantom limb pain can have a number of varying characteristics, such as stabbing, cramping, burning, or throbbing.[30] Changes in the central nervous system and peripheral nerve damage are thought to be the cause of phantom limb pain.[30] Oftentimes psychological factors, such as stress, are the triggers for phantom limb pain.[23]

Phantom limb pain and its causes and treatment are highly debated topics. Research in this area continues to make progress, but no evidence strongly supports any one approach as clearly successful in the management of phantom limb pain. A team approach should be used to address phantom limb pain and to find the best method for the client in the management of this pain.

Treatment methods for those with phantom limb pain may include analgesics, acupuncture, electrical nerve stimulation, and mirror therapy, among others. Isometric exercises of the phantom and residual limb initiated 5 to 7 days after the amputation and performed several times throughout the day may help to minimize pain. Active movement of muscles associated with the phantom limb can be beneficial, especially when the sensations are described as stuck, cramped, or tight. Daniel experienced this kind of phantom pain, describing his phantom hand as stuck in a fist position. He had positive results from active movement and visualization exercises with the phantom limb. Mirror therapy has elicited some positive results in decreasing the pain of phantom limbs.[31,82] The use of mirror therapy in the management of phantom limb pain is now widely accepted as standard therapy after amputation.[112] Biofeedback, transcutaneous electrical nerve stimulation (TENS), ultrasound, progressive relaxation exercises, and controlled breathing exercises have also been used.[95] Activities such as massaging, tapping, and applying pressure to the residual limb may be beneficial. A physician may treat the pain by prescribing oral medications, injecting anesthetics into a specific soft tissue area, or performing sympathetic nerve blocks. Surgical revision of the residual limb is sometimes necessary to alleviate the pain.[7,24,110] An individual also may take nonpharmaceutical oral supplements to decrease the pain. Management of phantom limb pain requires an interdisciplinary team approach.

Phantom Limb Sensation

Phantom limb sensations are sensations of the amputated limb. In its simplest form, the phantom limb sensation is the sensation of the limb that is no longer there. The phantom limb sensation is present because the neural system in the brain still exists, even when the input to the body is interrupted by an amputation.[66] Almost all individuals who have undergone amputation report this painless sensation.[65] Although phantom limb sensation is more common after traumatic amputation, it has also been known to occur in persons with congenital limb absence.[81] The distal part of the limb is most frequently felt, although sometimes the person feels the whole extremity. The sensation may dissipate over time, or the person may experience it throughout life. The individual may feel that the distal portion of the phantom hand has retracted closer to the end of the residual limb, in a phenomenon called telescoping. Research has recently begun to focus on the use of phantom limb sensation and its potential to improve control with a **myoelectric prosthesis**.

Neuroma

Severed peripheral nerves may form neuromas in the residual limb.[63,67] A **neuroma** is a small ball of nerve tissue that develops when growing axons attempt to reach the distal end of the residual limb. As the axons grow, they turn back on themselves, producing a ball of nerve tissue. If the neuroma adheres to scar tissue or to skin subjected to repetitive pressure, it can be painful when pressed. The diagnosis is made by palpating the neuroma and is confirmed with ultrasound.[10] Most neuromas occur 1 to 2 inches (2.5 to 5 cm) proximal to the end of the residual limb and are not troublesome.[7] To minimize negative effects of a neuroma, surgeons perform a traction neurectomy to move the eventual neuroma away from the skin closure.[63,67]

One treatment option for a painful neuroma is local steroid injections. If surgical intervention is indicated, the options are to (1) redirect the nerve more proximally into a padded area, (2) tie the nerve ending into a proximal wound bed to protect it, or (3) tie two nerve ends to each other to prevent the development of a neuroma. In addition, the residual limb socket may be fabricated or modified to accommodate the neuroma.[7,110,114]

Upper Extremity Range of Motion, Strength, and Endurance

The days and weeks immediately after amputation are the most critical for implementation of a comprehensive exercise program. Once medical approval has been provided, the client begins exercises designed to maintain and increase range of motion (ROM) and to strengthen the upper quadrant and trunk muscles. Daily upper extremity flexibility training and strengthening are critical to preparing the residual limb for prosthetic use. Depending on the level of amputation, the client may perform specific exercises that mimic the movements required to operate the prosthesis. Of utmost importance is the maintenance of ROM and strength to the shoulder flexors, abductors, and rotators, as well as the scapular protractors and retractors, because limitations in these motions may result in an increased risk of rejection of the prosthesis.[28] The therapist manually positions and holds the residual limb in the desired posture and asks the client to resist the hold, facilitating increased strength of the appropriate muscles. Isometric exercises enable the client to engage in a strengthening program without equipment. Exercises may also be performed with rubber tubing, elastic bands, or strap-on weights. As the client progresses, adaptive cuffs with D-rings can be used on cable machines (Fig. 43.4). It is appropriate for the occupational therapist to guide the client through a home exercise program for self-stretching and use of modified home or gym equipment to perform exercises.

FIG 43.4 Weight-lifting cuff with D-ring used on a cable machine to perform upper extremity strengthening exercises.

Body symmetry and proper trunk alignment can limit the possibility of cumulative trauma or overuse injuries of the upper limbs, neck, or back.[96] Therapeutic activities are facilitated in front of a mirror to increase visual feedback and body awareness of the client. Verbal and tactile cues are provided as necessary to promote proper body mechanics and alignment during therapeutic activities. The client will participate in physical therapy, along with occupational therapy, to address core strengthening and cardiovascular fitness. After amputation the use of a prosthesis increases cardiovascular demands; therefore it is important for the client to maintain an active lifestyle and engage in regular aerobic activities.

Myosite Testing and Training

When early prosthetic fitting is not possible, preprosthetic training for a myoelectric prosthesis can be initiated. A myoelectric prosthesis functions by detecting electromyographic (EMG) signals produced by muscles in the residual limb. Locating appropriate superficial muscle sites (i.e., **myosites**) is the most important aspect of the successful operation of a myoelectric prosthesis. Physical examination of a person's arm often reveals sufficient strength in natural agonist-antagonist pairs, such as the wrist extensor and wrist flexor muscles in the person with a transradial amputation, and the biceps and triceps muscles in the person with a transhumeral amputation. Individuals with a short transhumeral amputation often have an effective myosite in the pectoralis or deltoid anteriorly and in the infraspinatus or trapezius posteriorly. Use of an agonist-antagonist pairing for control of the prosthesis is called two-site control. Preference is given to distal myosites that are adequate in signal to allow the prosthetist room to position the electrodes within a well-suspended socket. In some cases trauma or nerve injuries do not allow the choice of a natural pair. In such cases a single muscle site can be used to control two functions. A strong contraction controls one operation, a weaker contraction controls another, and relaxing the muscle turns the system off.[70] Alternative methods for control also have been developed (these are discussed briefly later in the chapter).

Both the therapist and the prosthetist can perform myosite testing. A biofeedback system or myotester is used to identify the amount of signal generated by the muscle. Surface electrodes are positioned on the residual limb and connected to the myotester or biofeedback system. Examples of commonly used systems are the Myolab II (Motion Control), MyoBoy (Ottobock), and a biofeedback computer program or electric demonstration hand (Fig. 43.5). It is important that all electrodes have good contact with the skin and are aligned along the general direction of muscle fibers. Moistening the skin slightly with water may improve the EMG signal by lowering skin resistance.

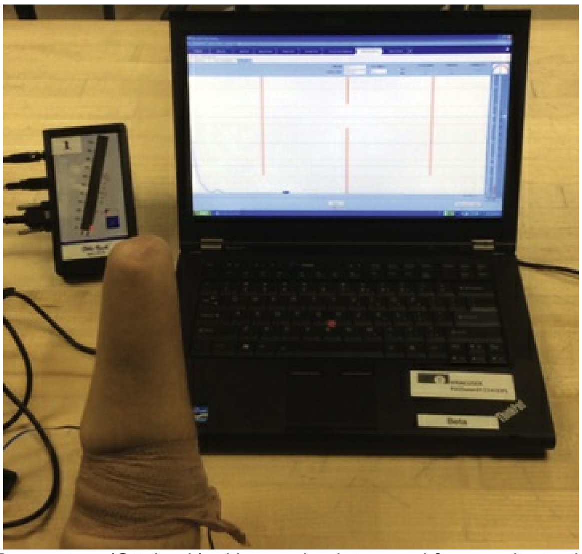

FIG 43.5 MyoBoy system (Ottobock) with myosimulator used for myosite testing and training.

The goal of myosite testing is to identify two muscle sites that would fit appropriately within the socket with the greatest microvolt difference between them, not necessarily the two muscle sites with the strongest signals. Selection is complete when the client is consistently generating sufficient signals to operate the prosthesis in its basic functions, such as opening and closing the **terminal device** (TD). The therapist should check with the prosthetist to determine the minimum signal required to operate the myoelectric system chosen for the client.[75]

The more proximal the level of the client's amputation, the more challenging it is for the prosthetist to fit the prosthesis and for the therapist to train the person to control the prosthesis. To help the client understand a desired muscle contraction, the therapist instructs the client to imitate the desired contraction or movement with both arms. For instance, the therapist can ask the client to raise the sound hand at the wrist (wrist extension) and imagine this motion with the phantom hand on the amputated side. Muscle groups are most frequently used according to their physiologic function. For example, the wrist extensors are used for hand opening and the wrist flexors for hand closing. The therapist often can palpate the wrist flexors and extensors on the residual limb during this exercise. The client is instructed to contract and relax each muscle group separately and on command. For this step a myotester is particularly useful because it indicates the magnitude of the EMG signal as the client contracts the muscle, in addition to the decrease in signal as the client relaxes the muscle. Many clients have difficulty relaxing a muscle completely; this causes a decrease in muscle signal separation.

The myotester can be used to train the muscles with both visual and auditory feedback. Various models are available to therapists. The goals of training at this point are to increase muscle strength and to isolate muscle contractions. As the client's confidence and accuracy improve, visual or auditory feedback should be removed. Practicing muscle contractions without feedback teaches the client to internalize the feeling of each control movement. The advantage of creating this internalized awareness of proper muscle control is that control and strengthening practice can be continued between treatment sessions without feedback equipment.[101] The therapist must learn to recognize muscle fatigue, which is frequently a side effect in this process, and should allow sufficient time for that muscle to recover during the treatment session.

Ideally the client with an amputation receives adequate training and practice in initiating these muscle contractions before receiving the completed myoelectric prosthesis from the prosthetist. Prosthetists commonly engage a client in muscle site training with the preparatory socket and prosthesis fitting. This training, which usually occurs when the prosthetist looks for optimal electrode placement and socket fit, is not adequate for most clients to operate a prosthesis immediately and successfully. Anxiety and frustration are common for clients during preprosthetic training in the use of a myoelectric prosthesis. A team approach during training with the therapist and prosthetist can minimize these responses. The client's success and effectiveness in using the prosthesis are closely related to the quality of the preprosthetic training.

Psychological Support

Psychosocial adjustment depends on various factors: the individual's character and essence, the quality of the social support systems available, sociocultural reactions to amputation, and the team's management of rehabilitation.[32] Social, personal, and spiritual contexts may be significantly altered for those who have experienced amputation. Through the interview with Daniel, the therapist identified successful adaptation and coping strategies already in place.

The process of adjustment to amputation is analogous to the grieving process. The client experiences identifiable stages of denial, anger, depression, coping, and acceptance.[32] Most clients move through these stages and ultimately adapt to the loss. It is important to note that depression rates in amputees are higher than general population rates for up to 2 years after amputation.[46] During any phase, clients may react with anger toward themselves, family members, and the medical team. The therapist should build a relationship of trust and respect with the client, one that encourages open discussion about the person's psychological adjustment to the amputation and loss of the limb. Positive reinforcement through involvement in the rehabilitation process and contact with people who have experienced similar amputations may help the client in returning to former life roles.[32] Meetings with a peer mentor or visitor are encouraged to facilitate a discussion about the rehabilitation process and the phases of recovery and psychological adjustment and also to provide problem-solving strategies. The client may be afraid to return to family, social, vocational, or sexual roles. Frequent discussions of fears and solutions to real or imagined problems are important for facilitating adjustment.[32] The therapist is encouraged to build a collaborative relationship with the client, to listen and understand his or her life roles, and to facilitate the rehabilitation to meet the individual's future goals.

Reactions after amputation are complex and unique to each individual. Although occupational therapists play a vital role in the psychological adjustment of the client, it is important that they communicate with and refer the client to a psychologist, spiritual counselor, or other behavioral health specialist as indicated.[109]

OT Practice Notes

The entire rehabilitation team is responsible for providing the client with the reassurance and motivation he or she needs. The team should focus on occupational therapy intervention and facilitation of participation and engagement in meaningful occupations.[76]

Choosing the Prosthesis

The occupational therapist and prosthetist begin by educating the client about the various upper extremity prosthetic systems available for and appropriate to each level of amputation. The client's age, medical status, amputation level, cognitive status, functional goals, and desire for a prosthesis are important factors in choosing the prosthesis. A discussion about the advantages and disadvantages of each prosthetic system and terminal device allows the team to make the appropriate recommendation. The prosthetist generally provides information about specific prosthetic options, and the therapist helps the client understand the options as they relate to his or her performance in areas of occupation. This discussion allows the client to stay informed throughout the entire prosthetic fitting and training process and establishes realistic expectations for the functional outcomes of the prosthesis.

Early fitting of a prosthesis has been shown to significantly enhance functional prosthetic use and acceptance.[79] Studies suggest that fitting an individual with a prosthesis within 30 days of amputation significantly increases the chances of acceptance of the prosthetic limb. This 30-day period is known as the "golden window."[14,62] Early fitting programs have been very successful in helping the client who has had an amputation incorporate the new extremity more rapidly into his or her daily activities.[4]

The importance of early fitting of a prosthesis cannot be overemphasized; it may be one of the most important factors in client acceptance and use of a prosthesis.

Types of Prosthetic Systems

The five most common upper extremity prosthetic systems are body-powered, electrically powered, hybrid, activity-specific, and passive prostheses. As discussed, the type of prosthesis recommended is based on many factors. Each type has its advantages and disadvantages; therefore more than one option is often required to maximize occupational performance.

Body-Powered Prosthesis

A **body-powered prosthesis** is cable driven and controlled by gross body movements. This type of prosthesis uses body motions proximal to the amputation to pull tension on a cable operating the terminal device. The client must have sufficient musculature and ROM in the upper quadrant to operate a body-powered prosthesis. He or she must be able to perform one of the following movements to control this prosthesis: (1) glenohumeral flexion, (2) scapular abduction or adduction, (3) shoulder depression or elevation, (4) chest expansion, or (5) elbow flexion.[68] Because of its simple design the body-powered prosthesis is durable, lightweight, and has low maintenance costs. The harness and cable system on the prosthesis also gives good proprioceptive feedback to the wearer on the position of the terminal device in space.[68] However, a body-powered prosthesis harness may restrict ROM and limit the functional envelope for operation of the terminal device. This design also limits the potential grip force of the terminal device, and for some users the hook may create an undesirable appearance (Box 43.1).

Box 43.1

Advantages and Disadvantages of a Body-Powered Prosthesis

Advantages

- Durable and can be exposed to environmental conditions (e.g., water and dirt)
- Provides proprioceptive feedback
- Lower maintenance costs than myoelectric prostheses

Disadvantages

- Restrictive harness
- Decreased grip force compared to myoelectric options
- Force is exerted on the residual limb
- Can be difficult to control for high levels of amputations

Electrically Powered Prosthesis

An electrically powered prosthesis, also known as a myoelectric prosthesis (mentioned earlier), uses muscle surface electricity to control the operations of the terminal device. The muscle generates an electric potential at the time of contraction. The myoelectric signal is sensed, amplified, and processed by a control unit that generates a motor, which in turn drives the terminal device.[21] Surface electrodes are embedded in the prosthetic socket, eliminating the need for harnessing or cable systems.

Myoelectric upper limb prostheses have opened a new world of freedom and function for persons who have had upper limb amputations. The advent of electronic microminiaturization has allowed the development of prosthetic devices with totally self-contained services of power, motor units, and electrodes.[49] Powered prostheses have existed for decades, but not until the 1960s were electrically powered prostheses introduced clinically. Ottobock, a firm based in Duderstadt, Germany, began this process by aiming for the development of an electromechanically driven prosthetic hand that would match the technical and cosmetic demands of a human hand.[72]

The electric motors used to operate the terminal device give myoelectric prostheses significantly increased grip force, upward of 20 to 32 pounds per square inch.[68] These types of prostheses provide a more natural appearance and increase the functional envelope of operation without the restriction of a harness or cable. Myoelectric prostheses are battery operated and therefore require regular maintenance for charging, repairs, and component replacement. The electrical components that drive the prosthesis also add to the overall weight of the device (Box 43.2).

Box 43.2

Advantages and Disadvantages of a Myoelectric Prosthesis

Advantages

- Improved cosmesis
- Increased and proportional grip force
- Minimal or no harnessing
- Provides a larger functional work envelope for use
- Minimal effort needed to control
- Can be fitted early in rehabilitation phase

Disadvantages

- Increased cost
- Frequency of maintenance and repair for battery
- Lack of sensory feedback
- Susceptible to interference from moisture or other environmental factors
- Increased overall weight

Daniel was first considered for a myoelectric prosthesis. He received myosite testing and training during the preprosthetic phase and demonstrated good strength and control. After discussions that included the prosthetist, occupational therapist, and Daniel, in which Daniel's age, level of amputation, and functional goals also were considered, a myoelectric prosthesis was recommended for him.

Hybrid Prostheses

A **hybrid prosthesis** combines body-powered and electrically powered components in one design. These prostheses are most commonly used with a transhumeral amputation. The components can be combined to create a variety of options. Often a body-powered elbow is used with an electrically powered terminal device, or an electrically powered elbow can be combined with a body-powered hook or hand.[12,68] All excursion of the existing cable is dedicated to one component, rather than to multiple components; this feature requires less overall force on the part of the wearer for operating the prosthesis. Advantages of hybrid prostheses include simultaneous control of the elbow and terminal device, decreased overall weight of the prosthesis, and decreased cost (Box 43.3).

Box 43.3

Advantages and Disadvantages of a Hybrid Prosthesis

Advantages

- Simultaneous control of elbow and wrist or terminal device
- Less weight than an entirely electrically powered prosthesis
- Increased grip force

Disadvantages

- Harness is required for operation of elbow
- May be difficult to operate with a short transhumeral or higher amputation because of the force required to operate the elbow

Passive Prosthesis

A passive prosthesis can serve in both cosmetic and functional restoration of the hand after amputation. A passive prosthesis is static and does not have an active grasp. Often the digits can be passively positioned to assist with stabilizing, carrying, or grasping objects. For example, for an individual who has undergone a thumb amputation, a static thumb post with a friction joint can be passively prepositioned to allow for opposition. Cosmetic restoration can be achieved with a rubberized glove or a custom-sculpted, painted covering that replicates the individual's remaining hand or fingers (Fig. 43.6). Typically these prostheses are made from flexible latex, rigid polyvinyl chloride (PVC), or silicone.[68] They are lightweight, require less maintenance, and can help promote a positive self-image for the user (Box 43.4).

FIG 43.6 Example of a passive cosmetic glove on a partial hand amputation. A, Without cosmetic glove. B, With cosmetic glove.

Box 43.4

Advantages and Disadvantages of a Passive Prosthesis

Advantages

- No harnessing or control cables
- Provides cosmetic restoration and positive body image
- Low maintenance
- Lightweight
- Digits can be positioned for static grasp or opposition

Disadvantages

- Does not provide active grasping function
- Cosmetic covers made of latex or polyvinyl chloride (PVC) can stain easily

Activity-Specific Prosthesis

Activity-specific prostheses are designed for a particular activity or task (Fig. 43.7). They are often used when body-powered or electrically powered prostheses cannot perform the needed function or provide the required durability for a specific activity. These prostheses are typically used for recreational or work activities, such as sports, hobbies, and tool use. The design is typically a lightweight socket with limited or no harness or control cable. Terminal devices specific to the activity can be easily interchanged using a Hosmer Dorrance quick disconnect wrist unit. Advantages of activity-specific prostheses are durability, decreased burden on the primary prosthesis, and increased independence and function in a particular activity (Box 43.5).[68]

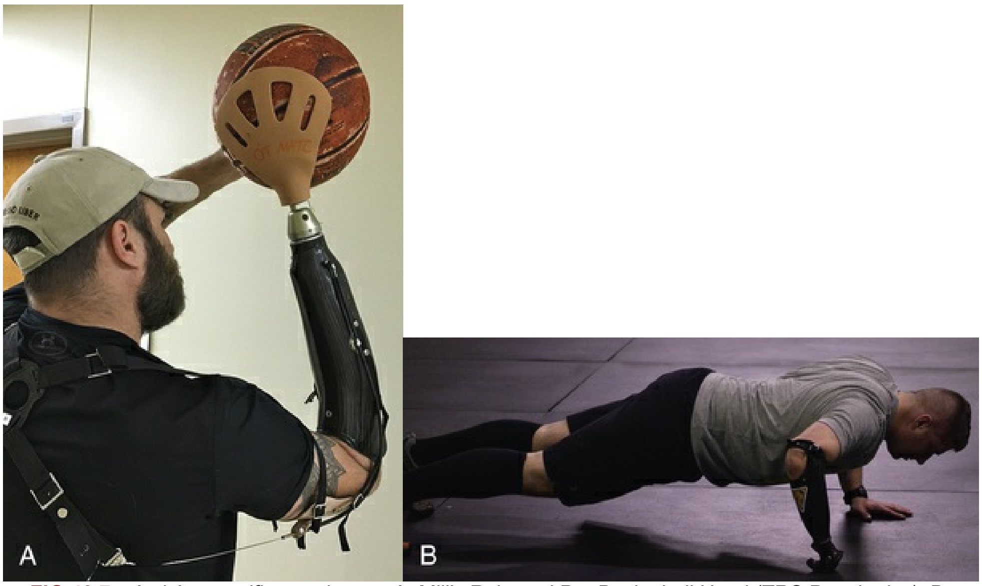

FIG 43.7 Activity-specific prostheses. A, Mill's Rebound Pro Basketball Hand (TRS Prosthetics). B, Shroom Tumbler for push-ups (TRS Prosthetics).

Box 43.5

Advantages and Disadvantages of an Activity-Specific Prosthesis

Advantages

- Allows enhanced function and task-specific participation in a variety of activities
- Minimal harness or cabling
- Durable and low maintenance
- Reduces wear and tear on primary prosthesis

Disadvantages

- Does not provide active grasp
- Appropriate for specific tasks only, not for a broad range of functions

Upper Limb Prosthetic Componentry

Various prosthetic components are available for each level of amputation. The higher the level of amputation, the greater the functional loss of the limb. Greater functional loss often necessitates a more complex prosthetic system. Each prosthetic system is custom made, individually fitted, and prescribed, according to the client's level of amputation, lifestyle, and goals.

Body-Powered Components

The first five components described in the following sections are common to all body-powered prostheses prescribed for the wrist disarticulation level and higher (Fig. 43.8). These components are the prosthetic sock, socket, harness and control system, terminal device, and wrist unit. (Components specific to each level of amputation are also discussed.)

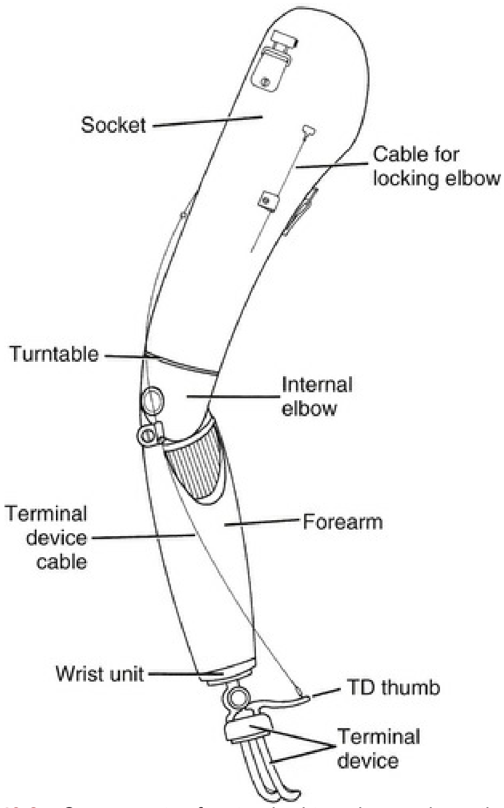

FIG 43.8 Components of a standard transhumeral prosthesis.

Prosthetic sock.

A prosthetic sock of knit wool, cotton, or Orlon Lycra is worn between the prosthesis and the residual limb. The function of the prosthetic sock is to absorb perspiration and protect against irritation that can result from direct contact of the skin with the socket. The sock compensates for volume change in the residual limb and contributes to fit and comfort in the socket.[98,117]

Socket.

The socket is the fundamental component, to which the remaining components are attached. A cast molding of the residual limb is used to construct the socket so as to optimize fit, comfort, and function. The original socket is made of a transparent, thermoform plastic material, which allows quick modification to accommodate changes in limb volume and to optimize fit. Once the limb volume has stabilized and a good fit has been found, the socket is made in its definitive form of carbon fiber. The socket should cover enough of the residual limb to be stable and provide suspension, but not so much that it unnecessarily restricts ROM of the residual limb.[98,114]

The socket is typically made of an inner flexible socket and an external rigid frame. The outer wall provides a structurally cosmetic surface and houses the hardware for the prosthesis. The inner wall maintains total contact with the skin surface of the residual limb to distribute socket pressure evenly. Flexible-frame sockets have been favored because they allow for volume and contour changes that occur when muscles contract and relax. In addition, wearers report that this type of socket is cooler than conventional alternatives.[5]

Harness and control system.

In a body-powered prosthesis the control system functions through the interaction of a Dacron harness and stainless steel cable. The harness is composed of a system of nonelastic straps, which provide suspension for the socket and house the cable system. Several types of harnesses are available, including the standard figure-eight, figure-nine, and chest strap models. The higher the level of amputation, the more complex the harness design system. Loss of muscle power and ROM may necessitate variations in the harness design. A properly fitted harness is important for both comfort and function.[89,98,114]

A transradial control system is a one-cable design (Fig. 43.9). A flexible, stainless steel cable, contained in Teflon housing, attaches to the harness proximally with a T-bar or hanger fitting and attaches distally to a prehension device or terminal device.[33] Recently Spectra fiber, an extremely strong material, has come into use in place of the stainless steel cable because it glides through the housing with less friction. The axilla loop is placed around the nonamputated side and serves as the primary anchor from which the other components originate.

FIG 43.9 Transradial body-powered prosthesis with a one-cable design and figure-eight harness.

A transhumeral prosthesis uses a two-cable design. One cable operates open and close of the terminal device, and the other cable allows the elbow unit to lock and unlock. Specific upper body movements create tension on the cables, thereby operating the various components of the prosthesis. A properly fitted control system maximizes prosthetic control while minimizing body movement and exertion.[4,89,114]

Terminal device.

The **terminal device** (or prehensors) is the most distal component of the prosthesis. Body-powered TDs are classified as either a voluntary open (VO) mechanism or a voluntary close (VC) mechanism.[71] The VO TD is held closed in a relaxed position, and it opens when the wearer exerts tension on the control cable that connects to the "thumb" of the TD. When the tension is released, rubber bands or springs close the fingers of the TD. The number of rubber bands or springs determines the holding force of the TD. The force of the pinch can be adjusted by changing the number of rubber bands (approximately 1 pound per rubber band). The VC TD is open in a relaxed position; it closes when tension is applied to the control cable, and it is automatically opened by a spring mechanism when the cable is relaxed. The amount of pinch force in a VC TD is determined by the amount of tension applied on the cable.[4,5,12,33,70]

Two styles of body-powered TDs are commonly prescribed, the hook and the hand (Fig. 43.10). The VO split hook is the most prescribed terminal device in the United States.[33] Hooks have two basic designs, canted or lyre shaped. "Canted" describes the slanted design of the hook fingertips, which provides visual feedback to the client during functional use. Lyre-shaped TDs provide symmetry for grasp (e.g., of cylindrical items). Because TDs do not provide sensory feedback, the client must rely on visual feedback during object manipulation.

FIG 43.10 Examples of body-powered terminal devices. *Right*, Model 5X Hook, adult size (Hosmer Dorrance Corp.). *Left*, Voluntary opening hand (Ottobock).

The hook design is made in a variety of materials, such as stainless steel or aluminum. Stainless steel TDs are prescribed for activities requiring a durable TD, such as yard work or construction. Aluminum TDs are recommended for lighter work and to reduce the total weight of the prosthesis for a person with a higher level amputation. Most TDs have a rubber lining or a serrated grid between the fingers. The rubber lining increases the holding friction and minimizes damage when the client holds objects.

A prosthetic hand is also available as a TD. It attaches to the wrist unit and is either passively operated or cable operated. The same control cable that operates the hook activates the prosthetic hand in either a VO or VC mechanism. As with the hook TD, the VO hand is preferred and prescribed more often than the VC hand. A flesh-colored rubber glove fits over the prosthetic hand for protection and cosmesis.[98] Body-powered hands offer limited pinch force. Additionally, the fingers that improve the cosmesis of the TD often block visual feedback during fine motor tasks.[33]

The client's lifestyle and activity demands determine the most appropriate TDs. It is important to provide the wearer with information about the advantages and disadvantages of each TD style. Many individuals who have undergone amputation choose interchangeable TDs, using a hand TD for social occasions and a hook TD for daily activities.[33]

Wrist unit.

The wrist unit connects the TD to the prosthesis. It serves as the unit for interchange and provides pronation and supination of the TD for prepositioning purposes. The wearer can passively or actively rotate the TD by turning it with the sound hand, by pushing the TD against an object or a surface, or by stabilizing the TD between the knees and using the arm to rotate it. The wrist unit for a particular client must be chosen according to its ability to meet the individual's needs in daily living and vocational activities.

Friction-held wrist units hold the TD in place by friction, which is provided by a rubber washer or setscrews. Tightening the washer or screws increases friction. The wrist is passively rotated and positioned by the other hand. Friction is sufficient to hold the TD against moderate loads while still allowing manual rotation of the terminal device. Friction-held units are mechanically simple but are not as strong as locking units.

The locking wrist unit allows the TD to be manually positioned and locked into place. In the unlocked position the TD can be prepositioned in almost any degree of rotation throughout a 360-degree range. In the locked position the locking wrist provides greater resistance under load than do the friction units.[33] The quick disconnect locking wrist unit is most common. The quick disconnect function allows the wearer to easily interchange TDs based on the needs of the activities performed.

The wrist flexion unit allows the TD to be manually flexed and locked into position. The wrist unit can be manually positioned into neutral, 30 degrees of flexion, or 50 degrees of flexion.[70] This unit is generally used on the dominant side of a person who has undergone bilateral amputation to facilitate midline activities close to the body, such as dressing and toileting.[4,71,98,114,117]

The N-Abler V Five-Function Wrist (Texas Assistive Devices) combines a rotational wrist with a flexion unit. It also allows quick disconnect of the TD.[104] This wrist unit provides the prosthetic user with flexibility in performing ADLs.

A ball-and-socket wrist unit is also available. This unit is unique in that it allows prepositioning in multiple wrist positions. It has constant friction, and the magnitude of loading is adjustable.[33]

As mentioned, the sock, socket, harness and control system, TD, and wrist unit are components common to all body-powered prostheses. The remaining body-powered prosthetic components—transradial hinges, elbow units, and shoulder units—maximize function at specific levels of amputation.

Transradial hinges.

A transradial prosthesis uses two hinges, one on each side of the elbow, that attach to the socket below the elbow and to a pad or cuff above the elbow. These hinges stabilize and align the transradial prosthesis on the residual limb. When properly aligned, the hinges help distribute the stress of the prosthesis on the limb.

Two hinge styles, flexible and rigid, are available for use with transradial amputations. Flexible hinges are used with amputations of the distal third of the forearm. They usually are made of Dacron and connect the socket to a triceps pad positioned over the triceps muscle. Their flexibility permits at least 50% of the anatomic residual forearm rotation, reducing the need to rotate the TD manually in the wrist.[33] Rigid hinges are used with amputations at or above the midforearm to protect the residual limb against torque load.[33] Rigid hinges usually are made of steel and are attached to a laminated Dacron biceps half-cuff positioned behind the arm, which is sturdier and provides more support than the triceps pad. They are now used less frequently, having largely been replaced by a design using a self-suspending socket, in which supercondylar flares mimic some of the function of the hinges and triceps pad. Team members consider the amount of residual function and the length of the limb when choosing the appropriate hinge style for the transradial prosthesis.[71]

Elbow units.

A prosthetic elbow unit is prescribed for the person who has had an amputation through the level of the elbow or higher. The elbow unit allows 5 to 135 degrees of elbow flexion and locks in various positions. The two main types of elbow units are internally and externally locking units. The more durable internally locking unit is prescribed for a person who has had an amputation 2 inches or more above the elbow. This unit connects the transhumeral socket to the prosthetic forearm. The locking mechanism is contained within the unit and attaches to a control cable. A lift assist, which consists of a tightly coiled spring attached to the elbow unit and forearm shell, helps reduce the amount of energy required to lift the forearm shell. The lift assist also allows a slight bounce in the forearm when the person is walking with the elbow unlocked, which enhances the appearance of a natural arm swing.

A friction-held turntable positioned on top of the elbow unit allows the prosthetic forearm to be rotated manually toward or away from the body. Lateral and medial aspects of a transhumeral prosthesis are shown in Fig. 43.11. The internally locking unit is 2 inches long and therefore not appropriate for an individual who has had an amputation proximal to the elbow.

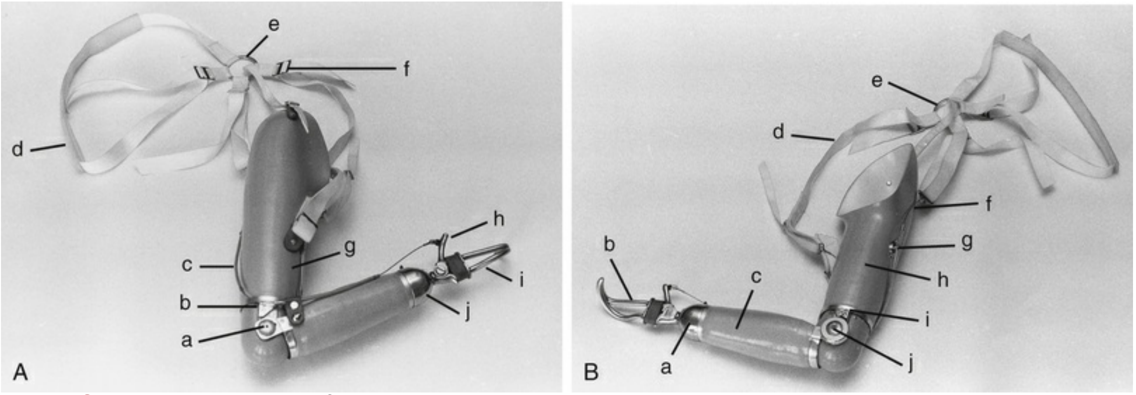

FIG 43.11 A, Lateral side of a transhumeral prosthesis: *a,* elbow unit; *b,* turntable; *c,* control cable; *d,* adjustable axilla loop; *e,* harness ring; *f,* figure-eight harness; *g,* elbow lock cable; *h,* terminal device (TD) thumb; *i,* hook TD; *j,* wrist flexion unit. B, Medial side of a transhumeral prosthesis: *a,* wrist unit; *b,* hook TD; *c,* forearm; *d,* harness; *e,* harness ring; *f,* control cable; *g,* baseplate and retainer; *h,* socket; *i,* turntable; *j,* spring-loading device.

The externally locking elbow unit is prescribed for a person who has an elbow disarticulation or an amputation within 2 inches above the elbow. This unit, which consists of a pair of hinges positioned on either side of the prosthesis, attaches the socket to the forearm. The cable attaches to one of the hinges, which locks and unlocks the unit.

Shoulder units.

With a high-level amputation, shoulder and back movements typically are not sufficient to allow use of a cable-operated shoulder unit. Therefore most shoulder units are manually operated and friction held. Two shoulder unit mechanisms that are often prescribed are the moveable friction-loaded shoulder unit and the locking shoulder unit. Shoulder units are classified by the degree of motion allowed in the prosthesis. A single-axis joint provides abduction; a double-axis joint provides positioning in abduction and flexion; and a triple axis and ball and socket joint allows for universal motion. A locking shoulder unit allows the prosthesis to be locked in various degrees of shoulder flexion. This shoulder unit allows for activities such as reaching for items in a cabinet or overhead.

With an interscapular thoracic amputation, all or a portion of the scapula and clavicle is removed with the arm. In these cases standard prosthetic components may make the prosthesis too heavy for practical use. An endoskeletal prosthesis, made from lightweight materials such as a single aluminum alloy surrounded by a soft foam shape, is often prescribed to decrease the weight. The system provides its own style of prosthetic joints, which will not withstand heavy-duty usage. An endoskeletal prosthesis with a lightweight cosmetic cover is commonly prescribed as a cosmetic prosthesis with limited functional value.

Electrically Powered Components

The two prosthetic components common to all powered prostheses are the terminal device and the wrist unit. (Elbow and shoulder units specific to each level of amputation are also discussed later.) Research and technological advances in myoelectric componentry are proceeding at a rapid pace. This section provides an overview of the components that are commercially available and readily used (Fig. 43.12).

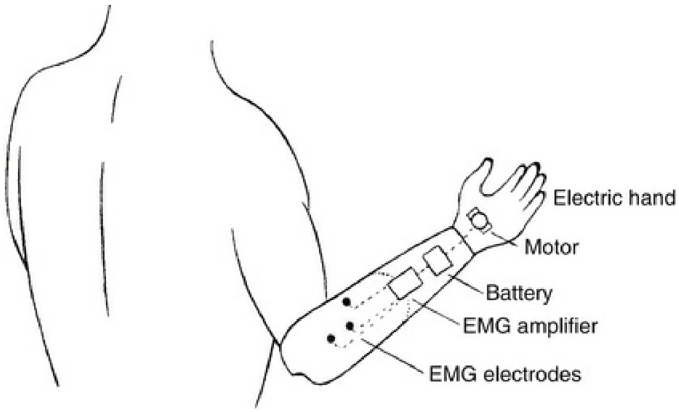

FIG 43.12 Typical electrically powered, myoelectrically controlled, transradial prosthesis with an electromechanical hand terminal device that is activated by electromyographic potentials. (From Billock JN: Upper limb prosthetic terminal devices: hands versus hooks, *Clin Prosthet Orthot* 10:59, 1986.)

Terminal devices.

Electrically powered terminal devices or prehensors are available in two speed systems: digital control and proportional control.[5] Digital control systems operate at a constant speed. In a proportional control system the myoelectric signal (power) to the hand is proportionate with the level of muscle signal the wearer generates; therefore the intensity of the muscle contraction directly controls the speed and pinch force of the hand.[5]

Myoelectric terminal devices come in two designs, the hook or the hand (Fig. 43.13). The electric hook has two "fingers" to provide precision pinch. Myoelectric TDs combine powered pinch force with a tip pinch for manipulation of small objects. The Electric Terminal Device (Motion Control) is designed with one nonmoving finger and a second, which opposes it. The System Electric Greifer (Ottobock) has two fingers, which move symmetrically together in opposition.

FIG 43.13 Examples of electrically powered prehensor terminal devices. *Left,* System Electric Hand (Ottobock). *Center,* Electric Terminal Device (Motion Control, Inc.). *Right,* System Electric Greifer (Ottobock).

The development of the electric hand has served to preserve the anthropomorphic nature of the human hand. The belief is that our environment is made up of objects designed to be handled by the human hand. Therefore, it would follow that a device designed with the same qualities as the human hand would offer the most function.[94] Electric hand terminal devices also provide an aesthetic quality and appeal. The cosmesis of a hand prehension mechanism has been shown to be a strong determinant for acceptance of the prosthesis.[13,18,69,74] One of the most commonly prescribed electric hands is the SensorHand Speed (Ottobock). This hand has a mechanism that drives the hand to open and close into a three-point prehension pinch. The motor also has a feature in the thumb that automatically increases pressure applied to an object being held if the device detects slippage.[70]

Advances in technology and myoelectric control have brought about the advent of multiarticulating prosthetic hands. Multiarticulating hands are defined by the multiple degrees of freedom they provide to assume a variety of grasp patterns. These TDs, which have powered articulating digits, offer prosthesis users increased functional grasp patterns that are unavailable with previous myoelectric hands designed with a single degree of freedom.[111] Individual motors in each digit drive the movement of the hand into a variety of preset pinch and grasp patterns. The two most common commercially available multiarticulating prosthetic hands are the bebionic 3 (RSL Steeper) and the i-limb ultra revolution (Touch Bionics). The bebionic 3 has 14 selectable grip patterns and hand positions, in addition to a manually positioned thumb.[9] The i-limb ultra revolution offers 24 preset grasp patterns and a powered thumb that switches between lateral pinch and opposition. This hand also offers the option for mobile app control.[47,48] Additional multiarticulating hand systems include the VINCENTevolution 2 (Vincent Systems) and the Michelangelo prosthetic hand (Ottobock). Product details are available from each manufacturer.

Multiarticulating hands provide the opportunity for advanced functionality combined with the natural appearance of the human hand. The prosthesis user can activate the preset grasp patterns by sending a signal associated with that selected grasp. For example, co-contraction, single impulse, or double impulse may trigger the hand to move into tip pinch or mouse grip. Education by the occupational therapist and prosthetist on the benefits and limitations of these advanced terminal devices should be provided to the client before a device is recommended and prescribed.

Wrist units.

Electric wrist rotators are used to provide an attachment point for the TD to the forearm. The rotator also provides the important function of forearm supination and pronation for prepositioning of the TD for functional use.[5,40] The rotator is not recommended for work that generates high torque[40]; it should be used only for TD orientation and prepositioning. Currently no electrically powered wrist flexion units are available. Wrist flexion is an important function for individuals who have undergone bilateral upper extremity amputation. It allows the user to reach midline for tasks such as dressing and eating. Manufacturers offer various options for wrist flexion units. For example, Motion Control's wrist flexion unit allows the wrist to be manually locked in three positions: 30 degrees of extension, neutral, and 30 degrees of flexion. Ottobock's System Electric Greifer wrist unit uses a friction joint for manual positioning of the wrist from +45 degrees to −45 degrees.[40] The need for wrist motion that replicates the requirements for prepositioning of the human hand will continue to drive development efforts with electrically controlled wrist units.[40]

Elbow units.

Electrically powered elbows reduce the need for the glenohumeral ROM or strength that typically is needed to operate body-powered prostheses.[68] Myoelectric elbows position the forearm and TD in space for activity performance. For manual humeral rotation a friction joint or turntable is used in addition to the elbow unit.[40] The functional advantage of a myoelectric elbow comes with the cost of increased weight. Locking of the elbow unit is performed in two ways: when the elbow is held for a stationary set of time or when a momentary switch is activated. Unlocking the elbow is controlled by the following: rapid contraction of the controlling muscle known as rate control, slow contraction of the controlling muscle known as threshold control, or by actuation of the momentary switch. When the elbow is locked in position, the myosites used to control the elbow are transmitted to control the TD.[40] Although advances have been made in the design and performance of electrically powered elbow units, functional performance still needs improvement.

Shoulder units.

Currently no electrically powered shoulder joints are commercially available. The LTI-Collier Locking Shoulder Joint (Liberating Technologies) can be fitted with an electric lock actuator. This locking shoulder joint has two degrees of freedom, flexion-extension and adduction-abduction. Manual operation of flexion-extension involves actuating a nudge control that disengages the lock on the joint, allowing it to swing freely. Releasing the nudge control engages the lock to hold the shoulder in a fixed degree of flexion. If the wearer cannot operate a manual nudge control, a myoelectrode or force-sensitive resistor can control the actuator.[40]

Prosthetic Training

Upper extremity **prosthetic training** begins after the final fitting of the prosthesis. The final fitting may be done with a preparatory prosthesis rather than a definitive prosthesis. The occupational therapy intervention is occupation based and includes purposeful activity and preparatory methods to facilitate therapeutic goals.

Evaluation of the Prosthesis

When the prosthesis is received, team members check to ensure that it meets the prescription's requirements, functions efficiently, and is mechanically sound. The prosthesis is checked for fit and function against specific mechanical standards developed from actual tests on prostheses worn by individuals. The tests performed are comparative ROM with the prosthesis on and off; control system function and efficiency; TD opening in various arm positions; amount of socket slippage on the residual limb under various degrees of load or tension; compression fit and comfort; and force required to flex the forearm or open/close the TD.[4,89,114] Ideally the prosthetist and the therapist coordinate fitting of the prosthesis and initiation of therapy. Communication among the client, therapist, and prosthetist is essential to ensure that the prosthesis fits and functions optimally.

Donning and Doffing the Prosthesis

Donning and doffing the full prosthetic system is a critical first step in training for the user. It is important for the client to be able to don and doff the prosthesis as independently as possible. The full prosthetic system includes the residual limb sock, prosthetic donning liner, prosthetic socket, and/or harnessing.[95]

The two most common methods of donning and doffing the body-powered prosthesis are the coat method and the pullover (or sweater) method. Either method can be used for unilateral or bilateral amputations. The method used depends on the client's choice and ease of use. The coat method is similar to placing one arm in a coat sleeve and manipulating the coat to a position where the other arm can reach the other sleeve. The residual limb is inserted into the socket while the harness and axilla loop dangle behind the back. The sound hand reaches around the back and slips into the axilla loop. The person then slips into the harness as if putting on a coat. The shoulders are shrugged to shift the harness forward and into the correct position. To remove the prosthesis, the person uses the TD to slip the axilla loop off the sound side and then slips the shoulder strap off the amputated side. The harness is slipped off like a coat.[4,89,114]

The person who has had bilateral amputations can use the coat method by placing the prostheses face up on a surface, placing the longer residual limb in the socket, and elevating the prosthesis, allowing the other prosthesis to hang across the back. The person then leans to the side and places the shorter limb in the prosthesis.[89,117] To remove the prosthesis, the person shrugs the harness off the shoulders and removes the prosthesis from the shorter side first. Before removing the prosthesis on the longer side, the person should position the prostheses somewhere convenient for the next donning.

For the pullover method the client positions the prosthesis face up, places the residual limb in the socket, and threads the opposite arm through the harness. The person then raises both arms above the head, allowing the axilla loop to slide down to the axilla and the harness to be properly positioned across the back and on the shoulders (Fig. 43.14). To remove the prosthesis the person raises both arms above the head and grasps and removes the prosthesis with the sound arm while allowing the axilla loop to slide off the arm.[89]

FIG 43.14 A and B, Pullover (or sweater) method for donning a transradial body-powered prosthesis.

A person who has had bilateral amputations dons the prostheses using the pullover method by placing the prostheses on a surface, face up. With the longer limb stabilizing the socket, the shorter residual limb is positioned under the harness and in the socket. The longer limb is positioned similarly under the harness in the socket, and the arms are raised, allowing the harness to flip over the head and across the back and shoulders. The person removes the prostheses by shrugging the shoulders to bring the harness up, grasping it with one TD, and pulling it over the head while allowing the residual limbs to come out of their sockets.

In the case of donning an electrically powered prosthesis, the client may use a pull sock to facilitate an intimate interface between the skin and socket. For this method a pull sock is placed over the residual limb, and a weighted cord from the pull sock is guided through a hole in the bottom of the socket. The client then pulls the sock off the arm and through the hole in the socket, creating optimal contact with the surface electrodes. Daniel preferred the pull sock method to don and doff his prosthesis because it provided a tight fit and good suction in his myoelectric socket.

Donning of the prosthesis should be performed with the electronic components in the OFF position to prevent any uncontrolled movements. Applying a silicone-based skin lotion to the skin before donning the pull sock enables the person to remove the pull sock with less effort. It may be necessary to experiment with different sock materials, powder on the skin, and various donning techniques until the most successful materials and techniques are identified. Good electrical contact is achieved after approximately 1 minute of donning. A wearer can moisten the skin at the electrode sites to eliminate the waiting period for skin warmth to occur. The prosthetic arm should be stored in the OFF position with the batteries removed. The hand should be fully opened when stored to keep the thumb web space stretched.

Wearing Schedule

A wearing schedule for the prosthesis is established and reviewed during the first training session. The client increases the wearing time gradually to develop a tolerance and decrease the likelihood of skin breakdown. The prosthesis initially is worn 15 to 30 minutes three times a day. Each time the prosthesis is removed, the skin must be inspected for redness or irritation. The skin must be closely monitored, and the wearing time is increased only if the skin remains in good condition. If no skin problems develop, the three scheduled wearing periods may be increased by 30-minute increments until the prosthesis can be worn all day. If skin problems occur, the therapist, prosthetist, or physician must be notified, and the prosthesis should not be worn until the problem has cleared. Restarting the initial wearing schedule may be necessary to decrease the risk of additional skin problems.[6]

Residual Limb Hygiene

The client is instructed in residual limb hygiene in the early phase of prosthetic training.

Perspiration is common when a prosthesis is worn because the residual limb is enclosed in a rigid socket. Excessive perspiration can cause irritation or maceration of the skin; therefore, it is important to teach the client to inspect the skin of the residual limb, each time the prosthesis is removed, to look for areas of redness or breakdown. The client is also instructed to wash the residual limb daily with mild soap and water and to pat it dry. To minimize sweating, education is provided to the client in the application of antiperspirants, socks, or liners which will not compromise the fit of the prosthesis or interfere with myoelectric surface electrodes.

Operational Prosthetic Knowledge

The wearer should learn and demonstrate knowledge of the terminology and function of each prosthetic component. A basic knowledge of the following terminology is recommended: socket and harness design and use; types of control systems; and basic mechanics of the prosthesis. This allows the client to communicate with the rehabilitation team, using terminology understood by all, about the operation of the prosthesis and any difficulties with or repairs needed for the device.[6,114,117]

Care of the Prosthesis

Instructions regarding care of the prosthesis are provided and reviewed. Generally the prosthetist educates the person in this area, and the therapist reviews and reinforces the information with the wearer. The socket should be cleaned daily with mild soap and water, or weekly with rubbing alcohol. Cleaning at night is recommended to allow the prosthesis to dry completely. Wearing the prosthesis when the socket is wet may lead to skin problems. The components should be cleaned and maintained according to the manufacturer's specifications. Daily inspection of the prosthesis helps prevent problems.[6] The client should be proficient in basic maintenance procedures, including daily socket cleaning and inspection; battery charging procedures for the prosthesis; component maintenance; harness adjustment; and cable system changes and rubber band replacement.[70,95] It is the role of the occupational therapist to ensure that the client is trained and independent in the maintenance and care of the prosthesis.

Intermediate Prosthetic Training

Controls Training

Therapy progresses through two phases of training: (1) prosthetic controls training and (2) use training. The goal of prosthetic controls training is to achieve smooth movement of the prosthesis with minimal delay or awkward movements with task performance.[6] Functional use training is designed to apply the skills learned during controls training and apply them to functional use of the prosthesis. Acquiring skill in the operation of the prosthesis is emphasized in controls training. The therapist educates the wearer on the importance of the practice drills that will ensure more successful function with the prosthesis in daily activities. Joint protection, energy conservation, and work simplification principles and techniques should be stressed during this phase of training. Each prosthetic component should be reviewed separately and understood before the components are combined into functional activities.

Body-Powered Prosthesis

Controls training for a body-powered prosthesis begins with the operation of each component, starting with the TD. For a transradial prosthesis there is a single control system to activate the TD. Scapula abduction and glenohumeral flexion are the motions used to open and close the TD. The client is instructed to activate the TD with the arm in various positions in space, such as overhead and leaning over toward the floor.[117] The client is instructed in how to exchange the TD if more than one is prescribed. To complete controls training with a transradial prosthesis, the client demonstrates the motions required to position and operate the TD until they are performed in one continuous, smooth, and natural sequence in both sitting and standing positions.[114]

Transhumeral prostheses operate through the use of a dual-control cable system. When tension is applied on the cable attached to the elbow unit, the unit locks and unlocks. The motions necessary to lock and unlock the elbow are a combination of scapular depression, humeral extension, and abduction. This movement places tension on the cable that attaches the harness to the elbow unit. The reminder “down, out, and away” may be repeated until the client develops a proprioceptive memory. The client is then asked to practice locking and unlocking the elbow in various ranges of elbow flexion and extension.[4,6,117] The client may also learn to operate the turntable that manually rotates the arm medially and laterally, allowing for internal and external rotation. The same motions of shoulder flexion and scapula abduction that flex the forearm with the elbow unlocked control the TD when the elbow is locked. The person is instructed to lock the elbow, first at 90 degrees, and to perform the motions to operate the TD. The sequence of elbow positioning, elbow locking, TD operation, elbow unlocking, elbow repositioning, and locking is repeated at various points in elbow ROM from full extension to full flexion.[4,117]

A prosthesis used for a shoulder disarticulation may have a manually operated, friction-held shoulder unit that the client pre-positions using the sound arm. A chin-operated nudge control may be used to operate the elbow unit if the client does not have the shoulder movements necessary to lock and unlock the elbow. The client still is instructed in the dual-control cable system of operation, as described for a transhumeral prosthesis. For clients with higher levels of amputation, such as shoulder disarticulation, chest expansion is used to assist with TD operation.

The progression of controls training for body-powered prostheses at each level of upper limb amputation is described in Fig. 43.15.

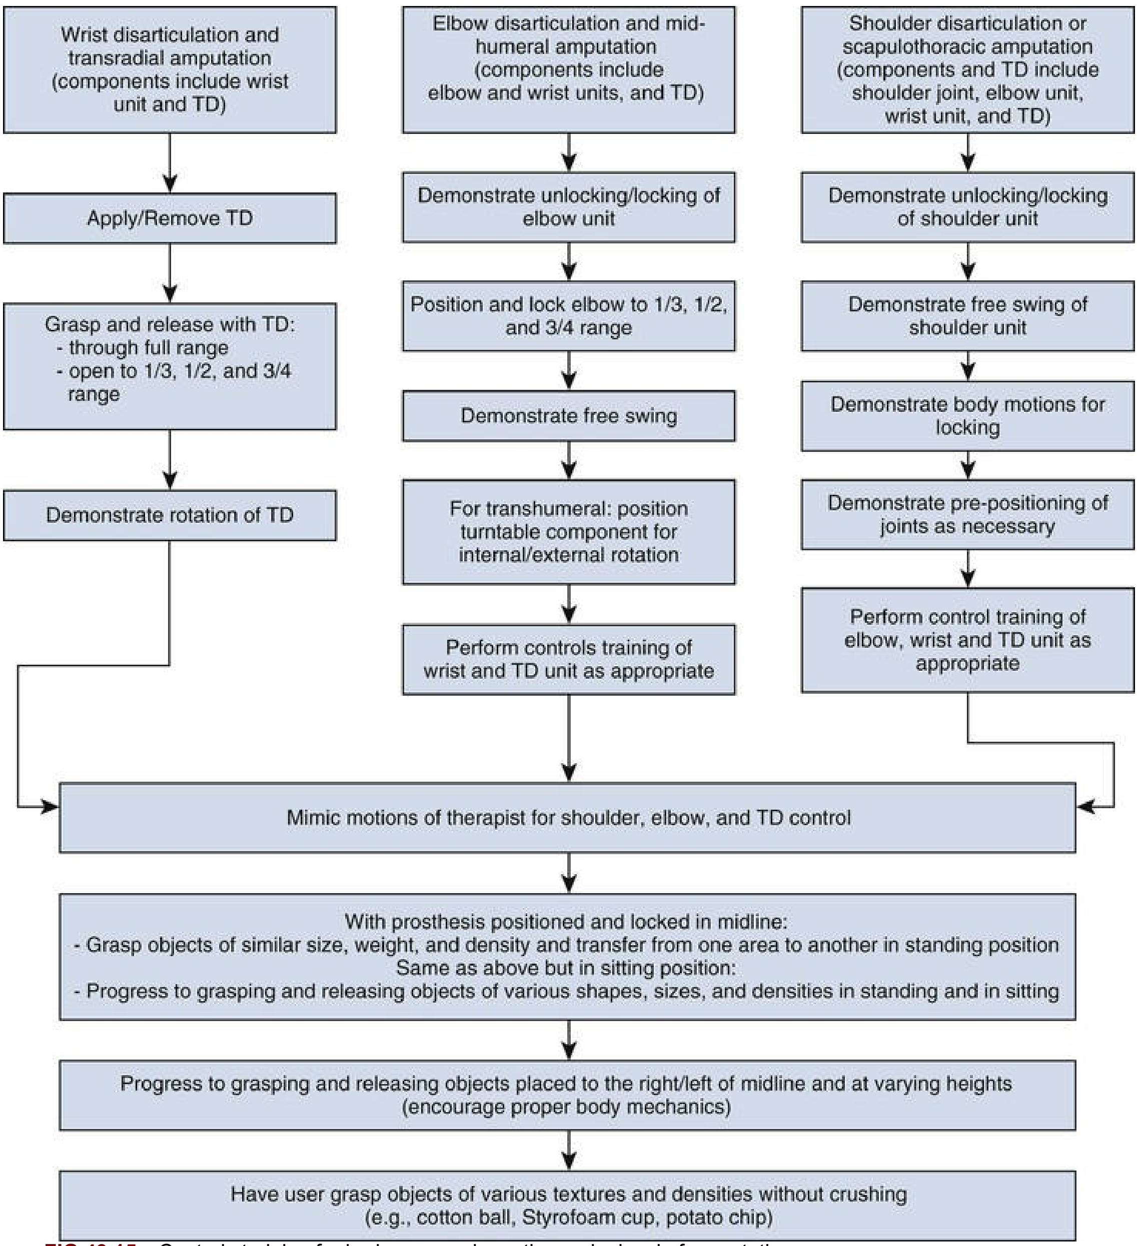

FIG 43.15 Controls training for body-powered prostheses by level of amputation. (From Smurr LM, Yancosek K,

Gulick K, et al: Occupational therapy for the polytrauma casualty with limb loss. In Pasquina PF, Cooper RA, editors: *Care of the combat amputee,* Washington, DC, 2009, Department of the Army, the Borden Institute.)

Electrically Powered Prosthesis

Each myoelectric prosthesis has a unique control system based on the manufactured componentry and/or the person's musculoskeletal integrity. Typically a two-site system is used, in which two separate muscle groups operate the TD. For transradial prostheses, wrist flexors and extensors are commonly used to open and close the TD; the biceps and triceps are often used with a transhumeral prosthesis. With higher level amputations (e.g., shoulder disarticulation), the muscles used for control are typically the pectoralis or infraspinatus.

Controls training typically begins with opening and closing of the TD. Simple opening and closing of the terminal device is practiced in various arm positions to ensure that the electrodes maintain contact with the skin in each position. Next, the client practices opening the TD through one-third, one-half, and three-fourths of range. If a proportional control system is used, the client may also practice opening and closing quickly and slowly. Daniel demonstrated difficulty with proportional control initially during training. To offer more practice, the therapist often will design a home program of specific patterns of terminal device action that the person performs. Control of the TD improves in accuracy and speed with practice and use throughout the other phases of training. The progression of controls training for myoelectric prostheses at each level of upper limb amputation is described in Fig. 43.16.

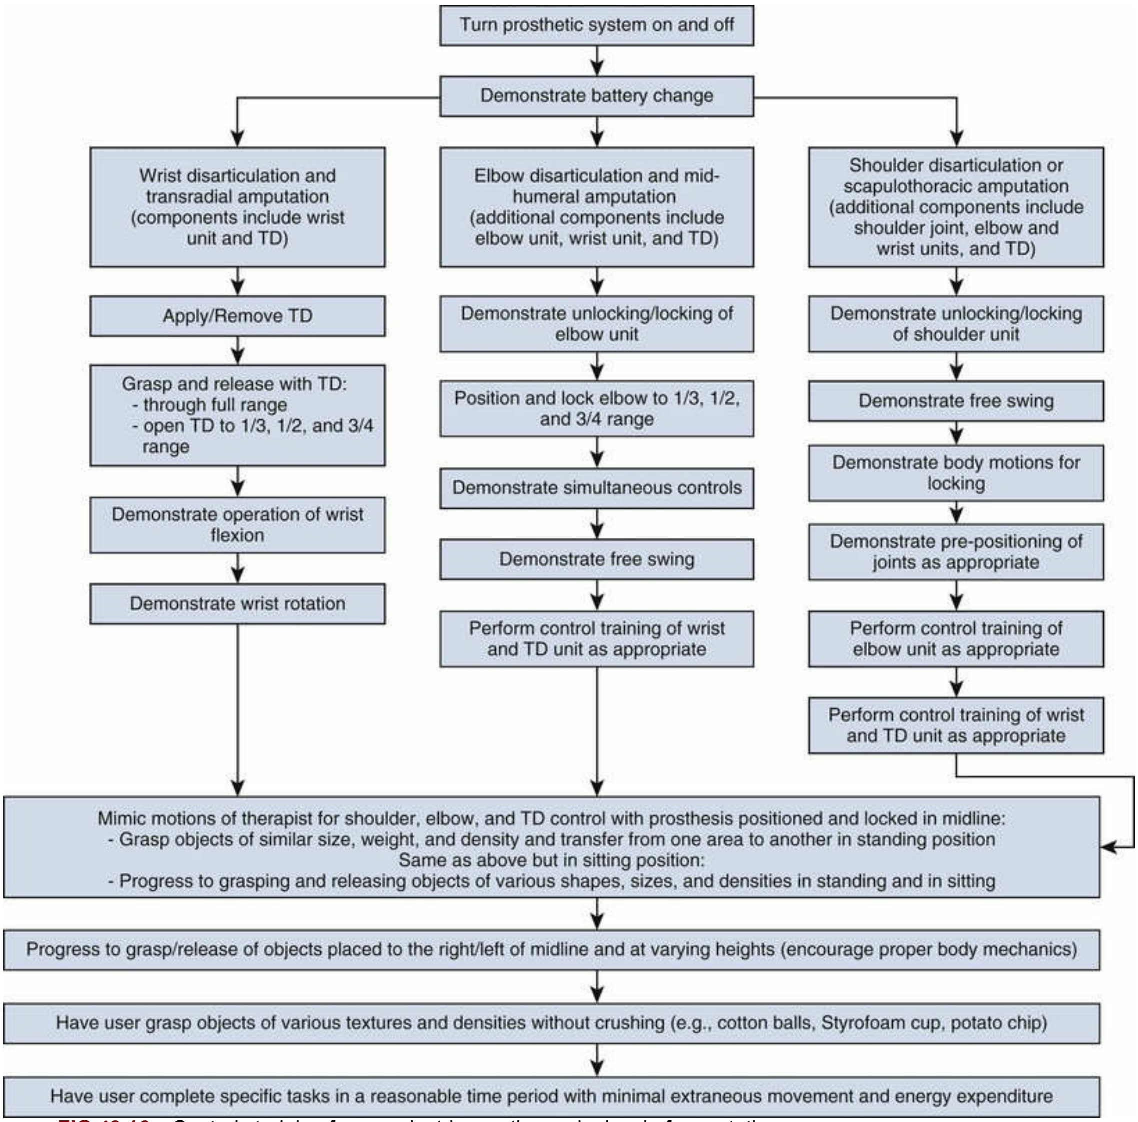

FIG 43.16 Controls training for myoelectric prostheses by level of amputation. (From Smurr LM, Yancosek K, Gulick K, et al: Occupational therapy for the polytrauma casualty with limb loss. In Pasquina PF, Cooper RA, editors: *Care of the combat amputee,* Washington, DC, 2009, Department of the Army, the Borden Institute.)

Use Training

Once the client understands how to operate and control the prosthetic components, he or she can begin to apply the mechanics of operation to activities. Instruction on pre-positioning the prosthesis is important because this involves moving the prosthetic units in their optimal position to grasp an object or perform a given activity in the most efficient manner, thereby avoiding awkward body movements used to compensate for poor pre-positioning.[89] The client is instructed in control drills in patterns of reach, grasp, and release of objects of various sizes, weights, densities, and shapes. The sequence (and progression) typically is from large, hard objects to smaller, softer ones. These objects should be placed in positions that require elbow and TD pre-positioning and TD operation both for prehension practice at tabletop or at various heights around the room. Working on reach, grasp, and release in multiple arm positions then follows. The client will attempt to grasp objects at counter height, at table height, overhead, on the floor, at cupboard height, alongside the body, and behind the body. This area of space in which the client can operate the prosthesis is referred to as the functional envelope.

Another goal of use training is mastering pressure control, or the gripping force of the TD. Particularly with myoelectric control, this skill involves close visual attention to appropriately grade the muscle contraction for a specific result in the TD. The client must learn how to pick up the object without applying too much force and crushing it. Good grasp control through training with foam, cotton balls, or wet sponges will help the client develop the control necessary to handle paper cups, vegetables, boxes, lotion bottles, and sandwiches, or even to hold someone's hand.[101]

The client with a transhumeral amputation who uses a body-powered or myoelectric elbow should ensure that the position of the terminal hand and the angle of elbow flexion are appropriate to complete the grasp in a natural manner. Often the client automatically adjusts the body using compensatory body motions (e.g., bending forward rather than adjusting the elbow position or prepositioning the hand). It is important to discourage this adjustment because it looks unnatural, becomes habitual, and may lead to secondary musculoskeletal problems in the neck, shoulder, or trunk. The ability to perform specific movements will eventually take less conscious effort, and movements will become automatic.

The wearer now has increased muscle endurance and prosthetic tolerance. Next, functional activities are introduced into the therapy program.

Advanced Prosthetic Training

Functional Training

Functional training applies the concepts of control and use of the prosthesis for completion of functional and meaningful activities. The goal is to perform functional tasks with automatic, spontaneous, smooth movements. Five characteristics of advanced prosthetic training can help guide therapy. First, a person's rehabilitation is individualized, and each client has a unique set of goals. Second, the client uses tools or interacts with an object such as a cooking utensil or a piece of sports equipment (Fig. 43.17). The third characteristic of advanced prosthetic training is that it involves complex, multistep tasks that are typically bimanual in nature (Fig. 43.18). The fourth characteristic is that the training involves the prosthesis of choice for the client. Training should focus on advancing and refining the control of the preferred prosthesis for functional use. The final characteristic is that the training and activity selection are meaningful to the client.[95] The key to successful functional training is to teach the client problem-solving techniques and ways to analyze each activity with respect to the environment in which it is performed. The client recognizes the altered environment and learns to successfully complete activities within it.

FIG 43.17 Example of functional training: interacting with an object such as a cooking utensil.

FIG 43.18 Individual with bilateral upper limb loss removing credit cards from a wallet. This is an example of a multistep, bimanual task that is taught during advanced prosthetic training.

Although there is no specific technique to accomplish most tasks, the therapist will offer guidance to enable completion of activities in an efficient way. A client with a unilateral amputation quickly learns to perform activities with one hand. Therefore when incorporating a prosthesis into bimanual tasks, the prosthesis is primarily used for stabilization or support.[114] Table 43.1 offers suggestions for ways some activities can be accomplished with a prosthesis.[120]

TABLE 43.1

Roles of Prosthetic Terminal Device and Sound Hand in Bilateral Activities of Daily Living

Activity	Prosthetic Terminal Device	Sound Hand
Cutting meat	Hold the fork with prongs facing downward; hold the knife as grip strength increases.	Hold knife. Hold fork.
Opening a jar	Hold the jar.	Turn the lid.
Opening a tube of toothpaste	Hold the tube.	Turn the cap.
Stirring something in a bowl	Hold the bowl with a strong grip.	Hold the mixing spoon or fork.
Cutting fruit or vegetables	Hold the fruit or vegetable firmly.	Hold the knife to cut.
Using scissors to cut paper	Hold the paper to be cut.	Use scissors in normal fashion.
Buckling a belt	Hold buckle end of belt to keep it stable.	Manipulate long end of belt into buckle.
Zipping a jacket from the bottom up	Hold anchor tab.	Manipulate pull tab at base, and pull upward.
Applying socks	Hold one side of sock.	Hold other side of sock, and pull upward.
Opening an umbrella	Hold base knob of umbrella.	Open as normal.

During advanced prosthetic training, therapy will focus on incorporation of the prosthesis into ADL and IADL performance. Practice in handwriting and activities requiring dexterity and fine motor coordination may be useful in this phase of the training process.[77,98,114] A rating guide developed by Atkins, the Unilateral Upper Extremity Amputation: Activities of Daily Living Assessment, provides a comprehensive checklist of functional activities that can be used as a reference to show progression with advanced prosthetic training (Fig. 43.19).[6] Vocational and recreational activities, including driving, community reintegration, and adaptive sports are introduced during this phase. The occupational therapist should bring the client into the actual environment, when possible, to encourage realistic, deliberate training with the prosthesis (Fig. 43.20). By the end of this phase of training, the client will have learned to perform functional tasks and meaningful occupations in the most efficient way. This would result in saved energy for the body and decreased biomechanical stress on the sound limb.[95]

FIG 43.20 Instrumental activities of daily living. A, Individual with bilateral upper limb amputation and bilateral lower limb amputation grasps a plastic bag for produce while grocery shopping. B, Father dresses his son using a body-powered prosthesis. C, Individual putting gas in a car using bilateral upper limb prostheses. D, Individual uses a myoelectric prosthesis to push a grocery cart while sipping a cup of coffee.

Adaptive Sports and Recreation

Adaptive sports and recreational activities are an important part of rehabilitation after limb loss. Various levels of recreational activity and adaptive sports options are available, from low to high intensity, and a number of activity-specific and customized prostheses are available to facilitate participation in these activities (Fig. 43.21). It is the role of the occupational therapist and interdisciplinary clinical team to encourage participation in adaptive sports and to train the client in the use of activity-specific prostheses. Modifications can be made to all types of sporting and recreational equipment. Additionally, a number of nonprofit organizations have been established to support individuals with amputations in their participation in adaptive sports and recreation. Participation in adaptive sports has been shown to promote social and psychological health and also helps individuals with a disability focus on their abilities rather than their functional limitations.[93,115] Studies have shown that adaptive sports participation for persons with disabilities improves overall quality of life and satisfaction across physical, social, and psychological domains.[119] The interdisciplinary team of health care providers should educate the client on the benefits of participation in adaptive sports and recreation, assist with modifications to equipment, and provide information on available resources to support reintegration into meaningful activities.

OT Practice Notes

Encourage the client to try a new sport or activity that may be outside his or her comfort zone. Reinforce the positive idea of finding a “new norm” in the context of occupational performance after amputation.

FIG 43.21 A, Mountain biking using an activity-specific terminal device. B, Individual with multiple limb loss rock climbing using activity-specific terminal devices.

Driver Training

The ability to drive is a valued occupation in today's society. For many clients, returning to driving after amputation is a primary goal. Driving is a complex process, involving an individual's physical, cognitive, visual, and behavioral abilities. The occupational therapist will make a referral for a comprehensive driving evaluation when appropriate. A driving rehabilitation specialist will do a clinical assessment and will make recommendations for adaptive equipment or vehicle modifications. The driving rehabilitation specialist may also provide behind the wheel training with the client as necessary. Modifications can be made to improve safety and comfort. For example, a person with a unilateral upper extremity amputation can have a spinner knob or driving ring installed (Fig. 43.22). Clients are always encouraged to contact their state's Department of Motor Vehicles or driver's licensing agency to determine whether any driving restrictions apply to persons with amputations.

FIG 43.22 Individual with left upper extremity amputation and bilateral lower extremity amputations uses hand controls and spinner knob for driving.

Considerations for Bilateral Amputations

In the case of bilateral amputations, adaptive equipment should be introduced as soon as possible to increase the client's level of independence. The equipment may include a universal cuff secured by elastic or Velcro to the residual limb to aid in eating, writing, and hygiene; a dressing tree with hooks to hold articles of clothing in a position conducive to donning them, to improve dressing independence; and loops added to items such as socks and towels. Individuals with bilateral amputations can learn to complete activities using foot skills, such as holding items between the toes in a functional pinch for dressing, eating, and reaching items. The therapist can also encourage the use of the chin, knees, and teeth for activity performance.[26] The therapist and client will problem-solve and analyze activities together, with emphasis placed on how to maximize the individual's environment to accomplish a particular task.

The use of an immediate or early postoperative prosthesis (IPOP or EPOP, respectively), is strongly recommended in bilateral upper extremity amputations.[107] Fitting an individual with an early temporary prosthesis not only promotes immediate participation and independence in ADLs, but also may facilitate acceptance and use of the permanent prosthesis.[29,56]

Bilateral upper extremity amputations present unique challenges for prosthetic selection, fitting, and training. A person with bilateral upper extremity amputations commonly is fitted with a combination of systems (Fig. 43.23). For example, an individual may be fitted with a body-powered system for one side and a myoelectric system for the other. It is important to include the client in this decision-making process and to include his or her goals when discussing prosthesis selection with the rehabilitation team. The progression and phases of training for bilateral upper extremity amputations are the same as for unilateral amputation. Techniques for donning and doffing, componentry, and controls training vary slightly to accommodate variations in the designs of the two prosthetic systems. Refer to donning and doffing techniques for bilateral upper extremity amputations presented earlier in this chapter under Prosthetic Training.

FIG 43.23 Individual with bilateral upper limb loss using a combination of prosthetic systems. On the right side he is using a transhumeral body-powered system with an activity-specific terminal device. On the left side he is using a transradial myoelectric system with an electric hook.

A client with bilateral amputations typically receives two prostheses that are attached to one harness. Operating one of the prostheses may transmit tension through the harness to the other prosthesis, causing it to operate. The client must learn to operate each prosthetic component without affecting the components on either side. This skill is called **separation of controls**, and the client may need extensive practice to master it. Each prosthesis operates according to the level of amputation, as described in the previous sections.

Outcome Measures

Outcome measures for upper limb amputations are used to assess progress and analyze the effectiveness of a prosthetic device.[85,118] Evaluation of upper extremity prosthetic use presents a unique challenge because only a limited number of measures have been validated for adults.[85] Traditional dexterity assessments, such as the 9-Hole Peg Test and the Purdue Pegboard, provide occupational therapists with a measure of progress in performance over time but are not validated as true determinants of the effectiveness of prosthetic use. Efforts continue in the development of outcome measures for prosthetic use through the Upper Limb Prosthetic Outcomes Measures (ULPOM) Working Group, whose goal is to develop a toolkit of validated outcome measures for upper limb amputees.[44,85]

For the purpose of this chapter, five assessments that have been recommended for use will be discussed. The Assessment of Capacity for Myoelectric Control (ACMC) is a measurement of an electrically controlled prosthesis in the performance of bimanual tasks. The assessment evaluates performance with the prosthesis in the areas of gripping, holding, releasing, and bimanual manipulation.[42,43] The Trinity Amputation and Prosthesis Experience Scales–Revised (TAPES-R) is a self-report measure that evaluates psychosocial adjustment, activity restriction, and satisfaction with the prosthetic device.[34] The Southampton Hand Assessment Procedure (SHAP) examines upper limb prosthetic use during manipulation of 8 objects and 14 ADL tasks (Fig. 43.24).[61] The Orthotics and Prosthetics User Survey (OPUS) is a self-report instrument that assesses for functional status, quality of life, and client satisfaction with the prosthetic devices and services. The survey is used to examine both upper and lower extremity function.[41] The final outcome measure that will be addressed is the Activities Measure for Upper Limb Amputees (AM-ULA); this is an observational measure of activity performance for adults with upper limb amputation that evaluates task completion, speed, movement quality, skillfulness of prosthetic use, and independence.[85]

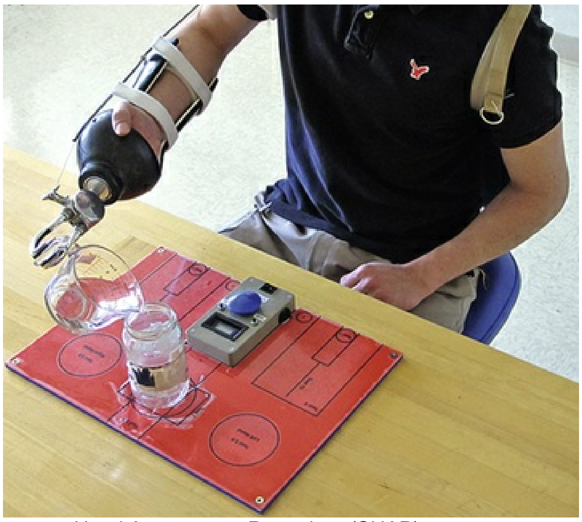

FIG 43.24 Southampton Hand Assessment Procedure (SHAP). (From Berning K, Cohick S, Johnson R, et al: Comparison of body-powered voluntary opening and voluntary closing prehensor for activities of daily life, *J Rehabil Res Dev* 51:253–261, 2014.)

Work is still needed in the development of normative data and outcome measures for upper extremity prosthetic use. Continued development of standardized assessments for this population would serve to identify standards of performance and provide an evidence base for intervention and practice.[16]

Current Research and Emerging Technologies

Research in the field of upper limb prosthetics continues to grow, thanks in part to the program

Revolutionizing Upper Extremity Prosthetics, which was established by the Defense Advanced Research Project Agency (DARPA), an agency of the U.S. Department of Defense.[22] The goal of the project is to improve upper extremity prosthetic function and "to create a fully functional (motor and sensory) upper limb that responds to direct neural control, within this decade."[22] As a result of this program and collaborations with various institutions, a number of advances have been made in signal control schemes, socket design, and prosthetic componentry.

Targeted muscle reinnervation (TMR) is a surgical technique used to increase the number of myosites (control signals) available for use, thereby increasing the potential for improved prosthetic function. This procedure maximizes the function of the intact residual nerves by transferring them to unused muscle in the residual limb. The goal is reinnervation of the "target" muscle so that the myosites physiologically correlate with the prosthetic movements.[53,102] TMR has also elicited a targeted sensory reinnervation response in which sensory nerves from the residual limb can be directed to the chest, resulting in perceived touch of the phantom limb. Targeted sensory reinnervation can provide sensory feedback while a prosthesis is used for enhanced control.[54] TMR has also been shown to have a promising effect in pain and neuroma management.[55]

Pattern recognition, a new development in myoelectric control, offers individuals with upper limb loss a natural, intuitive method of control with a myoelectric prosthesis.[80] Instead of the typical two-site control scheme, pattern recognition uses multiple electrodes to control several degrees of freedom for more complex movement. Various numbers and configurations of electrodes are used, based on the level of amputation and whether TMR surgery has been performed, which requires precise electrode placement. The goal of pattern recognition is to increase the overall picture of muscle activity in the residual limb by allowing the prosthetic user to perform a large number of movements with the prosthesis by simply reproducing the intuitive movements of the amputated limb.[39,53,80,90,92]

OT Practice Notes

An occupational therapy protocol for clients who have undergone TMR has been developed and should be used throughout their rehabilitation.

Currently surface electrodes only provide up to four channels of control in the forearm for myoelectric prostheses. A new control scheme is being researched that uses implantable myoelectric sensors (IMES), which are surgically implanted into various muscles in the residual limb. The goal is to improve the accuracy of signal reception, provide intuitive control, and enhance simultaneous control of multiple degrees of freedom of the prosthetic hand.[113]

Osseointegration is a surgical procedure in which an implanted device is fixed to the bone of the residual limb. A component of the implant protrudes from the skin and anchors the prosthesis directly to the residual limb, eliminating the need for suspension.[38] Osseointegration has been performed in Sweden and was recently approved by the U.S. Food and Drug Administration (FDA) for a feasibility trial in the United States at the University of Utah, under the auspices of the Utah Amputation Research Team (UART).[87] The procedure was developed as an alternative for individuals who cannot use a conventional prosthetic socket because of skin breakdown, residual limb length, shape and volume fluctuation of the residual limb, or poor maintenance of suspension as a result of perspiration.

The DEKA arm system was developed by DEKA Integrated Solutions Corp. (Manchester, New Hampshire) and funded by DARPA's Revolutionizing Prosthetics Program.[11,103,108] The prosthesis is controlled by a combination of mechanisms, including EMG signals, switches, and movement sensors. The movement sensor uses inertial measurement units (IMUs) attached to the user's shoe. The position of the foot operates the terminal device.[86] This prosthesis provides the individual with the ability to use multiple, simultaneous movements; in addition, it has up to 18 degrees of freedom, 10 of which are powered.

The Johns Hopkins Applied Physics Laboratory (APL), in collaboration with DARPA, has developed a prosthesis with 26 degrees of freedom, known as the Modular Prosthetic Limb (MPL). The prosthesis has 17 motors and contains more than 100 sensors, which provide a neural interface for intuitive and natural closed loop control.[51] The goal of this prosthesis is to replicate the human hand as closely as possible in terms of performance in a variety of metrics, including strength, dexterity, form factor, weight, and tactile feedback.[15]

An emerging practice in the area of upper extremity restoration is vascularized composite allotransplantation (VCA), also known as composite tissue allotransplantation (CTA). VCA is defined as "transplantation of multiple tissues such as muscle, bone, nerve and skin, as a functional unit (e.g., a hand or face) from a deceased donor to a recipient with a severe injury."[3] Hand transplantations are performed with the aim of achieving improved functionality, cosmesis, and psychological recovery, compared to prostheses.[27] Although this is a feasible therapeutic option, the risks of this surgical procedure must also be considered. Hand transplantation carries a risk of rejection, necessitates the lifetime use of immunosuppressive therapies, and requires dedicated time in intensive rehabilitative therapies.[25,27] As of June 1, 2011, 46 clients have received 66 hand transplants worldwide.[3]

Section 2 Summary

The rehabilitation process for individuals with upper limb loss can be challenging and rewarding. In the case of upper extremity prosthetic training, expertise on the part of the therapist and interdisciplinary rehabilitation team is essential. Occupational therapists play a vital role in the rehabilitation process by addressing residual limb management and care, in addition to preprosthetic and prosthetic training. Desired outcomes of occupational therapy include a positive self-image after limb loss, independent management of ADLs; and resumption of work, social, and leisure roles that support the client's health and occupational performance.

Careful assessment of the client's needs, a creative approach to therapeutic intervention, an emphasis on problem solving, and close communication with the rehabilitation team can make the challenge rewarding and the outcome successful.

Threaded Case Study

Daniel, Part 2

After the initial evaluation, regular occupational therapy treatment sessions were initiated on an outclient basis. Daniel was educated on the use of adaptive equipment, such as a rocker knife and buttonhook, and one-handed techniques to perform basic ADLs. He was a quick learner and adapted well to his loss, physically and psychologically. His family members were present throughout each treatment session and were active participants in his rehabilitation. His fiancée encouraged him to maximize his functional independence. The social support network that he had was critical in his rehabilitation success.

The occupational therapist educated Daniel and his family on the various prosthetic options available, and the advantages and disadvantages of each prosthetic system. Preprosthetic training was initiated while Daniel was still in the perioperative phase and sutures were intact. His residual limb was tested for possible myosites to use to control a myoelectric prosthesis. The occupational therapist, along with the prosthetist, was able to identify strong myosites for the flexors and extensors in the forearm. Preprosthetic controls training began with the use of a myotester and simulator. Daniel was educated in strengthening the muscles in his residual limb and performing isolated contractions for increased control. Daniel had good muscle tone and strength in his residual limb but had difficulty isolating the muscle contractions that control the terminal device. With practice and repetitive training and cueing, Daniel was able to accurately control the signals for hand open/close and wrist rotation on the myosimulator.

Once the sutures were removed, Daniel was casted and fitted with his initial myoelectric prosthesis. Because Daniel's arm was amputated through the forearm (transradial), he was fitted with a two-site myoelectric control system with a wrist rotator, a wrist flexion unit, and an electric hand terminal device. Daniel used the pull sock method to don his prosthesis to ensure a tight prosthetic fit and good skin contact with the surface electrodes. The names and operations of all of the component parts of the prosthesis were reviewed. Daniel's mechanical history of working on cars helped him to quickly learn and understand the operations of the prosthesis.

The next phase of therapy for Daniel was controls training with the prosthesis. This included practice in open/close of the terminal device in various arm positions, wrist rotation in both supination and pronation, and pre-positioning of the terminal device in various degrees of wrist flexion and extension. Training in grasp and release of objects of various sizes, shapes, and densities was completed with good performance. Daniel had difficulty performing proportional control during training but was able to improve with continued practice.

Once Daniel had mastered the basics of controls training, ADL training was initiated. This included tasks such as cutting food, buttoning a shirt, using a computer, and manipulating a wallet and credit cards. Daniel was encouraged to use his prosthesis as a stabilizer and functional assist during bimanual tasks. IADL training specific to Daniel's vocational and recreational interests included weapon manipulation, working on cars, woodworking, and driving.

One of Daniel's goals for occupational therapy was to continue to participate in the various sports that he loved, such as mountain biking and motocross. To maximize his functional independence in adaptive sports, Daniel was prescribed an activity-specific prosthesis. The activity-specific prosthesis had a quick disconnect wrist unit to allow easy interchange of terminal devices. Daniel brought his mountain bike into the clinic during therapy, and the occupational therapist and prosthetist educated him on the various sport-specific terminal devices available for this activity. Daniel's understanding and use of the terminal device was assessed in the clinic to ensure his safety with this high-level activity.

Throughout his time in occupational therapy, Daniel was able to reach his goals of functional independence with ADL and IADL performance with a prosthesis. During his rehabilitation Daniel reevaluated his goals for his career. He reported that he would always identify as a solider, but realized that he had the opportunity to pursue other occupational roles and opportunities through participation in adaptive sports. Daniel was connected with a nonprofit organization during his rehabilitation that specialized in motocross sports for disabled veterans. Through this peer mentorship and participation in various adaptive sports activities during his rehabilitation, Daniel was able to pursue his dream and began competitively racing in motocross events around the country. He medically retired from the army, married his high school sweetheart, and moved back to California to begin life after the military.

Section 3 Lower Limb Amputations

Jennifer S. Glover, Chelsey L. Cook

Threaded Case Study

Lena, Part 1

Lena is a 72-year-old woman who lives by herself in a one-story house near downtown. She was widowed 5 years ago and has two adult children who also live in town. Lena has adult-onset diabetes and chronic obstructive pulmonary disease (COPD). She worked part-time as a clerk at a department store until her 50s, when she retired because she could no longer stand comfortably for long periods of time. After retirement Lena would drive for shopping and appointments and would walk the short distance to church. The circulation in Lena's legs got progressively worse over the years, and she began to spend increasing amounts of time at home. Lena's day usually involved watching television, bird watching through the window, and occasionally painting ceramic figurines.

At age 62 Lena stubbed the toe on her left foot, cutting the toe. The circulation in her foot was not sufficient for it to heal, and the toe was amputated. She had another toe amputated 2 years later, and 2 weeks ago she had a below-knee amputation (transtibial) of her left leg because of wounds that would not heal.

Lena has just been transferred to a skilled nursing facility in her hometown. The occupational therapist met with Lena for her initial evaluation today, after which the two set goals for Lena's course of treatment.

Critical Thinking Questions

1. What is an occupation that will make Lena feel like herself again?
2. What treatment activities can be used to best address challenges presented by Lena's amputation and help her return to participation in her chosen occupations?
3. How can the occupational therapist help Lena prepare not only to return home, but also to reduce her risk of rehospitalization?

Levels of Lower Limb Amputation

Lower limb (LL) amputations are typically discussed as above-knee or below-knee; however, variability exists even within these categories (Fig. 43.25). Generally, the more proximal an amputation, the greater the functional challenge the person faces. Proximal LL amputations include hemipelvectomy and hip disarticulation amputations, resulting in loss of the entire lower limb; such severe amputations are typically performed in cases of trauma or malignancy. Wound healing from such proximal amputations is often slow, and skin grafting may be required for full healing. In cases of hemipelvectomy, a muscle flap covers the internal organs.

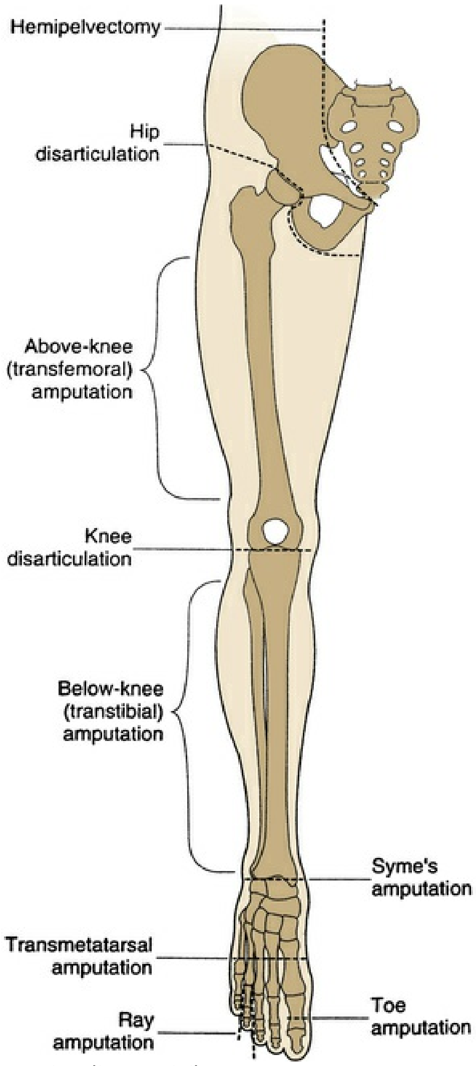

FIG 43.25 Levels of lower extremity amputation. (From Cameron MH, Monroe LG: *Physical rehabilitation: evidence-based examination, evaluation, and intervention,* St Louis, 2007, Saunders.)

A transfemoral amputation, or **above-knee amputation** (AKA), results in loss of the knee and everything distal to it. Residual limb length from an AKA typically varies from 10 to 12 inches (25.4 to 30.5 cm) from the greater trochanter[8]; transfemoral amputations can also be classified as upper, middle, or lower third, indicating the amputation distance from the ischium. A through-the-knee (disarticulation) amputation results in loss of knee joint function but allows a high level of prosthesis control and mobility.

A transtibial amputation, or **below-knee amputation** (BKA), preserves the knee and thus eliminates the necessity for a mechanical knee joint in the prosthesis. The residual limb from a BKA typically varies from 4 to 6 inches (10.1 to 15.2 cm) from the tibial plateau.[8] A **Syme's amputation**, or ankle disarticulation, results in loss of both ankle and foot function and is typically performed in cases of trauma or infection. A transmetatarsal amputation results in severing of the foot through the metatarsal bones, but the ankle remains intact. Clients may experience amputation of toes; although amputation of the first toe impairs ambulation by preventing toe-off (which is the end of the stance or support phase of gait), loss of the small toes does not usually result in impaired ambulation. In Lena's case, the amputation is considered a BKA because her left leg was amputated approximately 5 inches below the tibial plateau.

Causes of Lower Limb Amputation

In the United States 95% of LL amputations are performed as a result of complications of peripheral vascular disease (PVD)[50]; ultimately, 25% to 50% of these cases are caused by diabetes mellitus.[83] Trauma is the second most common cause of amputation in the United States, but it is the leading cause in developing countries because of land mines and other environmental hazards.[83] Amputation may also be performed in cases of malignancy in an effort to prevent it from spreading to other sites or systems in the body.

In Lena's case, diabetes mellitus and PVD resulted in poor circulation in her lower limbs. Because of this complication, blood flow to her left foot and leg was not adequate for her limb to heal, even from what initially appeared to be a small wound. Therefore, she was obliged to undergo progressive amputations of her left lower limb, eventually leading to the recent BKA.

Postsurgical Residual Limb Care

Skin care and positioning are extremely important throughout the course of rehabilitation, especially immediately after surgery. Once the surgical wound has begun to heal, some form of specialized postsurgical dressing will be used to help prevent swelling and to shape the residual limb for ease of future prosthesis use. Wrapping with an elastic bandage (e.g., Ace wrap) is a common method to control edema after surgery. However, smooth wrapping does require a skilled and consistent technique, which is necessary to prevent poor shaping of the residual limb. A series of gradually smaller residual limb shrinkers can be worn as an alternative to elastic bandage wrapping to encourage constant, even shrinkage of the residual limb to facilitate fitting with a final prosthesis. Both elastic bandages and shrinkers can be used early after surgery, even if the client's surgical wound still has a dressing on it. In such a case a nylon stocking would first be applied to prevent the bandage or shrinker from dislodging the dressing. Once the final prosthesis has been made and adjusted, the client frequently will continue to wear a shrinker during the day when he or she is not wearing the prosthesis and also at night. This shrinking and shaping process can take up to 3 months or longer in some cases, depending on the client's condition.

If the client (or his or her caregiver) is unable to demonstrate proper technique with wrapping or shrinker use, a Jobst compression pump may be used. The pump is an air-filled sleeve that surrounds the residual limb, placing constant, equal pressure on all sides, quickly shrinking and shaping the residual limb. A rigid dressing or cast is frequently used for active clients after surgery. The end of the cast is made to work with a simple training prosthesis, so the client can begin training for standing and walking immediately. Scar massage may be necessary later in the healing process to prevent adhesions and enhance comfort around the surgical site; this massage technique can be taught to the client.

The Ace wrap bandaging of Lena's residual limb was performed by nurses in the hospital. After Lena's arrival at the skilled nursing facility, the nursing staff consulted the occupational therapist to determine whether Lena had the cognitive and visual function and the necessary motor skills to learn how to apply her own wrap or shrinker and to perform her own scar massage.

Lower Limb Equipment and Prostheses

Movement and time out of bed are typically reduced immediately after LL amputation. The surgery itself can make movement uncomfortable, and many persons who have undergone amputation surgery have preexisting conditions that may further reduce mobility. For these reasons clients may require the use of bed rails or a metal trapeze bar hanging over the bed to help reposition themselves in bed and to transition between supine and sitting. Wheelchairs also present a challenge because the client is no longer able to support the affected limb by resting the now absent foot on the floor or on the footrest of the wheelchair. A **residual limb support** is basically a padded board that is placed on the seat of the wheelchair; it has an extended component on the side of the affected limb that projects forward from the seat of the chair (Fig. 43.26). This extension provides a surface for the residual limb to rest upon, thus placing the limb in a nondependent position and reducing stresses on the hip joint. A person with a BKA is often at risk for developing a flexion contracture of the knee joint, and residual limb support can facilitate extension of the knee in sitting, thus helping to prevent both edema in the residual limb and contracture of the knee joint.[116] A residual limb support is sometimes still referred to, in less acceptable terminology, as a stump support. For a person with bilateral LL amputations, the large wheels on the wheelchair must be placed farther back to accommodate the change in body weight distribution. Antitippers, which are commercially available wheelchair accessories, can also be used on the back of the chair to reduce the likelihood of tipping backward during weight shifting.

FIG 43.26 Wheelchair with support for residual limb. (Courtesy Comfort Company, Bozeman, MT.)

Most clients will use a walker during at least the initial phases of their rehabilitation. Some clients with LL amputations will go on to use a walker at all times for ambulation. Both four-footed (standard) and two-wheeled (rolling) walkers may be used, depending on the client's individual characteristics and needs. It has been suggested that using a two-wheeled walker may allow those with prosthetic limbs to ambulate more quickly and with less interruption,[106] but walker choice should always be made on the basis of a total assessment of the client's abilities and needs.

Many types of prostheses are available for the lower limbs, and technology is improving daily. For all prostheses, comfort, ease of application, appearance, and functioning of the prosthesis, including the client's ability to perform ADLs and IADLs with use of the affected limb, correlate significantly with the client's walking distance and with his or her perceived quality of life after an LL amputation.[64] It is very important for the rehabilitation team to keep this in mind during a client's fitting for and training with a prosthesis.

The main components of an LL prosthesis are the socket, a sock or gel liner, a suspension system, a pylon, and a terminal device. For some prostheses an articulating joint is also necessary. The socket is the direct connection between the residual limb and the prosthesis. A person's residual limb may change in volume during the day and over the course of time, presenting challenges for maintaining an adequate fit within the socket. This challenge is frequently addressed by adding socks to, or removing them from, the residual limb to adapt to its volume changes. Smart variable geometry socket (SVGS) technology was developed to help reduce this challenge.[37] An SVGS adds and removes liquid from the intrasocket environment on the basis of intrasocket pressure during wear, continuously accommodating residual limb volume changes and thus maintaining the fit of the socket without having to remove the prosthesis. Static elastomeric liners are also used for the prosthesis socket; the choice of liner is based on variables such as fit, comfort, friction tolerance, and price.[88] Various suspension mechanisms are used to attach the socket to the residual limb, including belts, straps, wedges, or suction; sometimes mechanisms are combined to ensure the appropriate fit.

The **pylon** is the structure that attaches the socket to the TD (Fig. 43.27). Vertical shock pylons function as shock absorbers for LL prostheses. Many clients who have had an LL amputation express a preference for walking with these devices.[35] Such shock absorption is especially beneficial during high-impact activities, such as running, and for other activities that are part of daily life for many clients, such as descending curbs and stairs. A pylon can be a basic, static device that provides minimal cosmetic benefits; it can also be a dynamic device, such as that outlined in the preceding paragraph, and can be modified to provide a close cosmetic match with the client's unaffected limb.

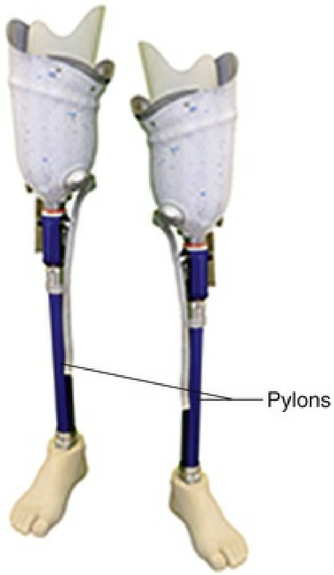

FIG 43.27 Typical pylon, the internal frame or skeleton of the prosthetic limb. (From GettyImages.com.)

The TD is the prosthetic foot, which provides a stable, weight-bearing surface and can itself function as a shock absorber. The many types of available TDs provide varying degrees of mechanical ankle movement and dynamic response, according to the needs and abilities of the client. Specialized TDs (indeed, entire LL prostheses) are designed to accommodate the challenges presented by various sports and activities (Fig. 43.28). To help select the best prosthesis, Lena's prosthetist consulted with her occupational therapist to explore the activities and lifestyle to which Lena wished to return.

Participation in Occupations

OT Practice Note

A thorough occupational profile obtained during the initial evaluation, along with evaluation and analysis of occupational performance, will help the occupational therapist identify areas of strength and of challenge for the client who has undergone a limb amputation.

For some clients, particularly those who have undergone a traumatic amputation, the activities to which they wish to return are ones they engaged in right up to the point of injury or illness. However, given the nature of PVD and diabetes, many clients with LL amputations experience a progressive decline in function over the course of several years. For these clients, amputation and subsequent rehabilitation, although difficult, may allow a return to fulfilling occupations that had been absent from the clients' repertoire for quite some time.

Participation in most ADLs will be affected by LL amputation. Although a client with an LL amputation will be learning new mobility techniques in physical therapy, he or she must also participate in occupational therapy to learn new functional mobility techniques with which to accomplish familiar tasks. Bathing, dressing, personal hygiene, grooming, and toilet hygiene will likely need to be addressed as part of an occupational therapy intervention program. Personal device care must be addressed if the client is using an LL prosthesis. Participation in IADLs will also be affected. Particular attention should be paid to care of others, care of pets, childrearing, community mobility, health management and maintenance, home establishment and management, meal preparation and cleanup, safety and emergency maintenance, and shopping. The areas of rest and sleep may also present challenges to a person with a new LL amputation. For example, a client's evening routine may be disrupted by having to perform it from a wheelchair instead of at an ambulatory level (sleep preparation). A client may experience difficulties interacting with his or her spouse in the sleeping space as they both adjust to a new amputation (sleep participation). The occupational therapist should assess how these occupations may be affected by the amputation and should help the client develop adaptations that facilitate improved rest and sleep. Treatments addressing phantom sensations may also benefit the client's rest and sleep (see Chapter 13 for further information).

Participation in educational, work, play, and leisure activities is usually affected by LL amputation and should be addressed during occupational therapy, as should social participation. Although intervention often assumes a greater role with these occupations later in the rehabilitation process, they still can be addressed even during the acute rehabilitation phase, thus reinforcing to the client that these are occupations in which a return to active participation is indeed possible. It is essential that the occupational therapist help clients to explore all avenues of an occupation in which they may wish to participate, ensuring that even activities that had been abandoned in the past are possible again.[58] As a result of changes in function after amputation, clients may not be able to return to participation in prior work or leisure activities or to participation at the level to which they were accustomed. In such cases the occupational therapist should help clients explore other opportunities that they might find fulfilling through identification of interests, skills, and opportunities.

Early in her course of occupational therapy at the skilled nursing facility, Lena spoke with her therapist about how much she missed walking to her church and helping to bake pies for its annual autumn festival. Lena said that she stopped doing this about 10 years ago because it became so difficult; she then discussed feelings of isolation and uselessness. Lena said that she had been known throughout her town for her pies, and she proudly recounted how each year people would tell her that she should open her own restaurant. Although Lena and her occupational therapist had initially set her long-term goals for independence with self-care and basic home management, they decided to add a goal for community reentry that focused on being able to reengage in this occupation.

Client Factors

Structures affecting movement, in addition to skin and related structures, are always altered by an LL amputation. However, the status of other body structures must also be assessed to determine the level of support or challenge these structures might present during the rehabilitation process.

Neuromuscular and movement-related functions will be altered by LL amputation, and this will affect occupational performance after surgery. This alteration of function may occur not only in the affected limb, but also in other parts of the body. Because of changes in the affected limb, greater stresses will be placed on the rest of the body; a person's unaffected leg and his or her arms will experience increased weight bearing during many functional activities, and both surgical wound healing and increased time in bed will place greater demands on skin functions.

Of particular importance is attention to sensations of pain. Up to 84% of persons who have had an LL amputation have experienced phantom limb pain.[20] In such an instance the client may experience sensations in the part of the limb that has been removed, such as feelings of cramping, squeezing, shooting, or burning pain. In these cases the therapist can use desensitization techniques (e.g., massage of the residual limb), exercise, hot and cold therapy, or electrical stimulation[83] to help decrease these sensations and allow the client to more easily and comfortably participate in chosen occupations.

Clients with PVD already have compromised cardiovascular function, and care must be taken to determine how much activity can safely be tolerated during therapy. A client's mental and sensory functions will affect the way therapy, including education, is delivered; they will also affect the types of prosthesis and equipment used.[57] Some clients may be able to incorporate new techniques quickly, recalling information from one session or even from reading material, and may be able to independently apply this learning to new situations. However, other clients will require adaptation of training and may require prolonged treatment to turn the new techniques they have learned into habits. Understanding a client's values, beliefs, and spirituality will further help the therapist to develop a treatment program and to choose interventions that are tailored to that client and best meet his or her needs.

The occupational therapist found that Lena would need to increase her upper body strength to help support herself during transfers and ambulation with the walker. She also needed to improve her postsurgical postural alignment and gait patterns to participate in her chosen occupations. Lena was experiencing pain and sensitivity in her residual limb. However, Lena's mental functions were found to be strengths, and her vision and the sensation in her hands, although slightly diminished, were functioning at a level sufficient to support her desired functional activities. Additionally, Lena's belief that good efforts yield results, in addition to her commitment to her spiritual and social communities, would facilitate her engagement in her occupational therapy program.

Performance Skills

The most overt effects of LL amputation will be evident in the area of motor skills. Adjusting posture, coordinating movements, maintaining balance, and bending are altered after surgery, and the client must address each of these skills in therapy to return to a full repertoire of occupations. Sensory and perceptual skills may also be affected by the amputation, and a client may have had prior difficulty with these skills caused by impaired sensory function. The client's processing skills (e.g., judging, sequencing, and multitasking) and communication and social interaction skills will affect his or her participation in treatment and the therapist's choice of treatment methods.

Lena's occupational therapist found that, as she had expected, Lena exhibited impairment in stabilizing, aligning, positioning, walking, reaching, bending, moving, transporting, lifting while standing, and pacing. The therapist also found that processing skills were at functional levels for Lena. However, Lena did exhibit difficulty with adaptation as she began attempting to perform activities with a changed body structure and in different positions. The therapist also noticed that Lena was having difficulty with social interaction skills, exhibiting trouble focusing and collaborating during many occupations. The therapist would need to address these areas in therapy to help Lena return to her optimal level of participation in occupations.

Performance Patterns

Whatever a client's performance patterns were before the amputation, they are likely to be altered after amputation. The client may already have useful habits, routines, rituals, and roles that can be drawn upon in therapy to facilitate his or her return to prior levels of occupational performance. However, for many clients, the occupational history will reveal prior impoverished habits and lack of or maladaptive routines that may present challenges to the rehabilitative process. Although Lena's diabetes and PVD placed her at increased risk for poor wound healing, she had never developed the habit of routinely checking her feet and legs for cuts or infections. This impoverished habit led to three amputations on her left leg. Lena's morning routine in her kitchen involved crossing the room many times and carrying multiple items in her hands at once. In conversations with her occupational therapist, Lena did indicate that she had already begun to drop things during this routine, that she had nearly fallen a few times, and that she worried about being able to safely make her own breakfast at home.

Psychosocial Repercussions

Amputation of a limb represents a loss and therefore involves a grief process. This process involves dealing with one's feelings regarding change in body structure, functional abilities, and participation in occupations. It can also involve anger, acknowledgment of unpleasant realities regarding one's health status, and fears about one's functional and financial future. Social acceptance and community function are also significant concerns for a person who has undergone an amputation. These are all areas that can be addressed by an interdisciplinary rehabilitation team in an effort to help the client adapt and should inform all aspects of occupational therapy intervention.

The occupational therapist may use several techniques to help a person adapt to his or her amputation and create a new sense of self. The therapeutic relationship and the therapeutic use of self can provide a safe environment and catalyst for the client to discuss feelings of loss, thoughts regarding body changes, and fears for the future. The therapist can teach the client coping skills for dealing with anxiety and depression, in addition to techniques for improving his or her postsurgical body image.[78] The consultation process can include recommendations for workplace adaptations and suggestions for how to make the home more accessible to a client with a new amputation. The therapeutic use of occupations that have been graded to the client's current abilities provides opportunities to master skills and experience success. The therapist's encouragement during such sessions not only fosters development and provides support, but also provides evidence to the client that recovery of function and return to participation in chosen occupations are indeed possible[78]; this knowledge fosters hope and a vision of the future.

It is important to recognize that an outside observer's rating of a person's adaptation to an LL amputation may not be the same as that person's self-rating. A surgeon may rate success on the basis of healing of the surgical wound, a prosthetist on the fit between residual limb and prosthesis, a physical therapist on the client's ability to ambulate, and an occupational therapist on the client's ability to participate in occupations. However, clients may place greater emphasis on other criteria in their determination of successful adaptation to an LL amputation. Some related variables that appear to be of primary concern to clients include feeling comfortable while being active in the presence of strangers, not feeling like a burden to one's family, being able to care for others, and being able to exercise recreationally.[64]

Context, Environment, and Activity Demands

An understanding of the client's contexts, environments, and demands of daily activities will help the therapist design a treatment program that will best help the client reengage in chosen occupations within his or her everyday environment. It will also help the therapist adapt the activity demands of the client's chosen occupations to facilitate greater independence and development of proficiency. Lena's occupational therapist took a detailed floor plan of Lena's bedroom and was able to move the furniture in her room into the skilled nursing facility, so it closely approximated her bedroom setup at home. When Lena performed her morning and evening ADLs in the room, she was then doing so in a more natural environment. Lena's therapist initially made significant adaptations to Lena's morning routine demands, wheeling Lena up to the sink in the bathroom for sponge bathing and bringing her clothes to her in the bathroom, where she would stand with the help of a grab bar, so the therapist could pull Lena's pants up. Over the course of time, as Lena improved her performance skills and her performance patterns and incorporated into her routine new ADL techniques taught during therapy, her occupational therapist was able to decrease the adaptation of activity demands, and Lena progressed to independence with routines that she would be able to sustain at home.

Additional Considerations With Elderly Clients

Although LL amputation may be performed to preserve function or to save the client's life, it does carry an increased mortality risk as the age of the client increases. One study of older persons who underwent a BKA found the survival probability after BKA to be 77% at 1 year, 57% at 3 years, and

28% at $7\frac{1}{2}$ years.[60] Because this increased mortality risk is related not only to the amputation surgery but also to preexisting health and environmental factors, attention to the overall health status of the client is of utmost importance.

Many body structures and functions are already compromised in elderly clients, making the rehabilitation process longer and more delicate. An elderly person may take more time to recover from the effects of anesthesia after surgery, including effects on cognition and the respiratory system. For unilateral amputees, leg balance on the unaffected limb is a significant predictor for prosthetic use.[91] Because balance may already be decreased and cognitive skills may have declined, elderly clients learning to use a prosthetic limb may experience greater challenges. Elderly clients have already experienced many losses, which may include family and friends, home, health, and function; the psychological sequelae of amputation can be all the more traumatic when layered over these previous losses.

Threaded Case Study

Lena, Part 2

Amputation of a lower limb has a significant functional impact on a person, but return to an active and fulfilling life is still possible. Lena required extensive assistance to take care of herself when she entered the skilled nursing facility, but her goal was to return home independently able to take care of herself and her home. During the course of occupational therapy, Lena realized that she had been slowly decreasing her participation in the very activities that helped her feel active and vital and helped her define who she was. She then decided to work with her therapist toward being able to reclaim these activities, particularly going back to her church and helping to bake pies for its upcoming autumn festival.

During the course of her occupational therapy, Lena's therapist presented her with activities that addressed the areas that Lena needed to improve to reach her goals. These goals, which Lena had identified as of interest to her, were adapted to provide an appropriate level of challenge. Because Lena liked to watch birds and had enjoyed decorative painting in the past, her occupational therapy sessions included building and painting birdhouses. This increased Lena's upper body strength and provided progressive challenges to her sitting and eventually standing balance, facilitating her return to independence with ambulatory tasks and providing an activity that Lena could perform at home and a product that she could donate to her church's fall festival.

As Lena's stay at the skilled nursing facility neared its end, she participated in community reentry sessions with her occupational therapist. Because Lena had mentioned her desire to help bake pies with the congregation for the fall festival, she and her occupational therapist visited the church together during a community reentry session; this gave Lena a chance to interact with some of the members of the baking committee so that they could see Lena's capable self, allaying their fears about interacting with a person with a disability and setting the expectation that Lena would be involved. Through supported engagement in this social community occupation, Lena gained confidence that she was still an accepted and desired member of her community. Together, Lena and her occupational therapist identified potential challenges presented by the layout of the kitchen. Lena engaged in trials and problem-solving strategies with her therapist to determine methods to allow safe participation in baking. In preparation for her return to the church as a member of the baking team, Lena then perfected these techniques in the occupational therapy kitchen back at the facility.

Lena's occupational therapist also worked with Lena to discuss the ways in which some of her prehospitalization habits and routines had contributed to high-risk situations and to identify strategies to help reduce her risks of rehospitalization. Lena learned how to perform her own lower body skin checks, and she was performing them regularly by the end of her stay. She went home with a daily routine that would help her stay active throughout the day, but also incorporated techniques that minimized periods of prolonged standing and reduced the amount of energy required to accomplish tasks. Lena's family then reorganized items in her kitchen, according to recommendations determined by Lena in collaboration with her occupational therapist, so that her environment placed less strain on her during daily activities. Lena went home independent in her daily activities, able to engage in individual and social occupations that made her feel happy and vital, and reclaimed a role that had long been abandoned.

Review Questions

1. List the common causes of acquired amputation.
2. Describe the role of the occupational therapist, as a team member, in the rehabilitation of an individual with an upper limb amputation.
3. What are the goals of amputation surgery?
4. Name three types of surgical techniques performed for amputations.
5. Name three ADLs that should be addressed immediately after amputation.
6. What is the purpose of a shrinker?
7. Name at least four postsurgical factors that can interfere with prosthetic training and rehabilitation. How is each factor managed?
8. What is the difference between phantom limb pain and phantom limb sensation?
9. Discuss the impact of the residual limb status on successful fitting and operation of an upper limb prosthesis.
10. Describe the goal of myosite testing for an electrically powered prosthesis.
11. Describe the typical psychological consequences of amputation surgery, and discuss how the occupational therapist facilitates adjustment to limb loss.
12. Define the “golden window” and identify its importance in upper extremity amputation rehabilitation.
13. What are the five most common types of upper limb prostheses?
14. List the motions used to operate the body-powered prosthesis.
15. Name at least two techniques for donning the body-powered prosthesis and describe them.
16. What is the importance of pre-positioning the terminal device?
17. Name three types of electric terminal devices. What are the advantages of each?
18. What components are specific to body-powered prostheses? To electrically powered prostheses?
19. List the five characteristics of advanced prosthetic training in the use of upper limb prostheses.
20. Discuss the primary function of a prosthesis in the functional performance of various ADL and IADL tasks.
21. What are the special considerations discussed in this chapter for treating persons with bilateral upper extremity amputations?
22. Identify and describe three outcome measures used with upper limb amputations.
23. How will advances in prosthetic technology and surgical techniques affect the outcomes for persons with upper limb loss?
24. Name two significant concerns for the residual limb immediately after surgery.
25. What is the purpose of a shrinker?
26. What should be done with the wheelchair to accommodate the residual limb? To accommodate a person with bilateral AKA?
27. Name the main components of an LL prosthesis.
28. What is the purpose of using a sock on the residual limb?
29. How will LL amputation affect other parts of the body?
30. How might LL amputation affect an individual's participation in occupations?
31. Which performance skills are most likely to be affected after LL amputation?
32. How can preexisting performance patterns affect a client's participation in occupations after an

amputation?

33. What are the potential psychosocial repercussions of LL amputation?
34. How can the demands of ADLs be adapted to foster greater independence after LL amputation?
35. What additional considerations does LL amputation present for elderly clients?

Cardiac and Pulmonary Disease

Maureen Michele Matthews

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, the student or practitioner will be able to do the following:

1. Demonstrate a beginning understanding of the cardiovascular function and how heart rate and rhythm and blood pressure impact engagement in occupation.
2. Identify the significance of ischemic heart disease and valvular diseases of the heart and the potential impact on these conditions on occupational performance.
3. Differentiate between modifiable and nonmodifiable risk factors, and discuss how these risk factors might be impacted by context and environment.
4. Identify signs and symptoms of cardiac distress.
5. Describe the course of action that should be taken if signs and symptoms of cardiac distress are present.
6. Define sternal precautions, and identify three modifications of activities of daily living for these precautions.
7. Identify how performance patterns are impacted for persons with cardiovascular or pulmonary disease.
8. Describe methods for determining the heart rate and blood pressure, and calculate the rate-pressure product given the heart rate and blood pressure.
9. Give a brief overview of the respiratory system, and identify its primary function.
10. Define chronic obstructive pulmonary disease, and identify how occupational performance might be impacted by chronic obstructive pulmonary disease.
11. Identify pulmonary risk factors and psychosocial considerations within the context of social justice.
12. Describe dyspnea control postures, pursed-lip breathing, and diaphragmatic breathing.
13. Describe a relaxation technique, and explain the benefits of relaxation from an occupational perspective.
14. List interview questions that will help the clinician know what the patient understands about intervention.
15. List the principles of energy conservation, and identify how you might focus patient education based on the environment of a client in an assisted living facility.
16. Explain the significance of a metabolic equivalent chart in the progression of activities of daily living and instrumental activities of daily living, and describe how to use it.

KEY TERMS

Atrial fibrillation
Blood pressure
Cardiac ablation
Chronic obstructive pulmonary disease
Diaphragmatic breathing
Energy conservation

Heart rate

Ischemic heart disease

Metabolic equivalent

Myocardial infarction

Pack-year history

Pulmonary rehabilitation

Pursed-lip breathing

Rate-pressure product

Sternal precautions

In this chapter the term *patient* is used instead of *client* to reflect the practice setting and the acute nature of the diagnoses in the individuals described in the case studies.

Threaded Case Study

Rudy, Part 1

Rudy, a 64-year-old, married man with diabetes, was enjoying his daily exercise of running 3 miles when he suddenly noticed fatigue and difficulty breathing. In the emergency room his heart rate was 140, his blood pressure was 128/70, and his respiratory rate was 20 with oxygen saturation at 93%. He was diagnosed with atrial fibrillation, and his previously diagnosed defective heart valve was failing. He underwent an aortic valve replacement and cardiac ablation.

Rudy had a large sternal incision. His sternum was stabilized with wire, and his physician identified sternal precautions to maintain the integrity of the healing bone. During the evaluation, Rudy got out of bed, walked to the bathroom, and got up and down from the toilet. He then returned to bed. His pain was minimal with medication, but he moved impulsively, frequently violating his precautions. Because his wife worked outside the home, he was home alone part of the day.

Rudy has an executive desk job and plans to return to work in 3 weeks. He added that he wants to be able to do everything he did prior to his recent decline. Rudy and his wife were anxious and asked lots of questions. Rudy stated, "I need to go to the bathroom and dress by myself." Rudy's wife said she was afraid of potentially harming Rudy by expecting too much of him and was also afraid that he would potentially harm himself by not limiting his activity level. Rudy expressed concern that his wife was avoiding intimacy based on her fears of hurting him. A barrier to recovery that Rudy revealed was his regular alcohol consumption. This was not in evidence as a problem in the medical record.

Critical Thinking Questions

1. What probative questions might the occupational therapist ask to clarify what Rudy means by "everything he used to do"?

2. What skills must Rudy acquire in order to protect his healing sternum?

3. What areas of occupation might the therapist choose for the next intervention session, and based on Rudy's occupational profile, what goals might be included in his occupational therapy intervention plan?

Individuals with disorders of the cardiovascular or pulmonary system may be severely limited in endurance and performance in areas of occupation, including activities of daily living (ADLs) and instrumental activities of daily living (IADLs). Occupational therapy (OT) services may benefit these individuals and are available throughout the continuum of healthcare. An understanding of the normal function of the cardiopulmonary system, the pathology of cardiopulmonary disease, common risk factors, clinical terminology, medical interventions, precautions, and standard treatment techniques will guide the occupational therapist in providing effective care and promoting recovery of function in clients with compromised cardiovascular or pulmonary systems.

Anatomy and Circulation

The heart and blood vessels work together to maintain a constant flow of blood throughout the body. The heart, located between the lungs, is pear shaped and about the size of a fist. It functions as a two-sided pump. The right side pumps blood from the body to the lungs; the left side simultaneously pumps blood from the lungs to the body. Each side of the heart has two chambers: an upper atrium and a lower ventricle.

Blood flows to the heart from the venous system. Blood enters the right atrium, which contracts and squeezes the blood into the right ventricle. Next, the right ventricle contracts and ejects the blood into the lungs, where carbon dioxide is exchanged for oxygen. Oxygen-rich blood flows from the lungs to the left atrium. As the left atrium contracts, it forces blood into the left ventricle, which then contracts and ejects its contents into the aorta for systemic circulation (Fig. 44.1). Blood travels from the aorta to the arteries and through progressively smaller blood vessels to networks of tiny capillaries. In the capillaries, blood cells exchange their oxygen for carbon dioxide.

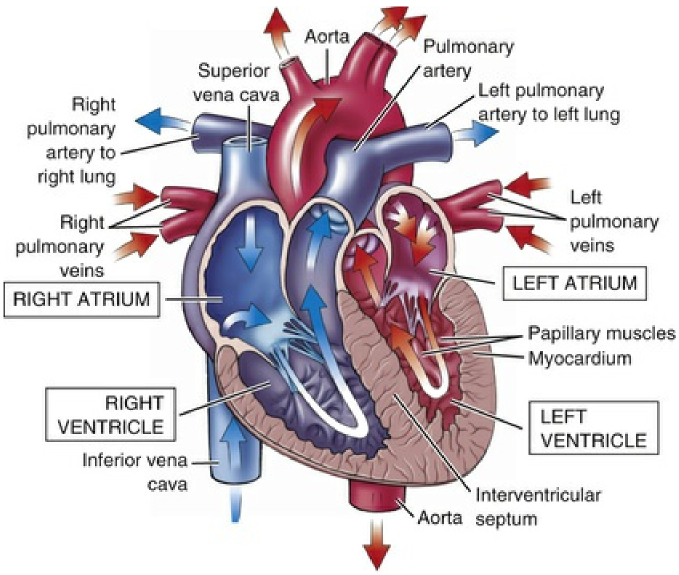

FIG 44.1 Coronary circulation. (From Herlihy B: *The human body in health and illness*, ed 5, St. Louis, 2014, Saunders.)

Each of the ventricles has two valves: an input valve and an output valve. The valves open and close as the heart muscle (myocardium) contracts and relaxes. These valves control the direction and flow of blood. The input valves are the mitral, or bicuspid, valve (between the left atrium and ventricle) and the tricuspid valve (between the right atrium and ventricle). The output valves make up the aortic and pulmonary valves.

The heart is living tissue and requires a blood supply (through an arterial and venous system of its own), or it will die. Coronary arteries cross over the myocardium to supply it with oxygen-rich blood. The coronary arteries are named for their location on the myocardium (Fig. 44.2). Cardiologists generally refer to these arteries by abbreviations, such as “LAD” for “left anterior descending” and “RCA” for “right coronary artery.” The LAD artery is on the left, anterior portion of the heart and runs in a downward direction; it supplies part of the left ventricle. Blockage of this coronary artery will interrupt the blood supply to the left ventricle. Because the left ventricle supplies the body and brain with blood, a heart attack caused by blockage of the LAD artery can have serious consequences.

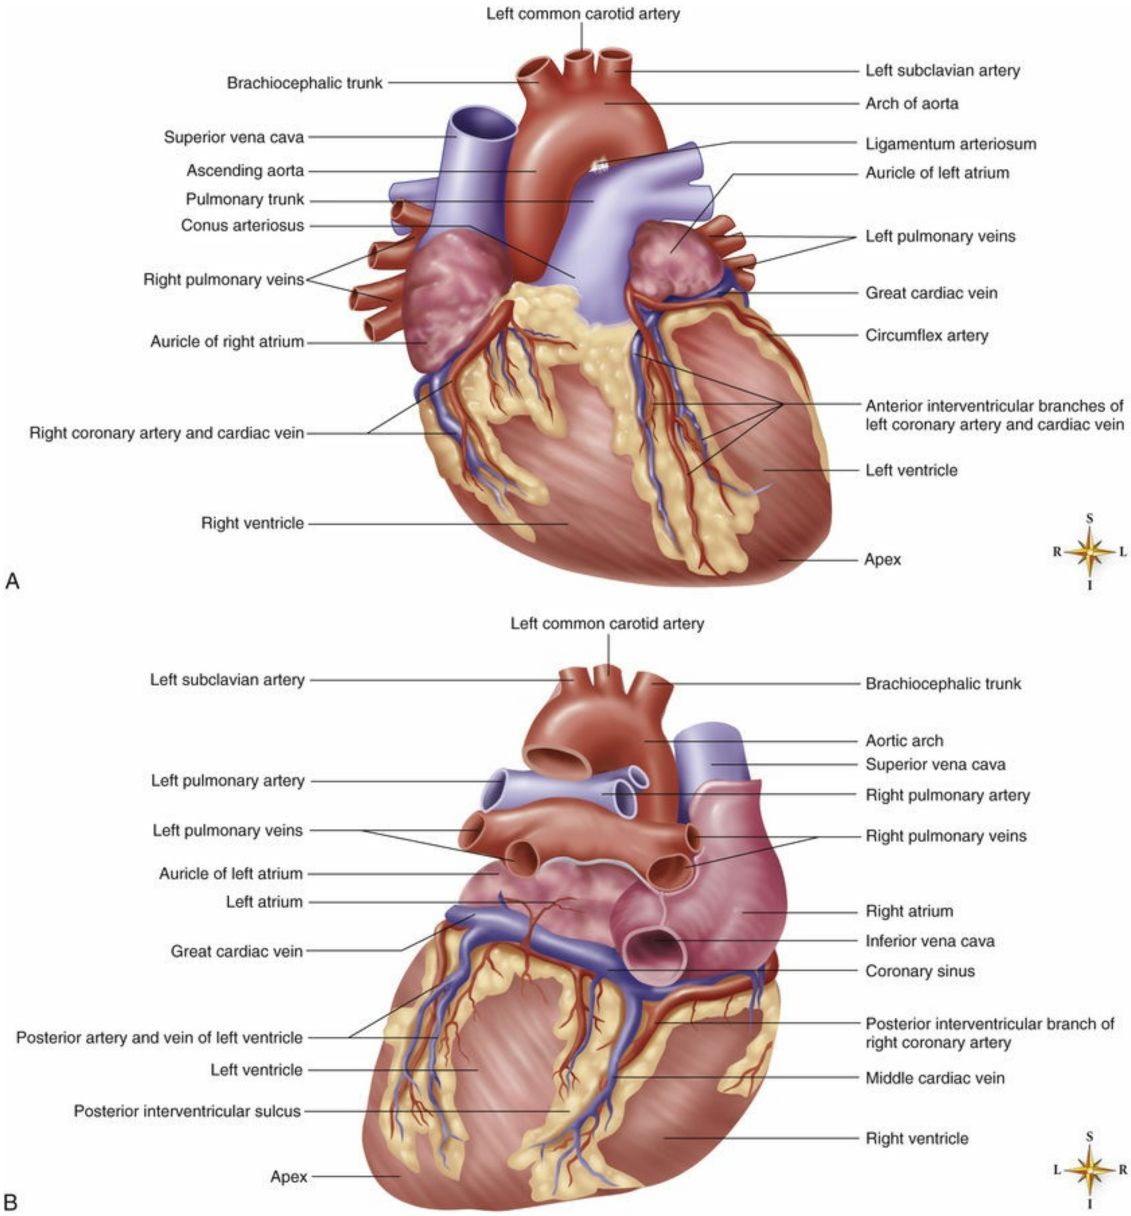

FIG 44.2 Anatomy of the heart. (From Patton K, Thibodeau G: *Anatomy & physiology,* ed 9, St. Louis, 2016, Elsevier.)

What Causes the Heart to Contract?

In addition to the ordinary muscle tissue of the heart, the myocardium is composed of two other types of tissue: nodal and Purkinje. These tissues are part of a specialized electrical conduction system that causes the heart to contract and relax (Fig. 44.3). An electrical impulse usually originates in the right atrium at a site called the sinoatrial node. The impulse travels along internodal pathways to the atrioventricular node, through the bundle of His, to the left and right bundle branches, and then to the Purkinje fibers. Nerve impulses normally travel this pathway 60 to 100 times every minute, first causing both atria to contract, pushing blood into the ventricles, and then provoking the ventricles to contract. The electrical impulse created by the heart's conduction system can easily be studied. Electrodes placed on a person's limbs and chest can pick up the heart's electrical impulse, which can be translated to paper as an electrocardiogram (ECG). The resulting ECG tracing is frequently used to help diagnose cardiac disease.

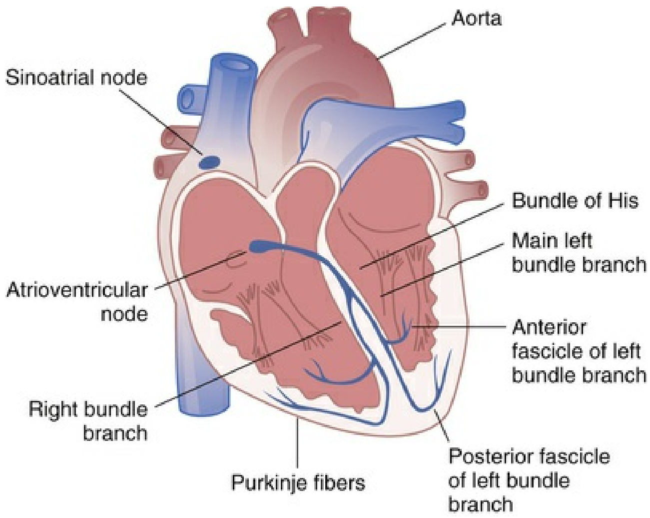

FIG 44.3 Cardiac conduction. (From Benjamin I, et al: *Andreoli and Carpenter's Cecil essentials for medicine,* ed 9, Philadelphia, 2016, Saunders.)

The sinoatrial node responds to vagal and sympathetic nervous system input.[20] This is why the **heart rate** (HR) increases in response to exercise and anxiety and decreases in response to relaxation techniques, such as deep breathing and meditation. Each cell within the electrical conduction system of the heart can respond to, conduct, resist for a brief period, and generate an electrical impulse. Because of this capacity, electrical impulses causing the heart muscle to contract can be generated from anywhere along the electrical conduction system. This is desirable when part of the conduction system has been damaged and is unable do its job, but it is undesirable when life-threatening conduction irregularities develop.

Cardiac Cycle

The cardiac cycle refers to a complete heartbeat from the generation of the heartbeat to the beginning of the next beat, and so includes the diastole, the systole, and the intervening pause. The cardiac cycle occurs in two phases: input (diastole) and output (systole). The frequency of the cardiac cycle is described by the HR (heart rate), which is typically expressed as beats per minute.

During the input phase, blood flows through the atria and into the ventricles. The atria contract and push more blood into the ventricles. Once the pressure inside the ventricles is equal to the pressure in the atria, the input valves (tricuspid in the right ventricle and mitral [or bicuspid] in the left ventricle) close. The ventricles then contract, which results in rapidly increasing ventricular pressure. When the pressure inside the ventricles exceeds the pressure in the blood vessels beyond, the output valves (pulmonary in the right and aortic in the left) open, and diastolic **blood pressure** (BP) is attained.

The ventricles continue to contract and squeeze blood under greater and greater pressure into the pulmonary and body circulation. Systolic BP is attained when pressure in the emptying ventricles falls below pressure in the blood vessels beyond, which causes the output valves to close.

Ischemic Heart Disease

Ischemic heart disease (ischemia) occurs when a part of the heart is temporarily deprived of sufficient oxygen to meet its demand. The most common cause of cardiac ischemia is coronary artery disease (CAD). CAD is the most common form of heart disease in the United States.[33]

CAD usually develops over a period of many years without causing symptoms. The internal wall of an artery can become injured. Once the wall is damaged, it becomes irregular in shape and more prone to collect plaque (fatty deposits such as cholesterol). Platelets also gather along the arterial wall and clog the artery, thereby creating a lesion in the same manner in which rust can clog a pipe. The artery gradually narrows and thus allows a smaller volume of blood to pass through it. This disease process is called atherosclerosis.

If a coronary artery is partially or completely blocked, the part of the heart supplied by that artery may not receive sufficient oxygen to meet its needs. Persons with partial blockage of a coronary artery may be free of symptoms at rest but have angina, a type of chest pain, with eating, exercise, exertion, or exposure to cold. Angina varies from individual to individual and has been described as squeezing, tightness, fullness, pressure, or a sharp pain in the chest. The pain may also radiate to other parts of the body, usually the arm, back, neck, or jaw. Angina has also been confused with indigestion. Rest or medication (or both) will frequently relieve angina. Usually, no permanent heart damage results. Angina is a warning sign that should not be ignored.

Chest pain that is not relieved by rest or nitroglycerin likely indicates a **myocardial infarction** (MI), or heart attack. A patient who has this type of pain should seek emergency medical help immediately. Individuals who attribute their symptoms to anxiety and stress are more likely to delay emergency care.[41] Substernal chest pain can be a warning sign that one or more of one's coronary arteries are blocked. If the blood flow to the heart muscle is interrupted and starved of the necessary oxygen, the heart will begin to die. This is an MI. If a substantial section of the heart is damaged, it will stop pumping (cardiac arrest).

Restrictions in activity are prescribed for the first 6 weeks after a heart attack because newly damaged heart muscle, like any injured body tissue, is easily reinjured.[14] During a heart attack, metabolic waste products accumulate in the damaged myocardium and make it irritable and prone to electrical irregularities such as premature ventricular contractions. A delicate balance of rest and activity must be maintained to allow the damaged area of myocardium to heal while also sustaining the strength of the healthy part of the heart. OT is frequently recommended to guide the patient toward a safe level of activity, or participation in occupation, during this acute period of recovery. Therapists teach persons with cardiac compromise: the signs of fatigue, when rest breaks are needed, and how to perform activities safely.

At approximately 6 weeks after an MI, scar tissue forms and the risk of extending the MI decreases. The scarred part of the heart muscle is not elastic and does not contract with each heartbeat. Therefore the heart does not pump as well. A graded exercise program will help strengthen the healthy part of the myocardium and improve cardiac output.[18] Cardiac rehabilitation is generally prescribed for persons recovering from heart attacks and for those recovering from cardiac surgery.

CAD can also lead to congestive heart failure (CHF). Similarly, infections can lead to CHF. This disease process develops over time with the heart becoming progressively weaker. CHF occurs when the heart is unable to pump effectively enough to meet the demand and fluid backs up into the lungs or the body. The fluid buildup in the lungs causes shortness of breath. Fluid overload is serious because it puts a greater workload on the heart as the heart strains while attempting to clear the excess fluid, which may result in further congestion. Heart size is often enlarged in persons with CHF because the heart muscle thickens (hypertrophy) from working so hard. Diuretics can be prescribed for persons with CHF to promote fluid loss through the urinary system. Low-sodium diets and fluid restrictions reduce the overall amount of fluid in the body. CHF cannot be cured, but with diet, medications, and rest, people with this condition can live longer and participate more fully in life.

Once an acute exacerbation of CHF is controlled, gradual resumption of activity will promote improved function. If activity is resumed too quickly, another acute episode may follow. Patients who have difficulty resuming their former level of activity may self-limit their recovery. OT can guide clients with acute CHF toward an optimal level of function via graded self-care tasks. “About

5.1 million people in the United States have heart failure,"[15] and "about half of the people diagnosed with heart failure die within 5 years of the diagnosis."[15] Table 44.1 delineates the four functional classifications of heart disease. OT can be of great benefit to persons with stages III and IV heart disease and can provide preventive programs for persons with stages I and II.

TABLE 44.1

Comparison of Three Methods of Assessing Cardiovascular Disability

Class	New York Heart Association Functional Classification[49]	Canadian Cardiovascular Society Functional Classification Severity of Unstable Angina[29]	Specific Activity Scale[16]
I	This category includes patients with cardiac disease but without resulting limitations in physical activity. Ordinary physical activity does not cause undue fatigue, palpitations, dyspnea, or anginal pain.	Ordinary physical activity, such as walking and climbing stairs, does not cause angina. Angina occurs with strenuous, rapid, or prolonged exertion during work or recreation.	Patients can perform to completion any activity requiring ≤7 METs (e.g., can carry objects that weigh 80 lb, do outdoor work [shovel snow, spade soil], and do recreational activities [skiing, basketball, squash, handball, jog/walk 5 mph]).
II	This category includes patients with cardiac disease resulting in slight limitations in physical activity. They are comfortable at rest. Less than ordinary physical activity causes fatigue, palpitations, dyspnea, or anginal pain.	Ordinary activity is somewhat limited. This includes walking or climbing stairs rapidly; walking uphill; and walking or climbing stairs after meals, in cold, in wind, when under emotional stress, or only during the few hours after waking. This also includes walking more than two blocks on a level surface and climbing more than one flight of stairs at a normal pace and in normal conditions.	Patients can perform to completion any activity requiring ≤5 METs (e.g., have sexual intercourse without stopping, garden, rake, weed, roller skate, dance the fox-trot, walk at 4 mph on level ground) but cannot and do not perform to completion activities requiring ≥7 METs.
III	This category includes patients with cardiac disease resulting in marked limitation in physical activity. They are comfortable at rest. Less than ordinary physical activity causes fatigue, palpitations, dyspnea, or anginal pain.	Ordinary physical activity is significantly limited. This includes walking one to two blocks on a level surface and climbing more than one flight of stairs in normal conditions.	Patients can perform to completion any activity requiring ≤2 METs (e.g., shower without stopping, strip and make the bed, clean windows, walk 2.5 miles, bowl, play golf, dress without stopping) but cannot and do not perform to completion activities requiring ≥5 METs.
IV	This category includes patients with cardiac disease resulting in an inability to carry out any physical activity without discomfort. Symptoms of cardiac insufficiency or angina syndrome may be present even at rest. If any physical activity is undertaken, discomfort is increased.	Patients are unable to carry out any physical activity without discomfort; angina syndrome may be present at rest.	Patients cannot perform to completion any activity requiring ≥2 METs and cannot carry out activities listed above (Specific Activity Scale, class III).

METs, metabolic equivalents.

From Goldman L, et al: Comparative reproducibility and validity of systems for assessing cardiovascular functional class: advantages of a new specific activity scale, *Circulation* 64:1227, 1981.

Valvular Disease

The heart valves, which are responsible for controlling the direction and flow of blood through the heart, may become damaged by disease or infection. Two complications result from valvular disease: volume overload and pressure overload. A fibrous mitral valve will fail to close properly, and blood will be regurgitated back to the atria when the left ventricle contracts. Volume overload results when fluid accumulates in the lungs, thereby causing shortness of breath. Volume overload increases the potential for **atrial fibrillation**, which results in irregular and ineffective contractions in both atria. Blood flow through the heart slows, and blood clots (emboli) may develop in the ventricles. Many cerebrovascular accidents are caused when emboli ejected from the left ventricle enter the circulatory system of the brain. Volume overload caused Rudy's shortness of breath and rapid heart rate.

If the aortic valve fails to close properly (aortic insufficiency), CHF or ischemia may result. Another disorder of the aortic valve is aortic stenosis (narrowing), which results in pressure overload. The left ventricle, which must work harder to open the sticky valve, becomes enlarged, and cardiac output decreases. Ventricular arrhythmia (irregular rhythm of heartbeats), cerebral insufficiency, confusion, syncope (fainting), and even sudden death may result from aortic stenosis. Surgery to repair or replace the damaged valves is frequently recommended.

Cardiac Risk Factors

Many scientific studies have been conducted to determine the causes of heart disease. The most famous of these, the Framingham study,[11] helped identify many factors that put an individual at risk for atherosclerosis. Risk factors are divided into three major categories: those that cannot be changed (heredity, male gender, and age), those that can be changed (high blood pressure, cigarette smoking, cholesterol levels, and an inactive lifestyle), and contributing factors (diabetes, stress, and obesity). The Framingham Heart Study continues with research milestones in identifying specific genetic and social factors associated with heart disease, dementia, and stroke.[13] Other factors that contribute to CAD include sleep apnea, alcohol, and preeclampsia.[38] There is a bidirectional link between CAD and depression. Persons with CAD are more likely to develop depression and persons with depression are more likely to develop CAD than others.[17]

The more risk factors that an individual has, the greater the individual's risk for CAD. All team members—the physician, nurse, physical therapist, case manager, social worker, nutritionist, and occupational therapist—should support the patient's attempts to reduce risk factors. In reviewing Rudy's case study, several risk factors are clearly present, whereas others appear to be absent.

Medical Management

A heart attack is a medical emergency, and treatment with aspirin and oxygen is usually initiated before diagnosis. Early treatment is usually started prior to confirmation of the diagnosis and includes aspirin, nitroglycerin, oxygen, and treatment of chest pain.[34] After emergency treatment, heart attack survivors are typically managed in a coronary care unit, where they are closely observed for complications. Approximately 90% of persons who have suffered an MI will have arrhythmia.[3] Heart failure, the development of blood clots (thrombosis and embolism), aneurysms, rupture of part of the heart muscle, inflammation of the sac around the heart (pericarditis), and even death are potential outcomes of MI. Close medical management is imperative.

Generally, patients are managed for 1 to 3 days after MI in an intensive care unit. Once their condition is stabilized, they graduate to a monitored hospital bed. Patients typically stay 5 to 10 days in the hospital after an acute MI. Vital signs are monitored closely while activity is gradually increased. OT personnel may be called on to monitor the patient's response to activity and educate the patient about the disease process, risk factors, and lifestyle modification.

Various surgical procedures can correct the circulatory problems associated with CAD. Balloon angioplasty, also called percutaneous transluminal coronary angioplasty (PTCA), and coronary artery bypass grafting (CABG) are most common.[10]

In PTCA, a catheter is inserted into the femoral artery and guided through the circulatory system into the coronary arteries. Radioactive dye is injected into the arteries, and the site of the lesion is pinpointed. A balloon is then inflated at the site of the lesion to push the plaque against the arterial wall. When the balloon is deflated and the catheter removed, circulation to the myocardium usually improves. During PTCA, a wire mesh tube, called a stent, may be implanted into the coronary artery to keep the artery open.[27]

If a lesion is too diffuse or if an artery reoccludes after PTCA, CABG may be performed. The diseased section of the coronary arteries is bypassed with healthy blood vessels (taken from other parts of the body), thus improving the coronary circulation. In performing CABG, the surgeon usually opens the chest wall by cracking the sternum (sternotomy) and spreading the ribs to gain access to the heart. Sternal precautions to prevent trauma to the compromised chest are generally in place for 6 to 8 weeks after a sternotomy. Ten-year survival rates after a CABG vary between 70% and 93% depending on the number of grafts, the sex of the patient, and the vein or artery recruited for the bypass.[6]

When heart rhythms are abnormal—too fast, too slow, or too irregular to support normal activity—medical intervention is indicated. Arrhythmias that cannot be controlled with medication may be managed by the insertion of a pacemaker in the chest. Wires are run from the pacemaker to specific spots on the heart. The pacemaker delivers a small electrical impulse to the heart muscle and sets the pace of the heart's electrical conduction. The impulse may be set to deliver a regular impulse or to send an impulse only if the heart rate drops below a certain number of beats per minute (demand). Modern pacemakers can monitor physiological responses such as BP and temperature. Implantable cardioverter-defibrillators (ICDs) may also be used to treat cardiac arrhythmias. An ICD can both pace the heart muscle and deliver a high-energy impulse to reset the heart muscle if certain dangerous arrhythmias develop.

Cardiac ablation is a medical procedure used to destroy small areas of the heart that are emitting dangerous signals that cause the heart to contract abnormally. Small catheters are threaded through a vein to the heart. The dysfunctional cardiac tissue is reached and an electrical impulse is sent to the site, destroying the abnormal tissue.[36]

When the heart's pumping ability has become too compromised by CHF or cardiomyopathy, a heart transplant or heart-lung transplant may be considered. After the healthy tissue of a recently deceased person is harvested, the patient's diseased organ (or organs) is removed, and the harvested tissue is transplanted into the patient's body. Transplant patients are typically maintained on special medication to decrease the risk for organ rejection. Nearly 50% of all heart transplant recipients survive for 10 years. Most recipients resume normal lifestyles, but only about 40% return to work.[39]

Ventricular assistive devices (VADs) and total artificial hearts are some of the newer options for individuals with end-stage heart failure or for extremely sick persons awaiting heart transplant. These mechanical circulatory support devices support the damaged heart by pumping blood mechanically. Surgically implanted, with a battery pack worn externally, these devices can allow patients to return home to a more active occupational level while they await a transplant. Nearly 80% of persons using these devices in clinical trials have survived the wait for a new heart.[19]

Valvular stenosis may be managed surgically with a valvuloplasty, in which a balloon is inflated in the damaged valve, stretching and breaking up scar tissue, thus opening and restoring blood flow within the heart. Damaged valves may need to be replaced in order to restore optimal blood flow. A valve replacement may require a sternotomy (opening of the breast bone) or only a small incision, in the case of a transcatheter valve replacement.[1] A sternotomy was performed to replace Rudy's valve.

Cardiac Medications

Knowledge of the purpose and side effects of cardiac medication promotes an understanding of the patient's response to activity. Table 44.2 lists common cardiac medications.

TABLE 44.2

Common Cardiac Medications

Category	Common Names	Purpose and Uses	Reason Prescribed
Anticoagulants (blood thinners)	Warfarin (Coumadin) Heparin	Decrease the blood's ability to clot	Prevent clot formation or enlargement; prevent stroke
Antiplatelet agents	Aspirin Clopidogrel (Plavix)	Prevent clots by preventing platelets from sticking together	Prevent clots after MI; with unstable angina, ischemic stroke, plaque
Angiotensin-converting enzymes—ACE inhibitors	Fosinopril (Monopril) Captopril (Capoten) Quinapril (Accupril)	Expand blood vessels, lower levels of angiotensin II; make the heart work more easily	Treatment of — Hypertension — Heart failure
Angiotensin II receptor blockers (or inhibitors)	Losartan (Cozaar) Irbesartan (Avapro)	Keep blood pressure from rising by preventing angiotensin II from having an effect on the heart	Treatment of — Hypertension — Heart failure
Angiotensin-receptor Neprilysin inhibitors (ARNIs)	Sacubitril/valsartan (Entresto)	Open narrow arteries, improve artery opening, improve blood flow, reduce sodium retention, decrease the work of the heart	Treatment of heart failure
β-Blockers	Atenolol (Tenormin) Propranolol (Inderal)	Decrease heart rate and cardiac output, lower blood pressure, and make the heart beat more slowly and with less force	Treatment of — Abnormal cardiac rhythms — Chest pain Prevent recurrent heart attacks; lower blood pressure
Calcium channel blockers	Amlodipine (Norvasc, Lotrel) Diltiazem (Cardizem, Tiazac)	Interrupt movement of calcium into cells of the heart and blood vessels	Used to treat high blood pressure, angina, and some arrhythmias
Cholesterol lowering medications	Statins (Lipitor, Crestor) Nicotinic acids: (Advicor) Cholesterol absorption inhibitors: (Vytorin)	Lower blood cholesterol levels	Lower LDL
Digitalis preparations	Digoxin (Lanoxin)	Increase the force of cardiac contractions	Treatment of — Heart failure — Arrhythmias — Atrial fibrillation
Diuretics (water pills)	Furosemide (Lasix) Hydrochlorothiazide (Esidrix, HydroDIURIL)	Cause loss of excess water and sodium by urination, thus relieving heart workload and buildup of fluid in lungs and body tissues	Lower blood pressure; reduce edema in lungs, stomach, and extremities
Vasodilators	Nitroglycerin Minoxidil	Relax blood vessels; increase supply of blood and oxygen to the heart while reducing its workload	Ease chest pain

HDL, high-density lipoprotein; LDL, low-density lipoprotein; MI, myocardial infarction.

Psychosocial Considerations

Depression, anger, anxiety disorders, and social isolation are common in individuals receiving cardiac rehabilitation. Improvement in event-free survival for persons receiving treatment for these problems was not found to have improved survival versus an untreated control group. However, the treated individual in a large randomized multicenter trial improved in socialization and mood compared with the control group.[2] "Nevertheless, even if psychosocial interventions ultimately are shown not to alter the prognosis of CHD patients, they remain an integral part of cardiac rehabilitation services to improve the psychological well-being and quality of life of cardiac patients."[23]

As patients begin to resume more normal activities, such as self-care and walking around the ward, feelings of helplessness may begin to subside. Patients feel more secure when familiar coping mechanisms allow them to respond to the stress, but some former coping mechanisms (e.g., smoking, drinking, consuming fatty foods) are harmful and should be discouraged and replaced by newly learned coping strategies, often those taught by the occupational therapist and other members of the intervention team. Typically, the nutritionist directs the patient toward healthy food choices, the physical therapist provides guidance toward exercise, and the nurse oversees management of medications.

Denial is common in patients with cardiac disease. Patients in denial must be closely monitored during the acute phase of recovery. Persons in denial may ignore all precautions and could stress and further damage their cardiovascular systems. Clinical evidence supports psychosocial counseling after MI that focuses on improving self-health appraisal, improving social support, and establishing an effective means of coping to improve quality of life.[48] The patient's family must be included in the education so that their misconceptions and anxieties do not compound the patient's fears. In Rudy's case, his wife's anxiety that she might accidentally harm him or that he might harm himself and Rudy's concern that his wife is avoiding intimacy and the self-identified barrier of alcohol consumption must be addressed in his intervention plan.

Depression and lack of social support adversely impact persons with CHF and need to be addressed.[43] Quality of life is impacted by one's sense of control and perception of symptoms at hospital discharge in persons with heart disease as much as 3 years after a cardiac event.[22] Patients' perceptions of their illness can have an impact on their ability to make the changes in lifestyle necessary for healthy living after an acute coronary event. The occupational therapist's understanding of client factors, specifically values, beliefs, and spirituality, can help the healthcare team better understand the uniqueness of each individual and positively impact recovery.

Cardiac Rehabilitation

During the first 1 to 3 days after an MI, the patient's medical condition is usually stabilized. This acute phase is followed by a period of early mobilization. Phase 1 of treatment, inpatient cardiac rehabilitation, includes monitored low-level physical activity, including self-care, reinforcement of cardiac and postsurgical precautions, instruction in energy conservation and graded activity, and establishment of guidelines for appropriate activity levels at discharge. Through monitored activity, the ill effects of prolonged inactivity can be averted while medical problems, poor responses to medications, and atypical chest pain can be addressed. See Table 44.3 for signs and symptoms of cardiac distress.

TABLE 44.3

Signs and Symptoms of Cardiac Distress

Sign/Symptom	What to Look for
Angina	Look for chest pain that may be described as squeezing, tightness, aching, burning, or choking. Pain is generally substernal and may radiate to the arms, jaw, neck, or back. More intense or longer-lasting pain forewarns of greater ischemia.
Dyspnea	Look for shortness of breath with activity or at rest. Note the activity that brought on the dyspnea and the amount of time that it takes to resolve. Dyspnea at rest with a resting respiratory rate of greater than 30 breaths per minute is a sign of acute congestive heart failure. The patient may require emergency medical help.
Orthopnea	Look for dyspnea brought on by lying supine. Count the number of pillows that the patient needs to breathe comfortably during sleep (one, two, three, or four pillows needed to relieve orthopnea).
Nausea/emesis	Look for vomiting or signs that the patient feels sick to the stomach.
Diaphoresis	Look for cold, clammy sweat.
Fatigue	Look for a generalized feeling of exhaustion. The Borg Rate of Perceived Exertion Scale is a tool used to grade fatigue (see Box 44.1). Cerebral signs—ataxia, dizziness, confusion, and fainting (syncope)—are all indications that the brain is not getting enough oxygen.
Orthostatic	Look for a drop in systolic blood pressure and hypotension of greater than 10 mm Hg with a change in position from supine to sitting or sitting to standing.

Phase 2 of treatment, outpatient cardiac rehabilitation, usually begins at discharge. During this phase, exercise can be advanced while the patient is closely monitored on an outpatient basis. Community-based exercise programs follow in phase 3. Some individuals require treatment in their place of residence because they are not strong enough to tolerate outpatient therapy.

There is a strong base of clinical evidence that cardiac rehabilitation improves survival and quality of life and reduces the cost of medical care in the long run. This has led the Center for Medicare and Medicaid Services to expand the indications for cardiac rehabilitation programs.[52] These physician-directed, exercise-based programs include regular monitored exercise, lifestyle modification, and medical therapy. Individuals are taught how to monitor their response to activity and what to do in the event of an adverse response.

The Borg Rate of Perceived Exertion Scale (Box 44.1) is a tool used to measure perceived exertion. The patient is shown the scale before an activity and instructed that a rating of “6” means no exertion at all and a rating of “19” indicates extremely strenuous activity, equal to the most strenuous activity that the patient has ever performed. After the activity has been completed, the patient is asked to appraise his or her feelings of exertion as accurately as possible and give the activity a rating.

Box 44.1

Instructions for Using the Borg Rate of Perceived Exertion Scale

During the work, we want you to rate your perception of exertion (i.e., how heavy and strenuous the exercise feels to you and how tired you are). The perception of exertion is felt mainly as strain and fatigue in your muscles and as breathlessness or aches in the chest. All work requires some effort, even if only minimal. This is also true if you move only a little (e.g., walking slowly).

Use this scale from 6 to 20, with 6 meaning “no exertion at all” and 20 meaning “maximal exertion”:

6—“No exertion at all” means that you don't feel any exertion whatsoever (e.g., no muscle fatigue, breathlessness, or difficulty breathing).

9—“Very light” exertion, such as taking a shorter walk at your own pace.

13—A “somewhat hard” work, but it still feels okay to continue.

15—It is “hard” and tiring, but continuing isn't terribly difficult.

17—”Very hard.” This is very strenuous work. You can still go on, but you really have to push yourself and you are very tired.

19—An “extremely” strenuous level. For most people this is the most strenuous work that they have ever experienced.

Try to appraise your feeling of exertion and fatigue as spontaneously and as honestly as possible without thinking about what the actual physical load is. Try to not underestimate and to not overestimate your exertion. It's your own feeling of effort and exertion that is important, not how this compares with that of others. Look at the scale and the expressions, and then give a number. Use any number you like on the scale, not just one of those with an explanation behind it.

Sternal Precautions

Precautions to prevent trauma to the new graft sites, incisions, and sternum generally last about 8 weeks after surgery and generally include the following: do not lift more than 8 pounds, do not push or pull with arms when getting into and out of bed or up from a chair, do not bring elbows above shoulders, avoid twisting and deep bending, hug a pillow when coughing or sneezing, do not drive until cleared by surgeon, and report clicking or popping noises to your surgeon. **Sternal precautions** vary widely among hospitals, surgeons, and therapy departments. This is likely because they were developed on anecdotal and indirect evidence. Concern has been expressed in the literature that sternal precautions that are too restrictive might interfere with long-term functional outcomes and that individualized precautions based on surgical closure techniques and individual patient profiles would yield an improved functional outcome.[4]

Occupational therapists play a key role in assessing and educating individuals on sternal precautions. Engagement of patients in functional activity frequently will challenge individuals to maintain precautions while engaged in an ADL. Therapists need to assess what factors interfere with the individual's ability to comply with precautions and subsequently make suggestions for modification to education and recommendations for discharge. Cognitive impairments can limit one's ability to comply and may be temporary in nature if influenced by medication or, of more long-term concern, if underlying conditions such a dementia are present. Given the potential for neurologic events such as a cerebrovascular accident (CVA) or a transient ischemic attack (TIA) after surgery, the therapist may be the first to observe deficits from such events, which may appear as a lack of ability to comply with precautions.

Monitoring Response to Activity

When the patient's response to an activity is being assessed, symptoms provide one indication that the patient is or is not tolerating the activity. HR, BP, **rate-pressure product** (RPP), and ECG readings are other measures that may be used to evaluate the cardiovascular system's response to work.

Heart Rate

Heart rate (HR), or the number of beats per minute, can be monitored by feeling the patient's pulse at the radial, brachial, or carotid sites. The radial pulse is located on the volar surface of the wrist, just lateral to the head of the radius. The brachial pulse is found in the antecubital fossa, slightly medial to the midline of the forearm. The carotid pulse, located on the neck lateral to the Adam's apple, should be palpated gently; if overstimulated, it can cause the HR to drop below 60 beats per minute (bradycardia). To determine HR, the clinician applies the second and third fingers (flat, not with the tips) to the pulse site. If the pulse is even (regular), the clinician counts the number of beats in 10 seconds and multiplies the finding by 6. The thumb should never be used to take a pulse because it has its own pulse.

All clinicians who assess HR, as well as the patient him or herself, should be able to note the evenness (regularity) of the heartbeat. HR can be regular or irregular. An irregular heartbeat may be described as regularly irregular, which means that there is a consistent irregular pattern (e.g., every third beat is premature), or it may be described as irregularly irregular, which means that there is no pattern to the premature or skipped beats. HR irregularities include skipped beats, delayed beats, premature beats, and beats originating from outside the normal conduction pathway in the heart. Although an irregular HR is not normal, many individuals function quite well with an irregular rate. Clinicians should note the client's normal rate pattern, as well as any variations. The therapist evaluating a client for the first time should compare his or her observations about heart rate and regularity with the patient's record. A sudden change in HR from regular to irregular should be reported to the physician. An ECG or other diagnostic test may be ordered on the basis of such findings. When the HR is irregular, the number of beats should be counted for a full minute. Patients can be taught to take their own pulse and monitor the response of HR to activity. As a general rule, HR should rise in response to activity.

Blood Pressure

BP is the pressure that the blood exerts against the walls of any vessel as the heart beats. It is highest in the left ventricle during systole and decreases in the arterial system with distance from the heart.[51] A stethoscope and BP cuff (sphygmomanometer) are used to indirectly determine BP. The BP cuff is placed snugly (but not tightly) around the upper part of the patient's arm just above the elbow, with the bladder of the cuff centered above the brachial artery. The examiner inflates the cuff while palpating the brachial artery to 20 mm Hg above the point at which the brachial pulse is last felt. With the earpieces of the stethoscope angled forward in the examiner's ears, the dome of the stethoscope is placed over the patient's brachial artery. Supporting the patient's arm in extension with the pulse point of the brachial artery and the gauge of the stethoscope at the patient's heart level, the examiner deflates the cuff at a rate of approximately 2 mm Hg per second. Listening is imperative when recording BP. The first two sounds heard correspond to systolic BP. The examiner continues to listen until the last pulse is heard and diastolic BP is attained.

Physicians usually indicate treatment parameters for the HR and BP of patients in medical facilities. Parameters are frequently written in abbreviations, such as "Call HO if SBP > 150 < 90; DBP > 90 < 60; HR > 120 < 60." (In other words, "Call the house officer or physician on call if systolic BP is greater than 150 or less than 90, if diastolic BP is greater than 90 or less than 60, and if HR is greater than 120 or less than 60.")

HR and BP will fluctuate in response to activity, and cardiac output is affected by both HR and BP. Measurement of the rate pressure product, or RPP (measurement of the workload or oxygen demand), can give a more accurate indication of how well the heart is pumping. The RPP is the product of HR and systolic BP (RPP = HR × SBP). It is usually a five-digit number but is reported in three digits by dropping the last two (for example, HR 100 × SBP 120 = 12,000 = RPP 120). During any activity, the RPP should rise at peak and return to baseline in recovery (after 5 to 10 minutes of rest).

Correctly reading and interpreting an electrocardiogram (ECG) is a skill that requires hours of learning and practice for proficiency. Electrocardiography is not available in most nonacute settings. The reader is referred to Dubin's *Rapid Interpretation of EKGs*,[12] which is an excellent resource for persons unfamiliar with the subject.

There are many similarities in the evaluation and treatment of persons with cardiac disease and those with pulmonary dysfunction. A review of the pulmonary system and its disease processes follows.

Threaded Case Study

Harriet, Part 1

Harriet is a 64-year-old widow and mother of an adult daughter. She retired 3 years ago from her housekeeping job because of fatigue and shortness of breath. Chronic obstructive pulmonary disease was diagnosed at that time. She has been smoking cigarettes since the age of 20 and currently smokes one pack per day. She shares a small one-bedroom apartment with her terrier, Sir Filo. There is a first-floor laundry room in her building. Harriet's daughter lives three blocks away and checks on her mother daily. Harriet's baseline level of function 4 weeks ago consisted of walking the dog around the block slowly, fixing meals, doing laundry, and performing activities of daily living independently. She also enjoys playing bingo on Tuesday nights at her local church and cards with her widowers-and-widows group. Her daughter assists her in grocery shopping and cleaning.

Harriet was released from the acute care hospital 3 days ago, her condition having been stabilized after an acute exacerbation of her chronic obstructive pulmonary disease. Since her recent discharge, her daughter empties Harriet's bedside commode, shops for groceries, and fixes dinner for Harriet and Sir Filo. Results of the occupational therapy evaluation indicated that Harriet became short of breath when combing her hair. She was unable to pace her activity, to coordinate pursed-lip breathing with activity, or to assume dyspnea control postures when needed. She was receiving 2 L of oxygen by nasal cannula at all times. Harriet wants to be able to feed Sir Filo herself, stating that dogs become attached to people who feed them. She does not want her daughter to empty her commode and wants to be able to prepare dinner for herself. She does not want to be a burden to her daughter but rather to enjoy visiting with her.

Critical Thinking Questions

1. What goals may Harriet find relevant in her therapy?

2. What safety concerns might arise?

3. Do Harriet's goals appear realistic given her baseline level of function?

Anatomy and Physiology of Respiration[3,30,32]

Whereas the heart provides oxygen-rich blood to the body and transports carbon dioxide and other waste products to the lungs, the respiratory system exchanges oxygen for carbon dioxide. The cardiac and pulmonary systems are interdependent. If no oxygen were delivered to the bloodstream, the heart would soon stop functioning for lack of oxygen; conversely, if the heart were to stop pumping, the lungs would cease functioning for lack of a blood supply. All body tissues depend on the cardiopulmonary system for their nutrients.

The respiratory system supplies oxygen to the blood and removes waste products, primarily carbon dioxide, from the blood. Air enters the body via the nose and mouth and travels through the nasopharynx to the larynx or voice box. From there, the air continues downward into the lungs by way of the trachea or windpipe. The trachea consists of ribbed cartilage approximately 10 cm long. When the trachea or pharynx becomes blocked, a small incision may be made in the trachea to allow air to pass freely into the lungs. This procedure is called a tracheotomy.

The trachea divides into two main bronchi that carry air into the left and right lungs. The bronchi continue to branch off into smaller tubes, called bronchioles. Bronchioles are segmented into smaller passages called the alveolar ducts. Each alveolar duct is divided and leads into three or more alveolar sacs. The entire respiratory passageway from bronchi to alveolar sacs is often referred to as “the pulmonary tree” because its structure is much like that of an upside-down tree, with the alveolar sacs representing the leaves.

Each alveolar sac contains more than 10 alveoli. A fine, semipermeable membrane separates the alveolus from the capillary network. Across this membrane, oxygen is transported and exchanged for carbon dioxide. Carbon dioxide is exhaled into the air after traveling upward through the pulmonary tree (Fig. 44.4).

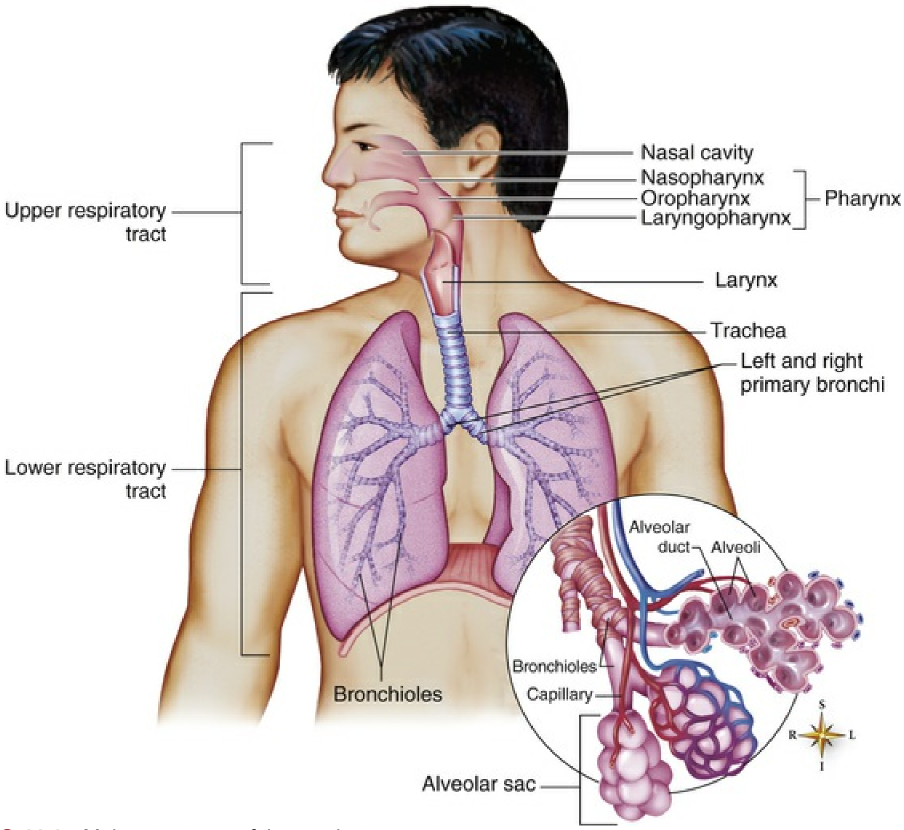

FIG 44.4 Major structures of the respiratory system. (From Patton K, Thibodeau G: *Anatomy & Physiology*, ed 9, St. Louis, 2016, Elsevier.)

With the exception of the nose and mouth, all the airways are lined with cilia and coated with mucus. Mucus and cilia provide a filtering shield that protects the fragile airway respiratory structures from dust and germs.

The musculature of the thorax helps in inspiration and expiration. During inspiration, the muscle power for breathing air into the lungs is provided primarily by the diaphragm. Originating from the sternum, ribs, lumbar vertebrae, and lumbocostal arches, the diaphragm forms the inferior border of the thorax. The muscle fibers of the diaphragm insert into a central tendon. Innervated by the left and right phrenic nerves, the diaphragm contracts and domes downward when stimulated. This downward doming of the diaphragm enlarges the volume of the thorax and causes a drop in pressure in the lungs relative to the air in the environment. Air then enters the lungs to equalize inside and outside pressure. Accessory muscles, the intercostals and scalenes, are also active during inspiration. The intercostals maintain alignment of the ribs, and the scalene helps elevate the rib cage.

At rest, expiration is primarily a passive relaxation of the inspiratory musculature. The lungs help draw the thorax inward as the inspiratory muscles relax. Forced expiration requires active contraction of the abdominal muscles to compress the viscera and squeeze the diaphragm upward in the thorax. Expiration can be further forced by flexing the torso forward and pressing with the arms on the chest or abdomen. As the volume of the thorax decreases, air is forced out of the lungs.

Accessory muscles in the neck and collarbone region can be recruited to assist in respiration when lung disease is active or other respiratory musculature is impaired.

Innervation of the Respiratory System

Breathing is mostly involuntary. A person does not have to think to take a breath. The autonomic nervous system has control over breathing. With anxiety and increased activity, the sympathetic nervous system will automatically increase the depth and rate of inspiration.

Inspiration and expiration have a volitional component. Volitional control allows us to control our breathing as we swim and to play the harmonica. Additionally, receptors within and outside the lungs can, when stimulated, cause changes in the depth and rate of breathing. Although the pons, medulla, and other parts of the brain provide the central control for breathing, they adjust their response to input from receptors in the lungs, the aorta, and the carotid artery.

Chronic Lung Disease[26]

Occupational therapy is frequently prescribed for individuals with chronic lung conditions that functionally impact their ability to participate in their usual occupations. Persons with **chronic obstructive pulmonary disease** (COPD), sarcoidosis, asthma, idiopathic pulmonary fibrosis, or cystic fibrosis may benefit from learning better ways to breathe and to conserve their energy. COPD includes two primary medical conditions: emphysema and chronic bronchitis. The air sacs of the lungs (alveoli) are damaged, lose their elasticity, and may become clogged with mucus.[37] It becomes harder to breathe, and as the disease progresses individuals experience a decrease in their IADL and ADL abilities. COPD is not curable, and the damage caused by the disease is irreversible. With medical management and lifestyle changes, the disease progression can be slowed and the individual's ability to participate in occupations can improve.

Emphysema is a medical condition in which the alveoli are gradually damaged. Although cigarette smoking is the leading cause of emphysema,[28] airborne irritants such as air pollution, marijuana smoke, and particles produced in manufacturing are contributing causes. Persons with chronic bronchitis experience shortness of breath (dyspnea) on exertion, and as the disease progresses, dyspnea occurs at rest.

In bronchitis the bronchial airway becomes inflamed, leading to increased mucus production, cough, and airway obstructions. When the airway is constantly irritated, a chronic cough with mucus results. Smoking is the major contributing cause of chronic bronchitis. Persons with chronic bronchitis are prone to upper respiratory infections, which worsens their disease process. Persons with severe chronic bronchitis are unlikely to recover fully.

Inflammation, fibrosis (thickening of the connective tissue), and narrowing of the terminal airways of the lungs are physiological changes that occur with peripheral airway disease. Smoking and other environmental pollutants irritate the airways, which leads to the development of abnormal terminal airways. Coughing and spitting up mucus from the lungs are common clinical manifestations of this disorder. The disease process may never progress beyond this initial phase, or it may evolve into emphysema and full-fledged COPD.

Asthma is characterized by irritability of the bronchotracheal tree and is typically episodic in onset.[35] Persons suffering from asthma experience wheezing and shortness of breath that may resolve spontaneously or necessitate the use of medication to calm the airway. Persons with asthma may be free of symptoms for periods between the episodes of wheezing and dyspnea. Some individuals appear to have a genetic predisposition to asthma. Allergenic causes of asthma may include pollen and respiratory irritants such as perfume, dust, and cleaning agents. Bronchospasm occurring with exposure to cold air or induced by exercise is sometimes the first clinical manifestations of asthma. Irritation of the airway leads to narrowing of the air passages and interferes with ventilation of the alveolar sacs. If left untreated, a severe asthmatic episode may result in death. Persons with severe asthma may be referred to occupational therapy to address declining ADL function.

Pulmonary Risk Factors

Smokers are 12 times more likely to die from COPD than nonsmokers.[50] Cigarette smoking also causes emphysema and chronic bronchitis. Clinical manifestations of the respiratory disease increase as the **pack-year history** increases. Pack-year history is calculated by multiplying the number of packs of cigarettes consumed per day by the number of years of smoking. A person who started smoking at the age of 20 and is now 64 has a pack-year history of 44 ($64 - 20 = 44 \times 1$ pack/year = 44 pack-years). Because cigarette smoke is a pulmonary irritant, it can also be a causative agent in asthmatic episodes. Other environmental irritants, such as air pollution, chemical exposure, and dust, are contributory risk factors in the development of COPD and asthma.[28]

Medical Management

COPD is a progressive, chronic disease. The onset of the disease is insidious. When patients initially seek medical attention, they are frequently seen in a physician's clinic rather than at a medical center. Besides evaluating the patient's medical history and symptoms and performing a physical examination, the physician will assess the patient's history of smoking and occupational exposure to respiratory irritants. Blood work and an x-ray examination will be performed to further assess the patient's clinical status. Most people with COPD take medication every day. Medications prescribed include anti-inflammatory agents (e.g., steroids and cromolyn sodium), bronchodilators (e.g., albuterol and theophylline) to help open the airway, and expectorants (e.g., iodides and guaifenesin) to help loosen and clear mucus. Flu shots and pneumococcal vaccines are recommended. Oxygen therapy may also be prescribed at a specific flow rate. Occasionally, persons receiving oxygen therapy may be tempted to increase the liter-per-minute flow in the erroneous thinking that more is better. This can result in retention of carbon dioxide and lead to failure of the right side of the heart.

Persons in acute respiratory distress may initially be managed with a ventilator before being weaned to oxygen. Ventilators provide mechanical assistance to the process of inspiration and do not increase the number of healthy alveolar sacs. Ventilators will not slow the end-stage disease process of COPD. Mechanical ventilation is frequently prescribed for persons with an acute exacerbation of the disease process caused by pneumonia, influenza, or CHF.

Pulmonary rehabilitation (PR) is a multidisciplinary, comprehensive program, tailored to the individual needs of each recipient. Psychological, emotional, physical, and emotional problems are addressed. The physician-directed team may include nurses; respiratory, physical, and occupational therapists; psychologists; and others with relevant skill sets. Pulmonary rehabilitation improves dyspnea symptoms in person with COPD, reduces the number of hospital days, and efficaciously utilizes medical services.[44]

OT Practice Notes

Frequently, the occupational therapist's role in treating clients with COPD involves salvage rather than prevention of the disease process. Earlier intervention by an occupational therapist is critical to prevent the disease.

Signs and Symptoms of Respiratory Distress

Dyspnea is probably the most obvious sign of a breathing difficulty. In the most severe form of dyspnea, the patient is short of breath even at rest. Clients with this level of dyspnea are unable to utter a short phrase without gasping for air. When reporting that a client has dyspnea, the practitioner should note the precipitating factors and associated circumstances—for example, “Harriet becomes short of breath when washing her face while seated in front of the sink.”

Other signs that the body is not getting enough oxygen include extreme fatigue, a nonproductive cough, confusion, impaired judgment, and cyanosis (bluish skin color caused by insufficient oxygen in the blood).

Psychosocial Considerations

Because COPD is a progressive, debilitating physical illness, it is not surprising that the psychosocial effects of the disease are considerable. Chan identified five themes related to barriers preventing engagement in occupation for people with COPD: uncertainty about progression of the disease, attributing the cause of the disease to external factors, progressing restriction in activity and isolation, anxiety and depression, and passive acceptance.[5] For persons with COPD, anxiety and depression are most strongly linked to decreased exercise capacity and shortness of breath.[9,45] Training in progressive muscle relaxation can be a successful tool for controlling the dyspnea and anxiety and for lowering the HR.[42]

Most cardiac and respiratory disease processes are preventable. Individuals with these diseases may lack basic skills in coping and setting limits with themselves or with others. The therapist's role includes encouraging the patient to engage in activities that will develop his or her skills and promoting the resumption of occupations that bring value, meaning, and participation back into the patient's life. With these skills, the patient begins to see himself or herself as a person actively making choices to get better. By working with Harriet on ways to engage with her dog when she does not have the endurance to take a walk, the occupational therapist not only teaches energy conservation but also conveys this information in a meaningful manner to the patient.

Pulmonary Rehabilitation

The goal of pulmonary rehabilitation is to stabilize or reverse the disease process and return the patient's function and participation in activity/occupation to the highest capacity. A multidisciplinary rehabilitation team working with the patient can design an individualized intervention program to meet this end. Accurate diagnosis, medical management, therapy, education, and emotional support are components of a pulmonary rehabilitation program. OT personnel are frequently part of the patient's team, which is headed by the patient and also includes the physician, nurse, and the patient's family and social supports. Respiratory therapists, dietitians, physical therapists, social workers, and psychologists may also be team members. Roles of team members vary slightly among facilities. Knowledge of specialized pulmonary treatment techniques is imperative for each team member when treating persons with pulmonary disease.

There are a number of recognized pulmonary rehabilitation guidelines. Both low- and high-intensity exercises are beneficial (higher intensity is better); arm exercises should be unsupported (active motion with no outside assistance), against gravity and with and without resistance; leg exercise should be included; and supplemental oxygen is helpful during rehab exercise.[44] The occupational therapist should apply these guidelines during ADL training. By continuing to maintain the higher level of activity gained in a pulmonary rehabilitation program, individuals can have sustained benefit from the program for years.

Intervention Techniques

Dyspnea control postures.

Adopting certain postures can reduce breathlessness. In a seated position, the patient bends forward slightly at the waist while supporting the upper part of the body by leaning the forearms on a table or the thighs. In a standing position, relief may be obtained by leaning forward and propping oneself on a counter or shopping cart.

Pursed-lip breathing.

Pursed-lip breathing (PLB) is thought to prevent tightness in the airway by providing resistance to expiration. PLB improves air movement, releasing trapped air in the lungs and helps to keep the airways open. Persons with COPD sometimes instinctively adopt this technique, whereas others may need to be taught it. Instructions for PLB are as follows:

1. Relax your neck and shoulder muscles.

2. Inhale slowly through the nose for a count of two.

3. Purse the lips as if to whistle.

4. Exhale—slowly, to a count of 4—through pursed lips as if trying to make a candle flicker without blowing it out.

Pursed lip breathing should be used when bending, lifting, or stair climbing.[7]

Diaphragmatic breathing.

Another breathing pattern, which calls for increased use of the diaphragm to improve chest volume, is **diaphragmatic breathing**. Many persons learn this technique by placing a small paperback novel on the abdomen just below the xiphoid process (base of the sternum or breastbone). The novel provides a visual cue for diaphragmatic movement. The patient lies supine and is instructed to inhale slowly and make the book rise. Exhalation through pursed lips should cause the book to fall.

Relaxation.

Progressive muscle relaxation in conjunction with breathing exercises can be effective in decreasing anxiety and controlling shortness of breath. One technique involves tensing muscle groups while slowly inhaling and then relaxing the muscle groups while exhaling twice as slowly through pursed lips. It is helpful to teach the patient a sequence of muscle groups to tense and relax. One common sequence involves tensing and relaxing first the face; followed by the face and the neck; then the face, neck, and shoulders; and so on, down the body to the toes. A calm, quiet, and comfortable environment is important for the novice in learning any relaxation technique.

Other treatments and considerations.

Physical therapists are generally called on to instruct patients in chest expansion exercises, a series of exercises intended to increase the flexibility of the chest. Percussion and postural drainage use gravity and gentle drumming on the patient's back to loosen secretions and help drain the secretions from the lungs. By isometrically contracting the arms and hands while they are placed on the patient's thorax, the therapist may transmit vibration to the patient. Vibration is performed during the expiratory phase of breathing and helps loosen secretions. Percussion and postural drainage may, however, be contraindicated in acutely ill patients and those who are medically unstable.

Humidity, pollution, extremes of temperature, and stagnant air have deleterious effects on persons with respiratory ailments. The therapist and patient should take these factors into consideration when planning activity.

Migliore's guidelines for the management of dyspnea provide a clinical progression and direction for the integration of dyspnea control techniques with the progression of activity.[31]

Individuals with chronic respiratory or cardiovascular limitations are frequently restricted in their ability to perform ADLs. OT intervention can promote improvements in the client's life management skills and quality of life.

Evaluation

Review of the Medical Record

A review of the medical record will identify the patient's medical history (diagnosis, severity, associated conditions, and secondary diagnoses), social history, test results, medications, and precautions.

Patient Interview

It is common courtesy and good medical practice to begin every encounter with a patient by introducing oneself and explaining the purpose of the evaluation or intervention. Good interviewing skills, including asking the right questions, listening to the patient's response, and observing the patient while responding, are considered integral aspects of the therapeutic use of self. Thoughtful, probing questions will help the patient and therapist identify areas of concern and lay the groundwork for establishing mutually agreeable goals. The therapist should observe the patient for signs of anxiety, shortness of breath, confusion, difficulty comprehending, fatigue, abnormal posture, reduced endurance, reduced ability to move, and stressful family dynamics. Interview questions should not only seek clarification of information that was unclear in the medical record but also clarify the patient's understanding of his or her condition and treatment.

A patient with a history of angina should be asked to describe what the angina feels like. If the patient has also had an MI, the patient should be asked whether he or she can differentiate between the angina and the MI chest pain. Clarification of symptoms before treatment can prove invaluable should symptoms arise. What clarifying questions might the therapist ask in evaluating Rudy or Harriet?

Asking patients to describe a typical day, to identify activities that bring on shortness of breath or angina, and to tell how their physical limitations interfere with the activities or occupations that they need to do or most enjoy doing will reveal problems that are meaningful and relevant to the patient.

Clinical Evaluation

The purpose of clinical assessment is to establish the patient's present functional ability and limitations. The content of an occupational therapist's clinical evaluation will vary from patient to patient and from setting to setting. Clients with impairments in the cardiovascular system will require monitoring of HR, BP, signs and symptoms of cardiac distress, and possibly ECG readings during an assessment of tolerance to postural changes and during a functional task. Table 44.4 provides a summary of appropriate versus inappropriate responses to activity. Individuals with disorders involving the respiratory system should be monitored closely for signs and symptoms of respiratory distress. If an oxygen saturation monitor is available, the patient's range of motion, strength, and sensation may be grossly assessed within the context of the ADL assessment. The patient's cognitive and psychosocial status will become apparent to a skilled clinician via interview and observation.

TABLE 44.4

Cardiovascular Response to Activity

	Appropriate	Inappropriate
Heart rate (HR)	Increases with activity to no more than 20 beats/min above the resting heart rate	HR more than 20 beats/min above the resting heart rate (RHR) with activity, RHR ≥120, HR drops or does not rise with activity
Blood pressure (BP)	Systolic blood pressure (SBP) rises with activity	SBP ≥220 mm Hg postural hypotension (≥10–20 mm Hg drop in SBP, decrease in SBP with activity)
Signs and symptoms	Absence of adverse symptoms	Excessive shortness of breath, angina, nausea, and vomiting; excessive sweating; extreme fatigue (rate of perceived exertion [RPE] ≥15); cerebral symptoms

After completing the evaluation, the clinician has sufficient information to formulate an intervention plan. In establishing the intervention goals and objectives, the clinician verifies that the patient agrees with the intervention plans and projected outcome. At this point it is helpful to assess the patient's perspective on barriers to attaining the goals identified. Asking “what might prevent you from being successful in…?” can yield unexpected information and identify other areas of concern. The occupational therapist discovered Rudy's possible alcohol dependence by using this type of probative question.

Intervention

Client goals, present clinical status, recent occupational performance history, response to current activities and occupations, and prognosis all help guide the progression of intervention for persons with cardiovascular or respiratory impairment. Clients with significant cardiac or pulmonary impairment, limited recent ability to participate in occupation, inappropriate responses to activities and occupations or orthostatic change, and a poor prognosis will progress very slowly. Individuals with little impairment of the heart or lungs, a recent history of normal occupational performance, appropriate responses to orthostatic change and activities and occupations, and a good prognosis will progress rapidly by comparison.

Progression and Energy Costs

The energy costs of an activity or occupation and the factors that influence energy costs can further guide the clinician in the safe progression of activity or participation in occupation. Oxygen consumption suggests how hard the heart and lungs are working and is indicative of the amount of energy needed to complete a task. Resting quietly in bed requires the lowest amount of oxygen per kilogram of body weight, roughly 3.5 mL O_2/kg body weight. This can also be expressed as 1 basal **metabolic equivalent** (MET). As activity increases, more oxygen is needed to meet the demands of the task. For instance, dressing requires 2.5 METs, or roughly twice the amount of energy that lying in bed requires (Table 44.5). Guided by a MET table, the patient's response to activity or occupation, the prognosis, and the patient's goals, the occupational therapist will be able to determine a logical intervention progression. As a general rule, once a patient tolerates an activity (e.g., seated sponge bathing) with appropriate responses, the patient may progress to the next higher MET-level activity (e.g., standing sponge bath).

TABLE 44.5

Basal Metabolic Equivalent Table of Self-Care and Homemaking Tasks

MET Level	Activities of Daily Living	Instrumental Activities of Daily Living, Work, Play, and Leisure
1–2	Eating, seated[25]; transfers, bed to chair; washing face and hands; brushing hair[25]; walking 1 mph	Hand sewing[8]; machine sewing; sweeping floors[5]; driving automatic car, drawing, knitting[46]
2–3	Seated sponge bath,[46] standing sponge bath,[46] dressing and undressing,[21] seated warm shower,[46] walking 2–3 mph, wheelchair propulsion 1.2 mph	Dusting,[25] kneading dough,[7] hand-washing small items,[8] using electric vacuum,[25] preparing a meal,[21] washing dishes,[46] golfing[46]
3–4	Standing shower, warm[21]; bowel movement on toilet[8]; climbing stairs at 24 ft/min[46]	Making a bed[21]; sweeping, mopping, gardening[46]
4–5	Hot shower,[21] bowel movement on bedpan,[21] sexual intercourse[46]	Changing bed linen[25]; gardening, raking, weeding; rollerskating,[16] swimming 20 yards/min[46]
5–6	Sexual intercourse,[46] walking up stairs at 30 feet/min[46]	Biking 10 mph on level ground[46]
6–7	Walking with braces and crutches	Swimming breaststroke,[46] skiing, playing basketball, walking 5 mph, shoveling snow, spading soil[46]

The duration of sustained physical activity must be taken into account when activity guidelines are being determined. Obviously, persons who have difficulty performing a 2-MET activity must still use a commode (3.6 METs) or bedpan (4.7 METs) for their bowel management. This is possible because a person can perform at a higher than usual MET level for brief periods without adverse effects.

At 5 METs, sexual activity is frequently a grave concern to persons with impaired cardiovascular function and their partners. Sexual intercourse is intermittent in its peak demands for energy. Few patients recall receiving counseling about sexual activity after a heart attack.[24] Bringing up the topic of sexual intimacy with both partners present is one technique that can put both the patient and therapist in an open frame of mind. Patients are frequently able to return to sexual intercourse once they can climb up and down two flights of steps in 1 minute with appropriate cardiovascular responses.[47] Providing the patient with information about when it is safe to resume sexual activity can reduce anxiety surrounding the resumption of sexual intercourse. Anxiety may be further decreased by discussing sexual activity guidelines with the patient and partner and identifying various forms of romantic intimacy, such as hand holding and kissing, when intercourse is not feasible. Besides instructing the patient to monitor HR and symptoms of cardiac distress before and after intercourse, the therapist should inform the patient and partner that cardiac medications might affect the patient's libido. The patient should be encouraged to inform the physician of problems related to sexual activity. In many cases the physician can adjust the patient's medications to control symptoms.

Energy Conservation

When patients are taught methods to conserve their energy resources, they will be able to perform at a higher functional level without expending more energy. The principles of **energy conservation** and work simplification are based on knowledge of the ways in which specific factors cause various cardiovascular responses. Ogden identified six variables that increase oxygen demand: increased rate, increased resistance, increased use of large muscles, increased involvement of the trunk musculature, raising one's arms, and isometric work (straining).[40] Upper extremity activity has also been shown to require greater cardiovascular output than lower extremity activity, and standing activity requires more energy than seated activity. Extremes of temperature, high humidity, and pollution make the heart work harder. By applying this information, a skilled clinician can suggest modifications in activity that will decrease the amount of energy needed for the task.

Energy conservation training should be individualized for each patient. Time management is an invaluable tool for energy conservation. Time management involves learning to plan one's activity or participation in occupation so that tasks requiring high energy expenditure are interspersed with lighter tasks, and rest breaks are scheduled throughout the day, especially after meals. The most important part of educating the client is incorporating his or her active involvement in planning the day. Client involvement increases the likelihood of realistic goal attainment. Rather than prescribing how Harriet might sequence her ADLs, IADLs, and rest breaks throughout her typical day, the therapist might engage her in a conversation about what works or does not work well for her in her current performance patterns. The therapist would then ask probing questions, such as "Have you tried taking your shower at a different time of day?" and "Would laying your clothes out the night before help your morning go more smoothly?" Such a client-centered approach engages the patient in the process of designing realistic performance patterns that incorporate principles of energy conservation according to his or her own circumstances and values. Through such collaboration, the therapist demonstrates respect for the patient's needs and increases the likelihood that changes will be implemented successfully.

Written material may augment energy conservation instruction. However, until the patient has successfully applied energy conservation principles to activity, the therapist should expect little follow-through with energy conservation recommendations. Practice and practical application of skills are critical to changing behavior.

The specific pulmonary rehabilitation intervention techniques of PLB, diaphragmatic breathing, dyspnea control postures, and relaxation techniques were discussed earlier in this chapter. Exhaling with exertion is another breathing principle for persons with compromised cardiac or pulmonary function. Franklin might be taught to exhale when having a bowel movement rather than holding his breath and straining. Harriet might be taught to exhale when lifting or lowering her pet's water bowl. This technique is more energy efficient and helps control systolic BP responses to activity. It is important for the patient to practice these skills during treatment. Therapeutic support is often critical in learning.

Lifestyle Modification

Modification of lifestyle is a key component in improving cardiovascular health. Exercise education should include the benefits of exercise; a graded program of increased activity and participation in occupation; stretching, strengthening, and aerobic activity; guidelines for monitoring HR, BP, and rate of perceived exertion; cool-down; safety issues related to clothing, environmental factors, and warning signs; a plan for resuming exercise if it is skipped for a period; and emergency guidelines. Although the physical therapist typically designs and oversees the exercise program, the occupational therapist can provide valuable insight into forms of exercise that might be meaningful to the patient. Modification of diet may be addressed by the dietitian but can readily be reinforced during meal preparation activities. To stop smoking, refrain from excessive alcohol consumption, and stop abusing drugs are challenging goals for clients who have developed these habits. Support groups, counseling, and medical management play key roles in successful cessation or modification of these risk factors. Occupational therapists believe that enabling the client's participation in rounds of personally meaningful and healthy occupations can also play a key role in supporting health and controlling such risk factors. The therapist worked with Rudy's treatment team to address his alcohol use concerns and helped him identify healthy occupational patterns (regular yoga) he had previously abandoned that would support sobriety.

Patient and Family Education

As members of the healthcare team, occupational therapists share the responsibility for patient and family education. The team must instruct the patient and family members in cardiac or pulmonary anatomy, the disease process, management of symptoms, risk factors, diet, exercise, and energy conservation and must reinforce the teaching. Inclusion of family members in an education program provides support indirectly to the client through the family unit. Such support is critical when the client depends on the assistance of a family member to accomplish everyday tasks.

Summary

Healthy persons are able to meet the varying demands of their bodies for oxygen because their heart and respiratory rates adjust to meet oxygen demand. When either the cardiovascular or the pulmonary system (or both) is compromised, the ability to perform normal activities or occupations declines. This chapter is intended to guide the occupational therapist in the treatment of clients with impairment of the heart or lungs and in designing programs to maximize clients' independent performance in areas of occupation to support participation in context. The two case studies presented in this chapter and related information portray the range of problems involving client factors, contextual issues, performance skills, and performance patterns that typically interfere with the client's ability to perform customary activities and occupations.

Threaded Case Study

Rudy, Part 2

Reflecting on the case of Rudy (who had undergone a valve replacement following a cardiac episode), the reader should consider the importance of really listening to the patient and following up with probative questions to develop more client-centered and thus more relevant goals. The first question the reader was asked to consider while reading the chapter was "What probative questions might the occupational therapist ask to clarify what Rudy means by 'everything he used to do'?" Rudy provided some clues in his occupational profile that yield themselves to further exploration. Besides returning to work, being able to dress himself, and managing his toileting, a therapist might further inquire as to (1) the role Rudy normally has in management of the home, how he previously showered, and in what other avocational activities he participates; (2) whether he and his wife would like to discuss safe resumption of sexual activities; and (3) the job-specific tasks that are most relevant for him to return to work.

With regard to the second question involving resumption of sexual activity, the therapist must first assess Rudy's understanding of his precautions and any factors that are interfering with his ability to apply those precautions. Besides asking Rudy to list his precautions and providing a written list of precautions, the therapist can better support Rudy's compliance by reviewing the at-risk postures prior to an activity as well as pacing the activity according to Rudy's ability to comply. The occupational therapist should consider if Rudy's memory and ability to apply precautions might be impacted by his pain medications, his premorbid personality, any neurologic condition associated with alcohol abuse, or perhaps even portend an impending CVA.

Finally, the reader was asked to consider what areas of occupation might the therapist choose for the next intervention session and, depending on Rudy's occupational profile, what goals might be included in his OT intervention plan. Performing the seated sponge bathing task and repeating bed mobility training while reinforcing sternal precautions would be a good choice of activities for the next therapy session. Rudy required frequent cuing and therapeutic intervention to keep him safe. By incorporating practice in safely pacing the activity and self-monitoring his HR and application of sternal precautions, his therapist will begin practical application of the skills essential to safe management of his cardiac condition. OT intervention will most likely end before Rudy returns to work. It is critical for him to understand how he might apply his sternal precautions at home and at work. The occupational therapist intervenes by using education to engage Rudy in a conversation about ways that he might adapt these principles to his work. Thus the therapist sets the groundwork for carryover of principles into that setting.

Threaded Case Study

Harriet, Part 2

When considering the case of Harriet, the reader was asked what goals she might find relevant in therapy. Harriet identified several meaningful goals during the initial occupational therapy evaluation, including feeding her dog Sir Filo, preparing her own dinner, and being able to empty her bedside commode herself. Another question involved the safety concerns that might arise in treating Harriet. Additional goals relevant to her safety include learning to pace her activity, coordinating her breathing with function, increasing her ability to assume dyspnea control postures when needed, and increasing her safety with oxygen. The oxygen line not only poses a potential trip hazard but also presents a fire hazard given her meal preparation goals and smoking habit. Smoking cessation is a goal that can be explored but will be meaningful only if Harriet wants to quit. Finally, the reader was asked to determine what goals appear realistic given Harriet's baseline level of function. Given her baseline level of function, all the goals she identified appear to be realistic.

Review Questions

1. Describe the heart, including its size, anatomy, and functional parts.
2. Name the heart valves, and give their locations and functions.
3. Discuss the relationship between the coronary arteries and health of the heart.
4. List and describe the symptoms of cardiac distress.
5. What are the typical psychosocial responses to a diagnosis of heart disease?
6. How is cardiac response to activity monitored? How does the therapist know that a change in level of activity is warranted?
7. Describe the functional parts of the pulmonary system.
8. What is COPD, and what is its significance for occupational performance?
9. What can the OT practitioner do to help prevent or reduce the incidence of COPD?
10. Demonstrate the recommended dyspnea control postures.
11. Compare pursed-lip breathing with diaphragmatic breathing. When should one be used rather than the other?
12. Describe the appropriate evaluation content and approach for patients with cardiac and pulmonary problems.
13. What is a MET, and what is the clinical value of a MET table for occupational therapists?
14. How would you teach energy conservation techniques to the following individuals, all of whom have cardiac or pulmonary disease?
    - A 40-year-old female marathon runner
    - A 50-year-old homemaker and adoptive mother of eight (including three children younger than 6 years)
    - A 60-year-old air conditioner repairman
    - A 72-year-old man who says his main pleasures are riding thoroughbreds, drinking good Kentucky bourbon, smoking cigars, and enjoying the company of lovely women

Cancer and Oncology Rehabilitation

Brent Braveman, Lauro A. Munoz, Jennifer Kaye Hughes, Jennifer Nicholson

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, the student or practitioner will be able to do the following:

1. Identify and describe the range of effects that cancer can have on occupational performance.
2. Understand the various types of cancer, which are most common in men and women, and the most common medical and therapeutic interventions.
3. Identify the types of occupational therapy interventions used to promote occupational performance in adults with cancer.
4. Explain the side effects of surgery, radiation therapy, and chemotherapy and their impact on occupational performance.
5. State the distinct value that occupational therapy adds to rehabilitation of the person with cancer.

KEY TERMS

Cancer
Cancer-related cognitive impairment

Cancer-related fatigue

Chemotherapy

Hospice

Lymphedema

Metastasis

Palliative care

Radiation therapy

Case Study

Kay

Kay is a 36-year-old mother of two children who lives with her spouse and works full time. She was diagnosed with invasive ductile breast cancer and underwent surgery followed by radiation and chemotherapy. She received occupational therapy as an inpatient and is now receiving follow-up services as an outpatient after expressing concerns to both her treating physician and nurse practitioner about her performance of daily occupations.

Kay was evaluated by the outpatient occupational therapist to identify challenges to occupational performance in any of her roles (eg, parent, spouse, worker, homemaker, volunteer, sports enthusiast, and religious participant). Kay is functioning independently in her self-care but is feeling stretched to her limits due to fatigue and mild cognitive issues caused by the radiation and chemotherapy.

Kay is also experiencing psychosocial distress related to her body image and impending reconstructive surgery. Kay told her occupational therapist, "I am barely making it through the day and am trying to hold it together while I care for my kids, take care of the home, and try to do some work. I am exhausted all the time and continually make stupid mistakes and feel confused over things that used to be so simple. I can't even imagine getting back to running or my volunteer work at my church. I am at the end of my rope!"

Critical Thinking Questions

- If Kay is able to bathe and dress herself and get support from her spouse over the short term, why does she need occupational therapy?
- Kay has identified fatigue and cognitive issues as primary concerns but is struggling with performance of all of her daily roles, so where should the occupational therapist begin?
- In addition to the physical symptoms that Kay is experiencing, what are the psychosocial issues that should be addressed by the occupational therapy practitioners working with Kay?

Introduction to Cancer and Oncology Rehabilitation

In 2015, an estimated 1,658,370 new cases of cancer were diagnosed in the United States, and 589,430 people died from the disease. Approximately 39.6% of men and women will be diagnosed with cancer at some point during their lifetime.[23] The most common cancers in men are prostate, lung and bronchus, colon and rectum, urinary and bladder, and melanoma of the skin. The most common cancers in women are breast, lung and bronchus, colon and rectum, uterine corpus, and thyroid.[3] Overall men have a 50% chance of developing some form of cancer in their lifetime, and women have a 33% risk of incidence. The number of cancer survivors in the United States is expected to reach 22 million by 2024.[24] **Cancer** is typically described according to where the cancer originates with the most common forms being melanoma (skin), carcinoma (skin or tissue lining organs), sarcoma (connective tissue), leukemia (bone marrow or blood-forming organs), lymphoma (immune system), multiple myeloma (plasma cells and bone marrow), and central nervous system (brain and spine).

Oncology rehabilitation including occupational therapy, physical therapy, speech-language pathology, and rehabilitation medicine has grown rapidly. Oncology rehabilitation services are provided at large National Cancer Institutes such as the University of Texas MD Anderson Cancer Center in Houston, Texas, at smaller cancer centers and community-based hospitals, and in the home. Rehabilitative services are provided at all stages of cancer or what is referred to as the *cancer care continuum*. The stages of the cancer care continuum include (1) pretreatment (newly diagnosed but no treatment initiated), (2) active treatment (treatment with a curative goal), (3) maintenance (long-term therapy with a goal of remission), (4) posttreatment or survivorship (medical treatment complete with no sign of disease), and (5) palliative care (treatment when cancer is incurable with a focus on comfort and function). Occupational therapy practitioners also have roles in cancer prevention through lifestyle redesign and occupational performance to support health.

Treatment Options

The range of cancer treatments is driven by the type of cancer, how early the disease is discovered, and how advanced the cancer has become. The length of time that treatment lasts and the impact of treatment on an individual can be wide ranging. The most common forms of treatment include the following[23]:

- Surgical removal of cancer cells/tumors from the body
- **Radiation therapy** focused on killing cancer cells and shrinking tumors
- **Chemotherapy** using drugs to kill cancer cells
- Immunotherapy focused on strengthening and using a person's immune system to fight cancer
- Hormone therapy, which uses hormones to slow or stop cancer cell growth
- Stem cell transplants, which restore blood-forming cells destroyed by high-dose chemotherapy or radiation

Precautions, Contraindications, and Medical Complexity

Providing safe occupational therapy intervention for people with cancer can be complex and requires specialty and sometimes advanced knowledge and understanding of how medications, treatments, and the status of body systems affect the course of evaluation and treatment. Medications and the disease process can influence the body that is attempting to maintain homeostasis. Some body functions that could be affected include changes in heart rate and rhythm, dizziness, blood pressure problems, changes in vision, and changes in cognitive status, appetite, or metabolism. Two key measures of body functions when the person is undergoing cancer treatments are vital signs and laboratory ("lab") values. Vital signs (i.e., blood pressure, arterial blood pressure, intracranial pressure, respiration rate, heart rate, and oxygen saturation) and laboratory ("lab") values are two important measures of body functions to monitor during intervention with cancer survivors. Lab values provide the practitioner with information regarding a client's biochemistry that could affect performance.[30]

Common lab values that should be reviewed prior to each occupational therapy intervention session include the following:

- Blood cell counts such as red blood cell count, white blood cell count, hemoglobin, and hematocrit.
- Coagulation panels such as prothrombin time, international normalized ratio, and partial thromboplastin time.
- Basic metabolic panels including blood sugar, calcium, creatinine, potassium, and blood urea nitrogen.

These lab values each have a range within which functional activity and participation in rehabilitation activities is safe and appropriate. Functional activity is contraindicated for lab values that are critically outside the normal range. Tests such as a complete blood count can help practitioners determine safe functional activity guidelines, particularly for patients who are undergoing or have just completed chemotherapy, radiation therapy, or bone marrow transplants. Criteria for exercise vary depending on the type of cancer, the treatment that a patient is receiving, and the patient's reaction medically and physiologically. Patients who may be able to safely exercise at one point in their course of treatment may be under activity restrictions at other times. Table 45.1 includes examples of three common lab values seen in the oncology setting which are (1) platelets, (2) hematocrit, and (3) white blood cells. The precautions associated with abnormal values for each are also noted. The ranges provided are reflective of commonly used values. Medical and rehabilitative practice in regard to lab values may vary, so practitioners should become familiar with the specific ranges considered normal in their setting and consult with the medical team to determine when participation in rehabilitation is contraindicated.

TABLE 45.1

Examples of Common Lab Values in the Oncology Rehabilitation Setting and Their Indication for Participation in Rehabilitation Activity

Lab Name	Normal Range	Accepted Values for Participation	Rehabilitation Implications	Other Findings
Platelets	150 k/uL–450 k/uL	140–440 k/uL	<5 K only active assistive movements/no Valsalva maneuvers <20 K active movements >50 K resistive movements Fall risk assessments are paramount when platelets are low	Check for petechiae: a reddish purple rash Check for any active signs of bleeding: nosebleeds, excessive bleeding from cuts, blood tinged sputum, swollen joints, etc. Below 20 K (+) increase risk for intracranial bleed
White blood cells (WBCs)	3.5 k/uL–10.5 k/uL	4–11 k/uL	(+) Risk for infection Neutropenia: absolute neutrophil count less than 0.5 cell/mm^3	Adhere to hand hygiene and infection control policies Patient may present with a fever when neutropenic
Hematocrit	Normal Male: 37%–49% Female: 36%–46%	Male: 40%–54% Female: 37%–47%	<20%: can result in cardiac failure/death <25%: defer therapy 25%–30%: ADL and exercise, as tolerated 30%: can add resistive exercise	Consult with medical team

Radiology and Imaging

Occupational therapy practitioners should consult and review imaging reports such as computed tomography scans (CT or CAT scans), magnetic resonance images (MRIs), ultrasound, or x-rays in the event of acute fractures, **metastasis** (the spread of cancer to another part of the body), or any changes in status that could affect precautions or treatment. These test results may influence the type of testing that the occupational therapy practitioner performs or alter the intervention plan. For example, evidence on an MRI may show new metastatic disease to the brain that would result in more intense cognitive testing. An MRI exhibiting new pathologic fractures could alter activities of daily living (ADLs) that require weight bearing or lifting.

In general, the occupational therapy practitioner should verify blood counts, vital signs, and images before evaluation and treatment. The practitioner should also verify any specific precautions that are associated with the type of cancer before attempting interventions including mobilization, weight bearing, manual muscle testing, or any activities that may have a resistive component.

Occupational Therapy and Cancer: Domain and Process

Because of the variations in types of cancers and the broad-ranging impact of the disease and its treatments, understanding the occupational therapy process and cancer requires consideration of the full domain of occupational therapy and the full scope of the occupational therapy process as represented in the Occupational Therapy Practice Framework.[7] Table 45.2 provides examples applied to Kay, who was introduced at the start of the chapter.

TABLE 45.2

Occupational Therapy Domain and Process in Oncology Rehabilitation

Occupational Therapy Domain	Examples Related to Kay
Occupations	Occupations related to Kay's identified roles of parent, spouse, worker, homemaker, volunteer, sports enthusiast, and religious participant. Physical, cognitive, emotional, and psychosocial factors can affect all areas of occupation including ADL, IADL, rest/sleep, education, work, play, leisure, and social participation.
Patient factors	All areas of patient factors must be considered including values and beliefs about health and illness as Kay confronts the impact of cancer on body functions such as respiration, sensation, cognition, and organ function and body structures such as bone, joints, and muscles.
Performance skills	Depending on the location of the cancer and the effects of treatment performance skills including cognitive abilities, motor skills, process skills, and social interaction skills.
Performance patterns	Kay's habits, routines, roles, and rituals used in the process of engaging in occupations can be disrupted by surgery or the effects of chemotherapy or radiation on level of energy, endurance, interest in continuing in roles, and interacting with others.
Contexts and environments	Cultural, personal, temporal, and virtual contexts can support or inhibit the occupational performance of persons with cancer. The physical and social environment including natural and built environments, objects, and relationships with family members, friends, coworkers, and others must be considered.
Occupational Therapy Process	
Evaluation	Identification of information about the Kay's needs, problems, and concerns.
Occupational profile	Summary of Kay's occupational history, patterns of daily life, interests, values and needs.
Analysis of occupational performance	Using assessment tools to identify the Kay's assets and problems.
Intervention	The skilled services provided by occupational therapy practitioners to facilitate Kay's engagement in occupational performance.
Intervention plan	Guides the actions of the practitioner and the approaches used to achieve the Kay's goals. Putting the intervention plan into action.
Intervention implementation Intervention review	Continuous process of reevaluating the intervention plan to improve outcomes.
Targeting of outcomes	Selecting the results to be achieved through occupational therapy interventions.

Common Assessments Used in Oncology Rehabilitation by Occupational Therapists

In addition to routine assessment of ADLs, instrumental activities of daily living (IADLs), and other areas of occupation through observation of performance, there are specific assessments or categories of assessments commonly used by the occupational therapist in treating the person with cancer. A few examples include the following:

- *Activities of daily living assessment* scales such as the Katz ADL Scale.
- *A-One* is a cognitive assessment that directly links functional performance (basic activities of daily living and mobility) to neurobehavioral deficits including cognitive-perceptual and motor impairments. The A-One is appropriate to use for patients over the age of 16 who present with damage to the central nervous system.
- *Brief Fatigue Inventory (BFI)* is a short assessment of the severity of fatigue experienced over the previous 24 hours and its impact on function.
- *Executive Function Performance Test* is a performance-based standardized assessment of cognitive function available for free in the public domain.
- *Functional Assessment of Cancer Therapy (FACT)* is a general assessment of quality of life.
- *Kettle Test* is a performance-based assessment of cognitive functional performance.
- *Multiple Errands Test (MET)* evaluates the effect of executive function deficits on everyday functioning through a number of real-world tasks.
- *Pain scales* such as rating pain from 0 to 10 where 0 is no pain and 10 is the worst pain imaginable or the Wong-Baker face scale that uses pictures to express “no hurt” to “worst hurt.”

Significant Secondary Conditions Related to Cancer and Cancer Treatment

In addition to problems caused directly by cancer, there are several significant secondary conditions that can be caused by the cancer or cancer treatment (eg, surgery, radiation, chemotherapy). The following are examples of such secondary conditions and brief explanations of the significance for occupational performance.

Cancer-Related Fatigue

The National Comprehensive Cancer Network (NCCN) has defined **cancer-related fatigue** (CRF) as "a distressing, persistent subjective sense of physical, emotional or cognitive tiredness or exhaustion related to cancer or cancer treatment that is not proportional to recent activity and interferes with usual functioning" (p. FT-1).[25] Occupational therapy practitioners can empower clients by helping them distinguish between other types of normal fatigue experienced in the past from CRF, as rest and sleep will only worsen the symptoms, which seems counterintuitive to most people. Clients further need to comprehend that CRF comprise much more than the physical realm. Hann and colleagues described CRF as having four subcomponents that are (1) general fatigue, (2) emotional fatigue, (3) physical fatigue, and (4) mental fatigue.[16] Occupational therapy practitioners play a vital role in helping each patient identify how each dimension directly contributes to CRF as well as strategies for addressing each aspect interfering with daily activity. The incidence of cancer-related fatigue experienced by patients with cancer is difficult to determine as published studies are restricted to prevalence data.[12] However, some studies reveal that CRF is experienced by a majority of patients during the course of treatment and one-third will experience persistent fatigue after treatment is completed.[12] In practice, almost 80% of patients report CRF as the most distressing symptom experienced as it can drastically decrease participation and performance of all occupations, roles, and routines.

CRF profoundly affects the quality of life (QOL) of both patients and their families, including mental, physical, psychosocial, and economic aspects.[12] CRF can result in an altered lifestyle, decreased participation, a decline in performance capacity due to inefficient use of energy, loss of control and identity, impaired volition and motivation, reduced ability to work, reduced self-efficacy, poor QOL, lack of social interaction, and loss of important roles.

All clients should be screened for CRF throughout the continuum of care recognizing that the experience of CRF is unique to each individual. There is no accurate objective report, and the most common measure is patient self-report (ie, using the BFI). It is also important to recognize that symptom severity is not equivalent to the degree to which symptoms interfere with the performance and participation in meaningful activities, therefore what matters is how CRF directly affects occupational performance and participation.[9,20]

Table 45.3 provides examples of each of the types of occupational therapy interventions identified in the Occupational Therapy Practice Framework: Domain and Process that are appropriate to CRF.[7]

TABLE 45.3

Examples of Occupational Therapy Interventions Associated With Cancer-Related Fatigue

Occupational Therapy Intervention Approach	Example
Create and promote	Create educational materials to guide patients in management of cancer-related fatigue or cognitive impairment.
Prevent	Screen for early signs of CRF and educate patients and family members on the potential for the onset of CRF with new treatments.
Establish and restore	Examine daily routines and establish habits and patterns that incorporate rest and exercise to minimize cancer-related fatigue.
Modify	Simplify ADLs and IADLs and add cuing strategies to compensate for cancer-related cognitive impairments such as impaired short-term memory and lowered attention span.
Maintain	Identify occupations and roles important to the patient and prioritize involvement in meaningful occupations that will allow the patient to continue role fulfillment. Use lifestyle redesign approaches to maintain strength, endurance, and mobility during and after treatment.

ADLs, activities of daily living; CRF, cancer-related fatigue; IADLs, instrumental activities of daily living.

Occupational therapy intervention for CRF varies depending on its severity and can include participation in the full range of human occupation. The following are some basic guidelines to follow in interventions for CRF:

- Remain client-centered, use active listening, and use a holistic approach focusing on therapeutic use of self.
- Assess the patient's motivation and volition for performance of occupations and roles.
- Assess all areas of function (physical, cognitive, psychosocial/emotional, etc.).
- Ensure that intervention will include an application of skills and use of occupation rather than remain solely didactic.
- Provide demonstrations and give homework to facilitate carryover of skills and learning.
- Assess response to treatment and indications that treatment or homework is too intense or counterproductive.

Cancer-Related Cognitive Dysfunction

Up to 75% of patients with cancer experience **cancer-related cognitive impairment** during or after cancer treatment with impairments in memory, executive functioning, and attention span. It is estimated that nearly 4 million cancer survivors have some form of cognitive difficulty.[17] Cognitive impairments resulting from cancer-related treatment can vary from subtle to dramatic and can be temporary or permanent. Table 45.4 correlates different treatments used in treating cancer with predicted cognitive impairments.[1]

TABLE 45.4

Common Cancer Treatment Methods and Their Predicted Cognitive Impairments

Chemotherapy	Inattention Lack of concentration Decreased working memory Impaired executive functioning
Radiation therapy	Inattention Decreased memory Impaired executive functioning Impaired visual perceptual skills
Steroids	Behavioral changes Decreased verbal memory Inattention
Sedatives	Decreased level of arousal Delirium Confusion/disorientation

In approaching intervention for cancer-related cognitive dysfunction, the occupational therapy practitioner has several options. These options are presented in Table 45.5. Which approach is used depends on the treatment context and the severity of the impairments experienced by the patient. It is important to note that the approaches are not exclusive and several maybe used throughout the episode of care.

TABLE 45.5

Intervention Approaches for Cancer-Related Cognitive Dysfunction

Cognitive behavioral strategies	Coping skills/relaxation Sleep hygiene and education Self/goal management
Remediation/restoration	Repeated practice of drills, exercises, or activities Relevant real-life tasks Computer-based training
Compensatory skills training	Environment or task modifications Adjustment of task features/sensory cues Involvement of the individual's mental operations; use of imagery
Meaningful functional activity	Promotes and maintains focus; concentration Decreases anxiety Improves psychological well-being

Chemotherapy-Induced Peripheral Neuropathy

Chemotherapy-induced peripheral neuropathy (CIPN) is experienced by patients undergoing treatment with certain neurotoxic chemotherapy agents such as the platinum drugs that cause dysfunction or damage to peripheral nerves, and functional recovery can take months to years depending on many factors.[18] CIPN can present as motor, sensory, autonomic, or mixed impairments and typically follows a symmetric stocking-glove distribution of impairment with the earliest symptoms developing at the fingertips and toes. Common symptoms that impair occupations include tingling, numbness, paresthesia, temperature sensitivity, pain, feeling of wearing gloves and stockings, weakness, and impaired balance.[31] Many patients report the effects of CIPN as painful, disabling, creating significant loss of function, and decreasing quality of life. Overall survival might be effected with dose reductions or discontinuation of treatment when severe symptoms arise.[21]

Standard sensory testing, balance tests, outcome measurements, and functional timed tests to better determine underlying problems related to performance skill deficits are appropriate for the patient with CIPN. Standard sensory tests will help establish a baseline and determine change over time as well as identify which type of sensation is potentially affecting occupational outcomes. It is also beneficial to assess balance and the patient's confidence with activities requiring balance.[10]

Intervention for patients with CIPN include compensation strategies for safety, foot care and proper shoes, strategies to reduce ischemic and thermal injuries and management of symptoms of autonomic dysfunction, falls prevention, and use of assistive devices to compensate for loss of sensation or weakness to promote independence and remain active in daily activities.[31] Activity pacing and gradation of activity is also beneficial as are use of energy conservation techniques to manage muscle fatigue. Exposure to different surfaces during functional tasks (ie, desensitization) can reduce anxiety associated with CIPN.

Cancer-Related Pain

Pain due to cancer is a complex symptom that affects a person's life, including physical functioning, the performance of activities of daily living, psychological, and emotional status and social interactions.[29] It is estimated that 33% to 50% of patients with cancer will experience some level of pain and estimates are considerably higher (over 70%) in patients with advanced disease.[15] Occupational therapy practitioners evaluate the impact of pain on a client's desired activities and quality of life and equip the patient with the skills and strategies to manage the pain. Practitioners must use their skills to validate the patient's pain and work to establish trust.[5,22]

Cancer-related pain and the fear of pain can have a significant negative affect on occupational performance. Strategies to facilitate occupational performance include collaborative activity analysis with patients, graded activities, identifying pain triggers, posture assessment, and visualization or mental strategies to overcome the pain cycle.

Deconditioning in Oncology

Occupational therapy practitioners working with clients in the oncology setting must emphasize the relationship between deconditioning and occupational performance. Deconditioning is best understood as a loss of functional capacity due to lack of activity, which is multifactorial in nature. Deconditioning, as associated with disease process and cancer-related treatments, can have a dramatic impact on quality of life. Additionally, deconditioning is often associated with poor responses to cancer-related treatments and, subsequently, poor survival. The literature also suggests that the mechanism for fatigue may be related to a "vicious circle between fatigue, physical inactivity, and deconditioning."[33] Occupational therapy practitioners can help individuals combat this cycle through mobilizing activities such as eating meals sitting up instead of lying in bed, walking to the bathroom instead of using a bedside commode, and performing simple ADLs while standing and walking short and safe distances.

Cardiovascular and Pulmonary Considerations

In the oncological setting, the occupational therapy practitioner must consider cardiovascular and pulmonary status as it relates directly to the client's occupational performance. The clinical picture becomes complex in oncology as the relationship between cardiovascular and pulmonary performance and activity tolerance are so tightly linked. Exercise tolerance is affected by a number of factors, including tumor burden, anticancer therapies, salvage surgical resection, and pleural effusion, to name a few. Baseline pulmonary and cardiovascular impairments must also be considered, as patients with cancer are typically older. Inactivity, as is commonly seen in these patients, can cause profound muscle atrophy, as well as a decline in cardiac performance. Physical activity, including occupational engagement and exercise, has been shown to increase cardiovascular and pulmonary measures as well as reduce fatigue, resulting in strong implications for the efficacy of skilled occupational therapy intervention in this patient population.

Psychosocial Issues (Body Image, Depression, Anxiety)

The individual diagnosed with cancer is faced with many psychosocial challenges such as distress starting at initial diagnosis and often lasting throughout survivorship. The word *cancer* is often associated with a "life-threatening" disease, although it is more recently referred to a chronic illness in the field of medicine. Beyond thoughts of death, clients begin to worry about how the diagnosis and treatment will affect not only their own occupational performance but also that of family and friends. Lyons suggested, "The awareness of mortality and resultant uncertainty can create tension in the lives of those with cancer." There are many effects of psychosocial challenges on everyday occupations including but not limited to altered or disrupted roles, routines, and habits; changes to social contexts; negative emotions, loss of control and identity; impaired motivation; and decline in quality of life.[19]

Body image and self-efficacy is a common psychosocial issue experienced by patients with cancer secondary to unavoidable changes to appearance and decline in function. Body image is a complex concept that goes far beyond one's experience of physical appearance. Body image is further defined as a multidimensional construct that involves perceptions, thoughts, feelings, and behaviors related to the entire body and its functioning.[13]

Moreover, Zabora and colleagues stated that 60% of cancer patients suffer psychological distress.[34] Distress can be defined as a multifactorial, unpleasant emotional experience of a psychological, social, or spiritual nature that interferes with effective coping.[26] Some literature, however, estimates that the proportion exceeds 60%, which is often what is seen in practice. Many individuals who are referred for occupational therapy services experience a higher incidence of psychosocial challenges, most likely secondary to a decline in function and occupation-based activities, than clients who are never referred to occupational therapy.[10] Occupational therapy practitioners are well suited to meet these psychosocial issues and trained to assess the needs of the whole person in different environments and contexts, which includes any psychosocial issues interfering with occupational performance and participation.[5]

Occupational therapy intervention for psychosocial issues can include adaptations to the physical and social environment to promote occupations.[5] The focus of intervention can include the following:

- Stress management and coping strategies to increase one's sense of control
- Relaxation techniques, guided imagery, and breathing techniques as part of a personal plan to manage anxiety
- Lifestyle management and redesign
- Cognitive behavioral techniques and adaptive solutions to practical problems
- Positive lifestyle change and adoption of healthy behaviors
- Interventions related to disturbance in body image
- Psychosexual therapy focusing on communication training, sensate focus, and body image exposure
- Expressive-supportive therapy focusing on expression of thoughts and emotions, receiving and offering support, coping skills
- Educational interventions including information disseminated in lecture formats to increase knowledge on disease and treatment with the aim of increasing self-efficacy

Although it is easy to direct the clinical eye to physical changes and manifestations of cancer, the occupational therapy practitioner working in oncology must have a keen awareness of a number of detrimental effects on occupational performance and participation that are not observable, namely anxiety and depression. People with cancer and their families experience a substantial amount of psychological morbidity. Depression and anxiety can impact functioning, quality of life, and survival. Tang and colleagues noted that cancer patients, especially in terminal cases, are predisposed to depressive symptoms as a result of progressive functional decline, accelerating symptom severity, deteriorating social support, and a self-perceived burden to others.[32] Pain associated with treatments is also correlated to depression and anxiety. Typical assessments found and utilized in the oncology setting to measure these issues include the Hospital Anxiety and Depression Scale, the Beck Depression Inventory (BDI), and the Beck Anxiety Inventory (BAI).

Lymphedema

Lymphedema, a condition caused by inadequate drainage of lymphatic fluid, is a common secondary condition associated with some forms of cancer treatment. Lymphedema is most commonly associated with breast cancer but can be seen with other forms of cancer, including lymphoma. There are multiple causes of inadequate lymphatic drainage, including blockage of lymphatic flow by a tumor, scarring and inflammation of the lymph nodes and vessels following radiation therapy, and surgical resection of a lymph node or multiple lymph nodes. Lymphedema can occur in the head and neck region but most commonly occurs in the arms or the legs. Scrotal edema also can occur post-surgery.

According to the American Cancer Society, lymphedema can begin soon after surgery or radiation but can also appear many years after treatment, and cancer survivors should be educated to the fact that they will remain at risk for lymphedema throughout their lives.[2] Eighty percent of individuals experience an onset of lymphedema within 3 years of surgery; the remainder develop edema at a rate of 1% per year.[28] O'Toole and colleagues[27] note that lymphedema can have significant functional implications, and increased attention has been given to lymphedema with increased survivorship. Treatment approaches for lymphedema include gentle exercise paired with diaphragmatic breathing, compression garments and lymphedema wrapping techniques, manual lymphatic drainage, pneumatic compression, and complete decongestive therapy (CDT). Certification in the management of lymphedema is available to both occupational therapy practitioners and physical therapy practitioners.

Palliative Care and Hospice

Palliative care and **hospice** are closely related. In both situations practitioners intervene with persons facing life-threatening illnesses. The official American Occupational Therapy Association document, "The Role of Occupational Therapy in End of Life Care," states the following:

Palliative care differs from hospice care in that it can be initiated at any point in the course of the patient's illness. Curative care interventions also may be used within the context of palliative approach, whereas curative services are not provided when a patient is receiving hospice care. A patient receiving palliative and curative services simultaneously may transition to a hospice service when curative therapies are no longer appropriate or desired and the end of life is more imminent.[6] (p. S67)

A key element of occupational therapy practice in palliative care and in hospice is remaining client centered and providing occupation-based intervention. The occupational therapy practitioner in hospice collaborates with the patient and the patient's family to identify goals and to assist the patient to remain self-determinant. Because persons with cancer may be under hospice care for a short time before death or for many months, and because hospice care is provided on an inpatient basis and at home, patients may wish to continue to perform occupations across the spectrum of occupational roles including worker, home manager, parent, spouse, religious participant, and others. The occupational therapy process is the same with the patient who is dying as it is with any other occupational therapy patient. Even those who are faced with imminent death typically have goals and wish to remain in control and self-determinant.

Summary

The number of cancer survivors is growing significantly and persons with cancer have rehabilitation needs including needs for occupational therapy intervention during and following active treatment. Cancer can result in a range of problems that affect occupational performance including cancer-related fatigue, cancer-related cognitive dysfunction, pain, cancer-induced neuropathy, lymphedema, depression, and a range of psychosocial issues related to body image, reproduction, and identity.

Although many persons with cancer may be able to physically perform basic ADLs and IADLs, the effects of cancer and its treatment such as surgery, radiation, and chemotherapy can be devastating. Occupational therapy assessment and intervention should be comprehensive and identify the full range of factors that are influencing occupational performance. Strategies including but not limited to energy conservation, work simplification, compensatory strategies for decreased attention or memory, prevention of edema and lymphedema, and to address psychosocial issues including body image and sexuality are appropriate.

Comprehensive oncology rehabilitation by the occupational therapy practitioner begins with an evaluation of occupational performance and the development of the occupational therapy profile. Remaining patient focused, theory driven, and evidence based during the intervention planning and implementation phases will help to ensure positive outcomes.

Review Questions

1. What are the most common forms of cancer in men and women, and what is the likelihood of experiencing cancer during one's life?
2. What are common treatment approaches for cancer, and how can they impact the occupational performance of persons with cancer?
3. Why is occupational therapy intervention for persons with cancer medically complex?
4. What areas of specialty and advanced knowledge must the occupational therapy practitioner have when working with persons with cancer?
5. What are common approaches to assessment of occupational performance in the person with cancer?

Special Needs of the Older Adult*

Samia Husam Rafeedie

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, the student or practitioner will be able to do the following:

1. Describe the importance of wellness and productive aging for the baby boomer generation.
2. Describe what an occupational therapist can do to help an older adult to age in place.
3. Identify the policies established for older adults in the United States and how they impact service delivery.
4. Describe the therapeutic benefits of utilizing occupations as a primary modality with older adults.
5. Describe how the learning needs and styles of older adults may differ from those of younger persons.
6. Describe the accepted theories of how aging occurs.
7. Describe how mental functions may change as a person ages.
8. Identify basic age-related changes in sensory functions and body structures.
9. Identify basic age-related changes in neuromusculoskeletal functions.
10. Identify basic age-related changes in cardiovascular, hematologic, immunologic, and respiratory functions.
11. Identify basic age-related changes in voice and speech functions; digestive, metabolic, and endocrine functions; and genitourinary and reproductive functions.
12. Identify basic age-related changes in skin and related structure functions.
13. Describe the concept of "flipping a nursing facility" and facilitating a paradigm shift with clients and colleagues alike.

KEY TERMS

Aging in place
Allostatic load
Andropause
Mild cognitive impairment
Old-old
Productive aging
Senescence
Shared governance

Threaded Case Study

Doris, Part 1

Doris has been an assistant to a local certified public accountant (CPA) for decades and is responsible for the bookkeeping and bills in her home. She enjoys sending e-mails on her personal computer and playing the piano. In fact, Doris was a piano instructor for many years and enjoyed teaching the young people in her neighborhood as a side job. Her husband, Don, says that this was the only thing that kept her going prior to her most recent fall. Doris is a 79-year-old mother of two, grandmother of four, and great grandmother of two who lives in Indiana with her husband of 55 years.

Doris and Don have recently moved into a senior living community right behind the skilled nursing and rehabilitation facility where she was admitted for 1 month following an incident at home where she fell and could not be assisted by her husband, who also has medical complications with his heart. Doris' family became concerned after recent falls at the new apartment, and Doris showing signs of increased forgetfulness and bouts of confusion. She was recently diagnosed with senile dementia–Alzheimer's type and has a past medical history of hypertension, spinal stenosis, diverticulitis, osteoarthritis, laser eye surgery, and a colonoscopy. Her admitting diagnosis is right hip fracture.

Doris' occupational therapy evaluation took place at bedside with her husband present. She required supervision for feeding and maximum assistance with grooming and bathing activities; she also required maximum verbal cues for thoroughness and attention to detail. Doris required supervision for upper body dressing and minimal assistance for lower body dressing and toileting. She required stand-by assistance for bed mobility and minimal assistance for all other activity of daily living transfers with the use of a front-wheeled walker. She was oriented ×2 (to her name and situation) and could follow simple directions. Her long-term memory and short-term memory were impaired. Upon observation, her oculomotor skills and visual fields appeared intact. However, she had two pairs of glasses; one pair was for reading and one was for distance, but she was uncomfortable with both pairs and said she was waiting for a new pair from her doctor. Range of motion was within normal limits in the bilateral upper extremities. She demonstrated good (4/5) manual muscle grades throughout both upper extremities and is right-hand dominant. No apparent tone impairments were noted, and she had no complaints of pain at the time of evaluation. Fine motor and gross motor coordination appeared within functional limits for both upper extremities. Minimal edema was present in both lower extremities.

Critical Thinking Questions

1. What intervention activities might be used to support engagement in meaningful occupation while Doris is at the rehabilitation facility?

2. What are the areas of concern with Doris' caregiver and home situation?

3. How will Doris' current and past medical history complicate the rehabilitation process?

Introduction

Occupational therapy practitioners have a unique opportunity to be at the forefront of healthcare delivery to our society's older adults. Occupational therapy's holistic and client-centered approach highlights strengths and resources as well as supports the complex and challenging physical, social, cognitive, and emotional changes experienced by this population. These changes may impact occupational independence, as well as participation in meaningful activity; therefore a careful and thorough approach to assessment and intervention is required to meet the needs of our aging population.

Americans born between 1946 and 1964 are members of the baby boom generation, and this cohort turned 65 years of age in 2011.[32] Chop estimates that from this time on, “approximately one American will turn 65 years of age every 8 seconds for the next 18 years” (p. 2).[32] In 2010, the U.S. Census Bureau reported that nearly 40.3 million people, representing 13% of the total population, belonged to the baby boom generation. Werner reported that more people were 65 years of age and over in 2010 than in any other census reporting period,[159] and this population increased at a faster rate (15.1%) than the total United States population (9.7%). By the year 2030, it is estimated that 22% of Americans (70.2 million) will be 65 years of age and older.[32]

Another fast-growing population of interest for occupational therapy is the group older than 85 years of age. This cohort is referred to as the **old-old** and is expected to increase from 5.5 million in 2010 to 6.6 million in 2020 (19% increase) according to Chop.[32] Opportunities for occupational therapy are also presenting themselves on the global scale with an estimated 1.3 billion people in the 65 years and older bracket worldwide. For the first time in history, people over 65 years of age will outnumber children under the age of 5, and according to Chop,[32] this will likely happen between 2015 and 2020.

These population trends demand special attention as occupational therapy practitioners work with older adults in a variety of settings including, but not limited to, home healthcare, assisted living, skilled nursing, inpatient rehabilitation, outpatient clinics, community health programs, adult day programs, and extended care facilities, as well as in palliative care. Not only will the role of occupational therapy in healthcare support the aging population with physical disabilities, but occupational therapy is also positioned to address aging in place, wellness, and prevention.

This chapter highlights the unique contributions occupational therapy practitioners can make when working with older adults who may have physical limitations but who are also getting older and experiencing the many developmental and biopsychosocial (biologic, psychological, and sociologic) changes that naturally occur from the moment a person is born. The third edition of the Occupational Therapy Practice Framework (OTPF)[5] is utilized as a foundation to paint a comprehensive picture from a top-down approach, starting with wellness and productive aging, then moving to occupation and participation in meaningful activity and, finally, highlighting body functions and structures that have the potential to physiologically decline as a person ages.

Wellness and Productive Aging

Improvements in healthcare technology and lifestyle have positively impacted the lifespan with people now living longer and healthier lives as a result of **productive aging**.[22] According to the National Institute on Aging,[108] people are living longer. In 1970, people were expected to live approximately 71 years, but this number has been on the rise. In 2008, the average life expectancy was 78 years of age, and moving into 2020, the U.S. Census Bureau[147] projects that this number will rise to almost 80 years, on average. Given this increase in life expectancy, the myths of aging would have society believe that with age comes disability and limitations, but this is not necessarily true.

Important information regarding nutrition, exercise, and health management can be accessed instantly by way of smart phones, computers, and other personal electronic devices. Older adults do experience problems with health if the body is not taken care of over time. The National Institute on Aging[108] reports that problems with health can arise if the body has been subjected to overeating, poor nutrition, and lack of adequate exercise and activity, as well as exposure to toxins (such as drugs and alcohol); therefore preventive measures are critical for the older adult population.

Healthy People 2020 includes a goal for improving the health of all Americans and strives to encourage collaborations across communities, empower individuals to make informed health decisions, and measure the impact of activities associated with prevention.[59] A gerontological approach is reflected in the work this organization has developed for older adults, including socioeconomic and lifestyle-related influences on health. Healthy People 2020 highlights the importance of independence and vitality with aging and uses a health-oriented approach rather than a disease-oriented approach. According to Healthy People 2020, common complaints experienced frequently by older adults include joint stiffness, weight gain, fatigue, loss of bone density, and loneliness. The research presented by this organization also indicates that these conditions can be prevented, or even eliminated, with activities such as exercise, stress management, nutrition counseling, and substance control.[22]

Occupational therapy practitioners work with older adults on all aspects of their lives so that they are ready to face the challenges ahead as they work to age in place and participate fully in life. With the holistic perspective occupational therapy brings to the table, it is essential that the field addresses promotion of health at both the individual and the community level. The basic tenets of occupational therapy have always helped with identification, realization, and change in the person, the occupation, or the environment in an effort to enhance participation and quality of life.[160] Community-based practice will be critical as more and more baby boomers require services. Occupational therapy practitioners have opportunities for employment in senior centers, community centers, and skilled nursing facilities where innovative programs can be designed and implemented.

An example of an innovative program developed by occupational therapists includes Farewell to Falls. Farewell to Falls is part of a fall prevention program developed at the Trauma Service of Stanford University Medical Center. According to Corman,[37] best practice in fall prevention should include a multifactorial risk assessment and intervention, with a focus on home safety and modifications,[96] medication management, and regular exercise. The development of this program also included best opportunities for patient compliance with suggestions related to behavior change by way of individualized assessment and home-based intervention.

The Home Safety Council and National Council on Aging named this program as one of the ten best programs nationally with respect to providing "creative programs and practices in home assessment and modifications" (p. 206)[37] in March of 2007. The program is designed to send an occupational therapist to a patient's home for two visits in order to complete a health and daily living skills interview, as well as a safety checklist and sensory-motor assessment. A basic fall prevention screening is completed, and simple home modifications are recommended. The program will even cover the cost of some modifications, such as grab bars. A pharmacy resident participates in the initial home visit to review medications and provide information on drug interactions and side effects. During the second home visit, the occupational therapist reviews the pharmacy-prepared medication report and prescribes an individualized exercise program for the patient. Patients receive a follow-up phone call once per month to encourage compliance, and after the first year of the implementation an occupational therapist reevaluates the patient during a home visit.[37]

Another example of an innovative program designed by occupational therapists and occupational scientists is the Lifestyle Redesign intervention,[68] which enables participants to, "infuse sustainable, personally satisfying, health-promoting activities into daily life" (p. xiii).[33] In a groundbreaking study, the USC Well Elderly Study[34] demonstrated in a dramatic way that occupational therapy intervention, based on sound occupational science principles, was more effective than other types of group activities and beneficial overall to older adults. During the 9-month study period, participants were randomly assigned to the Lifestyle Redesign intervention, a social activity control group, or a no-treatment control group. Participants who were assigned to the Lifestyle Redesign intervention group maintained or improved their health-related quality of life and life satisfaction.[68] These changes were a direct cause of involvement in the specific occupational therapy intervention, not merely involvement in busy work, or social activity.[33] In the profession's earliest days, occupation was seen as health promoting and necessary for a productive and satisfying life.[112]

Aging in Place

Aging in place is a phrase utilized in healthcare, among policy makers and advocacy groups, meaning to continue to live in the community, with some level of independence, rather than moving into an institution or care facility.[39] With the rise of healthcare costs and the increase in the number of older adults, the cost of healthcare programs has risen to staggering levels.[22] According to the Centers for Disease Control and Prevention (CDC), the national health expenditures as a percentage of the gross domestic product for national health programs (ie, Medicare, Medicaid, veterans' medical care) increased from 0.4% in 1962 to approximately17.4% in 2013.[27] Older adults with declining health spend more money on long-term institutionalization care than on any other kind of healthcare.[22]

The cost for long-term care varies by state, but on average, it costs $87,000 per year for a semiprivate room. It is estimated that by 2030, the cost for institutionalized care will grow to $190,600 per year.[22] This is a cost that few older adults will be likely to afford and is therefore not a realistic option when extensive medical care is needed. A person's health and well-being is strongly connected to the environment in which that person lives. Older adults who are physically and cognitively able to stay at home prefer to do so; however, those with physical or cognitive limitations, as well as other complex medical conditions, may need assistance or a more supportive environment.[124] The National Conference of State Legislatures and the American Association of Retired Persons (AARP) reported that 90% of seniors wish to stay at home as they age, and even if these older adults require some sort of assistance or ongoing healthcare during retirement, 83% would prefer to stay in their homes.[104] A small number of seniors prefer to move to a care facility (9%), and an even smaller percentage (4%) prefer to move in with a family member (2011). The AARP published an executive report highlighting policies that integrate land use, housing and transportation, efficient delivery of in-home services, provision of transportation options, and improvement of affordable and accessible housing to prevent social isolation.

Wanting to age in place is based on the accumulation of memories, habits, roles, and routines, or what may be described as the context or the environment. A number of helpful web-based resources focus on older adults and aging in place, as well as a number of services that can be utilized by older adults and occupational therapy practitioners working in the community. A growing number of developers and contractors use universal design principles in new construction and have an overall goal of creating aging-friendly communities—places where all areas of community are accessible and user-friendly for older adults and people with a variety of abilities and disabilities. Many housing alternatives are available for older adults to age in place, with the idea being that aging in place relates to the preferred place of residence. When there is a good person-environment fit, a person is more likely to increase or maintain occupational performance. This environment can be a single-family home, an apartment, an assisted living senior complex, or with family.

Until residences are more accessible, evaluations for home modification will continue to be an important part of occupational therapy intervention. Whether it is an actual onsite evaluation or a review of the home and community by report, evaluation of context is important when looking at the whole person. When performing a home evaluation, it is important to look at the fit between the person and the environment and then consider what modifications or services can help a person age in place. It is also critical to look beyond the physical and cognitive to the psychosocial, financial, and support-related change.

There are empowering movements in the community that support older adults who wish to maintain their independence and stay actively engaged in meaningful activity. One such movement is known as the Village to Village Network[153] and was developed to promote aging in place to foster a person's ability to continue to live in his or her home as safely, comfortably, and independently as possible, regardless of age, income, or ability level. The promoters of this network believe that older adults who are empowered can take control over their own lives, and as a cohesive and collective group, they can design and implement the future they desire for themselves.

A similar movement is the Green House Project, which has been growing since the early 2000s. Organizations are running successful Green House homes in a variety of settings, including skilled nursing facilities, assisted living centers, short-term rehabilitation centers, veterans' homes, and memory care facilities. On the Robert Wood Johnson Foundation (RWJF) website, this project is described as “a revolution in long-term care, creating small homes that return control, dignity, and a sense of well-being to elders, while providing high-quality, personalized care.”[121] Older adults are living happier and healthier lives, according to the research conducted by the RWJF. This is an alternative to traditional nursing homes and provides opportunities for older adults to contribute to the everyday operational tasks of the home, to engage in purposeful activity, and, most important, to age in place.

Occupational therapy practitioners have an important opportunity when working with older adults in community-based settings or healthcare facilities. The field thrives on empowering clients through meaningful occupations and “engagement in enjoyable and productive activity is paramount to productive aging” (p. 263).[124] Teaching our clients, caregivers, and colleagues about advocacy and empowerment changes perspectives and shifts attitudes in traditional medical settings, like skilled nursing facilities. There is an organizational structure known as **shared governance**, which is a nursing-derived concept that can lend a great deal to occupational therapy practitioners who are in leadership positions or seeking leadership opportunities in interprofessional settings. The emphasis is on a nonhierarchical matrix that disseminates accountability and decision making to front-line staff[36] working directly with residents, patients, clients, or elders in the various healthcare settings. Transforming the leadership style in health facilities with one of shared governance has many benefits, according to Myers and colleagues.[100] Some of these benefits include overall patient satisfaction, improved patient outcomes, improved patient care, increased staff morale, increased job satisfaction (leading to staff retention), personal and professional growth and development, increased staff autonomy and decision making, and improved communication among interdisciplinary team members. All of these benefits support a culture for aging in place and “flip” the very traditional (and at times, stigmatized) perception of a nursing home into a client-centered and occupation-based program where clients and clinicians equally thrive.

Clinicians are expected to be good stewards of limited resources, promote a positive work culture, and use best evidence when working with patients, caregivers, and colleagues through a lens of shared governance.[100] Occupational therapy practitioners are the experts of occupational analysis, occupational balance, and wellness. Therefore incorporating meaningful activity into an intervention should remain at the forefront of what occupational therapy practitioners do—provide therapeutic intervention based on everyday activities or occupations.

Occupations

Activities of Daily Living

Completion of activities of daily living (ADLs) is a significant component of independent living for older adults. Continued participation in the basic self-care tasks and routines followed by older adults is also viewed as critical in avoiding disability.[116] According to Robnett and O'Sullivan, 88% of people age 75 and older are independent with basic ADLs.[124] In a study by Jacobs and colleagues,[69] functional status declined progressively according to age with a trend from independence at age 70 to difficulty in performing ADLs at age 78, to dependence in performance by age 85. The study consisted of following a longitudinal cohort with a representative sample of 1861 people born between 1920 and 1921.[69]

According to Keeler and colleagues,[76] functional status has a dramatic impact on life expectancy, with declines in both ADLs and mobility resulting in decreased life expectancy and the remaining years of survival categorized as living with a disability. In fact, an association was identified between unmet needs for assistance in one to two ADLs and 1-year mortality, revealing a greater risk for mortality among older adults with mild disability.[58]

Of particular interest for the older adult population are the ADLs of feeding and swallowing and the connection between nutrition and chronic conditions. According to Thompson, approximately 15% of the older adult population living in the community and 50% of hospitalized older adults are malnourished, and the incidence of chronic disease in this population is high, “with 80% of older adults having at least one chronic disease and 50% having at least two” (p. 192).[144] An occupational therapy practitioner may consider several factors when weight loss or malnourishment has been identified as an issue. An individual who has been losing weight could have difficulty chewing because of poor dentition or ill-fitting dentures.[2] The death of a spouse or friend could impact appetite or a feeling of isolation during mealtime, limiting caloric intake.[62,144] An older adult may also have difficulty sitting comfortably at the table or maintaining safe posture required for feeding and swallowing. Older adults may also be losing weight because of difficulty preparing meals, transporting food within the kitchen, grocery shopping, or getting to the store or restaurant.

An older adult's ability to engage in functional mobility will impact other ADLs, including toileting and issues of continence. The likelihood of incontinence increases with age; Kuchel and DeBeau[82] reported that 23% of people who are 60 to 79 years of age and 32% of people 80 years of age and older are diagnosed with incontinence. Both men and women experience incontinence and may not feel comfortable initiating a discussion upon evaluation; however, the clinician can broach the topic in a sensitive manner. Quality of life, self-esteem, and self-concept may be affected by incontinence.[82] Treatment sessions can address management within the scope of ADLs, in collaboration with nursing and the physician. A referral to a specialist may also be warranted. It should be noted that side effects to medications impacting balance or cognition, access to toilets, and functional impairments (including the ability to transfer independently) are of concern for older adults living with this condition.

Incontinence and functional mobility impairments are also essential when addressing sexuality with the older adult population. Not only are physical abilities and limitations taken into consideration, but a number of chronic mental and psychological disorders, chronic illnesses and medication side effects, gender-specific health concerns, and lifestyle changes experienced over the lifespan should be taken into account.[63] According to Hillman,[63] only recently has society viewed aging and sexuality as an important topic that deserves attention from a clinical perspective. In her work, Hillman highlighted what clinicians can expect when working with baby boomers regarding sexuality and aging. Older adults may seek support for sexual dissatisfaction through medical and psychological treatment. Sexual disturbances may be a result of underlying interpersonal problems, which reflect changes in family structure over the course of time, such as divorce, stepfamily members, and multiple marriages. Eating disorders, institutionalization, openness to diversity, less traditional gender roles, and the influence of the Internet and related technologies will also impact the aging population seeking professional services.[63] This is an important area of human interaction and life satisfaction, and also a sensitive discussion to have with an older client. Should the client wish to engage in discussion, open-ended questions and a comprehensive occupational therapy intervention are encouraged. The extended PLISSIT model (Permission, Limited Information, Specific Suggestions, Intensive Therapy), or Ex-PLISSIT, extends the original model developed by

Annon,[9] which was a conceptual scheme for the behavioral treatment of sexual problems. By emphasizing the importance of explicitly obtaining permission during every phase of an intervention geared toward sexuality and rehabilitation, the Ex-PLISSIT model is a more contemporary approach available to practitioners.[142] The reader is referred to Chapter 12 on sexuality and physical dysfunction as well as the work of Kontula and Haavio-Mannila,[81] Bauer and colleagues,[16] and Hinchliff and Gott[64] for more research, clinical relevance, and adaptive approaches related to this topic.

Adaptive approaches with functional mobility should always be assessed carefully because many older adults experience changes in this area. An older adult may use an assistive device for mobility, although it may not be used all of the time. Sometimes individuals are self-conscious in public and may use a cane or walker only at home.[119] Others feel comfortable walking in their home environment or using the furniture to help maintain their balance but will use a device when walking long distances. It is important to ask each client about a variety of situations to ensure an understanding of how the client maneuvers in different settings, as prevention of falls is critical for this population. See Chapter 11 for information on individual and community mobility.

For older adults, falls are a major cause of "premature death, physical injury, immobility, psychosocial dysfunction, and nursing home placement" (p. 194).[145] Falls are more prevalent in the adult population who are 65 years and older, with one out of every three adults falling at least once per year.[124] Having one fall will increase the risk for an older adult to fall again, and alarmingly, among older adults, falls were considered the leading cause of fatal and nonfatal injuries in 2013, according to the CDC, with about 25,500 older adults dying from unintentional fall injuries.[28] In 2013, the CDC also reported 20% to 30% of older adults who experienced a fall also acquired injuries such as head trauma, lacerations, and hip fractures, costing the United States healthcare system approximately $34 billion when adjusted for inflation. As Leland and colleagues stated, "Falls are a serious public health concern among older adults in the United States" (p. 149)[85]; therefore occupational therapy practitioners should assess and intervene accordingly based on current evidence and practice guidelines. More information can be found through publications by the American Occupational Therapy Association (AOTA),[4] American Geriatrics Society (AGS), and the British Geriatrics Society (BGS) for specific algorithms and intervention approaches for older adults in the community, those living in long-term care facilities, and those with cognitive impairments.[3]

Instrumental Activities of Daily Living

Contrary to common belief, over 80% of people 75 years of age (and older) are free of functional limitations requiring assistance for instrumental activities of daily living (IADLs), according to Robnett and O'Sullivan.[124] Performance of IADLs is a factor in determining whether a person can continue living at home independently and should therefore be addressed when working with an older adult client. Difficulty in performing IADLs is associated with poor self-efficacy and decreased quality of life.[111,133] A change in performance of home management skills is sometimes the first sign that a person needs assistance in the home, and this may trigger considerations for moving into a family member's home or another community-based setting like assisted living.[52]

Living in the community requires a means of transportation, whether it is driving or utilizing public transportation. Maintaining the ability to drive is critical for older adults in that it allows the freedom they desire, and it promotes healthy aging and access to community resources, including shopping centers, medical appointments, and visiting friends and family.[53] According to the CDC, there were nearly 36 million licensed drivers in the United States who were 65 years of age or older in 2012,[30] and it is estimated that there will be more than 40 million older adult drivers by 2020.[106] The risk for accidents and injuries while driving increases with age, making the need for occupational therapy practitioners greater with this population. Occupational therapy practitioners can intervene at many levels, including in the areas of vision, cognition, functional mobility, and upper extremity strength, among others (Fig. 46.1).

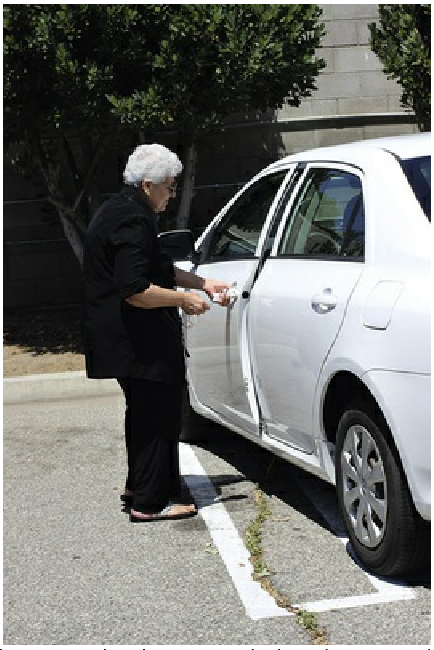

FIG 46.1 An older adult driver accessing the community in order to complete daily tasks. (Photo courtesy Ramez Ethnasios.)

According to Rosenbloom,[125] older adults are not likely to use public transportation when they turn 65 years of age; they prefer to continue to drive or use private cars. Public transportation has traditionally been utilized by those who are commuting to work and underutilized by this population for many reasons, including cost, accessibility, and a fear of being stigmatized.[125] In fact, the National Council on Disability (NCD) stated that some people with disabilities cannot work, even though they would like to, and completing basic IADLs such as shopping or visiting friends becomes a challenge due to a lack of safe and reliable transportation options.[105] Safety is paramount in the area of transportation and driving, as well as in the home.

Safety when functioning in the home is a primary concern and should be addressed on multiple levels. Common factors to assess include vision (particularly in the areas of visual acuity, contrast sensitivity, glare sensitivity, adaptation to the dark, and visual field cuts), whether sufficient lighting and contrast are available for the older adult to be able to see, whether the home is in good repair, whether the person can move around the environment successfully, whether the neighborhood is safe, and whether the older adult is cognitively intact to understand whether risks are present. Doris and Don recently moved into a new home and while they continue to unpack and organize personal items, the living space is cluttered with boxes and stacks of books, magazines, and clothing. This is creating a fall risk for Doris and limits the space in the hallways and rooms for safely using her walker. Doris has been diagnosed with Alzheimer's disease, so she is disoriented at baseline and the new living space further confuses her when she tries to use the bathroom in the middle of the night. Clearing a pathway in the hallway and removing items from the floors will decrease Doris' fall risk and promote functional mobility. The possibility of utilizing a bedside commode should also be discussed with both Don and Doris.

Other factors affecting a person's ability to safely remain in the home is pain. Pain can decrease mental flexibility, which includes immediate and delayed memory, as well as language; and it can also decrease physical functioning.[74,157] Depression can influence cognitive processing and has been associated with cognitive decline,[162] and older adults should be screened upon evaluation when assessing safety in the home. Once the physical portion of the home evaluation is completed with the particular client in mind—including abilities and inabilities—it is time to address components that are important to aging in place that can be considered part of the extended context or the environment. What services are available in the community? How can the person access these services? Is the person willing and able to access them? Is the person socially isolated? Does the person drive despite not being able to see well enough or not being cognitively intact? Can modifications be made to the routine that will keep the client safe and socially connected? What are the client's social supports? These are just a few of the many questions that a clinician needs to start asking when evaluating a client with regard to aging in place and safety in the home.

An occupational therapy practitioner may consider any of a number of home evaluations. Some of the home evaluations are based on performance and some are based on the physical characteristics of a home only. Psychometrically sound evaluations include the Safety Assessment of Function and the Environment for Rehabilitation,[86] the In-Home Occupational Performance Evaluation,[135] and the Home and Community Environment Assessment.[77] See Chapter 10 for an example of a home evaluation. A home evaluation was completed at Don's and Doris' home using the facility's home assessment form to capture information and make recommendations. It was decided that Doris would benefit greatly from a bedside commode for use during the middle of the night, to avoid walking to the bathroom. A shower chair was also recommended, as well as a long-handled bath sponge. Doris did not like using the long-handled reacher and decided she did not need that "gadget." Don was tasked with asking their oldest daughter for help unpacking and clearing the hallways and floors, and Doris agreed to allow their oldest daughter to help with finances until Doris and Don were "back on their feet."

Community-based occupations, such as taking a grandchild to school, going to the pharmacy, or shopping at a department store, can be intimidating to an older adult who has experienced a change in health status. Health management and maintenance is a critical area to explore, as is participating in religious and spiritual activities and expressions as a part of an intervention plan in the area of IADLs.

Illness, chronic disease, or injury can lead to limitations to IADLs, making it difficult for older adults to remain at home.[59] Older adults have the same responsibilities younger adults have, such as caring for pets, caring for a spouse or loved one, or child rearing. According to Brossoie and Chop,[22] there is a recent trend in grandparents raising their grandchildren. In 2010, the United States Census Bureau reported approximately 2.5 million grandparents claiming responsibility and providing basic needs for their grandchildren. This can become an enjoyable, rewarding, yet challenging responsibility, with financial restrictions, taking on new social roles, and coping with any social stigmas attached to the grandchild's parents, who are unable to care for their children.[22] Financial management is an area for occupational therapy assessment if an older adult client is a caregiver for a grandchild, particularly if the person is retired and has a limited income. Safety and emergency maintenance and preparedness should also be considered, such as having a list of emergency contacts and knowing what to do in case of a natural disaster.

Becoming a caregiver for an adult family member or friend is also a reality with the older adult population. The responsibilities often occur in a slow and progressive manner, and the full extent of functional decline is not realized by the caregiver or the person receiving the care.[102] For many caregivers, the initiation of services is subtle and not many other family members will recognize how much support the caregiver is providing to a spouse until it becomes a full-time job. Care recipients wish to stay as independent as possible and try to decline this care from loved ones and family members, until they reach a point where they simply cannot function without the support. In the United States, the trend is for the oldest daughter (or daughter-in-law) to provide assistance with basic ADLs and IADLs, whereas the son typically manages the finances and estate affairs. Other family members are also called upon for help, and certainly many offer to help.[22]

In many families, a child is not aware of the habits, roles, and routines of an aging parent until a health issue arises and a parent needs physical assistance in the home. Aging parents do not wish to move in with a child, as maintaining independence and control over their lives is important; however, approximately 86% of caregiving support is provided by family.[102] It is important to keep in mind the health and well-being of the caregiver, as you evaluate the needs of an older adult client. Caregiver burnout and stress are real indicators that the caregiver may need respite care to provide a break, or counseling to learn how to handle a new familial role as a caregiver. Older caregivers may also have their own medical conditions and limitations, which take a backseat to the needs and priorities of the care recipient. This was the case with Don, who also had a medical condition that impacted his ability to care for Doris. Not wanting to draw attention onto himself and away from his spouse, Don simply stated, "I have a heart condition; but I am just fine." Don was adamant about not "worrying the girls" with their problems and not wanting to rely on their daughters for support, as "they were busy with their own children and families." It was important to assess Don's ability to care for Doris by asking questions related to his role in Doris' everyday activities, but then to also question if his needs were being met and if he was able to take breaks during the day as he needed. According to a report published by the National Alliance for Caregiving[102], 57% of the caregivers in the survey reported good to excellent health; however, 17% reported fair to poor health, and the longer the caregiving occurs, the more likely the health of the caregiver declines.

In the United States, when adults are in a position of caring for their own children and their parents, they become members of the sandwich generation because they are "caught between two caregiving roles—caring for a child and caring for a parent" (p. 30).[22] The average woman in the United States can expect to spend more time caring for her aging parent than she did caring for her own children.[41] Caregivers also need support and attention from the occupational therapy practitioner. It is vital for the clinician to be aware of the context or environment, the requisite occupations the caregiver is responsible for, and to provide resources that address the emerging needs of the caregiver during an intervention. These resources may include referral for counseling, respite services, or assessment of coping skills and treatment to address prioritizing to better meet the needs of the caregiver and person receiving the care. During an intervention session, the occupational therapy practitioner discussed respite care with Don and encouraged him to call about a local support group for spouses who are caring for a loved one with Alzheimer's disease. He said that it sounded interesting but was not sure where Doris would go during the meeting. The occupational therapy practitioner and Don researched the support group and found that there was a respite program in the same building as the support group and he and Doris could go together. Doris would be safe and engaged in activity while he attended the meeting. Don also asked the clinician for resources on Alzheimer's disease and how to help a loved one in the home through compensatory strategies and "tricks" to keep them going. Don worried that Doris would stop doing what she loved—playing the piano—and then "things would snowball into bigger problems."

Unfortunately, there is a link between caregiving and elder abuse. Some studies suggest that "family members who provide care for persons with dementia are up to three times more likely to physically abuse the care recipient as those who care for relatives without dementia" (p. 620).[8] Elder abuse is defined as any knowing, intended, or careless act that causes harm or serious risk of harm to an older person, physically, mentally, emotionally, or financially,[103] and includes many different kinds of abuse. Elder abuse can be physical, emotional, or sexual in nature; other forms include exploitation, neglect, abandonment, and self-neglect. Elder abuse can take place in a private home, a healthcare institution, or a senior center and can be inflicted by a family member or a healthcare provider.

There are signs and symptoms to be aware of, as occupational therapy practitioners are considered mandated reporters and must contact the appropriate authorities (either directly or by way of a social worker or case manager, depending on the facility, employer, or policy in place). Once adult protective services is contacted, an investigation begins. The various signs or symptoms depend on the type of abuse and can be anything from shouting at an older adult or unexplained bruises, burns, and injuries with the outline of an object or hand, to torn clothing, poor skin condition, and indications that the older adult is withdrawn or frightened. Other signs to be aware of include poor hygiene, pressure ulcers, malnourishment or dehydration, or bruising around the breasts or genitals.[23]

Rest and Sleep

Sleep is an important occupation because of its restorative qualities, as well as its ability to support healthy aging and participation in meaningful activity.[4] According to the OTPF (third edition), the occupation of sleep and rest also includes sleep preparation. This can be described as undressing and grooming prior to going to sleep, listening to music as a form of unwinding, saying goodnight to loved ones, setting an alarm clock, or even locking the house door before retiring to the bedroom.[4]

The National Sleep Foundation (NSF) reports that 65% of people who are 55 years of age or older complain of sleep problems at least three times per week.[110] The NSF also recommends between 7 and 9 hours of sleep per night for an adult who is 65 years of age or older[110]; when this amount of sleep is not achieved, it can have significant effects on how one feels and responds to events during the day. This is particularly important when older adults are hospitalized, because it is challenging to achieve undisturbed sleep in a hospital setting. According to a pilot study with 48 older adults completed by Missledine and colleagues,[98] noise levels, light, and disturbances prevented a restful night's sleep with an average of 13 awakenings per night. This resulted in an average of 3.5 hours of sleep per night, which falls short of the recommended 7 to 9 hours. Occupational therapy practitioners can support hospitalized older adults by collaborating with the nursing team to reduce light and sound disturbances and post a "do not disturb" sign on the door to facilitate sleep hygiene and sleep preparation in the hospital setting. See Chapter 13 for additional information on sleep and rest.

Education

In 2013, approximately 25% of adults 65 years of age and older had at least a bachelor's degree and 83% of those who are 85 years of age and older had a high school degree.[146] Educational attainment is on the rise and is associated with longer work lives, with men achieving higher levels of education as compared to women.[43]

There is a program titled “Road Scholar,” previously known as Elderhostel, which offers thousands of courses appealing to older adults who are already well educated and focus on college-level studies and cultural enrichment. The courses most commonly taken are those related to financial planning, health and wellness, and contemporary civic responsibilities. Older adults choose to return to school for a variety of reasons, including transitions in life, to learn a subject area of interest, to meet new people, and to remain occupied and have “something to do.”[43] An occupational therapy practitioner should inquire about an older adult's educational level and complete an onsite assessment of the campus/classroom, if possible, for any environmental modifications, accommodations, or functional mobility concerns.

Work

The health of an older adult is associated with the ability to work. According to Adams and colleagues,[1] adults who are 45 to 69 years of age are approximately three times more likely than their younger counterparts (adults who are 18–44 years of age) to report an inability to work because of health reasons. In workers 50 years of age or older, researchers found that approximately 22% reduced their employment hours, 20% have tried to eliminate demanding physical aspects of the job, and 5% reported trying to accept fewer mentally challenging tasks while in the workplace.[19]

Studies have also pointed to planned or unplanned retirement, with health issues playing a larger role in nonprofessional jobs.[19] According to Goyer, over 50% of retired adults made the transition to retirement before truly wanting to retire, with 32% of these adults blaming a decline in health as the reason.[55] Ewald stated, “The ability to retire was determined primarily on the basis of finances and health, factors working as incentives or disincentives depending on individual circumstances” (p. 345).[43] Many older adults continue to work for the enjoyment and desire to do so; others continue to work because of financial necessity, including repayment of second or third mortgages that were taken out to support children or grandchildren who experienced financial distress in the market crash of 2008.

Work also positively impacts health and well-being. Older adults who are highly engaged in their work have been identified as being less stressed, less dependent on healthcare, and less likely to call in sick or utilize sick days. These adults also stay on the job longer than their less engaged counterparts.[49] According to Pitt-Catsouphes and colleagues, workplace-based health and wellness programs (HWPs) may be beneficial “for promoting positive health-related behaviors among older workers and for increasing their ability to continue to work” (p. 262).[115] This is an area in which an occupational therapy practitioner could thrive while supporting older adults in their quest to maintain health, wellness, and employment.

Volunteer work is also often part of an older adult's repertoire of occupations and is just as important as paid employment. About 25% of adults 65 years of age or older engage in some type of volunteering in the community for many reasons including achievement of higher levels of mastery, life satisfaction, and energy.[126] Others participate in volunteering for other reasons, such as making a contribution to society, meeting others, gaining career-related opportunities, enhancing self-esteem, reducing negative feelings, and strengthening social relationships.[35,154] Paid and volunteer work may present the need to do an onsite community evaluation so that the client can prepare for reengaging in these occupations (Fig. 46.2).

Leisure

"Although the aging process is one factor that influences occupational engagement, the older adult's individual perspective affects not only what the older adult is able and may need to do but also what the older adult chooses and wants to do" (p. 302).[136] According to a systematic review completed by Stav et al.,[136] leisure activities have positive health benefits and when incorporated into everyday activities, behaviors such as gardening, visiting friends, participating in clubs, or reading result in a variety of health outcomes. Some activities such as playing board games, taking a trip to a museum, and completing cognitive puzzles play a role in decreasing the risk of dementia and result in higher cognitive levels.[51,128,152] There are also global health benefits that have been identified in the literature, such as increased survival rates and increased coping and well-being strategies for widows.[70,71]

It is common for occupational therapy practitioners to work in adult physical rehabilitation settings that do not allow for direct billing and reimbursements of leisure activities as part of an intervention due to many third-party payer restrictions regarding treatment goals. However, in implementing occupations as ends and occupations as means, as described by Gray,[56] leisure activities can be utilized as a complement to ADL and functional mobility goals established for clients, as well as a therapeutic tool to address performance skills and client factors in the areas of vision, cognition, and motor control. Meaningful activities and creativity in intervention planning are important for success when working with this population. In the skilled nursing environment, it may be possible to design a functional maintenance program for a client that involves recreation activities to address particular functional or treatment goals as well (see Chapter 16 for more information).

Social Participation

Just as leisure activities have been proved to impact health positively, so has social participation. In their systematic review of the literature, Stav et al.[136] synthesized 33 different research articles and concluded that there is strong evidence linking participation in social activities with preventing decreased cognition and physical decline. Social activities identified in the review included attendance in groups outside of the home, regular visits and contact with friends, and participation in social networks. These types of activities also improved physical health and functioning in terms of ADL performance, as well as showed lower mortality rates and improved quality of life.[136]

The occupational therapy practitioner can be of particular support in assessing a community environment and making recommendations for adaptation to promote the participation and independence of older adults. Incorporation of family and friends into intervention, although directed by the client, can also ease concerns about what a client can safely do and can often support increased client participation in social activities.

The Wellness Program for Older Adults[94] demonstrated that occupational therapy intervention that addresses prevention efforts for older adults living in the community enhances ADLs, IADLs, physical and mental health, occupational functioning, and life satisfaction. Occupational therapy practitioners play a role in personal aspects of an older adult's life; therefore they can address modification of components of occupations that are important to an older adult either in a group setting or in individual treatment before it becomes problematic for the older adult. This can be done through a community model and results in an overall increase in participation by older adults and an increase in quality of life.

Policy Affecting Older Adults

To provide the best healthcare, occupational therapy practitioners should be aware of the policies affecting older adults in the United States. Policies not only impact the way clinicians document services, but they also impact reimbursement and payment systems in several settings including inpatient hospital settings, acute rehabilitation settings, skilled nursing facilities, home healthcare, outpatient, or even palliative care.

An overview of important financial and healthcare policies is presented here as a framework for working with this population. Practitioners and students are encouraged to research the specific policies related to their state of employment and, generally speaking, in the facilities of employment. Learning how policies impact practice is also learned on the job. A plethora of resources can be found online, and trusted online resources, such as www.cms.gov (Centers for Medicare and Medicaid Services), should be utilized for more detail and to stay abreast of changes that occur frequently.

A significant change in healthcare policy was the passing of the Patient Protection and Affordable Care Act (ACA) in 2010. This was part of President Barack Obama's healthcare reform legislation, which requires most individuals living in the United States to have health insurance through employer-based insurance, health insurance exchanges, or the optional expansion of state programs (including Medicaid).[61] There are specific provisions of this policy that impact older adults, including Medicare Part D's prescription drug plan (closing the coverage gap in prescription drug coverage through Medicare [also known as “the doughnut hole”]), the creation of a center in each state to provide funds to individuals who are Medicare or Medicaid eligible, as well as expanded services in the home and community for those who receive Medicaid.[148]

With the passage of the Social Security Act in 1935, the national government highlighted a realization that older adults required support and assistance, and since that time, Social Security has helped millions of older adults financially. In 1961 the first White House Conference on Aging was held; these conferences continue to be held once every decade (with the most recent conference in 2015) in Washington, D.C. In 1962 the Commission on Aging was established, and in 1965, the Older Americans Act was created, which was a catalyst for the creation of the Federal Administration on Aging. In 1965 Medicare was established as a federal healthcare insurance for older adults and Medicaid was also enacted, providing healthcare assistance programs for individuals with low income, including those with disabilities. In 1990, the Americans with Disabilities Act (ADA) was established, facilitating the integration of people with disabilities into employment, services, and healthcare.[23] Of course, all of these policies are implemented in a unique way, as the current situations in the United States change by way of politics and demographics.

Social Security is the Old-Age, Survivors, and Disability Insurance (OASDI) program. Current taxpayers pay for this program and the longer one works, the longer one pays into the system. This program is for older adults, retired workers, workers with disabilities, and dependents and survivors of workers who have participated in Social Security. Benefits can be received as young as 62 years of age; however, the benefit is greater for workers who wait until full retirement (which is based on their birth year).[131]

Supplemental Security Income (SSI) provides a monthly monetary payment for eligible individuals who have low income or resources. Criteria for eligibility include being 65 years of age or older, being legally blind, or being disabled. SSI is funded through the U.S. Treasury's general fund and is not recognized as an entitlement, like Social Security. The payment amount varies and depends on each individual's income, resources, and living arrangement.[23]

Medicare is a social insurance that is government-sponsored and covers people 65 years of age and older, certain people under 65 years of age with long-term disabilities, and adults with end-stage renal disease requiring dialysis or kidney transplant. Medicare is divided into four parts: Parts A, B, C, and D. Part A is known as hospital insurance and covers inpatient hospitalizations, limited skilled nursing care (100 days, renewable over the lifespan), hospice, and home healthcare. Part B is also known as Medical Insurance and covers doctors' services, outpatient care, home healthcare, durable medical equipment, and some types of preventive services. Part C is also known as Medicare Advantage plans (and includes Parts A and B) but is run by private insurance companies. Part D is also known as the Medicare Prescription Drug Coverage plan and is also run by private insurance companies.[132] Occupational therapy services (among other rehabilitation services) are covered under Parts A, B, and C, and coverage is specific to the setting in which services are being delivered. Documentation requirements and expectations vary from setting to setting; practitioners are encouraged to learn the details and keep abreast of the Medicare policies specific to the place of employment (see Chapter 8 for additional information on documentation).

Medicaid is a public assistance program that provides healthcare to people of all ages with low income, including those with disabilities. Medicaid is a federal and state partnership, not the responsibility of the federal government (as is Medicare). Eligibility differs by state, and each state has specific income levels and resource amounts for qualification. Medicaid is the largest payer of long-term services and supports in the United States, including nursing facility care and home- and community-based services. Nursing facility care is one of the mandatory services covered by Medicaid in all states; however, Medicaid does not currently mandate home- and community-based services. For all Medicaid services, individuals must meet the eligibility requirements for the state in order to qualify for long-term services and supports. There are financial requirements that must be met, and if an individual has more financial resources and supports than is considered the minimum requirement, a "spend down" occurs where the assets and income are depleted to the point where the individual does qualify for Medicaid services. In-home services, such as personal care services and community-based services, are also provided.[90]

The Aging Network and Older Americans Act defines an older adult as being 60 years of age or older. Caregivers of older Americans are also covered, according to this act. Funds are provided to the states and tribal organizations to offer specific services as mandated by the Older Americans Act. These services include nutrition services, congregate services and home-delivered meals (Meals on Wheels), supportive services including transportation, in-home care, adult day care, and preventive health services. One important service is the Long-Term Ombudsman program and the National Family Caregiver Support Program, which offers counseling, training, and respite care to caregivers.[23]

Finally, some older adults do carry long-term care insurance. These policies are sold by private companies and only fund about 7% of long-term services and supports in the United States.[23] Depending on the policy and coverage, home- and community-based services may be provided, as well as nursing facility care. Policies can be expensive and premiums typically rise as a person ages. When working with older adult clients, it will be necessary to understand the medical insurance the client carries and what services are covered by the insurance. Collaboration with the client, family members, case manager, and social worker is essential for best practice. Healthcare policy and insurance impact occupational therapy services, including evaluation, assessments, and intervention.

Threaded Case Study

Doris, Part 2

Several assessment tools were utilized with Doris as part of her occupational therapy evaluation and intervention plan. The Brief Cognitive Rating Scale (BCRS),[117] which is utilized with the Global Deterioration Scale (GDS),[118] was used initially to acquire a baseline for cognitive function. Doris scored 4.6 on the GDS, which indicates a moderate cognitive decline/late confusional state. At this level, definite concentration deficits are present, with marked deficit on serial 7s and frequent deficits in subtraction of serial 4s from 40. Doris was unsure of the weather and did not know her current address. There was a clear-cut deficit in long-term memory, and most of Doris' past history was obtained from Don. She could not recall childhood friends or teachers but could state the name of her high school. Confusion in chronology of personal history is also found at this stage.

The Cognitive Performance Test[24] was also administered, resulting in findings that were consistent with a moderate stage of Alzheimer's disease and difficulties completing detailed tasks. This score was consistent with Don's report of Doris' need for assistance with most IADLs and ADLs, and the outcomes of this assessment complemented those of the GDS.

The Geriatric Depression Scale[163] was also administered, and the outcome indicated that Doris should meet with her physician for diagnostic testing for possible major depressive disorder. The occupational therapy practitioner notified the charge nurse at the facility and asked her to relay this information to the admitting physician so that Doris could be evaluated by the proper healthcare provider. Lastly, the Canadian Occupational Performance Measure (COPM)[84] was utilized with Doris and Don. This assessment tool was an excellent way to find out what Doris wanted to do, needed to do, or was expected to do through a semistructured interview with Don and Doris. This tool is utilized not to assess performance but to assess self-perception of importance, as well as performance and satisfaction with performance in three general areas: self-care, work, and leisure.

Assessment and Intervention

Customary assessment and intervention strategies for adults with physical disabilities are recommended for older adults, as presented throughout this textbook. There are, however, many assessments and intervention approaches recommended for older adults specifically. Leland and coworkers[85] published occupational therapy guidelines for productive aging for community-dwelling older adults, which include evidence-based guidelines for this population. For a thorough and detailed table highlighting examples of standardized screening tools and assessments, please refer to these guidelines, published by the AOTA.

These recommendations are also published in the National Guideline Clearinghouse to clarify the role of occupational therapy in treating community-living older adults and to support productive aging efforts. Areas of intervention specifically named in the guidelines include those that improve IADLs, fall prevention, home modification, health management, and health maintenance. It is recommended that occupational therapy practitioners use standardized assessment tools and outcome measures for evaluating occupational performance consistently and whenever possible. Client-centered and occupation-based intervention plans that are meaningful and individualized show positive benefits to older adult clients. Performing functional and occupation-based activities within the older adults' actual environment will facilitate carryover and generalizing of information learned during intervention. Research shows that gains observed in physical performance (client factors and performance skills) do not always translate to an improvement in IADL performance.[111]

Intervention activities should always be meaningful and age appropriate. Many older adults enjoy occupations that are fun and playful, including games and crafts. These activities should be considered carefully, however, to be sure that they are meeting the needs of each individual client. A thoughtful interview should be completed, and a thorough occupational profile will support the use of occupation-based and client-centered practice. While searching for activities that present the "just right" challenge for the client, it may be tempting to use tasks that meet most specifications for intervention, but may also be demeaning. During the occupational therapy evaluation, Don mentioned, "I know you therapists mean well when you set up those cones and have Doris walk around them, but they really don't do her a bit of good. She needs to do real things so she can get back to our real home and take care of herself, because I can't do it all anymore."

If an older adult comments that an activity seems childish or questions why an activity is being used as part of therapy, participating will probably not prove to be a significant benefit. Remnants of the reductionist paradigm of the field exist in all practice settings, where clients are given a restorator bike for the upper extremities or asked to raise the weighted bar 15 times and repeat. At times, clinicians can function on autopilot and execute more of a cookie cutter approach to therapy, which is not meaningful or even therapeutic for the older adult client, or any client for that matter. It can lead to frustration, dissatisfaction, and confusion of the role occupational therapy plays in a variety of settings, such as skilled nursing facilities, inpatient rehabilitation facilities, and outpatient settings. The match between the client and the intervention task is especially important for members of this age group. Working with the client to problem-solve strategies for therapy and the best approach to meeting established goals will further engage the client in the intervention process, while increasing self-esteem and effectiveness. After completing the occupational therapy evaluation, the clinician reviewed the results with Don and Doris and asked about the goal for occupational therapy. Without hesitation Doris said, "Play the piano again"; and without hesitation Don said, "Be able to get around and do some of the things she needs to do to take care of herself." These goals were meaningful to Doris and would be utilized as a means to an end during her rehabilitation.

It is recommended that occupational therapy practitioners incorporate involvement or participation of physical, social, leisure, religious, work, or volunteer activities into intervention approaches and utilize an evidence-based approach to develop healthy routines and habits in this population. Health management approaches, self-management programs, and health education programs are also recommended.[11] The recommendations also encourage clinicians to consult with organizations that focus on aging to develop preventive educational and intervention programs for this population, including the area of driving to support productive aging.[111,136]

Educational programs and teaching aimed at older adult clients and their families or caregivers must also be considered carefully with respect to health literacy. To an older adult, this could mean anything from reading and writing to speaking and listening. In a literacy survey processed by the United States Department of Education, adults 65 years of age and older had the lowest average prose, document, and quantitative literacy.[83] Oftentimes, health professionals communicate at higher levels than older adults understand. According to Stableford,[134] "Many, if not most, older adults have trouble understanding both verbal and written health communication" (p. 324). The cause does not need to be linked to English as a second language, although at times this is a reason.

There are common assumptions that have been made about the learning needs of older adults. In 1984, Knowles identified specific concepts that he believed should be a foundation of adult education and included understanding why something needs to be learned (prior to learning it), motivating oneself to learn through internal forces (versus external forces), being solution driven and problem based, associating learning with social roles, tapping into the rich experiences of life to enhance learning, and lastly becoming more self-directed with respect to learning. All of this should occur as one's personality matures. These general assumptions do not always fit the needs and desires of older adult clients in occupational therapy for several reasons. However, older adult learners must have their developmental needs and interests met; therefore Knowles recommended an environment of mutual trust, respect, and acceptance of differences.[80]

Many obstacles can get in the way of an older adult understanding instructions during patient education, including family members, the healthcare provider's style, or the language being utilized. The experience of learning will be impacted by the assumptions being made about older adults; therefore it is critical to analyze learning assumptions being made about older adults by clinicians and educators.[31] In a review and critique of the portrayal of older adult learners, it was reported that society views older adult learners as a homogeneous group of people, not affected by age-related changes to the mind and body. Clinicians must pay attention to the diversity that exists among the older adult population with respect to age, race, ethnicity, educational levels, and income, as well as physical and cognitive abilities. Not all older adults are capable and motivated learners, as much of the literature would convey in this review.[31] Many older adults do have age-related changes associated with cognition, which impact their learning abilities. Others have decreased motivation to participate in learning opportunities secondary to lower socioeconomic status or residing in an isolated rural community.

Stress, anxiety, decreased vision, and decreased hearing can contribute to misunderstandings or lack of comprehension with written and verbal instructions provided by health professionals. Older adults take a longer amount of time to process information, and hearing information repeatedly helps older adults to make associations and connections to existing knowledge, so hearing information once prior to discharge will likely not be recalled upon reaching home.[87,88] Medical interpreters and translated brochures are helpful and recommended, as are "teach-back" strategies, where clients are asked to demonstrate what the healthcare provider just reviewed or taught to prove learning occurred.[134] Levy recommended other strategies,[87,88] such as chunking information in an organized way to promote effective storage of new information, being mindful of internal and external contextual factors during the learning process to facilitate recall in a new environment, and providing cues that offer opportunities for recognition or matching information with previously learned information.

The American Medical Association also recommends that clinicians apply the following verbal communication tips, which contribute to improved patient understanding: slow down, use plain/nonmedical language, show or draw pictures, limit the amount of information and repeat that information, use the teach-back technique, and create a shame-free environment where clients are encouraged to ask questions.[158] When using plain/nonmedical language, it is important to write down what the patient should do, how to do it, and why the patient should do it; these reminders facilitate communication with loved ones or caregivers who may not be present at the time of teaching. Additional suggestions made by Stableford[134] include framing the conversation first, before diving into the discussion, as well as encouraging the older adult to bring a friend or family member to appointments.

During initial contacts with an older adult, the occupational therapy clinician must take the time to listen to and get to know the client. By the time that intervention begins, the clinician will have an understanding of the client's learning style, deficits that may require specific types of teaching, and any cognitive or perceptual deficits that should be considered. The pace and style of the intervention will be individualized to meet the client's learning needs. If increased recovery time is needed for limitations in cardiovascular function, the clinician should plan for this and allow time to assess vital signs and monitoring. The clinician should also incorporate energy conservation or work simplifications into the intervention plan, if the patient needs these strategies. The client is the best judge of what fits within his or her life and goals, and this should ultimately be respected and interwoven into the intervention plan. Don and Doris were provided with printed information regarding compensatory strategies and durable medical equipment recommendations. Because Doris has Alzheimer's disease, the majority of the patient education was directed at Don, who was serving as the caregiver and would follow through with the strategies at home. Don requested information in the most "straightforward way" and preferred to be hands-on during intervention sessions. He often wanted to try the various hand placements during functional mobility and wrote down when and how to provide verbal cues to Doris during self-care activities. Don mentioned, "Writing things down helps; that way, I will not forget what I learned." Don also requested help making memory books and sequencing cards to help Doris complete tasks on her own. These requests were incorporated into Doris' intervention sessions, and Don attended every one of them.

One of the critical components of processing life changes—especially changes in health or changes in environment—relates to coping style. The emphasis is less on context and more on how the older adult deals with the reality of a situation. Older adults generally have a well-established style of coping, and regardless of whether their style may be effective or ineffective, it should be a client factor that is taken into account during evaluation or intervention. As a group, older adults have seen wide-sweeping political, social, cultural, economic, and technological changes in their lifetimes. Some of the old support systems such as an extended family have changed for many older adults, whereas others have taken new caregiver roles within the extended family that were not prevalent in previous generations—such as parenting grandchildren.

New support systems have become available for this population through technology and the Internet. Computers and personal electronic devices play a large role in keeping older adults connected to family, friends, and grandchildren who live in other states or countries (Fig. 46.3). This population also utilizes chat rooms and online dating services to establish relationships or for companionship.[14] Learning to use a computer and the Internet can be challenging initially; however, many community centers provide workshops and tutorials on how to send e-mails, surf the Internet, or join social media sites like Facebook.[22] The Internet is also a way for older adults to learn more about any given topic, and like their younger counterparts, they can use the Internet to learn more about medical conditions, health concerns, and to become more informed.

The Aging Process

The aging process is complex; many theories for why and how people age have been researched and published in the field of gerontology (the study of aging). It is inevitable that people age, and with the aging process comes a change in body structure and function. There is increased prevalence of degenerative diseases and the potential for physiologic decline in several body systems. Gregory and Sandmire stated, “From a strictly scientific standpoint, however, the distinction between aging and disease is, at best, a blurry one” (p. 53).[57]

Distinctions between aging and disease include the fact that aging is a universal process, shared by all human beings; it is intrinsic and dependent on genetic factors. We are constantly aging and it is a progressive process, which may ultimately lead to decreased functional capacity. The aging process is not reversible. Disease, on the other hand, is a selective process and varies from person to person; it is categorized as intrinsic and extrinsic with genetic and environmental factors to consider, as well as uncertainty with respect to progression, regression, or termination/cure with treatment. Disease does cause damage but has the potential for being reversible, and disease may be treatable and often has a known cause.[57]

Many of the physiologic changes associated with aging can be slowed down or prevented with lifestyle choices, such as incorporating a healthy diet and exercise into a daily routine. Many of the chronic conditions seen in older adults can also be prevented by adjusting behaviors and habits; however, these changes should happen in early to middle life so that the maximum effect can be achieved. Occupational therapy practitioners can play a role in this prevention by working with younger and older clients in wellness, prevention, and primary care.

Most biologic theories of aging can be roughly grouped according to two major suppositions: genetic theories on aging and environmental theories on aging.[45,57,97] One genetic theory claims that **senescence**, or the process of deterioration with age, results from the gradual mutations (alternations in deoxyribonucleic acid, or DNA) in somatic cells of the body. This is known as the somatic mutation theory, and it is believed that over time, the radiation and environmental factors people withstand over time actually mutate and alter critical genetic code, changing the sequence of amino acids found in enzymes and other proteins.[44,139] Two other genetic theories are related to the endocrine and immunologic systems, where there is decline over time; however, hormones and “biological clocks” regulate and control the aging process.[57]

The environmental theories on aging branch off into another direction, with one theory known as the *wear-and-tear* theory of aging (sometimes referred to as **allostatic load**). This theory basically states that it is inevitable that cells, tissues, and organs gradually wear out from continued use over time.[57] There is another theory called the *rate-of-living* theory of aging, which states that each living organism is given the ability to burn up a fixed number of calories within the lifespan, and once that number is reached, the organism dies.[78] The rate-of-living theory led to the *free radical* theory, which is similar to the wear-and-tear theory, “but attributes cellular and organismal aging to random accumulating damage of macromolecules by the highly reactive by-products of oxidative metabolism known as free radicals” (p. 59).[57] What is clear is that the explanation for aging is unclear, given so many theories that are constantly challenged and reevaluated. It is important for occupational therapy practitioners to adopt a holistic view of the individual and appreciate that, for example, hypertension, high cholesterol, and diabetes increase health risk exponentially. Such a view can also be taken of other areas in a person's life. Older adults with low vision who also have difficulty hearing and who have diabetic neuropathy with altered sensation in their fingers will have a greater challenge in adapting daily activities to achieve functional independence. Because aging is a process that is generally predictable from infancy through older adulthood, it is helpful to understand and appreciate the body structures and functions by system and how they change, or have the potential to change, as a person ages.

Changes in Mental Structures and Functions

The brain decreases in weight and size with older age, even in those with normal cognitive function.[127,138] Some neurons shrink with age and others are lost. It is estimated that we use only a small percentage of the neurons in our brain, so the effect of these changes could be very small. It is also normal to see neurofibrillary plaques and tangles in older brains,[127,138] although excessive levels can be indicative of Alzheimer's disease (see Chapter 35 for more details). Messages moving through the nervous system may not get through as quickly as they used to,[138] thereby slowing the speed of some cognitive functions such as memory. This reduction in the efficiency of transmission of signals in the nervous system may contribute to the declines seen in some mental functions.

Changes in cognition often affect the ability to function because information processing and problem solving are so vital to safety and independence in ADLs. Actual cognitive decline can have a major impact on the quality of life, and this is compounded when physical function, especially sensation, is impaired as well.[87] Many of these cognitive changes are related to treatable, temporary, or manageable medical problems. Many important considerations when working with an older adult include medication side effects, alcohol and nonprescription drug use, vision and hearing deficits, nutritional deficiencies, stress, sleep dysfunction, depression, and medical illnesses such as diabetes, high cholesterol, and high blood pressure. These conditions may also be predictive of functional decline.[40,122] Cognitive decline becomes more substantial with each new medical condition that develops.

Occupational therapists find that cognitive capacity greatly affects the client's ability to benefit from rehabilitation. A more detailed discussion of cognitive aging can be found in other sources.[13,87,89,122] Cognition as a mental function is also discussed in Chapter 26. Age-associated differences are seen in almost all aspects of cognition in healthy older adults, but this difference is typically minor, with more time and more extensive processing being required. Age-associated differences in cognition do not generally present serious implications for ADLs and IADLs.[87,122] Researchers have found that cognitive processing efficiency, especially for working memory, information processing, and reaction time, is 1.5 times slower in older adults than in middle-aged or young adults.[75] Generally, older adults can, with effort and training, remember details with the same accuracy as that of younger persons.

Robnett and Bolduc[122] described the cognitive changes of aging, relevant for rehabilitation. In a typically aging adult, orientation, for the most part, remains intact as part of crystallized intelligence (basic knowledge and skills that accumulate over the lifespan). With lifestyle changes, like retirement, difficulty remembering the date or the day can occur in older adults. Attention (to sustain attention or focus on a task, alternate attention between two tasks, or divide attention between two or more tasks), or selective attention (to pay attention to relevant stimuli and ignore noise) generally remains intact if there are no distractions with a typically aging adult. However, as adults grow older, they tend to be less able to ignore distractions while trying to attend to a task (such as driving). Crystallized intelligence remains intact or may continue to improve as one ages, particularly for overlearned material and skills needed for work. Older adults tend to see the "gray areas" and pride themselves on seeing beyond the "black and white." Lastly, fluid intelligence is the ability to problem-solve and find meaning at times of confusion, with the ability to develop inferences and understand relationships of various concepts without acquiring new knowledge. This includes skills such as judgment, awareness, and problem solving (executive skills). Fluid intelligence shows decline with aging to a degree. Older adults have more challenges with multistep tasks, and because learning requires multiple-step tasks, this process may slow down but does not stop in typically aging adults.[121]

Loss of memory is a concern for many older adults because memory involves the retention, storage, and retrieval of information. Memory requires adequate attention to sensory-perceptual cues at the initial stages of reception and encoding.[13,88,130] Age differences have been found to affect working memory—one component of short-term memory. Older adults exhibit poorer function in complex deliberate processing (ie, simultaneously performing a cognitive task while trying to remember the information for a later task) than they do in automatic processing (ie, remembering how to perform an activity).[75,122,130] Older adults also have a decreased ability to inhibit thoughts that are irrelevant to the task.[88,122] Age-related deficits have been found in the recall of information when it is retrieved from secondary (storage) memory levels, and this deficit worsens with advancing age.[87,89] However, the overall effects of age-related differences or changes in memory on daily function are minimal. Most healthy older adults are able to compensate for reduced processing resources by using the relevant context of situations, targeting environmental cues, providing environmental supports, rehearsing with elaboration, and developing new skills built on personal associations.

Intervention for the cognitive changes of aging includes utilizing calendars for orientation and making sure that calendars or dry-erase boards are up-to-date at extended care facilities or nursing homes. To address attention, occupational therapy practitioners can eliminate distractions when older adults are attempting to complete a complex task. Repetition for learning is important; however, clinicians should not assume that the client will remember patient education and strategies without writing them down. Providing written instruction or having a client write information down will be more effective for intervention and carryover. Older adults are more likely to use written lists to recall important items, unlike their younger counterparts.[122] Generally speaking, if material to be learned is interesting and the client can draw associations to his or her life, it is more likely that the learning will take place. Multimodal sensory input, such as hearing the information, reading the information, and writing it down, will also increase the likelihood of recall.

When impaired cognition (especially memory) interferes with relationships, diminishes daily function, or affects quality of life, the causes should be explored because many of them are potentially treatable. Problems with memory tasks, whether subjective or objective, are the most commonly acknowledged types of age-related cognitive changes.[15] Displaying decreased memory skills does not, however, indicate that a person has dementia. Mild forgetfulness is experienced by the young and old alike, and it should not cause alarm or lead a person to think about dementia. In fact, decreased memory, or age-associated memory impairment (AAMI), "is widespread and refers to memory skills that are lower than average. AAMI is not as serious and may or may not relate to mild cognitive impairment" (p. 114).[122] AAMI is a part of normal aging, affecting as many as 90% of older adults.[87] This is not a psychiatric disorder. Among the criteria for these cognitive changes is a decline in memory that is sufficient to worry the older adult but not in excess of normal age function, as seen with dementia. The decline must be within normal limits when the client is compared, through psychometric testing, with others who are the same age. Older adults who are tired, under stress, sick, or distracted are more likely to experience slower thinking and recall, experience more difficulty attending to and organizing information, and have difficulty recalling information, especially names, placement of objects, and tasks requiring multiple actions.[87]

According to Petersen and colleagues,[114] memory loss that falls outside of normal limits by one standard deviation on test scores, with more severe memory lapses evident in recent memory that are persistent and begin to interfere with work and social activity (not ADLs), is identified as **mild cognitive impairment** (MCI). In 50% of individuals with MCI, dementia develops within 3 years, although symptoms may have been evident for up to 7 years previously.[87,114] When cognitive impairment becomes so severe that it affects daily function, particularly a significant decline resulting in dependence in ADLs, a diagnosis of dementia is often made. This was the case with Doris, as Don mentioned that she began needing assistance with everyday tasks that included balancing the checkbook and preparing meals. Don encouraged Doris to stop driving, and months later she needed assistance with simple tasks like bathing, dressing, and grooming. Don would oftentimes find Doris in layers of clothing sitting on the floor unsure of what she was doing. Doris was no longer able to keep records of the bills or teach piano to the children in the neighborhood, which was difficult for both Don and Doris, personally and financially.

Differentiated from dementia is delirium, a condition that is estimated to affect 30% of hospitalized older adults.[151] The cardinal features of delirium include a transient state of fluctuating cognitive abilities, often characterized by hallucinations, decreased ability to focus, poor memory, and increased confusion.[47] People who are delirious can have difficulty following multistep commands and have disorganized thoughts, as well as an altered level of consciousness. Delirium can fluctuate during the course of the day, even with lucid intervals occurring. Although delirium can resolve, most people with the condition still experience some symptoms 6 months after diagnosis. Treatment is often nonpharmacologic and focuses on reorientation strategies such as the use of clocks, calendars, familiar objects from home, and personal contact to reinforce orientation.[66] Also beneficial in communication is frequent eye contact and the use of clear instructions. It is important to maintain a quiet environment as much as possible and to involve the client in both self-care and general decision making.

Clinicians working with older adult clients will encounter varying degrees of cognitive decline, and it is essential that they screen for cognitive impairments and consider cognition as a major factor when planning the intervention approach and carrying out interventions. Levy has suggested that occupational therapists can make an important contribution in the early detection and monitoring of cognitive decline by regularly assessing mental status on an informal basis during intervention and formally screening both during the initial evaluation and periodically.[87] Assessments such as the Mini-Mental State Examination,[48] with scoring adjusted for age, culture, and educational level, are helpful as screening tools. Other standardized assessment tools include the Montreal Assessment of Cognition (MoCA),[101] the Saint Louis University Mental Status (SLUMS),[141] and the Executive Function Performance Test (EFPT).[17] An assessment tool such as the Functional Activities Questionnaire[143] has been used to assess functional abilities in IADLs to distinguish older adults who are experiencing more severe cognitive impairment from those who are experiencing MCI.[140]

Approximately 20% of the people age 55 years or older experience some type of mental health concern,[26] and at times, what seems to be a loss of memory or decline in cognition can actually be another medical condition in disguise. Pathologic mental conditions often occur in older adulthood because of physiologically based changes in brain function or brain disorders. Less frequently, the cause is an inability to adapt to changes, losses, and transitions, or these factors may exacerbate an existing condition. Older adults who have adjusted poorly to previous stressors, who are overwhelmed by multiple simultaneous stressors, or who have little social support are particularly vulnerable. Depression, anxiety, and severe cognitive disorders are of concern for the older adult population, as is substance abuse and suicide.[122]

Depression

At least 1 out of 20 older adults (65 years of age or older) who live in the community are diagnosed with clinical depression.[122] The percentage of older adults with depression increases among the population living in institutions or in the hospital setting.[72] Depression oftentimes does go unnoticed or is mistaken for other ailments, grieving, or health conditions; however, a person can experience impaired cognition and depression simultaneously. There are specific differences between depression and dementia, requiring careful diagnosis from an appropriate healthcare provider based on the patient and family report. Signs and symptoms indicative of dementia include a gradual onset of cognitive impairments (over a period of years), unawareness of memory deficits, impairments on various neuropsychological testing, and progressively worsening impairments over time.[120] Signs and symptoms indicative of depression include a more sudden onset of cognitive limitations that happens near the same time as other depressive symptoms, self-report of memory impairment, impairments that are more limited in scope and severity on various neuropsychological testing, and reports of cognitive impairment not advancing, but resolving with treated depression.[120] Older adults are reluctant to seek care from mental health practitioners; however, intervention is critical as depression can lead to withdrawal from social engagement or the inability to perform self-care. This can spiral and the older adult could become isolated and experience occupational dysfunction as a result.

It is important for occupational therapy practitioners to be aware of the signs and symptoms of clinical depression, screen for the condition, make referrals, and to seek out support for clients and their family members if depression is suspected. An occupational therapy practitioner can use the Geriatric Depression Scale[163] or the Beck Depression Inventory[18] to assess a client in any clinical setting. In general, a person may have a sad or depressed mood; decreased interest in activities, attention, concentration, or memory; feelings of guilt and worthlessness; apathy or a lack of motivation; changes in sleep, appetite, weight, energy, or sexual desire; as well as suicidal thoughts.[6] Despite the myths of aging, many older adults do not have depression; depression is not an expected outcome of aging. Suicide is “not always a consequence of depression, [however] death is the most definitive outcome of depression” (p. 126).[122]

Suicide is a major risk in late-life depression. Caucasian men between the ages of 60 and 85 years have an increased risk for suicide, especially if they are 85 and older, have a medical illness, or live alone. Common indicators of possible impending suicide include a past history of suicidal attempts, symptoms of depression or other psychiatric disorders, discharge from a facility against medical advice, spontaneous recovery from a depressed mood, substance abuse; bereavement, or giving very personal items away.[60] Through psychotherapy, electroconvulsive shock treatment, or medication management, depression can be treated, and more than 80% of older adults with clinical depression who are properly diagnosed and treated can recover and return to their previous level of functioning.[107]

Anxiety

Older adults are less likely to report mental health concerns and more likely to emphasize their physical ailments, therefore anxiety disorder can also go unrecognized or untreated in this population. According to the Anxiety and Depression Association of America (ADAA), older adults with anxiety disorder likely had one when they were younger, and it is just as common among the older population as it is among the younger generation of adults.[10] Recognizing that an older adult has anxiety disorder can present with challenges, as older adults may present with increased numbers of comorbidities and other health concerns. Some symptoms described by the ADAA include headaches, back pain, or a rapid heartbeat. Therefore it is difficult to separate these symptoms from other medical conditions.

Older adults may not be as open to discussing anxiety or seeking professional because they were raised during a time when mental illness was more stigmatized and less talked about than in today's society. They may also be concerned about the loss of friends and relatives, decreased mobility, isolation, and increasingly stressful situations and are unaware themselves that this could be a treatable disorder. Anxiety disorders can manifest in various forms including intense apprehension with shortness of breath and chest pain; fear and the disproportionate avoidance of a perceived danger; as well as chronic, persistent, and excessive anxiety.[50] Occupational therapy practitioners can perform a screen for this disorder with basic questions recommended by the ADAA,[10] inquiring about what triggers the anxiety, if the client has had concern or fretted about a number of things, or if there is anything going on in life that is causing concern. Referrals should be made to a physician or psychiatrist as needed.

Substance Abuse

Substance abuse is not as prevalent among older adults as it is with younger adults; however, the problem does exist. In fact, substance abuse is on the rise and the baby boom generation will have an increased need for treatment of illicit drug use, according to the Substance Abuse and Mental Health Services Administration (SAMHSA).[137] Age-related physiological and social changes make this population vulnerable to the harmful effects of illicit drug use.

SAMHSA estimates that 4.3 million adults who are 50 years of age and older have used an illicit drug in the past year.[137] However, the more pressing concern is the abuse of alcohol.[46] Older adults may be taking several prescription medications that would negatively interact with alcohol. Symptoms of alcohol abuse include an increased tolerance of the effects of the substance and increased consumption over time. Older adults are more susceptible to the effects of alcohol, even when they consume less of it, because of age-related changes such as possible decreased liver and kidney function and reduced water content and body mass. Substance abuse can lead to increased accidents, increased risk for falling, poor nutrition, poor hygiene, increased mental health problems, and increased suicide risk, among many other medical conditions. Older adults should be screened by occupational therapy practitioners and referrals made to self-help groups such as Alcoholics Anonymous, counseling, psychotherapy, and a primary care physician for intervention.

Changes in Sensory Structures and Functions

The sensory systems of the human body are not immune to the changes that occur with aging. Older adults are often more susceptible to a number of diseases and chronic conditions, or to the cumulative effect of having a disease for a long period of time, which can take a toll on the visual and hearing systems.

Vision

Normal aging of the visual system takes place at varying degrees, depending on genetic factors and lifestyle choices. These changes in the visual system are related to the eye structure itself and to the mechanisms of visual processing in older adults. (For a full discussion of how the visual system works, please refer to Chapter 24.)

Because vision is such a critical sensory system in humans and plays a significant role in social interactions and safety, any decrease in vision can have an impact on an older adult's ability to engage in occupations. An occupational therapy practitioner may be seeing a client with low vision as a primary diagnosis or as an underlying secondary diagnosis; at times no diagnosis has yet been made. The clinician should encourage the client to see an eye care professional to obtain the best correction if glasses are worn and so that the client's eye health can be evaluated and addressed. Recommendations should also be made to the many professionals serving individuals with blindness and visual impairment.

It is estimated that 33% of adults have some form of vision-reducing eye disease by the age of 65.[42,156] Normal aging in the eye creates a number of changes. As the eye ages, the cornea becomes thicker and more opaque and the lens becomes less elastic, which in turn decreases accommodation, or the ability to make a change from distance to near vision. This condition is called presbyopia. Presbyopia occurs so universally that nearly everyone older than 55 requires some type of corrective lens to be able to read.[57] The lens of the eye may also become more opaque and eventually result in a cataract. Clouding of the lens can be gradual enough that an older adult is not aware of a change in color vision and a decrease in overall vision until the disease is well advanced and occupations have been affected. The iris muscles tend to atrophy, which causes the pupil to constrict. This makes it more difficult for the eye to bring enough light in for the retina to work effectively. The macula (used for central vision), which is part of the retina, has a decreased number of cones and therefore a decrease in effective color discrimination. The rods (peripheral vision) of the retina decrease and are less sensitive. There is also a decrease in the ability to transition between light and dark. Night vision is more difficult for older adults. The need for additional light increases with each decade, and the cones need increased light to effectively discriminate colors. Contrast sensitivity also decreases because of these changes in the eye structures. All these changes in the anterior portion of the visual system make it more difficult to adjust for the changing visual requirements of life.[57,129]

In addition to the natural changes in the visual system, the incidence of macular degeneration and diabetic retinopathy, which can destroy central vision, is high. Any neurologic disease that affects the brain will more than likely affect the visual system. This can be seen with diseases such as multiple sclerosis and Parkinson's disease. Peripheral vision is affected by various conditions, including glaucoma, retinitis pigmentosa, and field cuts related to acquired brain injuries such as stroke. Vision accounts for a high percentage of the sensory information that we use to participate in occupations. When visual acuity is reduced, as can occur in older adults, self-sufficiency in ADLs and IADLs may decrease, the potential for falls increases, and an increase in depression may be seen. It is an all-encompassing system that has an impact on every other perceptual system in the body.[92,156]

Vision functionally can be divided into central field functioning and peripheral field functioning. Each category tends to have a different impact and different intervention goals. Central visual loss (which is experienced with macular degeneration) takes away part or all of the fine detailed vision that we use for reading, shopping, community mobility, and leisure activities.[113] Something key to remember in any assessment or intervention is that if a client wears glasses, they should be worn to elicit the best performance.

Key areas of intervention to enhance participation are magnification, lighting, contrast, and organization. Magnification helps make the object larger on the retina so that the brain has more sensory input for processing. This may be accomplished by bringing the object closer to the client, such as with lenses, magnifiers, and electronic magnification. Because of occupational therapy's involvement in assistive technology and with the increase in all areas of technology, electronic visual enhancement may become the most popular adjustment among older adults in the future. There are ways to read, or to be read to, that are now economically feasible for almost every client. Computers come with magnification programs already installed for those with a visual impairment. Other electronic magnification devices can be used in multiple settings to increase the ability to see functionally. Each state has an agency whose mission is to provide low-vision service for individuals who are blind or have a visual impairment. There are also national and local service agencies and vendors for products.[65]

Lighting is an important component of vision and includes not only the type of light but also where it is placed. It should be close to the task and in a position that will eliminate any glare. Glare may be controlled by window dressings or by changing locations in a room. Glare is a component of contrast sensitivity.[65]

Contrast sensitivity is the ability to detect detail when gradation between an object and the background is subtle. An example might be a white banister on a white wall in a hallway that a client is unable to see or a client's inability to distinguish coffee when it is being poured into a black cup. With poor contrast sensitivity, it would be impossible to discriminate between the background and the object. This has a functional impact not only on living tasks but also on mobility. Contrast and contrast sensitivity are important determiners of how well someone sees in order to function. They are strongly associated with reading performance, mobility, driving, and face recognition.[129] Persons with central visual loss may isolate themselves from friends and family because they can no longer recognize those close to them and are embarrassed.

Decluttering spaces, grouping items by function, and further organizing objects can eliminate what has been called “visual static.” An older adult with low vision is then able to more easily find and use the tools needed during a task.[65]

With peripheral field loss (such as seen with glaucoma or retinitis pigmentosa), mobility becomes an issue because of loss of part of the visual field. Central vision is often spared during this disease process. With field deficits, older adults can have difficulty using their environmental context effectively and consistently. Other areas of participation that may be affected by visual field loss include driving, shopping, financial management, and meal preparation. Grooming may also be affected by field loss.[155] Many older adults with peripheral field loss are able to function independently within their living environment because they rely on the habit of navigation rather than their vision. However, the field loss becomes more apparent and function decreases when the older adult is in an unfamiliar situation. Intervention would include more effective use of scanning for detection of items. It is within occupational therapy's scope of practice to work on mobility as related to familiar space and ADL training. Teaching of mobility outside of familiar surroundings should be referred to an orientation and mobility specialist.

Hearing

Hearing is a multistep process in which sound waves result in vibration of the eardrum and movement of the ossicles. This movement is transferred to the fluid medium of the cochlea within the inner ear. The hair cells in the cochlea turn these vibrations into nerve impulses. Any impedance such as ear wax, ear infection, or hair cells that have died will have an impact on what is perceived as sound.[57] Generally, with normal aging there is a gradual progressive loss called presbycusis. Environmental factors may contribute to an increase in this loss, as may genetic factors and gender differences. Sound seems muffled to older adults. It becomes more difficult for older adults to be able to separate background and foreground noise.[57] Hearing loss is a common chronic condition seen in older adults. Anywhere from 33% to 87% of the older population in the community have some form of impairment.[113] There is increasing evidence that in addition to the ear and its parts, the central nervous system plays a part in the ability to perceive speech in a naturalistic environment.[161] With hearing loss, participation may be limited in the area of phone use, socialization, safety, and participation. Because the sound is muffled or the older adult has difficulty separating foreground and background noise, it may take longer to process what is being said. This loss is gradual and a person often compensates through lip reading. Older adults affected by hearing loss may isolate themselves from others and stop participating and socializing with family and friends.[65] Hearing loss should be taken into consideration when planning intervention and recommending adaptive strategies to older adults, as well as making referrals to other healthcare providers who specialize in hearing loss.

Dual Sensory Loss

When one sense is impaired, the other senses are relied on more heavily to interpret social cues, physical cues, and safety cues. With visual and hearing loss, or what is often termed *dual sensory loss,* the impact is that much greater. It is estimated that 23% of people older than 81 years have some degree of dual sensory impairment.[20] Dual sensory loss is typically considered hearing and vision, although a decrease in the tactile system could also make participation and adjustment difficult for an older adult. The combination of loss in more than two sensory systems is considered multisensory loss.

Smell and Taste

The ability to detect smells and correctly identify smells decreases with age. Most people over the age of 80 years have impaired olfaction, or smell,[99] and there is a high prevalence of people age 65 and older who report decreased smell sensation and complete loss of smell.[122] This is a sensory loss of major concern for occupational therapy practitioners who are assessing safety in the home and one's ability to live independently. Compensatory strategies such as natural gas and smoke detectors can be critical, as well as a family member or friend checking for food spoilage.

Due to the fact that the sense of smell is connected so intricately with the sense of taste, a decrease in olfaction can negatively impact eating and nutrition. Olfaction impairments have been associated with depressive symptoms and poorer quality of life, which can also affect the enjoyment of food, drink, and socialization.[54] As people age, the ability to distinguish between salty, sour, and bitter decreases; therefore older adults may use more salt on foods. The thirst sensation can also decrease, placing an older adult at risk for dehydration.[123] Older adults may purposefully reduce the amount of fluids they drink to avoid frequent and energy-depleting trips to the bathroom. Food and water intake is monitored in hospitals, long-term care, and rehabilitation facilities. It is also critical for caregivers and family members to encourage proper nutrition and hydration in the home.

Changes in Neuromusculoskeletal and Movement-Related Structures and Functions

Although age-related changes do occur in the musculoskeletal system, older adults also have the capacity to maintain or even increase their strength in later years. Exercise is highly effective in older adults,[22,57] as is a program of functional activity, as long as it is adapted to the client's unique needs.

Early in life the body builds bone mass, with a peak at around 35 years.[38,127] After this age, calcium is gradually lost from the bones, which results in loss of bone strength. This condition is termed *osteopenia* when bone volume reaches below-normal levels because of bone resorption exceeding bone synthesis. This is different from *osteoporosis,* in which the reduction in bone mass is significant enough to cause fractures. Primary osteoporosis occurs when the bones become more porous but no other disease is causing this process. Secondary osteoporosis can be due to a number of different processes, including rheumatoid arthritis, diabetes, and drug use, especially corticosteroids.[127] In the United States it is estimated that 10 million people who are 50 years of age or older have the diagnosis of osteoporosis, whereas another 34 million older adults have bone mass that is lower than normal, putting this population at risk for bone fractures. Risks for osteoporosis include estrogen depletion, testosterone depletion, calcium deficiency, cigarette smoking, alcoholism, or physical inactivity. The loss of bone mass can also contribute to a collapse of spinal vertebrae causing a kyphotic appearance in the back with a possible impact on respiration.[57]

Joints also exhibit normal age-related changes. Over time a reduction in joint range of motion of 20% to 25% can be seen.[91] As people age, the water content in tissues, including cartilage, decreases.[127] Cartilage also becomes stiffer and has less of a cushioning effect for the joint over time.[38] The cartilage surfaces become rougher in areas of each joint with the greatest stress, thereby reducing the smoothness of movement. These changes are more significant in areas of increased wear and tear, but they are even seen in sedentary individuals. At a pathologic level, articular cartilage can degenerate to such a point that pain and stiffness result, as well as impaired movement, which can be diagnosed as osteoarthritis (see Chapter 38 for further details). Although pain and decreased joint mobility are often factors limiting a person's function, arthritic changes can be seen radiographically in the joints, even in individuals with no other symptomatology. Changes are seen in tendons and ligaments, which also have reduced water content over time.[91] Increased cross-linking of collagen fibers occurs and can cause stiffness of the collagen. Tendon and ligament strength declines with age,[127] as does the strength of attachment to bone, which results in decreased joint stability and greater risk for injury. Doris was diagnosed with osteoarthritis, and the physical changes in her hip joint placed her at an increased risk for injury, which occurred when she fell in her new home. The hip fracture was stabilized with open reduction and internal fixation. Don was grateful that a total joint replacement was not indicated at the time because, as he reported, he worried about how her therapy would go, as she would not remember any of the restrictions after a replacement. Her orthopedic surgeon cleared her to weight-bear as tolerated on her leg. Doris did not have postoperative pain nor did she have any other precautions or restrictions (for further information on hip fractures and lower extremity joint replacements, please see Chapter 40).

In general, older adults exhibit some muscle atrophy.[127] This is due in part to age and in part to disuse, and it is difficult to distinguish the two. Some motor units and muscle fibers are lost over time, with the loss being most pronounced in fast-twitch fibers.[127] Denervation of fast fibers in aging can be followed by reinnervation from slow fibers and result in this conversion. It takes more time for older muscles to recover from use, and the recovery may not be complete, resulting in decreased muscle endurance. The decrease in muscle mass and contractile force is termed *sarcopenia,*[91] which can be a consequence of age or a disease process and results in decreased muscle power. Encouraging older adults to continue exercising or to resume exercise after a hospitalization cannot be overemphasized for its benefits and therapeutic effects. Regular physical training can improve muscle strength and endurance, even in the older adult population.[93] This type of exercise program (completed with caution and under the supervision of a healthcare provider) is also beneficial to the cardiovascular system.

Changes in Cardiovascular, Hematologic, Immunologic, and Respiratory System Structures and Functions

The cardiovascular system is responsible for pumping blood throughout the body, enabling oxygen and nutrients to be delivered to all systems, as well as removing waste products from all parts of the body. Therefore damage to this system can have a negative impact on the functioning of the entire body. Cardiovascular disease is the most common cause of death around the globe; however, with improved diets, increased exercise, and less smoking, mortality rates are decreasing in the United States.[57]

Although high blood pressure is a pathologic function and not part of normal aging, it is normal for systolic blood pressure to increase with age because of increased stiffness of the arteries.[79] Athletic individuals have lower systolic pressure than do sedentary individuals, but systolic pressure is still, on average, higher than that in younger individuals. Veins also dilate and stretch with age, and their valves function less efficiently,[127] so blood return to the heart is slowed down. With age the heart requires slightly longer rest periods between beats, or longer recovery, which may have an impact during activities requiring a higher heart rate. The maximum attainable heart rate declines with age, though not as steeply as in those who exercise. Cardiac output is also somewhat decreased, which may explain some of the fatigue felt by older adults during strenuous activities.[127] During exercise, older adults may become short of breath (dyspnea) and fatigue more quickly than younger adults. Older adults are also susceptible to postural, or orthostatic, hypotension, which is a fall in systemic blood pressure upon changing positions (such as rising from supine to sitting at the edge of the bed) too quickly. This can cause a person to feel lightheaded upon standing, increasing yet another risk for a fall.[57] The reader is referred to Chapter 44 for further information on cardiac and pulmonary diseases.

Arteriosclerosis is hardening of the arteries, which can occur in older persons; symptoms may include headache or dizziness.[79] Atherosclerosis is a form of arteriosclerosis in which plaques decrease the diameter of the arteries, and it is the predominant change that occurs in blood vessels with age. These fatty plaques and the proliferation of connective tissue in the walls of the arteries contribute to the slow destruction of the arterial walls and can lead to blockage of the artery, especially when there is a blood clot. There is evidence that this accumulation of plaque in the walls of the arteries begins in the first decade of life, with complications of atherosclerosis beginning as early as the fourth decade of life.[57] Heart attacks are more common in individuals older than 50 years of age; and the coronary artery disease that causes the heart attack is the number one killer of people in the United States.[73] Given the prevalence of atherosclerosis in older adults, it is important that occupational therapy practitioners do their part and address diet and exercise, stress and weight management, smoking cessation and lifestyle modification, as well as medication management and adherence to prescription medications.

One important hematologic condition in older adults is anemia. Anemia is defined as "a lower than normal oxygen-carrying capacity of blood" (p. 81).[57] It can occur in older adults during a hospitalization or when placed in long-term care settings. There is no single cause for the disease; it is treated more like a syndrome that has many different causes. People with anemia generally have pale skin, fatigue, and shortness of breath. Occupational therapy clinicians should check with the physician or nurse prior to treating someone who may have these symptoms in a hospital setting, as the person may require a blood transfusion.

The immune system is important to ensure that our bodies remain free of infections and cancer. The white blood cells in the immune system must be able to recognize healthy cells from invading microorganisms and parasites, or abnormal cancerous cells.[57] Immunologic function is decreased at multiple levels and typically gives rise to three categories of illness that affect older adults: infections, cancer, and autoimmune disease. The thinner skin of elderly persons provides less of a barrier to infectious agents with increased risk for skin tears and subsequent infection. Fewer cilia are found in the lungs, which reduces the body's ability to keep infectious agents out of the lungs. There is also evidence that immunity is decreased at a cellular level, with a reduction in adaptive immune responses, such as those of T cells.[127]

The function of the respiratory system is to deliver oxygen to and remove carbon dioxide from the bloodstream.[57] Production of mucus in the respiratory system, which helps prevent respiratory infections, is decreased, and thus older adults' susceptibility to these ailments increases. The cough reflex is also less effective.[127] Numerous changes occur and can result in chest wall stiffness, such as kyphosis (appears hunched over), calcification of the costal cartilages, and scoliosis. This limits chest expansion and requires increased use of the diaphragm for breathing. This heightened energy requirement just to breathe can increase older adults' fatigue even when at rest or during light activities. The efficiency of oxygen–carbon dioxide exchange also decreases because of increased residual volume in the lungs, enlarged alveoli, and fewer capillaries.[21]

The normal age-related changes to the respiratory system can be coupled with common diseases that increase in frequency from the fifth decade of life and onward to complicate this picture. These conditions include emphysema, pneumonia, chronic bronchitis, and lung cancer. Emphysema and bronchitis can be grouped together and discussed as chronic obstructive pulmonary disease (COPD), which is primarily caused by cigarette smoking or long-term exposure to unhealthy air (see Chapter 44 for more details). Energy conservation and work simplification techniques should be incorporated into intervention when respiratory dysfunction is limiting engagement in occupations. Pursed lip breathing techniques and diaphragmatic breathing can also be incorporated into a stress management approach.

Changes in Voice and Speech Functions; Digestive, Metabolic, and Endocrine Functions; and Genitourinary and Reproductive Functions

The vocal mechanism is affected by age and results in weakness, reduced intensity, hoarseness, trembling, and alterations in vocal pitch, which is a common characteristic of the older adult's voice. These changes in the vocal mechanism are in part due to the aging larynx and supporting structures, as well as an increase in calcium and hardening of the cartilage in the larynx. Blood supply to the vocal mechanism may be decreased, and there may be edema of the vocal cords that impacts the quality of voice and speech functions. The vocal pitch of older male adults increases, whereas the pitch of older females decreases. The trembling or jittering of the voice is caused by a decrease in neuromuscular control of the muscles that support the larynx. These changes are subtle and usually are recognized only by a trained professional; they may have minimal impact on the daily communication functioning of an older adult.[25]

A major function of the digestive system is to process incoming foods in order to deliver nutrients to the body. A common problem experienced by older adults in eating and swallowing is due to tooth loss and compromised dentition. Aging causes tissue, glandular, and muscular changes in the jaw, as well as changes in the tongue, salivary glands, and throat with a decrease in the number of salivary glands and reduced taste sensation. These changes may cause an older adult to exert greater effort in swallowing and require more time to swallow food. Some older adults will choose foods that are soft and easier to swallow, whereas others reduce their food intake, impacting nutrition and weight negatively.[7]

Eating can also be challenging when there is not the proper amount of saliva in the mouth to create a bolus. This condition can be caused by decreased saliva production, cigarette smoking, or medication side effects. If a person is having difficulty swallowing, an assessment of swallowing is recommended for dysphagia (difficulty in swallowing). This would be an assessment of a complex coordination of several muscles of the tongue, palate, pharynx, and esophagus and can be administered by an occupational therapy practitioner with advanced practice or a speech and language pathologist.[57] See Chapter 27 for more information on the assessment and interventions for eating and swallowing.

In the stomach, food is chemically digested by gastric acid. As people get older, the amount of gastric acid secretions decreases, whereas the incidence of peptic ulcers and gastritis increases. This can be due to drug ingestion, aspirin, caffeine, or alcohol; it can also be caused by a genetic predisposition causing inflammation of the stomach lining. The liver's ability to detoxify many foreign and potentially damaging chemicals that enter (or are produced by) the body also decreases with age.[57]

One common problem with older adults is diverticulosis, which is “the development of small sacs where the large intestinal lining has herniated through the intestinal muscular wall” (p. 87).[57] These pockets can become impacted with feces, resulting in an ulceration and inflammation of the mucosal lining (known as diverticulitis). This can be a painful experience for older adults and can complicate the bowel routine by causing constipation. In extreme cases, it can also lead to an intestinal obstruction.[57] An occupational therapy practitioner can address issues of feeding, digestion, and bowel routine in collaboration with nursing and dietary services as well as the client and family. Doris had a diagnosis of diverticulitis, and when asked about her experience with it, Don mentioned that it did cause Doris a lot of pain and it was something that he felt was at times more painful than the hip fracture. Don believed a reason why Doris got up and went to the bathroom so much at night was because of the constipation and her attempts to have a bowel movement. Doris stopped taking her medications for diverticulitis; however, Don believed it was something she needed to resume taking to prevent the discomfort experienced prior to admission. A follow-up appointment with Doris' primary care physician was recommended.

The kidneys filter the blood and help remove wastes and extra fluid from the body. They also help control the chemical balance within the body. The kidneys work with the ureters, bladder, and urethra to excrete urine and waste, and this process can be affected by muscle changes and changes in the reproductive system with respect to bladder control. As a person ages, the kidneys and bladder change because the amount of kidney tissue decreases, the number of filtering units (nephrons) decreases, and the blood vessels supplying the kidneys become hardened, causing the kidneys to filter blood more slowly. The bladder wall changes and the elastic walls become tough and less elastic, limiting how much urine the bladder can hold. The bladder muscles weaken and can cause the bladder or vagina to fall out of position (prolapse) in women. In men, the urethra can become blocked by an enlarged prostate gland. These conditions can place an older adult at risk for urinary incontinence or urinary tract infections. Collaborating with the client and the family, as well as the nursing team, to work on a bladder program is under the scope of practice of an occupational therapy practitioner and is a critical component of self-care and independence with ADLs.[149]

Oftentimes, occupational therapy practitioners work with clients who are undergoing dialysis for chronic (or acute) renal failure. Dialysis is a treatment that replaces the function of the kidneys by removing waste, salt, and extra water to prevent them from building up in the body. It also keeps a safe level of certain chemicals in the blood, such as potassium, sodium, and bicarbonate. One other effect is that of maintaining control of blood pressure.[109] Clients who are undergoing dialysis treatments can experience exhaustion after a treatment, weakness in the lower extremities, decreased blood pressure, muscle cramps, itching, insomnia, anemia, bone disease, fluid overload, and depression. It is critical to pace any occupational therapy intervention and teach energy conservation and work simplification techniques. Caregivers and family members should also receive the attention of the clinician, as dynamics in family responsibilities and relationships can be altered.[95] Meal planning and grocery shopping can be included in the intervention plan, as patients receiving dialysis must maintain a special diet with supplements and an extensive prescription medication list.

The endocrine system is another regulatory system in the human body and controls many aspects of the body's physiology, such as body temperature; basal metabolic rate; growth rate; carbohydrate, lipid, and protein metabolism; stress response; and reproductive events.[57] Because the endocrine system is responsible for producing and secreting hormones into the body, dysfunction of this system has widespread impact on the health and well-being of an older adult.

Gregory and Sandmire have described a hierarchy of control,[57] which starts with the higher brain centers that influence the activity of the hypothalamus. The hypothalamus releases hormones that control the activity of the pituitary gland, which in turn releases hormones that control the activity of lower endocrine glands and other tissues. These lower endocrine glands release hormones that control other body functions related to the thyroid gland, adrenal gland, testes, and ovaries. An overall decline in the production and secretion of hormones and the impact this has on the human body goes beyond the scope of this chapter; however, one condition that is prevalent in the older adult population is diabetes mellitus (DM).

Diabetes is a condition in which the body does not properly process food for use as energy. The pancreas makes a hormone called insulin to help glucose get into the cells of the body. With diabetes, the body either does not make enough insulin or cannot use its own insulin as well as it should. This causes sugars to build up in the blood.[29] Long-term complications such as blindness (resulting from cataracts and retinal damage), renal failure, nerve damage, atherosclerosis, and gangrenous infection often necessitating amputation (below or above the knee) are all factors that will impact participation in occupations. Non-insulin-dependent diabetes mellitus (NIDDM), or type 2, accounts for approximately 90% to 95% of all cases. In the United States, 21 million people have been diagnosed with DM, and 27% of those 65 years of age and older have the disease.[29] This is another area where occupational therapy practitioners can intervene with lifestyle modification programs, weight management, exercise and diet programs, and stress management. The client and family should be working closely together to address the needs of an older adult with DM.

Reproductive function will also change as a person ages. For women, menopause is associated with physiologic and psychological changes that can influence sexuality. There is a decrease in estrogen levels, which impacts the menstrual cycle as well as vaginal lubrication. The changes in estrogen levels also affect the vascular and urogenital systems. Women may experience changes in mood, sleep, and cognitive function, which can contribute to lower self-esteem, decreased self-image, and decreased sexual desire. Prescribed medications and current medical status can also impact sexuality and sexual drive.[12] There are medications and hormone replacement therapies that can be utilized to address these issues medically; therapy and counseling can also be of benefit psychologically.

For men, there is not a major or rapid change in fertility with age as there is with women. The changes are gradual in nature, and the condition is referred to as **andropause**. The changes for men primarily occur in the testes, with decreased testicular mass and a gradual decline of testosterone;

these changes may make it more challenging to achieve an erection. The testes continue to produce sperm; however, the rate of sperm cell production decreases and the tubes that carry the sperm may become less elastic with age. With the enlargement of the prostate gland, urination and ejaculation are negatively affected. Approximately 50% of older men are diagnosed with benign prostatic hypertrophy (BPH).[150] Fertility varies among older men; age does not predict male fertility. The volume of fluid ejaculated usually remains the same; however, there may be a decreased amount of sperm. Some men experience decreased sex drive, which can be caused by psychological concerns, lack of a willing partner, medication side effects, or other chronic medical conditions.[150]

Erectile dysfunction (ED) may also be a concern for aging men; however, this is not because of the aging process itself but because of other medical conditions or medication side effects. Hypertension and DM are known causes of ED, and medications can be used to treat this condition. Prostate cancer and bladder cancer are more likely to occur with age, and preventive measures and visits to a primary care physician are encouraged for early detection.[150] Occupational therapy practitioners can utilize their interview skills and the EX-PLISSIT model for sexuality to obtain information and provide information in the area of sexuality. There are also clinicians who have advanced practice in this area and can provide more intensive and comprehensive therapy. Referrals should also be made to sex therapists as needed.

Changes in Skin and Related Structure Functions

The integumentary system consists of the skin as well as accessory structures such as the nails, hair, oil glands, and sweat glands. An obvious sign of aging is the change in hair color to gray, as well as the thinning and loss of hair, experienced by many older adults. Because skin covers the entire body, another obvious sign associated with aging is the changing skin. As the aging process progresses, skin becomes more vulnerable to shearing forces, abrasions, and blister formation.[57] It is important for occupational therapy practitioners to protect the client's skin during functional mobility and ADL transfers from surface to surface, to avoid any shearing or tearing of the skin. Any open tears or wounds should be covered to protect the client and the clinician.

It is also important for older adults to protect the skin from ultraviolet rays of the sun. The turnover rate of the epidermis shedding and replacing itself every month starts to slow down with aging, slowing the amount of protective melanin pigment produced. This makes the ultraviolet light more dangerous and leaves older adults more prone to developing skin cancer.[57]

The thinning and wrinkling of the skin are results of the decreased amounts of collagen and elastin in the dermis of the skin. With the loss of elastin, the skin loses its resilience as a person ages, and with the loss of collagen, the skin is more susceptible to wear and tear. These changes are accompanied by a decreased flow of dermal blood supply, impacting the typical signs of inflammation in the skin. Older adults may not show initial signs and symptoms of tissue injury like sunburn, bacterial infection, or even skin cancer. Because the dermal layer of the skin holds sensory receptors, the changes in this layer will also affect tactile sensitivity of the skin while increasing the pain threshold at the fingertips.[57] These changes may make it difficult for older adults to perform fine motor movements, such as turning on a hearing aid, snapping buttons, or putting in earrings. Fine motor movements and dexterity should be assessed and compensatory strategies should be integrated into intervention for the completion of ADLs such as grooming and other meaningful activities.

Aging is a natural process and the changes described here are expected and typical. "It is this interdependence of our organ systems that, on the one hand, allows for appropriate compensatory adjustments to homeostatic disturbances in younger, healthy individuals but, on the other hand, can create a chain reaction of dysfunction in older, less healthy persons with decreased physiologic functional reserve" (p. 82).[57] When there is a chronic medical condition or injury, the aging process becomes more complicated; therefore it is important to consider prevention and wellness with the older adult and intervene with our clients when they are younger adults, if possible.

Threaded Case Study

Doris, Part 3

Strengths that were identified for Doris included the fact that she required minimal assistance or less during functional mobility and could feed herself with supervision. These were two areas that did not require much physical assistance from Don. Doris also showed active range of motion and strength in her upper extremities, which were considered within functional limits. Doris had a passion for piano and teaching young children to play piano, which was also a strength, as it was motivating for her and provided her with hope. Supports included her relationship and assistance from Don and their loving family. Don and Doris lived right behind the rehabilitation facility, and Don could visit Doris and learn from the occupational therapist each day for family/patient education.

Areas of potential occupational disruption included resuming instrumental activities of daily living and resuming her roles in the home management tasks of bookkeeping and paying the bills secondary to her cognitive deficits and expected limitations in the future, given her diagnosis of Alzheimer's disease. Barriers included safety in the home (and at the facility) secondary to the cognitive component, which is progressive in nature, requiring more and more compensatory measures. There is also concern about Don's health and his abilities to serve as the sole care provider upon discharge to their home.

Priorities included patient and family education, particularly with Don, in preparation for discharge. Don identified two major goals for Doris as being very important: safely performing toileting activities (particularly in the middle of the night) and resuming piano instruction. The occupational therapy practitioner recommended that Don also consider a caregiver support group and in-home support services for the physical work that he may not be able to complete with Doris, due to his own physical limitations and heart condition.

Doris' case has several layers, including a new home environment and medical conditions that added to the complexity of the aging process. All of these layers had to be considered when designing an intervention plan that could meet Doris' and Don's needs. Compensatory strategies and environmental adaptations were recommended for Doris, and caregiver education was paramount for the carryover and execution of the strategies in the home. Attention was given to the caregiver and his needs, as Don himself is an older adult with a complicated medical condition who also demonstrated physical limitations in his role as caregiver.

Don brought Doris' keyboard to therapy, and as Doris progressed in occupational therapy, she began to play the keyboard again. She was able to complete bathing and dressing activities with minimal verbal cues utilizing sequencing cards designed in therapy and was soon inviting other residents at the facility to the rehabilitation gym to sing along as she played the keyboard. Don said she finally looked like herself again. He attended a support group specifically designed for caregivers who were spouses of loved ones with Alzheimer's disease, and he agreed to in-home support services and respite services so that he could take time for himself. The new apartment was organized, and the hallways and floors were cleared. Don and Doris felt ready for the discharge to their home.

Summary

Older adults are an extremely diverse population with whom occupational therapy practitioners work; they provide complex challenges yet offer rewarding experiences and opportunities in both habilitation and rehabilitation settings. Older adults bring a lifetime of experiences, habits, wisdom, and problem-solving strategies to the occupational therapy process, as well as the possibility of functional decline as a result of the aging process. From the stories of "when I was your age" to the excitement experienced while surfing the Internet, this population presents opportunities and potential for the field of occupational therapy to truly make a difference with people who deserve comprehensive and holistic care.

Empowering older adults, their families, and their caregivers is a reflection of the respect and dignity the older adult population deserves. Baby boomers must be a priority to society and to healthcare, because their needs are growing as they continue to age. Meanwhile, the healthcare policies and systems driving reimbursement and documentation continue to challenge the delivery of services. An occupation-based, client-centered approach makes sense when addressing the needs of an older adult, because like any other client, the desired outcome is to live life to its fullest.

Review Questions

1. Describe four elements of treatment to enhance participation by an older adult with low vision, impaired hearing, impaired sensation, and low endurance.
2. Name three cognitive changes associated with aging, and provide three strategies to enhance the learning of new information.
3. List five age-related physical changes that a therapist would consider in a client who is 80 years of age.
4. Identify areas of occupation to assess when working with an older client who recently had significant weight loss.
5. Describe three key considerations when assessing an older adult's home for the potential to age in place.
6. What are the benefits to a shared governance structure in facilities providing care to older adults?
7. Describe the paradigm shift that can occur when "flipping a nursing facility."
8. Describe the significance of policies established for older adults in the United States with respect to documentation and reimbursement.

HIV Infection and AIDS

Michael Pizzi, Graham Teaford

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, the student or practitioner will be able to do the following:

1. Understand the stages of HIV and AIDS.
2. Describe the impact of medical interventions on HIV.
3. Describe how to assess a person with HIV or AIDS holistically.
4. Identify occupational therapy interventions directed toward optimizing health as an occupational participation.
5. Understand the importance of a health promotion and prevention perspective in occupational therapy services for people with HIV and AIDS.

KEY TERMS

Acute HIV infection
AIDS-dementia complex
Antiretroviral therapy
Opportunistic infection
Retrovirus
Seroconversion

Threaded Case Study

Billy, Part 1

Billy is a lawyer and internal medicine physician living with Tom, his partner of 15 years. He has lived for more than 20 years with a diagnosis of HIV infection, and the mode of infection for Billy is unknown. Billy has been practicing medicine successfully, as well as doing pro bono work as a legal advocate for people infected with HIV and with AIDS. He began highly active antiretroviral therapy approximately 15 years earlier. His $CD4^+$ count has remained above 500, and he has not had any opportunistic infections. He continues to be active in his career as a physician and with his pro bono legal work.

He has recently noticed that he has more difficulty with his memory, decreased fine motor coordination, difficulty coordinating his movements, burning sensations in his hands and feet, and lower extremity weakness. These changes have had an impact on his life in a variety of ways, such as difficulty remembering his appointments, taking his medications as scheduled, writing, and awakening at night because of pain.

During the course of developing an occupational profile, he stated that his primary concerns involve how these changes have affected his professional activities. He values his roles as both physician and attorney, as well as his paid employment and his pro bono work. His work has been affected by his diminished writing skills (requiring more time and effort to write legibly) and his pain (limiting his rest and causing him to have difficulty concentrating on work tasks). However, he is most concerned with his changes in memory because it has caused him to forget appointments and miss deadlines, has compromised the quality of his work, and has placed his professional competence and identity at risk. This deficit became his greatest concern because of his pride in having what he calls a “mind like a steel trap.” As a health professional, Billy possesses the knowledge required to care for his own health and well-being; however, he does not apply this knowledge to his own daily life. His partner, though supportive, is becoming increasingly angry, irritable, and concerned, and these emotions appear to have impaired his own occupational performance in work, home, and leisure occupations.

Origins and Current Status of HIV Infection

An estimated 36.9 million people globally are infected with human immunodeficiency virus (HIV) or have acquired immunodeficiency syndrome (AIDS).[55] In 2014, approximately 1.2 million people died of HIV/AIDS, and an estimated 2 million persons were newly infected with HIV. An estimated 34 million people have died of HIV/AIDS since the virus was first detected.[59]

HIV originated in Africa and has likely been present in humans since the late 19th century.[11] The virus has been present in the United States since the 1970s, possibly decades earlier, and has since spread globally.[27]

AIDS was first clinically identified in the United States in 1981.[16] These initial cases of AIDS in the United States were concentrated in men having sex with men, injection drug users, and persons receiving contaminated blood supplies (from transfusions or clotting factor for persons with hemophilia). By 1983, HIV, the virus that causes AIDS, was identified.[20] It soon became apparent that HIV is spread by contact with specific body fluids (including blood products, semen, and vaginal fluids). The eventual discovery of HIV as a virus made it apparent that AIDS does not discriminate among gender (Table 47.1 and Fig. 47.1), race (Table 47.2 and 47.4), culture, sexual orientation (see Table 47.1), or age (Tables 47.3). HIV affects all of humanity. It affects not only the people infected with the virus but also their parents, siblings, friends, lovers, children, and coworkers. After one's diagnosis of being HIV positive has been confirmed, an individual can become immobilized and drastically alter his or her occupational performance and participation in society, or the individual can treat the diagnosis as an impetus to act in positive, life-transforming ways.

TABLE 47.1

Distribution of the Estimated Number of Diagnoses of AIDS in Adults and Adolescents in 2015

Exposure Category	Male	Female	Total
Gay and bisexual men	26,375	_____	26,375
Male to male sexual contact	1202	_____	1202
Injection drug use	1412	980	2392
Heterosexual contact	2948	6391	9339

In 2015, 39,513 people were diagnosed with HIV infection in the United States. The number of new HIV diagnoses fell 19% from 2005 to 2014. Because HIV testing has remained stable or increased in recent years, this decrease in diagnoses suggests a true decline in new infections. The decrease may be due to targeted HIV prevention efforts. However, progress has been uneven, and diagnoses have increased among a few groups.

TABLE 47.2

Estimated Cumulative Cases by Race/Ethnicity

In 2015, the number of diagnoses of HIV infection in the United States was as follows:	
Race or Ethnicity	**Number of Diagnoses of HIV Infection, 2015**
American Indian/Alaska Native	209
Asian	955
Black/African American	17,670
Hispanic/Latino*	9,290
Native Hawaiian/Other Pacific Islander	79
White	10,509
Multiple Races	801

*Hispanics/Latinos can be of any race.

For more details on HIV infection and race/ethnicity, see CDC's Populations and Surveillance fact sheets.

TABLE 47.3

HIV Diagnoses by Age

Age in Years	Number of cases in 2015	Percentage
13-19	1,723	4
20-29	14,594	37
30-39	9,631	24
40-49	6,720	17
50-59	4,870	12
Over 60	1,855	5

Centers for Disease Control and Prevention https://www.cdc.gov/hiv/statistics/overview/ataglance.html

TABLE 47.4

AIDS Information Tracked by CDC on Various Racial and Ethnic Groups*

In 2015, the number of persons in the United States with diagnosed HIV infection classified as stage 3 (AIDS), by race/ethnicity, was as follows:		
American Indian/Alaska Native	96	3,543
Asian**	325	9,932
Black/African American	8,702	506,163
Hispanic/Latino†	3,870	222,227
Native Hawaiian/Other Pacific Islander	22	845
White	4,668	439,207
Multiple Races	620	35,000

*From the beginning of the epidemic through 2015.

**Includes Asian/Pacific Islander legacy cases.

†Hispanics/Latinos can be of any race.

For more details on AIDS and race/ethnicity, see CDC's fact sheets.

The majority of global HIV cases are caused by exposure to HIV type 1 (HIV-1), with HIV type 2 (HIV-2) being much less common and primarily found in western Africa. The global patterns of the HIV epidemic are complex and vary greatly by region and within different regions. The 2013 United Nations Global AIDS Report[54] identifies a number of trends:

- The estimated annual number of new infections globally declined from 3.4 million in 2001 to 2.3 million in 2012 (a 33% reduction).
- An estimated 1.6 million people died of AIDS in 2012, a decline from an estimated 2.3 million in 2005.
- Women account for 52% of the people living with HIV in low- and middle-income nations. In sub-Saharan Africa, the region most impacted by HIV, women account for 57% of persons living with HIV.
- Access to antiviral treatment has expanded, with the number of persons receiving treatment tripling in a 5-year period. As the number of persons receiving treatment has increased, life expectancies for persons infected with HIV have also increased. However, globally only a third of the persons eligible for treatment are currently receiving antiviral medications, with some populations and regions facing significant challenges. Among the most significant challenges are ensuring that more persons are aware of their HIV status.
- Tuberculosis deaths, the leading cause of death for persons living with HIV, have declined globally,
- Service integration is a priority as nations move from initial programs that developed in response to the health crisis posed by HIV toward a long-term integrated approach within the medical

system. These approaches vary considerably from nation to nation depending on needs and target populations.

- Global AIDS funding remains inadequate to meet the demands of the crisis.
- Discrimination against persons with HIV remains a barrier to treatment and prevention efforts.

Currently, an estimated 1.2 million persons in the United States have diagnosed or undiagnosed HIV/AIDS.[21] As of 2012, 12.8% of persons infected with HIV in the United States are unaware of their HIV-positive status.[10] According to estimates from the Centers for Disease Control and Prevention (CDC), more than 50,000 new cases of HIV infection occur in the United States each year. The number of new infections per year (incidence rate) has remained relatively stable. However, the number of persons living with HIV (prevalence rate) has continued to grow as mortality rates from HIV have decreased, in large measure as a result of available and effective antiviral medications.[13] The demographic trends in the United States have changed since the earliest years of the pandemic.

Although overall rates of new infections have been relatively stable in the United States, certain groups are at greater risk for HIV infection and bear a disproportionate burden of HIV. Among ethnic groups, African Americans are the most disproportionately affected population in the United States. African Americans represent approximately 12% of the U.S. population but account for 44% of all new infections and 41% of all persons living with HIV.[12]

Hispanics/Latinos are also disproportionately affected by HIV in the United States. Though representing 17% of the United States population, in 2013 Hispanic/Latinos accounted for 23% of new HIV infections.[9]

The earliest cases of HIV infection in the United States, though having a broad impact on society, were concentrated in white males.[16] In contrast, current infection patterns in the United States demonstrate changes in the groups currently at risk, as well as underscore the fact that HIV infection is not a concern of only one ethnic group.[11]

Although male-to-male sexual contact remains the most common means of transmission of new infections, heterosexual contact accounts for nearly a quarter of all new HIV infections.

The course of the HIV pandemic has changed significantly with the advent of effective medical treatments. For persons with access to effective medications, management of HIV has, to some extent, changed the focus of medical management to the chronic medical needs of persons with HIV infection rather than more acute management of **opportunistic infections**. In the earliest years of the pandemic, before effective pharmaceutical treatment, death typically occurred within 10 years of HIV infection and 1 to 2 years after the onset of AIDS.[7] Mortality rates and the frequency of opportunistic infections have decreased significantly. However, this also presents public health concerns. The health delivery model in the United States is not always effective in addressing the increasingly chronic needs of persons infected with HIV rather than the more acute cases that were more common in the earlier years of the pandemic.[19] Occupational therapy (OT) practitioners can potentially play a significant role in the promotion of health and management of chronic medical needs to ensure that persons remain active participants in meaningful occupations.

Infection Process

HIV is the virus that causes AIDS[20] and belongs to a class of viruses known as **retroviruses**. Retroviruses share a unique process of replication characterized by the viral genetic material being encoded by RNA rather than DNA. Retroviruses, including HIV, replicate as viral RNA is transcribed into DNA in the host cell. The cellular process is complex, with many components and processes occurring. The following is a simplified description of the infection process.

The process begins as the virus binds to a cell surface receptor.[39] During the attachment phase, HIV binds with the surface protein receptors on the cell membrane. The receptors operate in a lock-and-key fashion, with CD4 being the primary receptor for HIV (although other receptors and processes are also critical in the process of HIV cellular infection). The initial binding with surface receptors is a necessary stage for cellular infection.

Once the initial binding to cell receptors is completed, the virus passes through the cellular membrane and enters the cytoplasm. On entering the cytoplasm, the retrovirus uses an enzyme called reverse transcriptase to synthesize a proviral DNA copy from the viral RNA template (a process referred to as reverse transcription). During this process, the transcriptase reads the RNA material as it is converted to DNA that can be integrated into the host cells' genetic material. However, errors are frequently made in the replication process. As a result, not all copies of HIV DNA are identical. The modifications or mutations during this process contribute to the resistance of the virus to the body's immune system and to certain antiviral treatments.

The completed proviral DNA migrates to the nucleus of the host cell and is inserted into or integrates with the host cell DNA. Once this integration occurs, the integrated viral DNA (or provirus) is replicated along with normal cellular genes as part of the routine cellular division process. Virions containing HIV RNA and HIV proteins are assembled within the host cell body, and an enzyme called protease is required at this phase to divide the polypeptide chain into discrete functional enzymes. The completed HIV virions (containing HIV RNA and HIV proteins or enzymes) are released from the host cell membrane in a process referred to as budding. Once the virions are released and the transcriptase has completed division of the proteins, the mature virus is capable of infecting additional cells. The newly created mature virus resembles the original virus but may also have undergone some variation during the replication process, thus complicating medical treatment.

Transmission

HIV is transmitted through exchange of certain body fluids (blood, semen, preseminal fluid, rectal fluid, vaginal fluid, and breast milk) from a person with HIV. Sexual behaviors and injection drug use are the most common means of transmission for new infections.[22] Less common means of transmission include mother to child during pregnancy, birth, or breast feeding, and accidental exposure to infected needles (primarily occupational exposure). HIV is not transmitted through casual (nonsexual) contact with persons.[7]

In the early years of the AIDS pandemic, many people were infected with HIV because of contamination of the blood supply (primarily through transfusions or clotting factor given to persons with hemophilia). However, the blood supply is tested for HIV in the United States.[8] The risk of contracting HIV via blood products, transfusions, or organ/tissue transplants is very low.

The risk of infection to healthcare providers is also very low.[22] The risk for HIV infection following a needle stick is 0.3%, and the risk for infection after exposure of infected blood to the eyes, nose, or mouth is 0.1%.[18] The risk with exposure of nonintact skin to infected blood is less than 0.1%, and exposure of infected blood to intact skin probably poses no risk at all. It is important to remember that healthcare workers, or any other persons, are not at risk for HIV infection through casual, everyday contact with persons infected with HIV. The CDC recommends that healthcare workers practice universal precautions.

Universal precautions in the workplace include assuming that blood and body fluids from all clients are potentially infectious.[23] Healthcare workers should take certain precautions when working with all clients. Such precautions include the routine use of barriers (such as gloves) when anticipating contact with blood or body fluids. Workers should also wash hands and other skin surfaces immediately after contact with blood and body fluids. Finally, although the risk for HIV infection from an accidental needle stick is very low, this route of transmission constitutes the most likely risk for infection in healthcare workers. Workers should practice careful handling and disposal of any needles or potentially infectious sharp objects.

Diagnosis

HIV may be detected by using a variety of tests.[7] In general, three broad categories of tests are available: antibody tests, combination tests, and nucleic acid tests (NATs).[10] Antibody tests detect the presence of HIV antibodies following the initial HIV infection. It is important to note that during the process of **seroconversion** (the immune response producing detectable antibodies), the person may be infected but not have a positive antibody test result. The process of seroconversion (producing a positive antibody detection test result) may take up to 2 months after the initial infection, and the infected person is capable of transmitting HIV during this time. It is recommended that antibody tests be repeated 3 months after exposure if the initial test failed to detect antibodies. Combination tests detect both the antigen and HIV antibodies. NATs detect the virus itself in the blood rather than the presence of antibodies. It is expensive and is not typically used for standard screening purposes.

HIV infection can be categorized along a continuum ranging from asymptomatic persons with high $CD4^+$ counts to persons with clinical AIDS (representing the most advanced and serious stage of HIV infection). In 1993, the CDC revised the categories that determine HIV or AIDS status.[17] They include the following:

- Category 1 (C1): counts of 500 or more $CD4^+$ cells per microliter of blood
- Category 2 (C2): counts from 200 to 499 $CD4^+$ cells
- Category 3 (C3): counts below 200 $CD4^+$ cells

The second set of categories relates to the expression of HIV from a clinical perspective:

- Category A: individuals who have been asymptomatic except for persistent, generalized lymphadenopathy seroconversion syndrome. This includes the initial acute onset of HIV exposure.
- Category B: individuals who have never had an AIDS-defining illness but have had some symptoms of HIV infection, such as candidiasis, fever, persistent diarrhea, oral hairy leukoplakia, herpes zoster, idiopathic thrombocytopenic purpura, peripheral neuropathy, cervical dysplasia, or pelvic inflammatory disease.
- Category C: individuals who have or have had one or more of the AIDS-defining illnesses.

An individual is determined to have HIV infection if one category from each set applies. For example, AIDS would be diagnosed if the person is designated category 3 (<200 $CD4^+$ cells) and has had at least one AIDS-defining illness. Categories 1 and 2 and A and B are considered HIV positive (a less grave condition), whereas categories 3 and C are defined as AIDS. These categories are used primarily to pinpoint an individual's placement along the continuum of HIV infection.[37]

Occupational therapists and OT assistants have the opportunity to positively affect the daily lives of people with HIV and AIDS in all of these stages of illness. Promoting health, quality of life, and well-being is one focus of OT intervention.[2]

Threaded Case Study

Billy, Part 2

Billy appears to have more mental health issues surrounding his illness than physical concerns at this time. He does experience fatigue and slight memory problems. The occupational therapist may ask the following questions:

1. Is the fatigue experienced related to the medical condition or the mental health issues that Billy is experiencing?
   In this case, the fatigue that Billy reports could certainly be related to both physical and mental health issues. He could be experiencing **AIDS-dementia complex** (ADC), which is manifested, in the context of occupational performance, as altered cognitive processing and impaired memory. ADC appears to be related to the destruction of subcortical structures in the central nervous system (CNS) and is estimated to be present in more than half of individuals in whom AIDS is diagnosed. A peripheral neuropathy may also be developing, among other conditions. Having an awareness of these disease processes could lead to increased anxiety, fear, and possibly

depression, especially with regard to the impact on his worker role. Billy should be encouraged to discuss these fears in the context of his daily living occupational performance.
Billy's ability to use effective habits and routines in the workplace might reduce his anxiety about his diminished memory. Devices such as electronic organizers and calendars may be helpful to Billy as memory aids. A conversation about these issues would involve Billy's knowledge of his life situation, thus making the OT sessions very client centered.

2. If Billy is preoccupied with his change in health status, how does he function in his work, home, community, and other contexts?
   Using specifically guided questions, the therapist might examine the contexts in which Billy engages to elicit information that might have been unknown to him before OT interventions. He would benefit from an evaluation such as the Pizzi Holistic Wellness Assessment (discussed later).

3. Are there mental and physical health issues that can be incorporated into a prevention and health promotion OT program?
   Billy could engage in a reality-checking exercise in which he explores the positive aspects and strengths in his life (eg, good social support, advanced knowledge in the area of healthcare). These strengths can help him maintain a positive sense of self and engage in more health-promoting behavior on a physical level, such as a regular exercise program.

Pharmacology

After well over a quarter century of the HIV epidemic, there is still no cure. Over the years, researchers have made extraordinary progress in the development of medications to alter the course of the disease. The medications used to treat HIV infection have helped promote healthier functioning in people with HIV and AIDS, which facilitates continued occupational participation.[40]

Several classes of antiretroviral drugs are used to treat HIV infection.[7] They can be grouped into different classes of medication based on the mechanism by which the drug limits viral replication. These medications act on specific enzymes required for viral replication. By restricting viral replication, these medications can increase the $CD4^+$ cell count and thus improve immune function and, as a result, limit the individual's susceptibility to opportunistic infections. The general categories or classes of drugs are listed in Box 47.1.

Box 47.1

Antiretroviral Drugs Used to Treat HIV Infection

Reverse transcriptase inhibitors: These drugs influence the ability of the enzyme reverse transcriptase to convert HIV RNA into DNA.

Protease inhibitors: These drugs influence the ability of protease to activate proteins in the newly developed viruses and result in immature viruses that are incapable of infecting additional cells.

Fusion inhibitors: These drugs limit the ability of HIV to enter cells by methods that include blocking the specific receptor sites.

Integrase inhibitors: These drugs act on the integrase enzyme to prevent HIV DNA from being integrated into cellular DNA.

Entry inhibitors: These drugs (also known as fusion inhibitors) interfere with the binding of HIV to host cell receptors.

Data from McCutchan JA: Human immunodeficiency virus (HIV). In Merck manual online, 2009. http://www.merck.com/mmpe/sec14/ch192/ch192a.html.

HIV has considerable variation as a result of the replication process described previously. HIV quickly develops resistance to any of the antiretroviral medications used individually because of these mutations occurring during replication. Antiretroviral treatment is most effective when the medications are used in combination. Current protocols use multiple antiretroviral medications simultaneously to limit the ability of the virus to develop resistance to a single medication. The combination of medications has the benefit of reducing HIV blood levels more than is possible with a single medication, the combination helps prevent drug resistance, and some of the medications used in combination have a synergistic effect (increasing levels of other HIV drugs in blood). The most common combinations of medications include three reverse transcriptase inhibitors or two reverse transcriptase inhibitors and one or two protease inhibitors.

These combined antiretroviral medications are referred to as **antiretroviral therapy** (ART). The introduction of ART has significantly changed the course of the AIDS pandemic.[53] In the United States, more people than ever before are living with HIV. The increased survival rate is most likely due to a combination of an increasing percentage of persons knowing their HIV infection status and persons receiving access to ART. It is particularly important for people to be tested and be aware of their HIV status. This is significant because it increases the likelihood that these persons will receive ART at an appropriate time, but it is also significant that persons who are aware of being HIV positive are less likely to transmit the virus (further reducing the incidence of infection).

The use of ART has significantly extended the life expectancy of persons infected with HIV. Many persons treated with ART live decades after the initial infection.[53] As a result of the effectiveness of this treatment, the overall prevalence rate of HIV infection in the United States has increased despite incidence rates of the infection remaining relatively stable (see the section "Origins and

Current Status of HIV Infection"). Overall hospital use has declined since the introduction of ART, as well as morbidity and mortality in persons infected with HIV.[6] Medical management of persons infected with HIV now includes multiple medical conditions associated with aging or chronic conditions.

The improved survival rates resulting from access to ART have become a significant factor in the management of HIV infection. However, it should be noted that ART is not a panacea. Despite prevention and treatment successes (including ART), people still die of AIDS. The overall survival rate trends are encouraging, but there remain too many persons in whom HIV is not diagnosed until late in the course of the infection process, and this represents a missed opportunity for prevention and treatment.[21] ART also has potential complications resulting from medication side effects and other issues.

Adherence to ART is correlated with viral suppression, improved immune function, increased survival from HIV, and improved quality of life.[25] However, maintaining medication compliance is challenging for reasons other than side effects. Persons who begin ART are often young and frequently display minimal symptoms from HIV at the initiation of ART. Because HIV infection is a lifelong condition, it may be a challenge for persons to continue adhering to the medication regimen as prescribed. Reasons for poor adherence are many and complex, but there are several predictors of poor medication adherence. Low levels of literacy, psychosocial issues (including depression, limited social support, stress, and dementia), active substance use, cognitive impairment, complex regimens, age-related changes, medication fatigue, and medication scheduling issues are all predictors of poor medication adherence independent of side effects of the medications.[25]

Effective use of medications for the treatment of HIV requires consistency in maintaining the schedule of administration of the medications.[25] Failure to maintain consistency with the medications may result in HIV developing resistance to medications and allowing viral replication. ART reduces the viral load and allows the immune system to continue to function and prevent the presence of opportunistic infections. The effectiveness of the ART regimen can be measured by detecting the level of viral load present and by monitoring helper T-cell counts. In many instances, persons taking ART have a nearly undetectable level of virus. However, once a person is infected with HIV, that person is always able to transmit the virus.

Unfortunately, these life-enhancing medical regimens are associated with myriad side effects, many of which clients receiving OT services will experience. Understanding these side effects is important because they affect occupational performance. Side effects include CNS disorders, peripheral polyneuropathy, gastrointestinal disorders, hepatotoxicity, anemia, pancreatitis, osteopenia and osteoarthritis, lipodystrophy, hyperlipidemia, diabetes, and hyperglycemia. Because of the extensive and varied pharmacologic side effects, many people with HIV have great difficulty in deciding the appropriate time to begin a drug regimen.[32] Persons taking ART may also be at risk as a result of being unable to take ART consistently. This can occur because of either side effects or poor medication management (for example, persons with HIV-related neurocognitive deficits are 2.5 times more likely to be at risk for medication noncompliance than are persons without dementia).[31]

ART has been an effective medical intervention that has significantly altered the landscape of HIV infection by creating improved health and well-being for many infected individuals. Unfortunately, access to affordable healthcare is limited or nonexistent for millions of people worldwide, but recent efforts have made these important medications more accessible.[56] Despite best practice in medicine, a cure for AIDS remains elusive. However, thanks to medical advances, people continue to live full and productive lives while coping with the daily issues of living with HIV.

Aging and HIV Infection

A few issues related to aging in persons infected with HIV are important and require the attention of the OT practitioner. As ART prolongs the life of persons with HIV, the presence of HIV with other age-related conditions is becoming more common. Research has indicated that both hospitalizations and deaths from HIV-related causes have declined. The reduction in opportunistic infections and clinical AIDS has resulted in alternative causes of mortality in aging persons infected with HIV. Elderly persons with HIV are more likely to have additional medical comorbid conditions.[58]

Several considerations influence the health outcomes of elderly persons with HIV.[29] The elderly (classified by the CDC as persons older than 50 years) are a growing demographic in the United States for HIV infection. The number of persons older than 50 years infected with HIV has increased because of at least two factors. The first is sometimes referred to as an *aging cohort effect,* which describes a group of persons infected with HIV earlier in life and who age as a result of ART prolonging life expectancy. The other factor involves new infections diagnosed in persons older than 50 years. The incidence and prevalence of HIV infection have both increased in persons older than 50.

Some research suggests that persons in whom HIV infection is diagnosed after 50 years of age have worse outcomes than their younger cohorts do. One important factor appears to be that HIV infection diagnosed in persons older than 50 is at a more advanced stage than in their younger counterparts.

Possible explanations for the more advanced progression at the time of diagnosis in older persons with HIV includes less common routine screening for HIV in this population, poorer awareness of the risks for HIV infection and safer sex practices in this age group, and physicians perhaps being less likely to consider HIV clinically. The symptoms or signs of HIV infection may also be more likely to be attributed to comorbid medical conditions or to other conditions more commonly associated with aging populations.

Neurologic Sequelae of HIV/AIDS

Various medical complications are associated with HIV/AIDS, and multiple body functions and body structures can be affected by HIV/AIDS. Neurologic disorders related to HIV infection are common and may be potentially debilitating in the performance of activities of daily living (ADLs) and instrumental activities of daily living (IADLs).[35] Estimates of the frequency of neurologic disorders vary, but it appears that as many as 66% of persons with HIV may have peripheral neuropathy.[34] It is likely that at least 20% of persons with HIV infection have some type of neurocognitive impairment,[49] and some evidence suggests that more than 50% of persons on ART may have cognitive deficits.[30,52] The estimated prevalence of neurocognitive impairment varies considerably, in part because of the clinical standard used to determine the presence of cognitive impairment. If mild cognitive impairment is used as the criterion, the prevalence of neurocognitive impairment is significantly higher.[48] Despite the effectiveness of ART in improving overall immune function, neurologic deficits have persisted, although advanced stages of dementia are less common than before the use of ART.[53]

Neurologic disorders are of particular concern to occupational therapists working with persons with HIV/AIDS. HIV is capable of passing the blood-brain barrier and entering the CNS.[36] HIV has been detected in CNS structures, as well as in cerebrospinal fluid, in persons infected with HIV, including those who are asymptomatic and with functioning immune systems. The neurologic sequelae of HIV/AIDS can be an indirect result of the virus via opportunistic infections (resulting from compromised immune function) or a direct or primary effect of HIV. The presence of neurologic opportunistic infections has been greatly reduced in the United States since the advent of antiretroviral therapies.[49] However, primary effects of HIV on the CNS remain common and should be considered when addressing the needs of this population. Various neurologic conditions or clinical manifestations are associated with HIV/AIDS. However, this section focuses on neuropathies (the most common neurologic complication of HIV/AIDS) and AIDS-related dementia (which can have a profound impact on occupational performance) (Box 47.2). Not all persons display clinically significant neurologic deficits. However, neurologic deficits will develop in a significant number of persons as a result of this process.

Box 47.2

Neurologic Complications of HIV-1 Infection

HIV-1 Associated

HIV-1 encephalopathy

HIV-associated cognitive-motor disorder

HIV-1 meningitis

Vacuolar myelopathy

Peripheral neuropathy

Distal sensory polyneuropathy

Antiretroviral toxic neuropathy

Ascending neuromuscular syndrome

Mononeuritis multiplex

Inflammatory demyelinating polyneuropathy

HIV-associated polymyositis

Opportunistic Infections

Cerebral toxoplasmosis

Tuberculosis

Cryptococcal meningitis

Cytomegalovirus retinitis/encephalitis/polyradiculitis

Progressive multifocal leukoencephalopathy

Other viral/fungal/bacterial/protozoal central nervous system infections

Neoplasms

Primary central nervous system lymphoma

Metastatic systemic lymphoma

Metastatic Kaposi's sarcoma

Some changes in the course of neurologic deficits do appear to be a result of ART. Before ART, the more advanced stages of AIDS dementia were commonly found in the advanced stages of clinical AIDS. As ART has improved immune functioning and decreased the number of persons with advanced clinical AIDS, the number of advanced dementia cases appears to have decreased as well. Although HIV dementia is common in advanced AIDS,[47,51] it is also found early in HIV infection and without AIDS or in the presence of opportunistic infections. The prevalence rate is significantly higher when including persons displaying signs of neurologic involvement detected by neuroimaging but without clinical changes or when including persons with mild cognitive impairment.

Despite the effectiveness of ART in improving overall immune function, neurologic deficits have persisted,[53] and prevalence rates for dementia, when including mild cognitive impairment, have increased since the advent of ART, although advanced dementia is less common.[3,4,24,26] Some evidence also suggests that the cognitive deficits may be related to a combination of the aging process, extended period of HIV infection, medication side effects, and the comorbid neurologic conditions that are more common in aging persons.[5]

Neuropathies

Peripheral neuropathies are the most common neurologic complication of HIV. They can occur both as a primary effect of the virus and as a side effect of antiviral medications used to treat HIV.[36] It is often difficult to distinguish clinically between the two causes of neuropathy. Although many peripheral nerve disorders are associated with HIV, distal sensory polyneuropathy is by far the most common disorder. Persons with distal symmetric polyneuropathy frequently have burning, painful sensations on the distal end of the lower extremities, often accompanied by numbness or tingling sensations. Individuals may also have decreased sensation of thermal stimuli. If lower extremity weakness is present, it is more likely to be distal than proximal. Distal sensory polyneuropathy follows a stocking-glove distribution of sensory impairment involving the feet and hands (typically with greater lower extremity involvement initially), and impairment spreads proximally as the condition progresses.

The functional deficits associated with peripheral neuropathy may include numbness or impaired sensation, loss of balance because of diminished proprioception in the lower extremities, and abnormal pain sensations (dysesthesias). Distal sensory polyneuropathy results in damage to both large myelinated and unmyelinated nerve fibers and is clinically similar to diabetic neuropathy (in that small sensory fibers are also involved).

Occupational therapists should assess clients for pain. Chronic pain is a common condition associated with HIV infection in general and with distal symmetric polyneuropathy in particular. The pain may limit occupation performance and is frequently underdiagnosed and undertreated. Current evidence suggests that the pain sensations are probably caused by dysfunctional regulation of pain fibers in both the central and peripheral nervous systems and that it results in severe pain out of proportion to the extent of epidermal nerve fiber loss.

In HIV-associated distal sensory polyneuropathy, it is hypothesized that the abnormal pain may be caused by damage to peripheral nerve fibers as a result of multifocal inflammation and infiltration of activated macrophage into peripheral nerves, with subsequent abnormal activity occurring in uninjured neighboring nociceptive fibers. The abnormal inflammatory response and macrophage infiltration are also found in the dorsal root ganglion. It is possible that this results in changes in neuronal calcium and sodium channels and ectopic impulse generation causing abnormal neuronal hyperexcitability. Finally, it is possible that remodeling occurs in the dorsal horns as a result of A-fiber sprouting and synaptic formation within lamina II of the spinal cord.

Dementia

AIDS dementia complex (ADC) is also referred to as AIDS-related dementia, HIV-associated dementia, AIDS encephalopathy, or HIV encephalitis and is a common neurologic condition associated with HIV infection.[46] Dementia associated with HIV infection has been identified since the earliest years of the HIV/AIDS pandemic and has been characterized by the cardinal features of progressive dementia with motor and behavioral deficits.[41] ADC appears to be a result of the presence of HIV in the CNS and is a primary effect of the virus. HIV can enter the CNS shortly after the initial infection. The most likely mechanism for entry appears to be infected monocytes passing through the blood-brain barrier.[52] The precise mechanism by which infected cells within the CNS are activated and cause dementia is not known at this time. It is possible that the brain may act as a sanctuary for HIV replication inasmuch as the blood-brain barrier may prevent ART from passing through the barrier to the CNS and create a viral reservoir.[43] The cells that are most frequently infected are macrophages, microglial cells, and astrocytes (although many other cells may also be infected within the CNS). It appears that neurons are rarely if ever infected by HIV.

ADC remains a complication in persons infected with HIV despite the introduction of ART.[50] ADC is characterized by subcortical involvement and is considered a subcortical dementia. There is evidence of damage to the basal ganglia and caudate nuclei,[28,42] and the clinical manifestations of ADC have some similarities to other subcortical dementias, including Parkinson's disease and Huntington's disease. Persons with ADC frequently display motor disturbances, such as imbalance, unsteady gait, tremors, difficulty performing fine motor tasks (including handwriting), weakness, and motor-processing delays and reduced speed of motor responses (primarily in the more advanced stages of ADC) (Box 47.3).

Box 47.3

Clinical Manifestations of AIDS-Dementia Complex

Affective: Apathy (Depression-Like Feature)

Irritability

Mania, new-onset psychosis

Behavioral: Psychomotor Retardation (Slowed Speech or Response Time)

Change in personality

Social withdrawal

Cognitive: Lack of Visuospatial Memory (Misplacing Things)

Lack of visuomotor coordination (eye movement abnormalities)

Difficulty with complex sequencing

Impaired concentration and attention

Impaired verbal memory (word-finding ability)

Mental slowing

Motor: Unsteady Gait, Loss of Balance

Dropping things

Tremors, poor handwriting

Decline in fine motor skills

ADC may cause impairment of visuospatial function, executive function, and recall of information, as well as slowed psychomotor speed. Persons with ADC may have impaired episodic memory (the ability to remember facts, places, and subjective historical information) and deficits in retrieving information. It appears that ADC spares semantic memory (ability to recall facts and information unrelated to personal experience) and the ability to retain information until the relatively advanced late stages of ADC. Unlike Alzheimer-type dementia, persons in the earlier stages of ADC may not have significant deficits in naming objects or other language functions associated with the cerebral cortex but will probably have deficits in retrieving and manipulating retained information, as well as slowing of information processing.[38]

Persons with ADC may also exhibit behavioral changes, potentially including increased agitation, apathy, isolation, or changes in personality. Cognitive deficits are also present in the earliest stages of ADC. The cognitive deficits are most likely to involve executive function (including delays in information processing, limited attention to tasks, and visuospatial deficits). In the early stages of ADC, the manifestation of these deficits in executive functioning is different from dementia of the Alzheimer type, in which the person typically has more pronounced memory deficits, word retrieval deficits, decreased comprehension or other language difficulties, and disorientation. However, as the dementia reaches more advanced stages and the deficits become more global, it may be difficult to differentiate ADC from dementia of the Alzheimer type.

ADC appears to influence dopamine production, and a subtype of persons with ADC may exhibit mood disorders, including mania, probably as a result of the dopaminergic changes caused by ADC.[38] The likelihood of dopamine involvement is also supported by the movement disorders described previously.

The incidence and prevalence of HIV dementia or ADC have changed in the ART era. It appears that the incidence of ADC has decreased with the use of ART, but prevalence rates are increasing. One hypothesis is that new multiple patterns or progressions of ADC have arisen following the introduction of ART.[36] The first type is a subacute progressive form of dementia that is seen in untreated persons and marked by severe progressive dementia similar to the pattern seen before ART. The second pattern involves a chronic active dementia seen in persons prescribed ART who have poor compliance or exhibit viral resistance. These persons are at risk for progression of the dementia. The final category is chronic inactive dementia, in which persons receiving ART with good adherence and viral suppression remain neurologically stable but have some degree of cognitive impairment or early-stage ADC.

Advanced ADC was most common in the late stages of AIDS before the use of ART. The use of ART appears to have decreased the frequency of advanced stages of dementia in persons infected with HIV. However, the incidence of cognitive impairment and ADC has not abated despite the use of ART. It appears that mild cognitive impairment and early-stage ADC are more common than later stages of ADC as a result of ART, but the overall incidence of cognitive deficits has remained at higher than 20% for persons infected with HIV.

It is important to be aware of the clinical manifestations of ADC during different stages of the dementia.[41]

Early Stages of AIDS-Dementia Complex

During the early phases of the disorder, it is possible for the deficits to be overlooked or be attributed to other causes. The early stages are consistent with subcortical dementia and are characterized by difficulty concentrating and attending to tasks and delayed processing of information, which may require extended time for completion of ADLs; minor forgetfulness and difficulty with executive functioning tasks are not unusual. Motor deficits also occur frequently and include tremors, gait imbalances, lower extremity weakness, and slowing of motor function. Persons may also display behavioral changes, including increased withdrawal from ADLs or social situations, agitation or irritability, and other changes in personality.

The early stages of ADC can potentially have an impact on a number of ADLs and IADLs. Persons may have particular challenges with IADLs involving executive functioning and may have difficulty managing finances, medications, or scheduling and keeping appointments. In particular, tasks involving multiple steps and sequencing may be problematic and lead to difficulties with related IADLs. Persons with HIV-related neurocognitive deficits are much more likely to be at risk for medication noncompliance than are persons without dementia.[31] Persons may also have difficulty with tasks requiring sustained attention (for example, the person may have difficulty reading or listening to lengthy conversations). The motor deficits related to ADC may be minimal in the early stages but may be observed by noting difficulty with ADLs involving fine motor coordination, including handwriting, managing clothing fasteners, using utensils during meals, and performing grooming activities (such as shaving or applying makeup). The person may also have difficulty maintaining balance while walking, tremors, and weakness.

Later Stages of AIDS-Dementia Complex

As ADC progresses, the deficits become more generalized or global and may be difficult to distinguish from other types of advanced dementia. It is worth noting that given the use of ART, many persons with ADC or minor cognitive impairment have maintained relatively stable cognitive functioning without significant progression of symptoms over an extended period. In these cases, although deficits are present, the person may not progress to later stages of ADC. Late-stage ADC remains most common in people with significant progression of HIV or AIDS. By the late stages, ADC is characterized by global deterioration involving cognition, motor skills, behavioral deficits, and limited insight into the client's condition and deficits. As ADC progresses, the person will probably exhibit significant cognitive deficits, disorientation, general confusion, and impaired speech and language ability. Motor symptoms also progress at this point, with continued weakness, changes in muscle tone (spasticity in particular), ataxia, and dyskinesia. Some behavioral changes are also common as ADC progresses, including disinhibition of behavior and incontinence of the bowel or bladder. At this point in the disorder, persons with HIV will probably require assistance in performing all IADLs and most ADLs. Refer to Table 47.5 for a summary of the stages of ADC.

TABLE 47.5

Staging of AIDS-Dementia Complex

Stage/Grading	Manifestation
0	Normal
0.5	Subclinical or equivocal—Minimal or equivocal symptoms Mild (soft) neurologic signs No impairment in work or activities of daily living
1	Mild—Unequivocal intellectual or motor impairment Able to do all but the most demanding work
2	Moderate—Cannot work or perform demanding activities of daily living Capable of self-care Ambulatory, but may need a single prop Major intellectual disability or cannot walk unassisted
3	Severe—Major intellectual disability or cannot walk unassisted
4	End-stage—Nearly vegetative Rudimentary cognition Paraplegic or quadriplegic

HIV/AIDS Pathologies: Client Factors

People with HIV are living longer and healthier lives as a result of improvements in medications, health education, and behavioral changes. However, medications are costly and often provided only to those who can afford them or have other access to them. Thus people with HIV who are not privy to information on community resources or whose accessibility is otherwise limited experience numerous opportunistic infections (infections resulting from a compromised immune system), such as *Pneumocystis pneumoniae* infection or Kaposi's sarcoma (the latter being less common).

OT practitioners may see a diverse population of people with AIDS who have numerous occupational deficits. Many physical and psychosocial factors indicate the need for OT. Factors experienced by people with HIV and AIDS include, but are not limited to, the following:

- Fatigue and shortness of breath
- Impairment of the CNS
- Impairment of the peripheral nervous system
- Visual deficits
- Sensory deficits (including painful neuropathies)
- Cardiac problems
- Muscle atrophy
- Altered ability to cope with and adapt to changes that the illness creates
- Depression
- Anxiety
- Guilt
- Anger
- Preoccupation with illness versus wellness

All of these factors affect clients' occupational performance in meaningful, health-promoting daily occupations. OT can benefit all people with HIV and AIDS who experience any of the aforementioned problems.

Positive Prevention

Reflecting the changing needs of people with HIV and in consideration of the improved drugs to combat the disease and its secondary conditions, the term *positive prevention* has been developed and used by the CDC.[15] The Serostatus Approach to Fighting the Epidemic (SAFE) helps reduce the risk for transmission to supplement current risk reduction programs. Several action steps are recommended that focus on diagnosing HIV: linking infected persons to appropriate preventive services, helping them adhere to treatment regimens, and providing support to develop healthy habits for sustaining behavior that reduces the risk associated with HIV infection. It is one of the first programs to dovetail traditional infectious disease control with behavioral interventions. Although occupational therapists may primarily intervene with people who have already been infected, prevention can still be integrated into a holistic program of care.

Prevention and health promotion can be a primary area of intervention in OT. In primary prevention, the practitioner may develop and implement health education and risk reduction strategies to help individuals and communities understand the impact of reducing risk in occupational participation. An OT primary prevention strategy could be the establishment of a developmentally appropriate lecture or workshop on abstinence and safe sex for schools, religious groups, and community centers. These workshops could incorporate mental health strategies, culturally relevant information, and interpersonal skill-building exercises, areas in which OT practitioners are well educated.

Secondary prevention, wherein OT services are provided for people who are already infected with the virus, would include activities that create and promote healthy lifestyles and thereby prevent future opportunistic infections and promote balance and well-being. OT intervention focused on providing secondary prevention can significantly affect communities that have large numbers of people who are infected with HIV. An emphasis on establishing and maintaining the habits and routines that support engagement in occupations would be appropriate for secondary prevention programs.

Tertiary prevention is provided when clients suffer from a disability that is secondary to the disease. Tertiary prevention includes a strong emphasis on rehabilitation; health promotion programming can also be included to positively affect a person's lifestyle and provide hope for continued and healthful functioning. Strategies that support continued participation in occupations, even if the occupation has been modified, would be addressed in tertiary prevention programs. An example would be the use of adaptive equipment to support continued engagement in a desired occupation (eg, woodworking, cooking) when muscular weakness or peripheral nerve damage compromises occupational performance.

Assessment

Pizzi has developed two assessments that focus on enhancing health and well-being (see Chapter 5): one is for general use, and the other is for use in people infected with HIV.[45] The one related to HIV specifically is the Pizzi Assessment of Productive Living for Adults with HIV Infection and AIDS (PAPL; Fig. 47.2).

Pizzi Assessment of Productive Living for Adults with HIV Infection and AIDS (PAPL)

Demographics

Name____Age__________

Sex______Lives with (relationship)____

Identified caregiver____

Race _____________Culture___________Religion_____________________________

Practicing?____________________How does spirituality play a role in your life, if any?____

Primary occupational roles:

____

Primary diagnosis:

____

Secondary diagnosis:

____

Stage of HIV____

Past Medical History:

____

Medications:

____

Activities of Daily Living (use ADL performance assessment)

Are you doing these now?

____

Do you perform homemaking tasks?

____

(For areas of difficulty) Would you like to be able to do these again like you did before?_________ Which ones? ____

Work

Job ______________________________________When last worked___________

Describe type of activity____

Work environment ____

If not working, would you like to be able to?______________________________

Do you miss being productive?____

Types of activity engaged in____

If not, would you like to?________Which ones?______________________________

Would you like to try other things as well?______________________________

Is it important to be independent in daily living activities?_____________________

Play/Leisure (interests and current participation)__________________________

Location:

____

Does it interfere with doing important activities?___________________________

Sexual function:

Cognition

(Attention span, problem solving, memory, orientation, judgment, reasoning, decision making, safety awareness)

Time Organization

Former daily routine (before diagnosis)

Has this changed since diagnosis?____

If so, how? ____

Are there certain times of day that are better for you to carry out daily tasks?

____

Do you consider yourself regimented in organizing time and activity or pretty flexible? ____

What would you change, if anything, in how your day is set up?

____

Body image and self-image

In the last 6 months, has there been a recent change in your physical body and how it looks?___________How do you feel about this?______________________________

____

Social environment (Describe support available and utilized by patient)

Physical environment (Describe environments where patient performs daily tasks and level of support or impediment for function)

Stressors

What are some things, people, or situations that are/were stressful?_______________

____

What are some current ways you manage stress?______________________________

____

Situational Coping

How do you feel you are dealing with:

a) your diagnosis

____

____

b) changes in the ability to do things important to you?

____

____

c) other psychosocial observations

____

____

Occupational Questions

What do you feel to be important to you right now?

Do you feel you can do things important to you now? In the future?

Do you deal well with change?

What are your hopes, dreams, aspirations? What are some of your goals?

Have these changed since you were diagnosed? How?

Do you feel in control of your life at this time?

What do you wish to accomplish with the rest of your life?

FIG 47.2 Pizzi Assessment of Productive Living for Adults with HIV and AIDS (PAPL). LTG, long-term goals; STG, short-term goals. (Courtesy Michael Pizzi © 1991.)

One of the first assessments in OT specifically designed as a client-centered and subjective health promotion tool is the Pizzi Health and Wellness Assessment (PHWA).[45] An occupational history format is used. The emphasis of the PHWA is to explore an individual's self-perception of health and strategies for self-responsibility. It is vital that practitioners incorporate the goals, beliefs, values, attitudes, and occupational meanings identified by the client being served. Reductionistic interventions (eg, range of motion, strengthening, cognitive retraining) are incorporated into meaningful occupations and not addressed separately.

The PHWA is a self-assessment tool that incorporates both a qualitative and a quantitative component. Clients self-assess six areas of health on a scale of 1 through 10. They then address each area with the help of the practitioner in terms of their self-perception of occupational participation in the respective area. This dialogue helps clients become aware of important health issues affecting their daily occupational performance. In each area of health, the client explores strategies to optimize health and determines which strategies could be used to promote health and well-being.

Even when it appears that a specific intervention positively changes occupational performance, the person experiences wellness through self-discovery of how to best manage his or her well-being. After self-discovery, the therapy process unfolds collaboratively between the client and therapist.[45]

Immediate and meaningful occupational areas and self-identified health concerns are identified through this assessment. A holistic view of the client is inherent in the assessment and is guided by the principles of health promotion and the values of OT.

PAPL (see Fig. 47.2) is a holistic assessment for therapists to gather data on the physical, psychosocial, emotional, and spiritual aspects of the client's life. The resultant data are synthesized via the practitioner's clinical reasoning skills to produce a collaborative intervention that is client centered. All areas of occupational performance are addressed.

Holistic assessments are useful for practitioners because they address the multitude of issues and problem areas experienced by people with HIV and AIDS. The clinical reasoning of practitioners will then be challenged to integrate knowledge and skill in all areas of OT to best serve the client's needs.

In as many as 10% of persons infected with HIV and experiencing chronic pain, no specific cause is known.

Intervention

The OT intervention process involves both the therapeutic use of self by the practitioner and the therapeutic use of occupations and activities. OT practitioners engage and facilitate engagement in meaningful and productive daily life occupations through a variety of techniques, strategies, and inventive programming. Promotion of healthy lifestyles while living with the disease is crucial for all clients infected with HIV. Interventions are individually tailored to meet the many physical, psychosocial, and contextual issues of people with HIV and AIDS. Because of the diverse features of HIV and AIDS, there are many considerations for practitioners when developing plans and goals. These considerations, listed in the following sections, also incorporate several occupational interventions that can be implemented.[44]

Prevention of Disability

Occupational therapists can play a significant role in primary prevention by participating in occupation-based education for various community groups to reduce the risk for infection and by promoting health. Occupational therapists can address secondary prevention through various health promotion strategies to enhance occupational engagement and performance with an emphasis on maintaining performance patterns, including significant habits, routines, rituals, and roles. OT intervention addressing tertiary prevention can focus on health promotion and rehabilitation to enhance occupational performance.

Education and Health Promotion

Occupational therapists can provide educational opportunities for clients to address multiple concerns, including energy conservation strategies to address fatigue, generalized weakness, and deconditioning, which are primary physical manifestations of HIV. Energy conservation, work simplification, and occupational adaptations are used to enhance productivity and participation. Education can address proper nutrition, which is vital for people with HIV and AIDS. In addition, occupational therapists can provide educational interventions to promote awareness of clients' medical status and medication management, as well as to improve awareness of side effects of the medications.

Maintaining and Restoring Performance

Occupational therapists work with clients with HIV/AIDS to maintain or restore occupational performance in the presence of changes in client factors related to HIV/AIDS. Considerations for OT interventions include the following:

1. Control and choices of daily living options must be provided as much as possible. Frequently people infected with HIV feel a sense of loss of control as the virus slowly invades body systems and manifests itself by further limitations in occupational performance. Providing choices can prove beneficial to clients when the virus compromises control in life.

2. Most clients with symptomatic HIV and AIDS have an altered worker role. Specific interventions regarding alternatives to work and productive living are necessary if work is a valued role. Physical as well as psychosocial work assessment for holistic work-hardening programming is vital.

3. Habit training and adaptation of the routine of daily living are essential interventions and include performance of favored occupations with respect to physical and cognitive status; the level at which the person feels comfortable adapting routines; and times of day, contexts, and with whom the person chooses to perform the occupations. Whenever possible, clients must be given choices of scheduling within their own personal routines and not those that fit health professionals' schedules.

4. Short- and long-term goals must be readily adapted and changed as needed.

Complementary therapies must be considered as interventions before and during occupational performance. Such therapies can include progressive relaxation, biofeedback, prayer, therapeutic touch, traditional Chinese medicine techniques, myofascial release, craniosacral therapy, imagery, and visualization.

Modifications, Adaptations, and Compensatory Approaches to Intervention

Occupational therapists can provide intervention that includes a variety of modifications, adaptations, and compensatory techniques to promote occupational performance skills and patterns. Such approaches include the following:

1. Adaptive equipment and positioning can be used to assist clients in returning to independent performance of ADLs, work, and leisure occupations. Often people with HIV may reject such equipment even though it can benefit them. This rejection signals a rejection of the sick role and sometimes a denial of diminished abilities. This attitude must be respected until the time when the person chooses, if at all, to use the equipment.

2. Changes can be made in the physical environment or performance patterns to help the client continue important roles despite medical changes, including fatigue. Energy conservation approaches and work simplification can be useful to allow continued participation in ADLs.

3. A variety of strategies can be used to compensate for cognitive changes that may have an impact on occupational performance, including activities that involve executive function (medication management, work responsibilities, financial management) and motor performance. Occupational therapists can adapt tasks to compensate for neurologic deficits, including sensory loss related to peripheral neuropathies. Therapists can also be involved in modifications to optimize function in persons with ADC and related cognitive deficits.

Advocacy and Psychosocial Considerations

Occupational therapists can be involved in both advocating for clients with HIV/AIDS and helping support client efforts for personal advocacy. More unique psychosocial aspects of HIV rehabilitation are present than in most other physical or psychosocial cases.

Many people with HIV have lost numerous friends to the same disease for which they are receiving therapy; have undergone loss of work and family as a result of discrimination, rejection, or physical inabilities; and may have lost life partners to the same disease. For many clients, all of these losses can occur before the age of 40. Women with HIV experience the aforementioned losses but must also frequently cope with poverty and homelessness; women are often underrecognized in the epidemic.

There is no known cure or vaccine for HIV to date, although research is promising. This is a major consideration as a stressor of daily living.

The aforementioned considerations are several areas of intervention that can help maintain and restore occupational performance and prevent secondary conditions and impairments from emerging.

Threaded Case Study

Billy, Part 3

Billy required assessment to determine how the changes in client factors and body functions have altered various areas of occupation and life roles. After developing the occupational profile, several types of OT interventions are needed to strengthen the mind, body, and spirit. Promotion of the therapeutic use of self, with a nonjudgmental and caring, compassionate attitude, will help Billy relax during OT sessions and engage him in discovering the best ways to establish balance and well-being in his life. As a result of his apparent depression and fatigue, he may be experiencing altered occupational role performance. Fatigue and depression can also impair cognition. Understanding exactly how these roles are compromised and the underlying impairments in body function will help the therapy process unfold, with specific interventions being implemented as appropriate. Billy, as determined through the occupational profile, is a habit-oriented man. Helping him explore his daily habits and routines, understanding the areas in which he senses an impairment (along with OT evaluation data), and encouraging him to adapt to change can help him to restore both his emotional health and his physical well-being.

Using an occupation- and client-centered approach and understanding the disease process afford the occupational therapist unique insight into the best ways to assess and treat people with HIV and AIDS. Promoting health and well-being will also establish a higher quality of life. The focus of OT is always to enable participation in meaningful life occupations that support life satisfaction and quality of life.

Summary

Many changes have taken place since the earliest days of the HIV/AIDS epidemic. These changes include the demographics of persons infected by the virus, the areas globally in which infections are concentrated, populations infected in the United States, treatments available, survival rates, and medical management of the condition. Fortunately, the development of antiretroviral treatments has extended the life expectancy of many persons with HIV in the United States (and increasingly on a global basis). These encouraging developments also present a number of challenges in managing the chronic health and medical needs of persons infected with HIV.

OT has many roles in addressing the needs of persons with HIV/AIDS. It can help address the range of client factors and performance skills that are affected by HIV/AIDS. Prevention is critical in the management of HIV, and OT can help emphasize prevention and reduce the incidence of HIV infections. OT can also address the needs of persons infected with HIV.

OT assessment should focus on developing an occupational profile that includes the individual's previous occupational performance patterns, roles, habits, and routines to better understand how HIV influences function. Specific assessments can identify which client factors are most affected by HIV and provide guidance for OT interventions. Of particular importance in assessing client factors are the common neurologic deficits that can greatly influence functional performance and are often present even in the absence of opportunistic infections or AIDS.

Occupational therapists can promote function and independence in ADLs and IADLs by a variety of means and interventions. These approaches include prevention of disability, education/health promotion, maintaining/restoring performance, modifying/adapting environments, compensatory strategies, advocacy, and addressing psychosocial factors. Through the use of these interventions, OT can help persons with HIV maintain active participation in individual meaningful daily activities and be active in the community.

Review Questions

1. What is the difference between HIV infection and AIDS?
2. What are the routes of HIV transmission?
3. Name three side effects of the drug regimen that affect the quality of life of persons who have HIV or AIDS.
4. Differentiate primary, secondary, and tertiary prevention programs.
5. Identify one potential neurologic, physical, and psychosocial problem seen in clients who have HIV or AIDS.
6. Why might a client be hesitant to accept the use of adaptive equipment to engage in occupation?
7. What are at least three health promotion and prevention goals for a client with HIV? For a client with AIDS?
8. How might you address caregiver concerns regarding sexuality issues when both partners are in their sexual prime?
9. If a client with AIDS came to you about the perception of prejudice from other healthcare personnel, how might you respond?
10. List and discuss at least four strategies to promote the health and well-being of Billy and his partner, Tom.

Polytrauma and Occupational Therapy*

Sharon Dekelboum, Karen Parecki

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, the student or practitioner will be able to do the following:

1. Understand the definition of polytrauma.
2. List several standard occupational therapy assessments used for polytrauma patients.
3. Understand the areas in which the occupational therapist needs basic knowledge to care for polytrauma patients.
4. Understand the term *emerging consciousness*.
5. Understand the importance of an interdisciplinary approach to polytrauma care.
6. Describe the continuum of care process available within the Veterans Affairs system of care.
7. Describe the multisystem effects of a blast injury.
8. Understand the impact of posttraumatic stress disorder on the recovery process.
9. Identify the use of assistive technology in this population.
10. Describe how return-to-work/return-to-school programs can be included in rehabilitation services.
11. Understand the importance of treating the client and family as a unit.
12. Understand the implications of sensory loss for the rehabilitation process.

KEY TERMS

Age-appropriate treatment interventions

Amputation

Assistive technology
Blast injury
Emerging consciousness
Interdisciplinary
Polytrauma
Posttraumatic stress disorder
Sensory loss
Shrapnel
Skull flap
Traumatic brain injury
Triage

Polytrauma

Threaded Case Study

Alex, Part 1

Alex, a 25-year-old Caucasian man, sustained a polytraumatic injury from the blast of an improvised explosive device (IED) while serving in Iraq. As a result of the blast, Alex incurred a traumatic head injury (diffuse axonal injury and temporal lobe contusion with subarachnoid hemorrhage), a right arm degloving injury, maxillary and mandibular fractures, and traumatic amputation of his right leg below the knee along with a femoral fracture. Additionally, his injuries included a penetrating eye injury with subsequent surgical excision of the foreign body. He also demonstrated clinical signs of posttraumatic stress disorder. Alex is married and his wife was 3 months pregnant at the time of his injury. He was living in Hawaii before his deployment to Iraq; there are two steps at the entrance of his single-level home. His role in the Marines was corpsman (medic).

Alex was referred to occupational therapy 1 month after injury when he arrived, medically stable, at the polytrauma rehabilitation ward. Initially, Alex had a Rancho 2-3 level with an altered level of consciousness and was evaluated with the Coma Recovery Scale–Revised (CRS-R).[15] Additionally, he was assessed for positioning needs, splinting needs, range of motion (ROM), and gross strength. Because of decreased arousability, restlessness, and an inability to consistently follow commands, much of the psychosocial components, including occupational history and profile, were obtained by interviewing his wife.

Within a week Alex demonstrated improved cognitive abilities as measured by the CRS-R, and functional mobility and activities of daily living (ADLs), and cognitive and visual-perceptual screening was initiated. Alex required minimal assistance for bed mobility, maximal assistance for transfers and wheelchair mobility, and moderate to maximal assistance for all ADLs. Cognitively, he was able to follow simple one-step commands 80% of the time, easily became overstimulated and distractible in anything but a quiet environment, had poor endurance, easily became frustrated, and had difficulty with orientation, problem solving, and other executive skill functions. Safety awareness was also impaired. In addition, Alex's visual-perceptual skills were impaired, and he demonstrated dysmetria and double vision. Strength and ROM in his left upper extremity were within normal limits; however, his right hand had decreased strength and ROM. Coordination was slightly impaired on the right but normal on the left. Alex also demonstrated signs of hypervigilance and reported difficulty sleeping.

The objectives of occupational therapy intervention included (1) increasing independence in performance of ADLs; (2) increasing independence in transfers and wheelchair mobility; (3) achieving and maintaining optimal ROM in all joints of the right upper extremity for function and maintaining ROM in all other joints for optimal seating and positioning; (4) improving visual-perceptual skills or implementing compensatory strategies to promote safety and ease in ADLs, mobility, and performance of instrumental activities of daily living (IADLs); (5) promoting the highest level of functional cognition, including implementation of compensatory strategies and cognitive prosthetics to increase independence and safety in all functional skills; (6) achieving optimal independence in performing IADLs, including parenting skills; (7) optimizing independent ability to access the community, including transportation; (8) optimizing independence in return-to-school and return-to-work skills; (9) receiving appropriate durable medical equipment to meet both short-term and long-term needs (including wheelchair, cushion, ADL equipment, and prosthetic limb care needs); (10) optimizing the ability to relax and promoting good sleep hygiene; and (11) educating the family and patient in all aspects of care needs, compensatory strategies, and safety recommendations.

Because of significant impairment in cognitive skills, an interdisciplinary team approach was implemented to ensure that compensatory strategies were carried over throughout the day. As Alex gained insight into his deficits and how they were currently having an impact on his life (community skills, employment, parenting, independence in self-care, and self-efficacy), he had mood fluctuations that ranged from depressed to feeling hopeful and accepting of his current situation. Additionally, supporting the family members and working with Alex and his wife as a couple on their roles in the relationship and how those roles have changed were addressed through psychology service and with a family therapist.

Throughout the chapter, consider the short-term and long-term consequences of Alex's injuries. The many body systems that were affected with this type of polytraumatic injury will have effects on client factors, performance skills and patterns, and the relationship of activity demands to the selection of optimal equipment and strategies to optimize his performance in all aspects of his life.

Critical Thinking Questions

1. How would you determine what occupations need to be addressed and in what order would you address them?
2. Thinking about client factors, how would you prioritize treatment interventions?
3. How would you integrate your treatment plan and interventions with the needs of the client, family, and whole treatment team?

The definition of **polytrauma** stems from the Latin *poly*, meaning many, and *trauma*. The term is generic and has been in use for a long time for any case involving multiple trauma. U.S. military doctors commonly use the term to describe seriously injured soldiers returning from Operation Iraqi Freedom (OIF, Iraq) and Operation Enduring Freedom (OEF, Afghanistan).[34]

The term *polytrauma* is now consistently used by U.S. military medical personnel and the Veterans Administration (VA) to describe the multiple, extreme, often totally incapacitating complex of traumatic injuries that individual U.S. service members suffer in the aftermath of war. The severity and complexity of these multiple wounds and injuries would have proved fatal in previous wars. Advances in medicine, especially in battlefield medicine, as well as quick evacuation of these patients to complex trauma centers have decreased the mortality rate. Many polytrauma injuries include multiple, severe **shrapnel** injuries leading to multiple **amputations**, wounds, loss of normal body function and systemic complications, brain damage, sensory impairment, and partial to full paralysis. These types of complex injuries are not typically seen, even in the trauma centers of major urban areas that are accustomed to gang warfare.

Polytrauma centers have been developed throughout the Department of Veterans Affairs to address the complex medical and rehabilitation needs of these patients. The VA defines polytrauma as “injuries to more than one physical region or organ system, one of which may be life threatening, and which results in physical, cognitive, psychological, or psychosocial impairments and functional disability.”[10] Not only has the VA taken on the challenge of finding best-care practices to optimize the long-term outcomes of these clients, but the civilian sector has also begun to adopt the term *polytrauma* and has set out to provide treatment for this population as well.

Types of Blast Injuries

One of the most common causes of polytrauma is exposure to a blast, such as from an improvised explosive device or a rocket-propelled grenade. According to the Defense and Veterans Brain Injury Center (DVBIC),[8] **blast injury** can have different effects on the body based on proximity to the blast and the body's reaction to the blast. The DVBIC indicates that “exposure to blast events can affect the body in a number of ways, in addition, these different injury mechanisms can interact and result in more impairments or prolonged periods of recovery.”

- *Primary blast injury* is the result of exposure to the overpressurization wave or the complex pressure wave that is generated by the blast itself. This blast wave travels at high velocity and is affected by the surrounding environment; for example, the effects of the blast wave may be increased in a closed environment such as a vehicle. Air-filled organs such as the ear, lung, and gastrointestinal tract and organs surrounded by fluid-filled cavities such as the brain and spinal cord are especially susceptible to primary blast injury.[13,23] The overpressurization wave dissipates quickly and causes the greatest risk for injury to those closest to the explosion.
- *Secondary blast injury* is the result of energized fragments flying through the air; these fragments may cause penetrating injuries.
- *Tertiary blast injury* may occur when the individual is thrown from the blast into a solid object

such as an adjacent wall or even a steering wheel. These types of injuries are associated with acceleration/deceleration forces and blunt force trauma to the brain, similar to that observed following high-speed motor vehicle accidents.

- Finally, with severe blast-related trauma, *quaternary blast injury* can occur as a result of significant blood loss associated with traumatic amputations or even the inhalation of toxic gases released by the explosion.[9]

Impairments from a polytraumatic injury are not predictable, and the outcome for each individual is unique. Some of the common sequelae include brain injury; spinal cord injury; amputation; infections; orthopedic problems such as fractures; wounds; psychological stressors such as **posttraumatic stress disorder** (PTSD); crush injuries; burns; auditory and vestibular impairments; eye, orbit, and facial injuries; dental complications; renal, respiratory, cardiac, and gastrointestinal compromise; peripheral nerve injuries; and pain (Table 48.1).

TABLE 48.1

Overview of Explosive-Related Injuries

System	Injury or Condition
Auditory or vestibular	Tympanic membrane rupture, ossicular disruption, cochlear damage, foreign body, hearing loss, distorted hearing, tinnitus, earache, dizziness, sensitivity to noise
Eye, orbit, face	Perforated globe, foreign body, air embolism, fractures
Respiratory	Blast lung, hemothorax, pneumothorax, pulmonary contusion and hemorrhage, arteriovenous fistulas (source of air embolism), airway epithelial damage, aspiration pneumonitis, sepsis
Digestive	Bowel perforation, hemorrhage, ruptured liver or spleen, sepsis, mesenteric ischemia from air embolism, sepsis, peritoneal irritation, rectal bleeding
Circulatory	Cardiac contusion, myocardial infarction from air embolism, shock, vasovagal hypotension, peripheral vascular injury, air embolism–induced injury
Central nervous system injury	Concussion, closed and open brain injury, petechial hemorrhage, edema, stroke, small blood vessel rupture, spinal cord injury, air embolism–induced injury, hypoxia or anoxia, diffuse axonal injury
Renal injury	Renal contusion, laceration, acute renal failure from rhabdomyolysis, hypotension, hypovolemia
Extremity injury	Traumatic amputation, fractures, crush injuries, compartment syndrome, burns, cuts, lacerations, infections, acute arterial occlusion, air embolism–induced injury
Soft tissue injury	Crush injuries, burns, infections, slow-healing wounds
Emotional or psychological	Acute stress reactions, posttraumatic stress disorder, survivor guilt, postconcussive syndrome, depression, generalized anxiety disorder
Pain	Acute pain from wounds, crush injuries, or traumatic amputation; chronic pain syndrome

Adapted from the Centers for Disease Control and Prevention: *Explosions and blast injuries: a primer for clinicians.* http://www.cdc.gov/masstrauma/preparedness/primer.pdf.

Although the polytrauma population is defined as a unique population, the principles of treatment and the factors that must be considered when planning treatment are applicable to all rehabilitation populations.[16,28] Some of the factors include young age at the time of injury, developmental stage and life role participation, including work and family role, familiarity with **assistive technology**, and military culture, as well as ethnic background, PTSD/acute stress reaction, previous or current substance abuse, high incidence of mental health complications and suicide risk, and vocational and community reintegration factors. Additionally, this population may need the support of a case manager for an extended period because their life roles and secondary conditions start to have an impact on their function (Fig. 48.1). The need for services over the course of time requires that age-appropriate treatment interventions be provided to meet the client's occasional needs.

FIG 48.1 Learning to assemble a new wheelchair.

Treatment and implementation of treatment **triage** begin at the acute onset of injury.[12] The priority in the field and once in the hospital is medical stabilization. Once the patient is medically stable, the occupational therapist (OT) may be consulted, even while the patient is in the intensive care unit. As soon as the individual is ready for a rehabilitation program, his or her needs are again triaged to see which type of rehabilitation program will be the best fit. Within the VA system is the polytrauma system of care, which is broken down into several levels of rehabilitation programs, the most acute being the polytrauma rehabilitation center (PRC—inpatient rehabilitation), the polytrauma transitional rehabilitation program (PTRP—residential treatment), polytrauma network sites (PNSs—outpatient rehabilitation), and polytrauma support clinic teams (outpatient rehabilitation).[10] Additionally, the VA offers polytrauma telehealth for those who are not able to come to a local polytrauma site (Fig. 48.2).

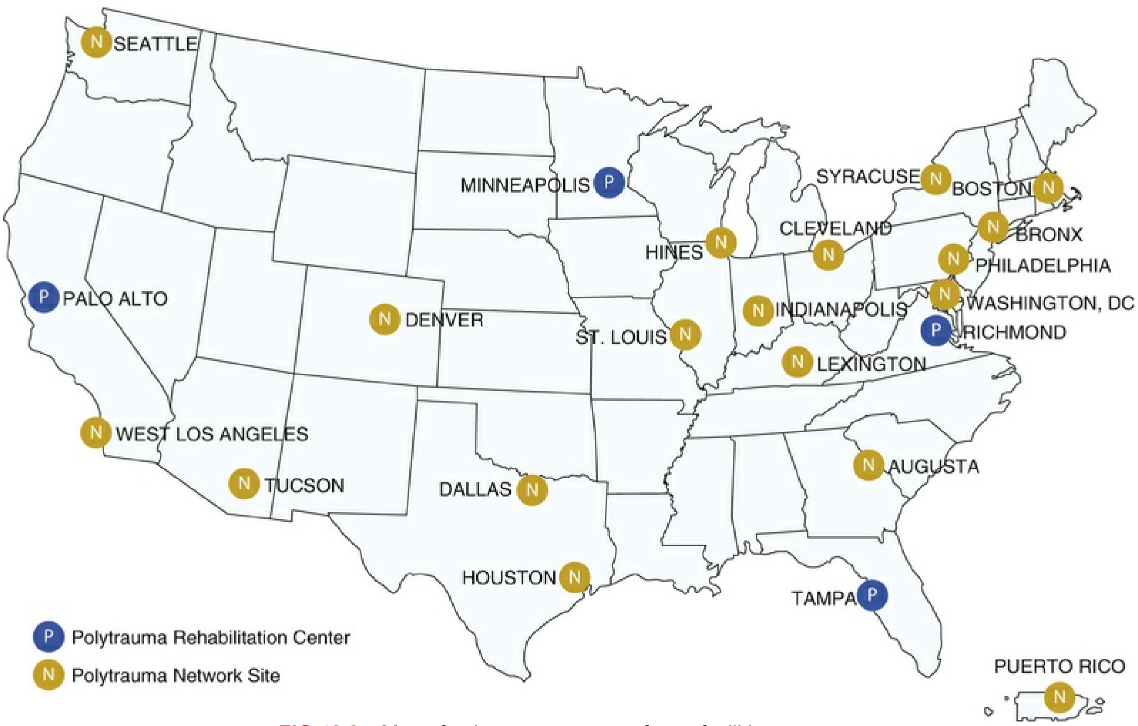

FIG 48.2 Map of polytrauma system of care facilities.

Polytrauma Rehabilitation Centers

Polytrauma rehabilitation centers (PRCs) provide acute, comprehensive, inpatient rehabilitation and comprehensive **interdisciplinary** evaluation of patients with varying levels of acuity or severity. A patient at any level on the Rancho Los Amigos (RLA) Level of Cognitive Function Scale[17] may be admitted (see Chapter 34 for further information on RLA levels). These evaluations help determine the range and types of services needed to manage the full scope of medical, rehabilitation, and psychosocial sequelae resulting from combat injury and the most appropriate setting in which to deliver these services.[10] PRCs maintain a full team of rehabilitation professionals, as well as consultants from other specialties related to polytrauma. PRCs also serve as consultants to other facilities in the polytrauma system of care.

As an OT serving on a polytrauma team, it is imperative to have knowledge and experience in treating a wide variety of conditions. For example, rehabilitation care is often focused on head/brain injury. Therefore the therapist must have specialized skill in the rehabilitation of **traumatic brain injury** (TBI), including cognitive rehabilitation, visual-perceptual skill training, **sensory loss** training, and behavioral skill training.[16,28] Additionally, OTs need to have a solid understanding of the rehabilitation of physical disabilities, including upper extremity rehabilitation, amputation care, functional mobility, burns, wound prevention, balance, and hand therapy, including splinting.

Moreover, the OT must be skilled in psychosocial rehabilitation, with a focus on family care, as well as how to work with patients with PTSD, anxiety, and pain.[18] Finally, the OT must be proficient in retraining patients in the performance of ADLs and IADLs, as well as community reintegration training.

The OT is just one member of an interdisciplinary team assigned to the PRC. Some of the other team members include the rehabilitation physician (physiatrist), nurses, social work case managers, speech-language pathologists, physical therapists, recreation therapists, counseling psychologists, and neuropsychologists. Some teams also include family therapists, military liaisons, blind rehabilitation and outpatient specialists, and massage therapists. Consulting services play a large part in the care of these patients. Consultants frequently involved in care include plastic surgeons, orthopedists, pain management specialists, psychiatrists, dentists, audiologists, neurologists, ophthalmologists, and internists. The key component in the treatment of more acute polytrauma patients is working within and in conjunction with a large team to best serve the patient. The interdisciplinary team meets regularly to ensure that all treating specialists are working as a fluid team to address the primary issues and ensure that the treatment is clinically appropriate and patient centered. Interdisciplinary communication is essential to ensure that all members of the team are reenforcing techniques and compensations that are initiated by the different disciplines or to collaborate on what techniques and compensations may be most effective to implement for that patient. This often requires co-treatment between disciplines to ensure the best care.[7,35,36]

Once a patient is admitted to a PRC, the OT is consulted. The OT will always start with a chart review and assess the precautions for the client. This population frequently has **skull flaps** removed and must therefore wear helmets when out of bed. Clients with polytrauma often have infections such as methicillin-resistant *Staphylococcus aureus* and *Acinetobacter*, which require contact precautions (gown and glove); they may also be at risk for seizures, have visual deficits, be at risk for falling, and have behavioral difficulties, as well as PTSD. Once the OT is aware of the patient's background and precautions, the next step is to contact the treatment team to determine whether any additional information is available and then meet with the client. One of the most important pieces of information to gather is the client's and family's goals and expectations for the rehabilitation program. These goals, as well as the extent of the brain injury, will direct care of the client.

The occupational therapy evaluation is tailored to the needs of the client. For example, clients at RLA levels 1 to 3 will be evaluated with the Coma Recovery Scale–Revised (CRS-R)[14] and the Coma–Near Coma Scale.[31] Clients will generally be considered to be at the level of **emerging consciousness** if they demonstrate minimal arousal, limited capacity to interact with the environment, a significantly impaired ability to follow commands and communicate, and little to no intentional movement.[2] At this level there is no functional use of objects, which limits the client's engagement in ADLs. A client at the level of emerging consciousness will then follow a different pathway from an acute rehabilitation patient. Interventions for these clients often include sensory stimulation, maintenance and restoration of neuromuscular and movement-related functions, prevention of secondary disability, and family education and involvement (see Chapter 34 for additional details). The goal of occupational therapy intervention is to increase arousal, improve functional use of objects, work with the speech-language pathologist to determine the most accurate form of yes/no communication, and be able to follow basic commands. In addition, the OT is involved in maintaining or restoring ROM to the upper extremities through passive ROM exercises, splinting, and tone management techniques. The OT will also ensure optimal positioning for seating and maintenance of skin integrity through cushion and wheelchair evaluation. Once a patient emerges from the minimally conscious state, he or she will transition out of the emerging consciousness program and become an acute rehabilitation candidate (Fig. 48.3).

JFK COMA RECOVERY SCALE - REVISED ©2004

Record Form

This form should only be used in association with the "CRS-R ADMINISTRATION AND SCORING GUIDELINES" which provide instructions for standardized administration of the scale.

FIG 48.3 JFK Coma Recovery Scale. (From Giacino JT, Kalmar K, Whyte J: The JFK coma recovery scale—revised: measurement characteristics and diagnostic utility, *Arch Phys Med Rehabil* 85(12):2020–2029, 2004.)

Acute rehabilitation begins with an evaluation of the patient and leads to clinical decision making for triage of needs. Goal setting is based on clinical reasoning with direct input from the client and family members. Goals must reflect occupational performance of functional outcomes. Common evaluation tools focused on assessing body functions include basic goniometry for upper extremity ROM; manual muscle testing; and coordination testing, including standardized assessments such as the Moberg Pickup Test, Purdue Pegboard Test, Jebson-Taylor Hand Function Test, and the Minnesota Rate of Manipulation. Sensory testing is performed, and if needed, Semmes-Weinstein filaments can be used. Basic ADLs and IADLs are assessed. Some examples of assessments that are used for ADLs/IADLs are the Kohlman Evaluation of Living Skills, Executive Function Performance

Test, Canadian Occupational Performance Measure, and the VALPAR 5 Workstation Analysis. Transfers and functional mobility are assessed, in addition to skin maintenance and seating needs. Visual-perceptual skills are evaluated; some standardized tools that are used include the Motor Free Visual Perceptual Test, the BiVABA, and Dynavision, and nonstandardized assessments for neglect, saccades, acuity, and color perception are also administered. Finally, basic cognitive skills are evaluated with tools such as the Loewenstein Occupational Therapy Cognitive Assessment, Test of Everyday Attention, Contextual Memory Test, and informal assessments such as components of functional task performance.

Once the evaluation is complete, it is the OT's role to ensure that the client engages in functional activities that promote and maintain optimal upper extremity ROM for later functional tasks. This includes basic self-care tasks along with tone management, splinting, and ROM exercises. Additionally, maintenance of skin integrity is a priority. Many polytrauma clients have shrapnel wounds, burns, and pressure wounds from bed surfaces, seating surfaces, and splints. It is critical that the OT work with the medical provider, nurses, and physical therapist to ensure that the client has optimal skin integrity and contact surfaces that relieve pressure.

If sensory impairments are present, they must be addressed for the client to function within the environment. With decreased sensation in areas such as pain, touch, and temperature, the OT must make sure that the client has training in the use of compensatory strategies for safety. If the patient has hearing loss, it is critical that the therapist face the patient when speaking, speak at a louder volume, or ensure that the client uses appropriate devices to compensate for the hearing loss. Finally, with visual loss, it is important to maintain a clutter-free environment for the client, keep all necessary items and furnishings in the same place at all times, and orient the client for safe functional mobility within the room. The OT also works closely with the blind rehabilitation outpatient specialist to ensure that the client can perform basic ADLs and IADLs by using low-vision or blind rehabilitation techniques and devices.

After these performance components are evaluated, the OT can focus on basic ADLs. This includes issuance of and training on any assistive devices or durable medical equipment needed to optimize independence. For example, a client may need a long-handled mirror to inspect the skin for wounds or observe a healing amputation site. A client may also require specialized feeding tools such as plate guards or rocker knives for one-handed feeding. In addition, clients may require shower benches or grab bars if balance or mobility issues are present. Part of basic ADL performance includes the ability to get to places safely, such as the toilet or shower. Therefore the OT must address any seating and mobility needs for a client who is nonambulatory. A seating evaluation can be performed as part of the wheelchair assessment for a client who is nonambulatory. Wheelchair issuance includes training on safety, training on mobility, and an evaluation of visual-perceptual skills for safe propulsion of the chair. Ambulatory clients who have deficits that affect getting to the toilet or shower safely because of balance issues or motor planning would also need occupational therapy services. Caregiver training is also initiated with ADL and functional mobility training, and, as a client progresses, the training needs to be readdressed.

IADLs are also addressed for this population. It may start with simple meal preparation, basic money management, or simple homemaking skills and progress to higher-level money management skills; work-, school-, and family care–related skills; time management; and community living skills. It is important to incorporate cognitive retraining and compensatory strategies to optimize independence in these skills. Clients are often issued and trained on the use of cognitive prosthetic tools such as electronic cognitive devices (ECDs), alarm watches, and global positioning system (GPS) devices. Use of these tools and the strategies provided for executive skill functions such as pathfinding, problem solving, organization, and planning is then integrated into community reintegration sessions. Community reintegration also includes training on use of public transit, as well as driving rehabilitation.

Many clients who have sustained polytrauma experience PTSD, anxiety, and pain. A polytrauma OT may initiate training in the use of biofeedback for management of stress, relaxation, and management of pain. Additionally, the OT addresses sleep hygiene in conjunction with psychology services, medical service, and nursing. The client is able to learn and practice these sleep hygiene techniques while in the PRC to support the use of these skills after discharge.

Throughout the inpatient stay, a client with polytrauma may have many medical procedures and off-unit medical appointments that interrupt the scheduled occupational therapy sessions. These procedures may result in a change in status and thereby necessitate reevaluation and reassessment of the client's functional and cognitive status. Updating of goals and priorities must continually be on the forefront as the client's status or the client and family goals change. The families are generally very involved in all aspects of the client's care and are incorporated into the treatment-planning process.

Threaded Case Study

Alex, Part 2

On completion of his inpatient PRC stay, Alex was independent in basic ADLs, transfers, and manual wheelchair mobility on indoor and outdoor surfaces. He was fitted for a prosthetic limb and had achieved functional grip strength in his right hand and sufficient coordination to don and doff the prosthesis. Alex was issued an ECD to assist in his memory deficits, performance of IADLs, and organizational skills. He still required minimal assistance to perform basic IADLs such as meal preparation, household management, and financial management. With visual-perceptual skill retraining, Alex no longer complained of double vision and was able to identify and reach for targets accurately. With the use of compensatory strategies, such as deep breathing, biofeedback, and sleep hygiene skills, Alex was sleeping well and was less anxious, and his tolerance of frustration had improved. Distractibility continued to have a negative impact on his time management skills and ability to follow through with assignments; however, he was able to create a less distracting environment for himself with cueing. His safety awareness improved, although supervision was still required for higher-level judgment and safety. As Alex transitioned to the polytrauma transitional rehabilitation program (PTRP), his occupational therapy program continued and progressed in accordance with his inpatient recommendations. Occupational therapy objectives for the PTRP included (1) promoting the highest level of functional cognition, including implementation of compensatory strategies and cognitive prosthetics to increase independence and safety in all functional skills; (2) achieving optimal independence in IADLs, including parenting skills; (3) optimizing independent ability to access the community, including transportation; (4) optimizing independence in return-to-school and return-to-work skills; and (5) receiving appropriate durable medical equipment to meet both short- and long-term needs.

Polytrauma Transitional Rehabilitation Program

The PTRP provides comprehensive, postacute cognitive retraining and community reentry rehabilitation to patients with TBI who have progressed beyond the needs of basic rehabilitation interventions. The goals of this program are to integrate clients back into their community, assist them in achieving independent living, and help them return to their life roles. Not all clients who enter the PTRP have been through a PRC; many are direct referrals from other VA facilities, from PNSs, and from outside private facilities or military treatment facilities. Because these clients have already achieved the goal of basic inpatient rehabilitation—that is, independence in ADLs and basic functional mobility—the focus while involved in the PTRP is on the higher-level skills needed to return to the community. There is more of a cognitive retraining focus with an emphasis on group work and community. The majority of clients reside within the PTRP facility; however, some clients have already transitioned back to the community and come to the facility for the day program.[20]

As is similar with all rehabilitation settings, the occupational therapy program begins with an evaluation of the patient and leads to clinical decision making. Goal setting is based on clinical reasoning, input from the patient and family, and the interdisciplinary team goals. OTs in the PTRP use many functional nonstandardized evaluation tools, but they also use standardized TBI evaluation tools such as the Mayo-Portland Adaptability Inventory (MPAI-4).[21] The MPAI-4 focuses specifically on the most frequent sequelae to be considered during rehabilitation planning or other clinical interventions, such as physical, cognitive, emotional, behavioral, and social problems. MPAI-4 items also assess major obstacles to community integration that may result directly from a brain injury, as well as the environment and context of the activity. With input from other team members, including psychology and neuropsychology, speech-language pathology, and physical therapy, realistic goals and community reintegration training can be initiated.

The OT addresses a client's ability to participate in basic IADLs such as money management, including establishing banking accounts, budgeting, financial planning, and paying bills. Additional areas addressed include cooking skills, home management and organization, health management and maintenance, child rearing, pet care, safety awareness and emergency responses, and shopping. The use of compensatory strategies and cognitive prosthetics is integral for IADL retraining, especially for clients with disorders in memory and executive functions. Many of these clients are issued and trained on use of an ECD, which is then reinforced throughout all therapies within the program.

Community reintegration training facilitates the client's ability to access the community. This includes training a client on the use of public transit, addressing driving needs, or addressing the client's ability to procure transportation in the community. It also requires the client to learn pathfinding skills, often with the use of a GPS device, and executive skill functions such as trip planning, budgeting, time management, and problem solving. The OT provides opportunities for practice in using strategies and cognitive prosthetics (such as ECDs, smart phones, or GPSs) to aid the client in becoming successful in this occupational performance area.

Another key component of this rehabilitation program is training and interventions to assist the client in meeting the goals of returning to school and learning. This includes training in basic academic skills such as math, note taking, and general study habits. It also includes exploration of educational needs and interests, some of which may lead to prevocational or vocational participation. The OT must also address any assistive technology needs such as computer access, ECDs, and specialized software designed to increase ability to succeed in school-based programs.

If return to work is the primary goal for the client, the OT must assist him or her in gaining the skills needed to return to productive employment or volunteer activities. The OT may work on goals to identify and select work opportunities based on the client's level of function, as well as likes and dislikes. Occupational therapy services are often provided to retrain the client in how to identify job opportunities, complete and submit appropriate application materials, and prepare for interviewing. Work habits, such as attendance, punctuality, appropriate relationships with coworkers, appropriate dress, completion of assignments, timeliness, and compliance, must also be addressed. The use of cognitive prosthetics is incorporated to assist the client in succeeding in these areas. Finally, the client may not be ready to engage in full-time or even part-time paid employment, and thus volunteer exploration and participation may be the first step in returning to the workforce. The OT may provide job coaching at the work or volunteer site to identify adaptive or compensatory strategies for successful performance.

The OT also needs to address leisure exploration, participation, and social skills to improve a clients' reintegration into the community. Key elements in addressing these skills include social skills groups, practice on appropriate interactions within the milieu or environment, and role-playing with feedback. Peer interaction, both within the program and within the community, as well as family and community interactions allow greater practice and skill training. Leisure exploration may include administering interest checklists and assessing abilities and opportunities available. It also includes training in the ability to plan for leisure, obtaining and maintaining equipment and supplies, and balancing leisure participation with work and self-care needs. The OT may work in conjunction with the physical therapist and the recreation therapist to ensure that adaptive sporting equipment and assistive technology are available as needed to best meet the leisure needs of the client.

Stress management also needs to be addressed. Many of these clients experience stress related to adjusting to their limitations, changes in their life roles and patterns, pain or sleep issues, and PTSD. Biofeedback may be used to aid these clients in learning techniques to decrease overall stress reactions, manage pain, and improve sleep. Sleep hygiene education, as well as various mind-body techniques, can also be introduced and incorporated into this program.

Overall, OTs working in the PTRP have to address all the aforementioned areas in the context of clients' current physical and cognitive abilities while also addressing how to improve their current functional abilities. Any physical limitations in areas such as ROM, strength, and coordination are addressed to improve functional performance. A client's sensory issues, such as low vision or visual-perceptual skill deficits, must be addressed and compensations incorporated into treatment planning for all the previously mentioned areas of function. Finally, cognitive skills, remediation, and compensation must be addressed to ensure that the patient has an optimal outcome in these areas of function.

As the patient transitions out of the PTRP, the OT plays a role in helping the patient relocate to appropriate housing, makes recommendations for levels of assistance still needed, addresses caregiver training if required, and ensures that prerequisite skills for the housing option are in place. The OT will address any durable medical equipment and environmental modifications that the client may need.

Threaded Case Study

Alex, Part 3

After 3 months in the PTRP, Alex demonstrated improved integration of his ECD into performance of IADLs. He is now using it for appointment reminders, direction finding, list making, note taking, and medication management, with occasional cueing from the therapist. Although Alex is still unable to drive, he has learned to use the local public transport system and is able to access restaurants, malls, grocery stores, and specialty stores in the local area. Pathfinding with use of the ECD and computer maps is adequate for familiar areas. Safety awareness has improved, and Alex is now safe to be left alone for long periods, is able to independently access his local community, and demonstrates improved reasoning and insight in decision making/problem solving. Alex is now independent in light hot meal preparation and basic home management tasks such as laundry and cleaning. He began to volunteer part-time in the local preschool program to address work skills and child care skills. Training in the use of biofeedback has continued, and Alex has become more skilled at self-regulation.

As Alex completed the PTRP, he moved home with his pregnant wife and was referred to a PNS for further occupational therapy intervention. The objectives of OTs in the PNS included (1) promoting the highest level of functional cognition, including implementation of compensatory strategies and cognitive prosthetics to increase independence and safety in all functional skills; (2) achieving optimal independence in IADLs, including parenting skills; (3) maximizing his ability to independently access the community, including transportation; (4) optimizing independence in return-to-school and return-to-work skills; (5) receiving and training on appropriate durable medical equipment to meet both short- and long-term needs; and (6) optimizing independence in the use of stress management and coping skill strategies, including mind-body techniques.

Polytrauma Network Sites

PNSs are outpatient clinics that serve two roles. The first is to provide specialized, postacute rehabilitation in consultation with rehabilitation centers. The OT consults with and provides follow-up based on recommendations made by the inpatient therapists. Depending on the client's current status and outcomes, the client's occupational needs can range from reeducation of caregivers in skilled nursing facilities to seating and mobility needs for returning to school or the workplace. Ambulatory clients who have deficits that affect getting to the toilet or shower safely because of balance issues or motor planning would also need occupational therapy services. Another focus may be on reinforcing the integration of assistive technology and other compensatory techniques for optimal independence in performance skills and patterns. The OT creates a treatment plan based on the client's needs (environment, client factors, client and family goals, activity demands, and current performance skills), not one that is based on the particular diagnosis. Treatment is provided in the context and environment most appropriate to meet the needs of the client.

A significant increase in the incidence of mild traumatic brain injury (mTBI) has been seen in service members as a result of serving in the OIF/OEF conflicts.[11] There is no standard, agreed-on definition of mTBI. The Department of Veterans Affairs uses the following definition of mTBI in all its TBI screening evaluations: a client with mTBI is one who has experienced a traumatically induced, physiological disruption of brain function as manifested by at least one of the following[8,22,24,30]:

1. Any period of loss of consciousness

2. Any loss of memory of events immediately before or after the accident

3. Any alteration in mental state at the time of the accident (eg, feeling dazed, disoriented, or confused)

4. Focal neurologic deficit or deficits that may or may not be transient but in which the severity of the injury does not exceed the following:

a. Loss of consciousness of approximately 30 minutes or less

b. After 30 minutes, an initial Glasgow Coma Scale (GCS) score of 13 to 15

c. Posttraumatic amnesia not longer than 24 hours

Common symptoms of mTBI include headache, dizziness, nausea and vomiting, sleep disturbances, sensitivity to light, sensitivity to noise, slowed processing, memory difficulties, irritability, depression, and visual changes. An individual may experience symptoms at the time of the event or weeks later following the mTBI. In most people who sustain mTBI, symptoms resolve within 3 months.[33] However, 15% to 30% of individuals have ongoing symptoms and are at risk for developing postconcussive syndrome.[1,29] In postconcussive syndrome, the aforementioned symptoms or clusters of symptoms persist for longer than 3 months.[5]

Postconcussive syndrome can have an impact on outcomes at any stage of polytrauma rehabilitation. Sometimes postconcussive syndrome does not become apparent until many of the life-threatening injuries have been stabilized.[19,30] While in the acute phase of rehabilitation, the symptoms may have an impact on function; however, the focus may be more on the acute injury, not on the persistent postconcussive symptoms. While in the postacute phase, postconcussive symptoms are identified during higher-level functional activities. Clients can also be treated for PTSD when mTBI and postconcussive symptoms are recognized.

Clients who experience multiple blast exposures are at higher risk for more complicated mTBI. This, in conjunction with exposure to stressful environments, increases the risk for mTBI and acute stress reaction/PTSD. This is true for mTBI sustained in automobile accidents in the private sector as well.[4] The stressful environment, multiple exposures, and acute stress reaction/PTSD can have a significant impact on natural recovery from mTBI.

The symptoms of acute stress reaction, depression, and PTSD are very similar to those of mTBI/postconcussive syndrome and can include difficulties in memory and concentration, sleep problems, impaired attention, irritability, and headache. The best approach for identifying the cause of the various symptoms is to incorporate the treatment team. The PNS uses an interdisciplinary team model to determine the most likely cause of the deficits and the most appropriate treatment to address the symptoms (Fig. 48.4).

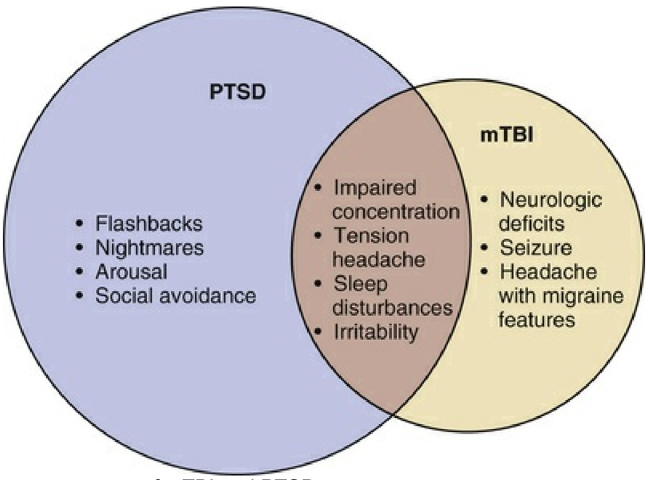

FIG 48.4 Common symptoms of mTBI and PTSD. (From Ruff RL, Riechers RG, Ruff SS: Relationships between mild traumatic brain injury sustained in combat and post-traumatic stress disorder, *F1000 Med Rep* 19:64, 2010 [government publication].)

When the PNS system was developed in 2007, there were no standards for rehabilitative treatment of mTBI. As this diagnosis became so prevalent from the OIF/OEF conflicts, the Department of Defense and the Department of Veterans Affairs developed best-practice guidelines.[11] Additionally, an occupational therapy– and physical therapy–specific guideline was developed by the Proponency Office for Rehabilitation and Reintegration (OT/PT: Clinical Practice Guidance: Occupational Therapy and Physical Therapy for Mild Traumatic Brain Injury). The clinical guidance document recommended treatments focused on client education, visual dysfunction, headache, cognition, resumption of roles, and emotional well-being.

Studies show that mTBI needs to be approached and treated differently from moderate or severe TBI. The goal is to increase awareness of deficits in those with more severe TBI, whereas with mTBI, studies have shown that focusing on abilities, stress management/coping skills, and compensatory strategies improves outcomes.[3,6,8,27,32,37] Clients with mTBI tend to be overly sensitive to errors and have decreased perceived self-efficacy, which can lead to decreased self-esteem, depression, and isolation. These factors can affect return-to-life roles and community reintegration. Clients may be able to follow through with routine and familiar tasks yet may demonstrate difficulty in problem solving, insight, and self-control.[26]

OTs working in the PNS system start the initial interaction with the client during the evaluation. This includes the use of standardized assessments, self-report tools, and observation of performance of functional tasks. The therapist also provides visual-perceptual screening because visual deficits are frequently seen in clients exposed to multiple blasts. From that screening, the therapist can then refer the client for further assessments as needed. The evaluation also includes screening for ADL needs, cognitive deficits, current use of assistive technologies, home modification needs, home management skills, organizational skills, predriving skills, physical rehabilitation needs, emotional regulation, sleep hygiene, pain, headache, and relaxation skills. Additionally, the OT will address current needs in relation to study skills, vocational needs, community reentry skills, return and transition to life roles (including follow-through with entering school, the workforce, or both), managing a household for the first time, higher-level money management, and parenting skills.

The therapist focuses on client goals in relation to activity demands and any deficits identified. The therapist will address the aforementioned areas by intervention consisting of remediation techniques and training in compensatory strategies, assistive technology, and biofeedback/mind-body techniques. This may include removing distractions, creating routines, and integrating self-awareness training tools. Client education is also an integral part of treatment. Client education may consist of discussing the effects of mTBI, expected outcomes, and how typical stressful situations and sleep problems can have an impact on function. Within the context of this education, the therapist must provide guidance on strategies for increasing insight, using compensatory mechanisms, and achieving effectiveness in participation in desired occupations. Overall, it has been documented that outcomes are better for mTBI when clients receive adequate education.[25,28]

Because the PNS works with many returning service members who bring combat driving skills to the civilian environment, their safety in driving skills must be assessed. Such driving skills include attention, multitasking ability, reaction speed, and visual-perceptual skills, as well as addressing stress reactions and hypervigilance. Many soldiers avoid driving or rely on others for assistance. OTs address predriving skills by assessing and remediating performance components. The VA has therapists who are driving rehabilitation specialists. These specialists are trained to evaluate this population by working both with driving simulators and behind the wheel. They also can provide driver's training and adaptive controls or vehicles as indicated.

The PNS as a team is tasked to monitor and follow clients' needs for their lifetime. These network sites provide proactive case management for existing and emerging conditions and identify local resources for both VA and non-VA care.

Threaded Case Study

Alex, Part 4

Alex was initially evaluated by the OT at the PNS on a weekly basis and then once a month. Alex's primary concern on initial PNS evaluation was the upcoming arrival of his baby. Although some child care skills were addressed during his volunteer experience, he was unsure of how to care for a newborn, combined with the stressors of lack of sleep, poor tolerance of frustration, and distractibility. Trial and training with a programmable infant simulator were successful in the integration of self-regulating strategies and ECD use and increased his confidence in his abilities. After training in the use of GPS, a feature of his ECD, Alex is able to navigate in unfamiliar areas with confidence. He also completed a driver's rehabilitation program and has been cleared to drive independently. Alex has enjoyed his volunteer experience and has identified teaching as a vocational goal. He is now taking one course per semester at the local community college and is implementing the study skills taught during his PNS sessions.

Monthly, Alex brings in a list of difficulties identified (tracked in his ECD) in work, home care, and child care, and he works with the OT to further address these needs. At the 1-year postinjury mark, Alex reports that he has a well-balanced life with volunteering, school, family, and social/leisure activities.

Long-Term Management/Polytrauma Support Clinic Teams

Long-term polytrauma management is accomplished in clients' home communities where they are monitored by either the PNS or polytrauma support clinic teams. These teams are groups of rehabilitation providers who deliver follow-up services in consultation with regional and network specialists. They assist in managing the long-term effects of polytrauma through direct care, consultation, and the use of tele-rehabilitation technologies, as needed. Polytrauma telehealth is a burgeoning field in rehabilitation. Telehealth is the use of electronic information and telecommunications technologies to support long-distance clinical healthcare, client and professional health-related education, public health, and health administration.

Technologies used in telehealth typically consist of videoconferencing, the Internet, store-and-forward imaging, streaming media, and terrestrial and wireless communications. Even though new applications are increasingly being found for the use of these technologies, significant barriers remain in making these technologies an integral part of daily healthcare practice.[38] The OT's role in telehealth is either as a presenter, consultant, or direct care provider.

The polytrauma system of care encompasses all the programs described earlier and ensures that there is a smooth, seamless continuum of care for these clients, including case management for life.

Summary

Polytrauma can result in substantial impairments that affect all areas of occupation. The injuries can vary from mild to severe and can include multiple body systems and affect performance skills and patterns. When treating these clients a therapist must take into consideration the specific client factors and the context and environment in which activities will occur. The goal of occupational therapy is to facilitate the client's achievement of optimal independence and functioning at each stage of recovery. Polytrauma affects the entire family unit, and thus rehabilitation goals must be client and family centered and coordinated and reinforced by all those working with the client.

Review Questions

1. What is the definition of polytrauma?
2. Differentiate between primary, secondary, tertiary, and quaternary blast injury.
3. What are some common sequelae of polytrauma?
4. What makes a polytrauma client from the OIF/OEF conflicts unique in today's rehabilitation population?
5. In the inpatient/acute unit, what primarily drives the rehabilitation course?
6. Why is an interdisciplinary team more effective than siloed care in treating polytrauma patients?
7. What are the common symptoms of and interventions for mTBI and PTSD?
8. What are the roles and treatment interventions for OTs in treating an emerging consciousness patient?
9. How does the focus of treatment change as the patient progresses through the polytrauma system of care?
10. How does PTSD affect the recovery process for a polytrauma patient?

Occupational Therapy in Hospice and Palliative Care

Janice Kishi Chow

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, the student or practitioner will be able to do the following:

1. Define hospice and palliative care.
2. Explain the therapeutic value of occupational engagement while living with a life-threatening illness.
3. Describe the role of occupational therapy in hospice and palliative care, as described in the current (2014) OT Framework ("Occupational Therapy Practice Framework: Domain and Process," third edition[4] [OTPF-3]). Discuss how clinical reasoning adjusts to accommodate the dying process.
4. Identify outcome measures for hospice and palliative occupational therapy.
5. Articulate strategies for clinician self-care.

KEY TERMS

Actively die
Chronic disease
Chronic illness
Clinician self-care
Dying trajectories
Grief
Grieving process

Hospice
Loss
Palliative
Palliative care
Terminal
Terminal illness
Terminal phase
Transitions

Case Study

Kay

Kay watched Dr. Kato's lips move. "You have pancreatic cancer …" The movement of his mouth didn't seem to match the sounds she heard. "… with liver metastasis and biliary duct obstruction …" Kay slowly turned to watch her daughter Liz frantically write down every word. Dr. Kato further explained that surgery was not indicated, given the extent of metastasis (ie, the cancer's spread to multiple organs), but palliative chemotherapy might slow the growth of the tumors. and a stent in her biliary duct could reduce her jaundice. These procedures would lessen her symptoms but were not curative. Dr. Kato paused and then said, "You have a **terminal** disease and probably 6 months or less to live." Liz's pen froze in place. As she and Kay recalibrated their gaze on Dr. Kato, he suggested hospice to support Kay and her family during this difficult time.

Kay followed through with the recommended treatment plan in disbelief. Divorced at age 50, Kay had worked long hours as a housecleaner to support herself and four children until her retirement at age 62. At 82, she highly valued being able to take care of herself and remained fiercely independent. Kay enjoyed spending time with family and friends, attending church on Sundays, participating in a weekly Bible study, traveling, and cooking for others. "I can't be dying," she would say to herself, "I have plans to travel, see the grandkids married, and be a great-grandmother!"

Within 3 months of her diagnosis, Kay began experiencing increased fatigue, weakness, and abdominal discomfort. The hospice nurse and physician adjusted her medications to control her pain, but she became frustrated by not being able to maintain her self-care routines. Each day, she was less able to do for herself. An unspoken realization arose within her and her family that she would not get better and now required more help. Her children and grandchildren assisted with homemaking, financial affairs, and transportation, but Kay insisted on attending to her own bathing, dressing, and toileting as much as possible. She compromised by moving in with Liz, her eldest daughter, in order to get assistance as needed. Seeing Kay's angst about remaining as independent as possible, the hospice team consulted occupational therapy (OT) services.

Critical Thinking Questions

1. Is the hospice team appropriately consulting OT services for someone who is declining and dying?
2. How will the occupational therapist help Kay meet her goals as she continues to decline?
3. How will the occupational therapist know if the intervention is effective?

Kay is one of more than 1.5 million Americans who receive **hospice**, or end-of-life care, annually.[92] In addition, an estimated 133 million Americans live with a **chronic disease**, or an incurable illness not yet in the terminal stages of the disease process.[32,45,88] The geriatric population in the United States tripled in the past 50 years and is expected to triple again in the next 50 years.[113] In the foreseeable future, more people will be living longer with chronic conditions[32] but dying with more complex diseases.[90] The needs of those with incurable illness, chronic or terminal, will increase exponentially. *What is occupational therapy's role in addressing this crisis? Is occupational therapy, a profession known for promoting health and well-being through occupational engagement, effective with people* *who are declining and dying?*

This chapter provides a background on hospice and palliative care, presents the evidence base for hospice and palliative care OT, describes the role of OT with this population within the parameters of the current (2014) OT Framework, the "Occupational Therapy Practice Framework: Process and Domain," third edition[4] (OTPF-3), and recommends clinician self-care strategies to support ongoing quality care.

Hospice and Palliative Care

Derived from two Latin words, *hospis,* for both host and guest, and *hospitium,* for the dwelling offering hospitality,[35,93] *hospice* initially referred to monastery-based hostels during the 11th to 15th centuries that were set up throughout Europe along pilgrim routes to provide shelter for weary travelers, the poor, and the sick as they sojourned to sacred places.[7,35,97,107] When religious orders lost their influence and the monasteries ceased to exist in Britain, the number of hospices waned for three to four centuries.[77,97]

In the 17th century there was a resurgence of hospice care. In 1633 St. Vincent de Paul founded the Sisters of Charity in Paris to care for the orphaned, sick, and dying in the community.[35] In 1842 Madame Jeanne Garnier further defined hospice by being the first to use the term “hospice” to specifically describe care for the dying.[7,35] In 1879 the Irish Sisters of Charity opened Our Lady's Hospice of Dublin, which expanded to England with the opening of St. Joseph's in 1905 in London.[7,93]

As hospice care developed, the mid-20th century brought advances in modern medicine. The discovery of antibiotics and the development of cardiopulmonary resuscitation brought hope that certain fatal illnesses could be cured.[14,45] Healthcare shifted from a model of healing to a biomedical culture focused on cure and the elimination of disease.[14,45] Health became defined as “the absence of disease.”[110] Those living with an incurable, terminal disease, however, were ignored and marginalized, considered as failures of medical advances in this new model of healthcare.[14,45]

In response to the neglected needs of the terminally ill, Dr. Cicely Saunders opened the first modern hospice, St. Christopher's Hospice, in south London in 1967.[14,45] Taking a radically different approach from that of previous hospice centers, Saunders based St. Christopher's Hospice on solid research. Dr. Saunders was a strong opponent of euthanasia and desired to find effective pain management options so patients could live fully until the end of their lives.[56] Defying conventional fears of addiction and the practice of only using opioids as a last resort, she integrated evidence on the effective use of opioids for pain management with a fixed-schedule dosing regimen to promote pain control, rather than dosing only as pain occurred.[14] Based on her own research of 340 cases in 1960 and 1100 in 1967, Saunders defined “total pain” as the integral relationship between physical, mental, and spiritual suffering and gathered an interdisciplinary team to provide medical, psychosocial, and spiritual support through the dying process.[14,93]

Soon the modern hospice movement came to the United States. In 1975 the first U.S. hospices opened in Connecticut and New York, funded by grants and contributions.[45] In 1982 Congress established the landmark Medicare Hospice Benefit, providing federally funded home hospice care.[23,89] Today, hospice care is defined as noncurative comfort care and psychosocial support for those with a life expectancy of 6 months or less.[114] As of 2013 there were approximately 5800 hospice programs in the United States, spanning all 50 states, the District of Columbia, Puerto Rico, Guam, and the U.S. Virgin Islands.[92] Sixty-six percent of hospice care is provided in the client's home (private residence, nursing home, or residential facility), 26.4% in an inpatient hospice facility, and 7% in an acute care hospital.[92] Although the Medicare Hospice Benefit has fallen below the cost of care and the Affordable Care Act will further reduce hospice payments by 11.8% over the next 10 years, hospice care remains accessible to all Americans.[89]

As the needs of the terminally ill were gradually being addressed, the needs of the chronically ill became more apparent.[45] **Palliative care** subsequently formed to help alleviate suffering of those with life-limiting illness not yet in the terminal phase, or end-stage, of the disease process.[45] Both hospice and palliative care affirm life; see dying as a normal process; seek to provide relief from pain and distressing symptoms; help clients remain as active as possible until death; neither hasten nor prolong death; and provide support to both client and family.[87,119] Palliative care, however, can be used at any stage of the disease process and in conjunction with curative treatments, whereas hospice is a specialty of palliative care, reserved for the last 6 months of life.[1]

When Kay considered her doctor's recommendations for hospice, she wondered if she would die faster while on hospice care as opposed to pursing aggressive treatments. Using retrospective statistical analysis of 4993 clients, Conner et al.[24] compared the mean survival rate of hospice clients with that of nonhospice clients who had congestive heart failure or colon, lung, pancreatic, prostate, or breast cancer, at similar stages of illness. The mean survival rate of the six diagnoses combined revealed that hospice clients lived an average of 29 days longer than nonhospice clients who pursued curative treatments. In another study, Ternel et al.[109] found that lung cancer clients who received palliative care in the early stages of their disease process lived 2.7 months longer and reported lower rates of depression than lung cancer clients who waited until the end-stages. Researchers speculate that hospice clients may live longer due to avoidance of aggressive, cure-directed interventions that carry a high mortality risk for debilitated clients (eg, high-dose chemotherapy); improved treatment monitoring; increased social support among the multidisciplinary team; and early symptom management, which stabilized the disease process.[24,109]

Based on this current evidence and given the extensiveness of her disease process, Kay will most likely live longer and have a better quality of life with early symptom management and hospice care. Her doctor exemplifies how healthcare providers need to understand the benefits of hospice and palliative care. Knowing about local services, initiating discussions about end-of-life issues, and making timely referrals may promote early symptom management, increase psychosocial support, minimize needless suffering, and support the utmost quality of life in the end of life.

Evidence Base for Occupational Therapy Services

Kay's daughter wanted to support her mother's independence and ability to do things that mattered to her, but her mother was dying. *Is there evidence that OT is effective with someone like her mother?*

Occupational therapists are uniquely qualified to address the critical needs of the terminally ill.[32,61] According to the National Consensus Project for Quality Palliative Care (2009), occupational therapy optimizes function and supports the best quality of life for both client and family within an interdisciplinary team.[87] Occupational therapists support occupational engagement through consideration of environmental, contextual, and personal factors that may limit a client's participation and satisfaction[3] while simultaneously preparing clients and families for death through the relinquishment of occupational roles, closure, and legacy transmission.[9,48,51]

Notwithstanding occupational therapy's unique qualifications for hospice and palliative care, OT remains underused, dependent upon referring providers. Under the Medicare Hospice Benefit, OT services are made available on an as-needed basis to all hospice clients by a physician's order.[17] Outside of hospice care, Medicare does not recognize the term **palliative**.[91] However, with a physician's order, palliative OT services are covered as a home health benefit under the standard Medicare Part B, with a therapy cap per calendar year of $1,920; as an inpatient hospital benefit under Medicare Part A; and under Medicaid and private insurance with variances in reimbursement and copayments.[18,19,92] In the context of constrained funds and insurance reimbursement, occupational therapy is reliant on the referring provider's understanding of OT services and its therapeutic benefits.

Unfortunately, providers often presume that their hospice and palliative care clients do not need OT services. Despite literature showing that clients with incurable diseases desire rehabilitative services to address their unmet occupational engagement needs,[60,104,120] the terminally ill are not seen as "proactive, occupational beings … who engage purposefully in occupations as part of living with a life-threatening illness."[78] Providers often deem OT services unnecessary due to the client's assumed decline.[9,78,104,120] Medicare also narrowly defines OT's role as rehabilitative; that is, to provide adaptive equipment training, home safety assessment, and caregiver instruction for safe body mechanics.[20] Providers may not realize their client's unique occupational needs beyond mere activities of daily living (ADLs) nor understand the range of services occupational therapists can offer beyond equipment training. Occupational therapy is not being used to its fullest capacity to support the needs of people living with chronic and **terminal illness**.

Weakening OT's cause further, there is a paucity of evidence supporting the efficacy of OT in hospice and palliative care. Palliative rehabilitation has been shown to promote function and quality of life in palliative and hospice clients with cancer, congestive heart failure, and respiratory diseases; however, studies have frequently focused on the effect of exercise on function or have not distinguished OT outcomes from those accomplished from the rest of the multidisciplinary team.[54,85,122] There is currently no high-level evidence study that generalizes the value of occupational engagement and the efficacy of OT intervention in the end of life.[62] Some researchers speculate that the limited literature may be due to lack of an accepted and a specific OT outcome measure[82]; the difficulty distinguishing OT-specific outcomes from those achieved by other members of the interdisciplinary palliative care team[34]; and the ethical issues of research as a client's symptoms worsen.[121] Cyclical in nature, lack of evidence results in lack of funding and workforce, further reducing therapeutic efficacy.[44,61]

Like beacons in the dearth of literature, studies by Jacques and Hasselkus,[53] Lala and Kinsella,[72] Lyons et al.,[78] Vrkljian and Miller-Polgar,[116] and Sviden et al.[108] have emerged, highlighting the therapeutic value of occupational engagement for clients living with a life-threatening illness and thus implying the need for OT in hospice and palliative care. Based on qualitative design methods, semistructured interviews, and participant observations, these five studies found that occupational engagement helps develop a sense of normalcy, restoration, health, well-being, and pleasure. Occupational disengagement can lead to loss of control, a sense of helplessness, and disruption of self-identity.[72,116] Adjustment and modification, and/or engagement in new occupations foster a renewed sense of health, efficacy, and meaning.[78,108,116] This research establishes that occupational engagement is essential for health and wellness throughout the life span, regardless of the person's disability, diagnosis, or prognosis. However, further investigation is urgently needed to directly support occupational therapy's role in hospice and palliative care.[61]

Despite the lack of evidence supporting the use of OT in hospice and palliative care, Kay's hospice team had already seen positive OT outcomes with previous clients. The team knows that OT is effective not only for equipment and caregiver training, but also for problem-solving in innovative ways to help people "do what is important." Regardless of Kay's prognosis, her declining function, and ample help, an OT consult was highly appropriate to uphold what Kay found meaningful. Upon receiving a doctor's referral, Tess, an occupational therapist, called Kay to arrange an initial visit.

Role of Occupational Therapy

What would Tess's role be in Kay's care? Similar to other areas of care, hospice and palliative occupational therapy seeks to promote health and well-being through engagement in meaningful occupation, yet distinguish itself with specialized knowledge of the grieving process, dying trajectories, and the terminal phase of life. Integration of these factors into the OT Framework (OTPF-3) shapes the unique role and purpose of occupational therapy in the care of those living with life-threatening disease.

The Grieving Process

Central to working with Kay is understanding how she is responding to the loss of her life. Rando[98] defines two types of **loss**: *physical loss* and *symbolic loss*. Physical loss is tangible, such as Kay's loss of strength and ability to care for herself. Symbolic loss relates to psychosocial significance, such as her consequent loss of independence, self-reliance, and privacy.

Grief is a normal, universal, individualized, and emotional reaction to loss.[69,97] Anticipatory grief can also occur in expectation of eventual loss.[69] Grief responses may be culturally and socially defined and expressed in social, physical, cognitive, spiritual, psychological, and emotional behaviors.[69,99] Expression about loss may be directly articulated ("I am angry that I am dying") or wrapped up in an indirect symbolic language ("I am angry that my wheelchair does not work properly").[70,98] It is essential that Tess identify Kay's losses, both physical and symbolic, and the meaning Kay assigns to these losses, to fully support her **grieving process**.[69,98]

Dr. Elisabeth Kübler-Ross's five stages of grief model remains the best-known and cited theory on the grieving process.[70,106] Although research refutes sequential progression through all stages,[49] Kübler-Ross's five stages (denial, anger, bargaining, depression, and acceptance) provide a framework for clinicians to understand the dynamic process clients and their loved ones may experience through disease progression and dying.

Tess had yet to meet and assess Kay, but she had experience working with clients at different stages of the grieving process. In *denial* of being in the end-stages of heart disease, Paul, one of Tess's clients, vehemently declined OT services because he was "taking care of himself fine." Unfortunately, it took a collapse at home for him to accept that he indeed was ill and needed help. Simona, another client, readily accepted OT services but constantly lashed out in *anger* at Tess for not fully addressing and "fixing" her functional limitations rather than acknowledging that her cancer was progressing. *Bargaining* for more time, Bob followed all of Tess's recommendations with great fervor. Tess had to gently and repeatedly explain that therapy would help make the most of today but would not cure him. Dissimilarly, seeing his situation as futile, Kevin remained tethered by *depression* and refused any of Tess's interventions despite potential for rehabilitative gains. Realizing her disease was progressing, Joan was in *acceptance* that she was dying. She knew OT would not cure her but remained open to Tess's visit to maximize her ability to transfer to a wheelchair so she could sit out on her porch. When Joan transitioned toward the end-stages of the dying process and became unable to get out of bed, she positively reflected on being able to sit out in the sun for a few days and was at peace ending OT services.

Initially, Kay was in denial of her illness. As symptoms began to affect her daily life, she became angry with God that she was sick and would likely not see her great-grandchildren born. Her anger sapped her energy further. She prayed for God to save her, but as she became more ill, she began to accept she was dying. When Tess contacted her, Kay thought she had nothing to gain, but perhaps nothing to lose, working with an occupational therapist. She agreed to meet Tess later that week.

Dying Trajectories

Although there are uncertainties regarding when people will die, there are some evidence-based patterns, or **dying trajectories**, that describe common changes in health status as the client approaches death. Lunney et al.[76] interviewed 4190 terminal U.S. clients and their caregivers and identified four common trajectories of dying: the sudden or unexpected death trajectory; the chronic organ failure trajectory; the dementia/frailty trajectory; and the cancer trajectory. A knowledge of established dying trajectories helps guide and suggest appropriate and timely interventions.

Sudden or *unexpected death* may be due to trauma, cardiac arrest, or a cerebrovascular accident.[45,47] Clinicians are unable to provide treatment for the client at this point; however, bereavement support is still imperative for family and friends. Grief may be complicated by violence, lack of making amends prior to death, or inability to say a final "good-bye." Survivors may have emotional, financial, or psychosocial dependence on the deceased. Caregivers may be lost without their caregiving roles. For these individuals, bereavement support draws upon the multidisciplinary team and may include counseling services, social services, support groups, and training in life skills for role transitions into a new period of their lives.

The *chronic organ failure trajectory* applies to conditions such as heart failure and chronic obstructive pulmonary disease and is characterized by decline with an oscillating, or sine wave, pattern between chronic health and acute exacerbations.[45,86] The span of decline can be 2 to 5 years, with a low health status in the last 6 to 24 months and significant decline in the last 3 months.[45,86,102] With each acute event, the client has a sharp decline and a period of recovery; however, the client typically does not return to his or her previous baseline. Although clients may have gains after medical intervention and return home, the cumulative effect is an overall functional decline. Each acute event also has a risk of death; despite long-term functional decline, death may still seem sudden.[86]

Occupational and physical therapists are often consulted to rehabilitate only to have the client quickly readmitted for another rehabilitation course after a sequential exacerbation. Clients and their families are stressed by being on "a roller coaster of decline and transient improvement."[45] To alleviate unnecessary pain and suffering, it is critical that palliative care be incorporated to educate clients and their families on the complexity of the disease process, initiate discussions about goals of care, and provide reasonable options that support quality of life.[45]

People who do not develop organ failure or cancer often develop dementia or generalized frailty of multiple body systems.[45,86] Less predictable than the cancer trajectory, the *dementia/frailty trajectory* is a progressive decline that begins at a low baseline of cognitive or physical function and may be variable over 6 to 8 years.[86] Dementia is typically characterized by gradual cognitive and functional decline, whereas frailty is defined by weakness, weight loss, fatigue, slowed performance, and low activity.[39] This general decline often leads to inability to recover from trivial illnesses.[39,86] Death may soon follow an acute event, such as a femoral neck fracture, pneumonia, infection, or aspiration.[39,83,86,101] Mitchell et al.[83] found that of 323 nursing home residents with dementia, 40% endured at least one burdensome intervention in the last 3 months of life, such as hospitalization, tube feeding, or parenteral therapy; residents with proxies who understood the resident's poor prognosis and dementia/frailty trajectory were less likely to have burdensome interventions in the last 3 months. Given the lengthy period of decline of these chronic conditions, palliative care is essential to control pain and other negative symptoms; maximize functional status through rehabilitation, wellness programs, and psychosocial support; educate clients and their families on the disease and dying process; and initiate discussions and care planning in order to avoid unnecessary, burdensome interventions at the end of life.[39,83,101]

The *cancer trajectory* is one of the most predictable patterns.[45,86] Many cancer clients may remain quite functional until 5 to 6 months before death.[45] In the last 2 to 3 months, clients begin to experience weight loss, decreased self-care performance, and increased pain management.[45,86] During the rapid decline phase, clients often become bedridden and typically die within a few months to weeks.[38,45,86]

Because the hospice nurse had reported that Kay was still getting up and getting dressed daily and walking household distances, Tess foresaw a meaningful window of time to help Kay develop and work toward personal goals.

The Terminal Phase

With experience in hospice care and self-study, Tess has learned much about the dying process, or the **terminal phase**. Understanding what dying "looks like" is an asset not only to educate and allay the fears of her clients and families, but also to appropriately direct Tess' interventions. Although there is some variation if the client has an acute event or a sudden death, common patterns typify the terminal phase.

During the months before death, the client endures changes caused by disease and prepares for death. In the 6 to 12 months before death, clients may be less active; complain of increased fatigue, weakness and pain; have bowel and bladder problems (incontinence, constipation, or diarrhea); and functionally decline.[50] In anticipation of death, they may begin to withdraw from others, experience a range of emotions, and ponder spiritual and existential concerns.[50] In the last 1 to 3 months, the dying may be less communicative, sleep more, and eat less.[58]

There are many salient changes as clients **transition** and begin to **actively die**. In the final weeks to days they may be less responsive and more disoriented to their surroundings, yet have a surge of energy and be restless.[50] They have minimal to no oral intake, exhibit hemodynamic changes (decreased blood pressure, faster or slower pulse, and tachycardia), and have decreased to no urine output.[47,50,58,84] Clients' extremities may become **mottled** (purplish discoloration of skin) and feel cold to touch.[47,58] They may have hallucinations of deceased relatives and express an urgency to "leave" ("I need to catch the train").[45,50] In the last days to hours, fluid may accumulate in the pharynx, causing a crackling sound in the chest, commonly known as a **death rattle**.[12] Caregivers and family may observe **Cheyne-Stokes breathing**, which is marked by periods of **agonal** breathing (rapid, shallow breaths) separated by **apneic** periods (no breathing) for 1 to 3 minutes.[47] When breathing stops, the heart will cease to beat several minutes later.[47] Death is confirmed upon determination that the heart has stopped; breathing has ceased; and the pupils are dilated and fixed.[84]

As clients progress from the beginning to final stage, regular communication with the hospice team is imperative to help manage physical symptoms, discontinue unnecessary interventions, and address psychosocial needs in order to provide the utmost care for clients and their families.

OTPF-3—Domain

The domain describes the body of knowledge and expertise of occupational therapy. Constructs include occupations, client factors, performance skills, performance patterns, context, and environments. *How does the charged nature of life-threatening illness shape the domain of occupational therapy?*

Occupation

Occupational engagement is critical to a person living with a life-threatening disease.[72,78,116] Regardless of the level of performance, participation in ADLs promotes involvement in life[108] and maximizes physical and mental function.[78] Rest and sleep are essential as "a respite from physical discomfort and psychological stressors."[31] Educational and play occupations encourage social engagement with peers, feed a need to learn, foster discovery of new occupations, build self-esteem and mastery, and promote goal setting.[30,118] Work occupations provide means to make contributions to one's community.[78] Social and leisure occupations foster social support, a sense of belonging, and enjoyment (Fig. 49.1).[78]

FIG 49.1 Participating in ADLs, such as a father walking his daughters to school, helps to keep a client with a life-threatening illness engaged in living.

Research has also identified occupations specific to the end of life. Jacques and Hasselkus[53] found that hospice clients gravitated to activities "that mattered." In the context of dying, the most mundane tasks, such as playing cards or sharing a pie with family, transformed into extraordinary events. Precious time focused on preparing for death by putting one's affairs in order, making amends, and saying good-bye to loved ones. Bye[9] noted that clients often desired closure, such as going home to die. Bye[9] and Hunter[51] both identified the importance of building a legacy through passing on belongings or instilling one's values.

Although the hospice team had requested OT for Kay primarily to help her with self-care tasks, Tess looked forward to speaking with Kay further to inquire about other occupations of interest that she may be capable of performing.

Although the team requested OT for Kay primarily to help her with self-care tasks, Tess looked forward to speaking with Kay further to inquire of other occupations of interest, if able. It is critical clinicians not dismiss opportunities to engage in occupation based on a patient's prognosis nor get locked into occupation only being ADLs. We need to take the time to identify the client's valued occupations; determine whether client factors, performance skills, performance patterns, context, and environment support participation in choice occupations; and see if modification can allow continued engagement.

Client Factors

Client factors are "specific capacities, characteristics, or beliefs that reside within the person and that influence performance in occupation"[4] (OTPF-3, p. S8). The OTPF-3 further breaks down client factors into values, beliefs, spirituality, body structures, and body functions.[4] The disease and dying process can affect each of these constructs.

Values, beliefs, and spirituality.

Values, beliefs, and spirituality collectively connect meaning with our occupational experiences. **Values** are principles that personally define "what is good, right, or important"[4] (OTPF-3, p. S22). **Beliefs** are assumptions about the world, with or without evidence, that shape our values.[4] **Spirituality** is the process of finding meaning in our lived experiences and connection with others.[4,79] When we satisfactorily participate in valued occupations, we experience coherence with our beliefs, validation of our actions, and a sense of purpose in our lives.

Incurable disease may cause angst and struggle with our values, beliefs, and spirituality. Although life-limiting illness may help prioritize "what matters" with regard to remaining time and resources,[53] disease may limit the ability to satisfactorily maintain valued and self-defining roles and occupations.[66] Faced with their mortality, clients may question beliefs, the purpose of life, and the reason for suffering and loss.[79] Clinicians need to determine the client's values, supporting beliefs, and what is meaningful in their lives to help them reframe perceptions, accommodate illness, and experience self-worth in the face of decline and functional loss.

Kay highly valued self-sufficiency. As a child, she was frequently sick and unable to help out with household duties like her siblings. Her mother often called her "a weak child." Although she regained full health in her adolescence, she continued to see herself as "weak" and overcompensated with self-reliance. Now, unable to fully care for herself, she felt worthless and a burden to her children. Countering these self-labels, however, is Kay's belief that God knows her and has a plan for "good" in her life. Can Tess help Kay draw upon her spiritual beliefs to help her find purpose, meaning, and inherent value despite functional dependence on her children?

Body structures and body functions.

Hospice and palliative care address an array of illnesses. Although cancer was the prevalent disease seen in hospice care in the 1970s, diagnoses other than cancer now make up 63.5% of the hospice admitting diagnoses, and cancer diagnoses account for 36.5%.[92] The top four noncancer diagnoses include dementia (15.2%), heart disease (13.4%), lung disease (9.9%), and unspecified debility (5.4%).[92] Smaller yet salient groups include stroke, kidney disease, liver disease, non-ALS motor neuron disorder, and human immunodeficiency virus infection/acquired immunodeficiency syndrome (HIV/AIDS).[92] Among **chronic illnesses**, the Centers for Disease Control and Prevention

(CDC) lists heart disease, cancer, chronic lower respiratory diseases, stroke, Alzheimer's disease, diabetes, and kidney disease as the leading causes of U.S. deaths, with heart disease and cancer comprising 48% of all deaths.[15,16] With such a range of illness in hospice and palliative care, this chapter is unable to address the full array of pathologic issues; however, four general guidelines may help the clinician consider how incurable illness affects body structures and function and, consequently, occupational engagement.

1. **Learn the pathology of the client's primary diagnosis.** Find out which structures are affected and how the disease compromises body function. Be aware of how the disease and symptoms change with disease progression. Consider how these changes will affect occupational engagement. In Kay's situation, pancreatic cancer will affect the function of the pancreas, which produces digestive enzymes and hormones to control blood glucose levels.[55] Pancreatic cancer is often undetected at early stages because there are no screening tests and symptoms are vague or nonexistent.[2,55] As the tumor grows, symptoms become more apparent. A tumor in the head of the pancreas may obstruct the bile duct, backing up bile into the liver and bloodstream and causing jaundice in the skin and eyes, darkened urine, and light-colored stools.[55] The tumor may block the digestive system, causing nausea and vomiting.[55] With continued growth, it may push against surrounding organs, resulting in abdominal pain and distention.[55] As cancer cells rob nutrients from normal cells in the advanced stages of the disease, the client will experience weakness, fatigue, and weight loss (cachexia).[2,55] Each sequential stage will pose increasing difficulties for Kay because digestive problems, pain, distention, and fatigue will progressively limit her function (see Chapter 45 for more details).

2. **Account for a secondary diagnosis or premorbid conditions.** These factors may complicate the primary disease process and have an exponential effect on body structures and function. Kay had a history of chronic obstructive pulmonary disease (COPD) and experienced dyspnea with moderate exertion. As her pancreatic cancer progresses, the abdominal pressure may cause shortness of breath and anxiety. Tess will need to address both her COPD and her cancer symptoms in treatment (see Chapter 44 for more details).

3. **See the body systems as integrated.** Impairment of one body structure can affect multiple body systems. Pancreatic cancer can spread into the lymphatic system, impairing drainage of lymph in the surrounding areas. Severe edema may develop in the abdomen and lower extremities, causing pain, immobility, and poor skin integrity.

4. **Be aware of the mind-body connection.** Clinicians need to consider the psychological implications of disease in order to holistically care for clients. At the early stages of her disease, Kay was dyspneic with moderate exertion. Although her symptoms were more related to her COPD at the time, she assumed her breathlessness was due to her growing tumor pushing onto her diaphragm. Kay would spiral into anxiety, feeling that she was about to suffocate and die. The context of living with a life-limiting illness may heighten emotional reactions and existential pain.[45] Somatic pains that seem excessive or not congruent with the identified organic pathology may be of psychogenic origins.[21] Also, physical changes to body structures due to surgical intervention (eg, amputation, mastectomy, or facial surgery) or disease progression may result in an altered body image, greatly affecting self-esteem, emotional well-being, spirituality, socialization, intimacy, sexuality, and function in daily activities.[105] The psychological impact of life-limiting disease can significantly affect occupational engagement.

Working with Kay, Tess will need to be aware of how cancer and COPD will affect multiple body functions and systems along the disease trajectory. With such knowledge, Tess will effectively address Kay's limitations and support her occupational engagement through the dying process.

Performance Skills and Patterns

Our values draw us to what we feel is important. To engage in these valued occupations, we rely on body structures and functions to support performance skills.[4] With practice and continued use of performance skills, we become proficient, develop habits, and blend habits into performance patterns.[4,64] These performance patterns structure our daily lives, define our roles in society, and provide purpose.[64]

Incurable disease can impair body functions and structures and limit performance skills. Loss of performance skills disrupts habits, dissolves routines, and collapses one's ability to uphold defining roles.[4,64] Although palliative medical interventions may stabilize symptoms and OT may help provide a window of improved functional performance, people with incurable illness continue to face decline. Inability to fulfill roles may rob a client of his or her self-identity, invalidate social membership, and erode the sense of self-worth.[64] A social death occurs long before the biologic death.[59]

When addressing performance skills and performance, consider what are the client's defining roles, habits, and routines.

- How has disease disrupted or limited these factors?
- Can these roles be modified or adapted to allow continued participation?
- Can the client's expectations of role requirements be reframed?
- Can the client participate in a role without performing a skill?
- Can new occupational roles be introduced and tried?
- Can the client be affirmed of inherent value, regardless of current role performance (Fig. 49.2)?

FIG 49.2 Illness can impact a client's ability to perform defining tasks, such as baking for the family.

Environments and Contexts

As Tess walked up the path to Liz's single-story home, she noted no steps or barriers to the front door. As a home hospice OT, Tess valued being able to visit Kay in her home environment. The OTPF-3 states that occupational engagement takes place "within the physical and social environment situated within context"[4] (OTPF-3, p. S8). Context describes the variety of interrelated conditions surrounding the client that are influential on occupational engagement, yet "less tangible than the physical and social environments"[4] (OTPF-3, pp. S8, S27). When working with clients with progressive disease and declining performance, OT practitioners may find that the environment and context are the only factors that can be modified and addressed to maximize occupational engagement.

Physical environment.

As disease affects performance, the *physical environment* may limit occupational engagement and compromise safety for both client and caregiver in the home, school, workplace, community, recreational facilities, and places of worship. Depending on the client's prognosis and available resources, remodeling may not be an option; however, providing durable medical equipment (eg, a wheelchair, ramps, shower chair, or raised toilet seat), rearranging furniture, moving items to more accessible locations, or installing additional supports (eg, grab bars, handrails, or bedrails) may enable partial or full engagement in choice occupations, increase safety, and decrease the burden on the caregiver.[82]

Tess looked forward to assessing whether she could help make Kay's environment more accessible. Because Kay had just moved in with Liz, perhaps she would need help building a personal and functional space to safely, efficiently, and privately access belongings and attend to her self-care. Tess's experience had taught her that simple changes could make a significant impact, such as clearing hallways to allow passage of a four-wheeled walker, raising the height of a favorite chair with a cushion for greater ease with standing, and moving a bed so that the client could turn to a less painful side while getting up. Other times Tess had used more involved interventions, such as setting up a tilt-in-space recliner wheelchair to enable a client confined to her bed to get outside or training another client to drive a scooter to attend a grandchild's baseball game at the far end of the park. Knowing that decline is inevitable with terminal illness, Tess continuously looks for ways to modify the environment to maximize occupational engagement.

Social environment.

The social environment is a critical and an essential source of support for the chronically and terminally ill. The *context of death and dying*, however, may hinder positive interaction between the client and the social environment. Family and friends may unintentionally isolate a loved one by avoiding conversations about dying and death.[26] Clients and caregivers may feel shunned by the lack of medical and social services for those with life-limiting illness in our cure-centric healthcare system. As the client physically declines, the caregiver's needs will increase, causing further stress and strain on the social environment. Bye[9] found that in the end of life, OTs' work with caregivers influenced OT outcomes more than did addressing the client's functional status. Clinicians may need to educate family, friends, and caregivers on positive communication strategies; the dying and grieving process; and available social and healthcare resources in the local area. To ease the burden of care, clinicians can train caregivers in safe body mechanics, the use of equipment, and techniques to enable occupational engagement.[82] To develop the client's locus of control, clinicians can coach clients in how to direct their own care.[9,25,97]

Kay's family seemed to be well connected with community and medical services, but it was less clear to Tess how they were coping with Kay's decline and impending death. Were they able to speak freely about their feelings, fears, grief, and concerns? Did engrained family dynamics support or isolate Kay? Tess recalled working with another client, Joe, and his family on new ways to communicate. As Joe's dementia progressed, his family struggled to visit because he repeated himself multiple times in the same conversation. Tess coached Joe's children on facilitating life review conversations, helping Joe to recall new details about the past. Tess also drew upon Joe's love of cooking by asking about family recipes and then working with him to make a dish with plenty of leftovers on Fridays. When his children visited on Saturdays, Joe would proudly serve them a meal. As they ate together, Joe and his children would talk about how Joe made the dish, reflect on their favorite dishes, and build new experiences together.

In addition to the context of death and dying, the *temporal context* in the social environment may complicate the grieving process. Chronic and terminal illness can occur at any stage of life. When expected temporal experiences are missed due to illness, there may be a great sense of loss. Parents of disabled children may repeatedly mourn each developmental milestone missed as their child ages.[6] The death of a child may trigger profound anguish over an unfulfilled life.[98] We are grieved by the deaths of a young mother of two toddlers, the 63-year-old who had only one year before retiring, the high school senior expecting to leave for college in the fall, and the 80-year-old hoping to hold her first great-grandchild. We expect people to be able to experience their lives fully and meet their personal goals (Fig. 49.3). Clinicians need to be mindful of the temporal contexts of people's lives; understand how illness is interrupting the presumed life plan; support the client and family through an ongoing grieving process; frame the value of one's life; assist in setting realistic new goals; and help clients leave a legacy by which to be remembered.[30,51,97]

FIG 49.3 High school graduation, as shown here, is an example of a temporal experience that can be disrupted by illness.

How would Tess be able to help Kay reconcile how cancer was disrupting her life plan? Could Tess help Kay build a legacy to leave for her great-grandchildren through which they could come to know their great-grandmother?

Although death, dying, and the temporal context may complicate living with life-threatening illness, the *virtual context* may support and enhance occupational engagement. Encapsulating interactions that are simulated, real-time, or near-time situations with no physical contact,[4] the virtual context may enable the client with limited accessibility to connect globally through texting, email, social media, video conferencing, and cell phones. The hospitalized client may be able to build a virtual shared space for social engagement and a sense of being at home while away from home.[103] One of Tess's OT colleagues had taught a client to use video calling to maintain his relationship with his grandchildren living out of state when he was no longer able to travel. Such interaction supported ongoing participation in his valued role as grandfather, hundreds of miles away.

Despite decline and loss of functional performance, the client may experience continued occupational engagement through attention to and modification of physical and social environments. Giving special consideration to the death and dying, temporal, and virtual contexts may help support the client and family through the grieving process, sustain participation in valued roles, and develop a new, virtual space in which to connect with others.

OTPF-3—Process

In the context of the grieving and dying process, providing hospice and palliative OT services involves evaluation, intervention, and targeting intervention outcomes to support occupational engagement throughout the life span.[3,4]

When Tess knocked on the front door of Liz's house, she heard shuffling steps approach the door. The deadbolt clicked, the doorknob turned, and Tess looked up to see Kay peering from behind the door. "Hi, I'm Tess … Mrs. Shimada?" Kay replied, "It's Kay. Come in."

Evaluation

The evaluation process seeks to find out what are the client's goals, needs, and functional baseline, in addition to supports and barriers to occupational engagement.[4] Through preparation, evaluation, and analysis, the OT develops an occupational profile and determines appropriate interventions.[4]

After the OT receives a consultation to evaluate and treat, *preparation* for the evaluation process begins with gathering data from a chart review, staff and caregiver reports, and clinical observation.[97] In addition to areas that may affect occupational engagement, special attention is given to the grieving and dying processes. Information may need to be verified by the client and/or family; however, preparation may prevent redundant questions, conserve the client's energy, build a foundation for an occupational profile, and provide segues for therapeutic interaction (Table 49.1).

TABLE 49.1

Preparation Guide for an OT Evaluation

Area of Concern	Subtopics	Sources of Information	Questions
Medical history	• Primary diagnosis (Dx) • Symptoms • Secondary Dx • Comorbidities • Prior medical issues • Mental health status	Physician, nursing, and mental health services notes Staff and family reports	• What were the events leading up to admission for the primary Dx? • How long since the initial Dx? • How is the client coping/grieving? • Do comorbidities complicate treatment (Tx)? • How do/will medical issues affect occupational engagement?
Medical orders	• Precautions • Contact isolation • Advance directive	Medical orders Physician, nursing notes	• Are there orders that should be in place that are not (eg, total hip precautions)? • Review advance directive. • Will precautions affect Tx?
Social history	• Age • Marital status • Work history • Education • Cultural background	Physician, nursing, social work, and mental health services notes Staff and family reports	• Do these client factors support or limit occupational engagement?
Areas of occupation	• Values • Leisure interests • Roles • Routines • Performance • Goals	Physician, nursing, social work, mental health services, physical therapy, or previous occupational therapy (OT) notes Staff and family reports Observation	• What is the client's previous level of occupational engagement/performance? • How much assistance was needed? • Any discharge needs? • Any end-of-life goals and wishes?
Environmental contexts	• Physical environment • Social environment	Home health services, physical therapy, social work, nursing, mental health services, and physician notes Staff and family reports	• See Discharge Planning Checklists (Table 49.3)

Building on the preparation process, *evaluation* begins by identifying the client's needs and goals and developing an occupational profile. The evaluation process may vary, depending on the client's physical, emotional, and cognitive stamina (Table 49.2). A palliative care client in the early stages of the disease process may have a relatively high activity tolerance and occupational performance capacity, despite living with a life-threatening disease. A more formal assessment may be indicated to determine more progressive interventions. For a hospice client with poor activity tolerance, a formal assessment process may be invasive and burdensome.[9,82,97] In a qualitative study of hospice occupational therapists, Bye[9] found that clinicians often used a "low-keyed" approach of observation and interview with the client, staff, and caregivers rather than exhausting clients with a formal assessment. Although administering an incomplete assessment may compromise validity and reliability, subsets of assessments may also address the client's particular need while accommodating the client's limited endurance.[5] For example, using only the grooming portion of the Functional Independence Measure (FIM),[40,63] rather than completing all areas of self-care, may provide evaluative data and conserve the client's energy to complete the single goal of brushing the teeth that day.

TABLE 49.2

Evaluation Strategies for the OTPF-3 Domains

Domains	Evaluation Strategies
Occupation	
ADLs IADLs Rest/Sleep Education Work Play Leisure Social Participation	• Chart review, interview, family reports • Focus on areas pertinent to client's goals and interests • Administer assessments only if data support client's goals; client is willing; and client has the emotional, cognitive, and physical stamina to participate. • Possible occupation-based assessments: • Occupational Circumstances Assessment Interview and Rating Scale (OCAIRS) (client report)[36] • Canadian Occupational Performance Measure (COPM) (client report)[74] • Functional Independence Measure (FIM) (subtests as indicated)[40,63]
Client Factors	
Values, Beliefs, Spirituality Body Functions Body Structures	• Chart review, interview, and family reports • Observation • OCAIRS[a] (values, beliefs, and spirituality) • Only assess body structures and functions that support client's goals and interests. For example, instead of doing comprehensive manual muscle testing, assess just hip and knee flexors and extensors to determine if at least grossly 3+/5 and safe to attempt functional transfer.
Performance Skills	
Motor Process Social Interaction	• Observation • FIM[a] (subtests as indicated) • OCAIRS[a] (client report) • COPM[a] (client report)
Performance Patterns	
Habits Routines Rituals Roles	• Chart review, interview, staff and family report • OCAIRS[a] (habits, routines, roles)
Context and Environments	
Cultural	• Chart review, interview, staff and family report

Personal Physical Social Temporal Virtual	• If client will be going home, see Table 49.3 (Discharge Planning Checklists) • OCAIRS[a]

[a]Administer assessments only if data support the client's goals, and the client is willing and has the emotional, cognitive, and physical stamina to participate.

ADLs, Activities of daily living; *IADLs*, instrumental activities of daily living.

Given the challenges of assessing people with life-threatening illness, are there accepted assessments for hospice and palliative care occupational therapy? Currently, there are no established hospice and palliative care OT outcome measures or assessment tools.[46,82] However, two occupation-based measures may be appropriate for use with hospice and palliative care clients: the Occupational Circumstances Assessment Interview and Rating Scale (OCAIRS)[36] and the Canadian Occupational Performance Measure (COPM).[74]

The OCAIRS is primarily a descriptive assessment of occupational engagement. Based on the Model of Human Occupation (MOHO),[65] the OCAIRS addresses all the domain areas of the OTPF-3 by evaluating volitional, habitual, and performance components in physical and social contexts. This 20- to 30-minute, standardized, semistructured interview is portable and flexible enough to accommodate the client's level of endurance. The OCAIRS has adequate reliability[42,43,57] and excellent to adequate validity.[8,71,117] The brief, MOHO-based interview format may enable the clinician to determine the client's goals and assess multiple domains quickly without excessively burdening the client. There are no studies on the use of the OCAIRS in hospice and palliative care. However, an unpublished quality improvement study found the OCAIRS an effective assessment tool for developing a rich narrative with hospice clients.[22]

Based on Canadian Model of Occupational Performance–Engagement (CMOP-E),[10] the Canadian Occupational Performance Measure (COPM)[74] is an extensively researched assessment tool with excellent reliability[27,95] and excellent validity.[11,13,29,81,100] This portable, 15- to 30-minute, semistructured interview is primarily an evaluation assessment that organizes occupational engagement under self-care, productivity, and leisure categories, with an emphasis on occupation performance.[74] The client identifies occupational performance issues and self-rates performance and satisfaction on a Likert scale.[74] The COPM was shown to be problematic for the terminally ill because the focus on occupational performance was psychologically distressing for clients confronting functional decline and disease progression.[94] However, as a client-centered and individualized measure with excellent psychometric strength, the COPM may be a good alternative to measures with preset performance levels[82] and appropriate for higher functioning palliative care clients.[94]

The OCAIRS and COPM are two possible hospice and palliative OT assessments. Both are brief, semistructured interviews that can accommodate low endurance. The OCAIRS accounts well for volitional and environmental components, which may be the only modifiable factors as the client loses functional performance.[9,97] Although better suited to higher functioning clients, the COPM offers excellent psychometric strength and clinical utility. Further research is needed to validate the appropriateness of the OCAIRS and COPM in hospice and palliative occupational therapy.

The evaluation process requires the clinician to assess the client's stamina and apply clinical reasoning to ascertain the appropriate approaches and assessment tools to use. After drawing from numerous sources, the clinician integrates and *analyzes* evaluation findings. Based on identified supports and limitations of occupational engagement, the clinician prepares to develop a treatment plan and implement intervention.

Kay's evaluation.

As Tess followed Kay into the living room, she observed Kay occasionally skimming the wall with her hand and leaning on the console *(movement function/gait pattern)* before sitting down on the couch *(motor skill–functional transfer)*. Kay pointed to the seat across from her for Tess. Liz came in, introduced herself, and asked if she could join the conversation. Tess said it would be fine with her if it were all right with Kay. Kay nodded in agreement.

Kay asked right away with a smile *(social interaction skills)*, “Are you here to give me a job?” Tess explained that her job was to help Kay be able to “do” what she felt was important, or her occupations. Although Kay's cancer will cause decline, Tess would try to help modify and accommodate everyday tasks, routines, and activities as much as possible. The reason for Tess's first visit is to get to know Kay better and define her goals and needs.

With Kay's permission, Tess initiated the OCAIRS interview. Folding questions from the OCAIRS into a casual conversation, Tess was able to find out that Kay's current *roles* are being a mother, grandmother, and friend. She enjoyed traveling, cooking, and going to church *(interests),* but her *routines* have slowly changed due to her fatigue, abdominal pain, and occasional shortness of breath *(body structures/function).* Kay used to attend different events three times a week for church or to meet friends but has attended church only twice in the last month *(routine, performance skills).* Although she is still able to get to the toilet independently, she needs minimal assistance from her daughters for bathing and dressing.

When asked what she *values* most, Kay replied God, her family, and being independent. Liz added that her mother worked hard to send all four kids to college and taught them to be self-sufficient. Kay said she is most proud of *(personal causation)* her children and grandchildren, adding, "They are all good people who get along with each other. I can't ask for more." She reflected that her life had been tough at times, but she felt that "God made me a better person through it all *(spirituality).*" Tess asked how she got through tough times in the past *(interpretation of past experiences).* Kay explained her *belief* that God had a purpose for her and her kids, which kept her going *(spirituality)*. Tess asked how she was doing getting through this challenging time. Kay paused and said, "I regret not being able to see my great-granddaughter, expected in 6 months, but I have to believe that God is somehow using me now *(grieving–acceptance, spirituality).*" Kay added, however, that she feels like a burden on her children and grandchildren because they are all taking turns from their jobs and schoolwork to help her out *(social environment, belief).* Liz tried to reassure Kay that she was not a burden, but Kay just looked down.

Tess then asked Kay, "If there were two things that you could do with greater ease, what would they be *(goals)*?" Kay looked up and said without hesitation, "Getting dressed and taking a shower by myself without being so tired." Tess asked if doing things differently or making changes was difficult for her *(readiness for change).* Kay said, "Sometimes. Especially if it means that things will never be the same."

Kay began to fatigue from the interview *(motor skill-endurance).* To allow her to rest, Tess asked her if it would be okay for Liz to show her Kay's bedroom, the bathroom, and places she likes to spend time *(physical environment).* Kay agreed and remained in the living room. While Liz showed Tess the main living areas and Kay's bedroom and bathroom, she mentioned that Kay was "still getting around, but is getting weaker." Tess asked Liz how she was doing. Liz replied that her mom's illness had been so sudden, and the whole family was struggling with watching their feisty mother and grandmother wither. "She's the glue of our family. I don't know what I'm going to do without her. My sister thinks she should get more chemo and go to rehab *(grieving–denial vs. bargaining),* but I know that's not going to help her *(grieving–acceptance)*." Tess listened intently and then remarked on how Liz and her family seemed to be working well together. Liz laughed, "What do you mean? We don't agree on things." Tess replied, "Maybe, but you talk with each other. Many families don't." Liz paused. "I guess we do," she said.

Tess and Liz returned to the living room to find Kay asleep on the couch *(motor skill–endurance)*. Not wanting to tire Kay further, Tess asked Liz if she could come back the next morning to discuss possible ways to make it safer for Kay to do her self-care and get around the house. Liz readily agreed.

Although Tess would have liked to spend more time with her client, Kay was obviously too fatigued. However, based on her OCAIRS and home assessment findings, Tess was able to determine Kay's goals, which were to be as independent as possible in dressing and bathing. Kay is limited by fatigue, abdominal pain, and shortness of breath, but she continues to have fair motor strength, fair to good balance, resilience, and strong social support. Perhaps with additional equipment, modification of her routine, and the use of energy conservation principles (also referred to as fatigue management), Kay might be able to become more independent with her self-care and get out into the community for a bit longer. Tess also thought about that great-grandchild coming and wondered if Kay would want to somehow share a part of herself with the baby.

Intervention

Using analysis of the evaluation data, the clinician collaborates with the client to develop a plan, implements intervention, and continually reevaluates treatment effectiveness.[4] Like the evaluation process, intervention remains focused on the client's goals and considers the changing needs of the dying and grieving process. The context of dying shapes the selection of occupations and interventions.

The **intervention plan** is the map to care. Taking the client's goals, the clinician translates them into treatment goals. In hospice and palliative care, the client's goal may not be realistic (eg, “I want to get better”). The clinician may have to dig deeper to understand if there are other ways to feel “better,” such as participating in a beloved hobby or spending time with family. The clinician and client collaborate to develop the optimal plan and desired outcomes.

Another frequently mentioned goal is “to return home.” In the context of dying, the wish to return home may be even stronger. Similar to other areas of care, clinicians need to access the physical and social environments and determine if discharge home is feasible and safe. Table 49.3 presents discharge planning checklists.

TABLE 49.3

Discharge Planning Checklists

Physical Environment Checklist	
Entrances	• Accessible entrances? (Primary and secondary entrances) • Door wide enough for wheelchair or scooter? • Accommodation for turning radius? • Ramp or railing needed? • Access to driveway or car drop off? • Will client be able to safely access home at current level of function and expected level of function? Will ambulance/gurney services be needed at discharge?
Bathroom	• Accessible entrance with room for turning radius? • Tub/shower accessible? Modifications needed? • Shower chair, grab bars, and shower hose? • Bedside commode, raised toilet seat or toilet frame needed? • Is it possible to provide safe care in this area at client's current and expected level of function?
Bedroom	• Accessible entrance with room for turning radius? • Clear pathways and access to belongings? • Bed: • Height too high/low for transfers? • Bed rail needed? • Hospital bed needed? • Room for hospital bed? • Bedside commode needed? Space available? • Room for mechanical lift if needed? • Is it possible to provide safe care in this area at client's current and expected level of function?
Living space, outdoor areas, community areas	• Accessible entrance/area for wheelchair or walker? • Accessible sitting areas? • Modifications needed to enable occupational engagement?
Caregiver's area	• Living space for caregiver that allows for sleep, self-care, respite, and privacy?
Social Environment Checklist	
Caregiver stamina	• Does the caregiver have the emotional, spiritual, and physical stamina to provide the care needed? • What are the caregiver's coping strategies? • Does the caregiver have a support system? • Are there multiple caregivers to allow for respite?
Caregiver education and training	• Knowledgeable about: • Dying and grieving process? • Proper body mechanics? • Caregiver techniques? • Use of equipment (eg, lift, hospital bed)? • Community supports?
Dying and death context	• Does the client feel supported or isolated? • Does the client have support to speak about dying and death?

Tess discussed with Kay her goals of dressing and bathing with less assistance. Kay was open to working with Tess on changing her routine and trying out adaptive equipment. Tess used Goal Attainment Scaling (GAS)[67] to develop treatment goals and to later serve as an outcome measure of treatment efficacy. GAS (Table 49.4) was initially developed for mental health services. It is based on the premise that goals are best defined by the client's challenges[52]; it provides a means to detect meaningful change relevant to clients and their families that may be difficult to capture on standardized measures[37,80,112]; and it can be administered in a time-effective manner.[37] Goals are rated on a 5-point scale, ranging from −2 to +2; −2 is a “much less than expected” outcome, 0 is an “expected” outcome, and +2 is a “much more than expected” outcome.[67,80] Preintervention and postintervention scores can be converted to a standardized score to show outcome changes.[112] Tables are available for easy conversion of outcome scores to T-scores.[68] There is insufficient evidence to determine test-retest reliability.[33,52] Concurrent validity is fair to poor.[33,52] Congruent validity is fair.[52] Despite its low to moderate psychometric strength, GAS is still widely used based on its clinical utility[33] and provides an individualized, client-centered outcome measure when standardized tests are not available.[80] (Box 49.1 presents Kay's GAS goals.)

TABLE 49.4

Goal Attainment Scaling (GAS)

Rating	Level Description
−2	Much less than expected outcome
−1	Somewhat less than expected outcome
0	Expected outcome
+1	Somewhat more than expected outcome

+2	Much more than expected outcome

From Kiresuk T, Sherman R: Goal Attainment Scaling: a general method of evaluating comprehensive mental health programmes, *Community Ment Health J* 4:443–453, 1968; and Mailloux Z, et al: The issue is—Goal Attainment Scaling as a measure of meaningful outcomes for children with sensory integration disorders, *Am J Occup Ther* 61:254–259, 2007.

Box 49.1

Kay's Treatment Goals

Goal 1: Using energy conservation principles and adaptive equipment, Kay will be able to complete her bathing routine independently.

−2: Kay will be able to complete her bathing routine with min A.

−1: Kay will be able to complete her bathing routine with CGA.

0: Kay will be able to complete her bathing routine with SBA/set up.

+1: Kay will be able to complete her bathing routine with set up.

+2: Kay will be able to complete her bathing routine with modified I.

Today's score: −2

Goal 2: Using energy conservation principles and adaptive equipment, Kay will be able to dress herself independently.

−2: Kay will be able to dress herself with min A.

−1: Kay will be able to dress herself with CGA.

0: Kay will be able to dress herself with SBA/set up

+1: Kay will be able to dress herself with set up.

+2: Kay will be able to dress herself with modified I.

Today's score: −2

Cumulative raw score for 2 goals: −4

Standardized score: +25

min A, Minimal assistance; *CGA,* contact guard assist; *SBA,* stand-by assist; *modified I,* modified independence.

When the intervention plan has been established, **intervention implementation** begins. Interventions used in hospice and palliative care include pain and symptom control,[3,46,82] occupational modification,[3,60,82] and training of both the client and caregiver.[9,97] (Table 49.5 presents symptom control strategies, and Table 49.6 lists examples of interventions.) Although these interventions seem similar to those used in other areas of care, qualitative studies of hospice OTs have found that the OT practitioners uniquely balance maximizing occupational engagement for today with preparing clients for death through occupations that promote closure during the intervention process.[9,46,53]

TABLE 49.5

Symptom Control Strategies[a]

Symptoms	Control Strategies
Pain, dyspnea, anxiety	• Work with team on use and timing of medications with daily routines. • Understand source of symptoms (physical, psychological, or both). • Identify triggers of symptoms. • Identify any positions that exacerbate symptoms.

	• Provide means for better positioning and body mechanics that reduce symptoms. • *Dyspnea:* Side-lying sleeping; avoid compressing abdominal/chest area. • *Pain:* Good body mechanics with daily tasks. • *Anxiety:* Note posturing that may cause muscle tension. • Assess and address quality of sleep and sleep hygiene. • Relaxation techniques • Stress management • Mindfulness training • Adaptive breathing techniques (eg, pursed-lipped breathing) • Make referrals as indicated to other disciplines (eg, massage and physical therapies, psychology, chaplain, social work).
Nausea, vomiting	• Identify triggers. • Work with team (speech and physical therapy, nursing) on positioning to avoid dysphagia. • Coach on positioning that reduces symptoms while performing daily tasks. • Relaxation techniques • Mindfulness training
Fatigue	• Identify and address psychological stressors that may exacerbate fatigue. • Assess and address sleep hygiene. • Analyze daily tasks; coach on simplifying and/or modifying tasks. • Instruct in energy conservation principles (ie, pacing, prioritizing, delegating, sitting with tasks).

[a]For additional resources and information, please refer to Chapter 7 (Teaching Activities in Occupational Therapy), section 2 (Therapeutic Use of Self: Embodying Mindfulness in OT); Chapter 13 (Sleep and Rest); Chapter 27 (Eating and Swallowing); Chapter 28 (Evaluation and Pain Management); Chapter 33 (Cerebrovascular Accident [Stroke]), Chapter 38 (Arthritis); Chapter 41 (Low Back Pain); and Chapter 44 (Cardiac and Pulmonary Diseases).

TABLE 49.6

Examples of Interventions

Types of Interventions	Examples
Occupations	• Completes a morning routine with adaptive equipment. • Prepares own breakfast using energy conservation principles. • Does grocery shopping with use of a scooter. • Writes a legacy letter expressing hopes, dreams, and values to children. • Makes amends with estranged sibling. • Gives possessions away to desired loved ones. • Sits outside on porch to have a cup of coffee with a friend.
Activities	• Practices getting into and out of shower using grab bar. • Develops a list of affairs that need to be attended to. • Decides whom to give belongings to. • Participates in life review about raising children.
Preparatory methods	• Floats heels off pillow to prevent skin breakdown. • Provides retrograde massage to reduce upper extremity (UE) edema. • Provides a shower chair and shower hose. • Determines appropriate wheelchair and seat positioning. • Recommends installation of equipment (eg, grab bars, ramp, lift). • Provides long-handled equipment for dressing and bathing tasks.
Preparatory tasks	• Hand-strengthening program with putty or exercise hand ball • UE range of motion (ROM) program • Practices how to ask caregiver for help. • Practices how to do pursed-lipped breathing to control shortness of breath (SOB).
Education	• Caregiver instruction in ROM, edema control, positioning, and body mechanics • Instruction in use of adaptive equipment with bathing and dressing • Instruction in use of energy conservation strategies • Instruction in use of power wheelchair
Training	• Caregiver training in ROM, edema control, and positioning • Caregiver training in use of mechanical lift and body mechanics • Caregiver training in how to fold up wheelchair and stow it in car • Training in use of power chair • Training in manual wheelchair mobility • Training in pursed-lipped breathing to reduce SOB with ADLs
Advocacy	• Therapist advocates for client's interests in team meeting. • Therapist explains to family that client does not want to continue with aggressive rehabilitation anymore.
Self-advocacy	• Client directs own care. • Client makes a request for palliative treatments.
Groups	• Day hospice program • Group to discover new occupations, such as drawing or computer use • Legacy writing group • Support group

For additional resources and intervention strategies, please refer to Chapter 10 (Activities of Daily Living [ADLs]); Chapter 11 (Mobility), section 1 (Functional Ambulation) and section 2 (Wheelchair Assessment and Transfers); Chapter 13 (Sleep and Rest); Chapter 16 (Leisure Occupations); Chapter 17 (Assistive Technology); Chapter 33 (Cerebrovascular Accident [Stroke]), Chapter 38 (Arthritis); Chapter 41 (Low Back Pain); and Chapter 44 (Cardiac and Pulmonary Diseases).

To help Kay increase her safety and independence in bathing, Tess suggested equipment for the bathroom, such as grab bars, a shower chair, and a nonskid mat. Kay practiced transferring into and out of the shower using the shower chair. Liz said she would have someone install the grab bars at the shower entrance, in the stall, and by the toilet. Kay felt that she would be more stable getting in and out by herself with the grab bars, but reassured Tess that she would have her daughters stand by. To reduce Kay's fatigue, Tess instructed her in energy conservation principles, coaching Kay on pacing, prioritizing tasks, sitting with activity, and using long-handled equipment. They discussed situations and thoughts that might trigger Kay's dyspnea and practiced pursed-lipped breathing and mindfulness techniques to help her center herself. Tess gave Kay permission to not take a shower every day and to delegate other tasks so she could focus on what was important to her. She also showed Kay how to utilize a four-wheeled walker not only for stability, but to carry her things and allow her to take a break on the walker seat. At first Kay seemed hesitant, but when Tess mentioned she would probably be more independent with the walker, she decided to try it.

Although it was not specifically a part of Kay's treatment plan, Tess integrated a *therapeutic use of self-strategy* in order to connect with Kay and bring out Kay's previous occupational roles. At the end of one session, Tess noticed a picture of Kay's children by her bedside and commented, “I have two kids I'm raising on my own. Any parental advice?”[111]

Kay paused. “I never thought I'd have to raise four kids by myself,” she said.

Tess asked, “How did you do it?”

“Forgiveness,” Kay replied softly.

“Forgiveness?”

“I wasted a lot of energy being angry at my ex-husband. When I hit a wall, I realized I needed to make a change for the better. I had to choose to forgive him and not wait until I felt like I could forgive. When I finally did, a big weight lifted, and I was freed up to live my life and be there for my kids.”

“Did he ask for forgiveness?” Tess asked.

“Are you kidding? Of course not … have you ever tried oregano tea?

Surprised by the sudden change of subject, Tess replied, “No, never heard of it.”

“My neighbor told me it's a good household remedy for a nagging cough. I thought it was the strangest idea. But once, when I couldn't get over my cold, I decided to steep some. Terribly bitter, but surprisingly soothing. Sometimes you have to try something totally different for a change for the better.”[a]

Kay smiled, and Tess suddenly realized that their roles had been reversed. Kay was the OT for the day. Although weak and tired, in that moment, Kay was the strong, vibrant, self-reliant mother teaching Tess.

Tess returned the next week. Kay was able to bathe herself after Liz set things up. With Kay using the grab bars and sitting while she completed her bathing routine, Liz felt more comfortable leaving for periods of time and providing Kay privacy. By implementing the energy conservation suggestions of pacing, putting out her clothes the day before, carrying things with the four-wheeled walker, sitting down, and using long-handled equipment, Kay was able to get dressed with modified independence and without shortness of breath. She had a brighter affect than the previous week and seemed pleased with her progress.

At the end of the session, Tess did an **intervention review** of Kay's treatment plan (Box 49.2). Kay had made great progress over the past week. Although her progress may be momentary, it was evident that having more independence and privacy was priceless to Kay.

Box 49.2

Review of Kay's Treatment Goals

Goal 1: Using energy conservation principles and adaptive equipment, Kay will be able to complete her bathing routine independently.

−2: Kay will be able to complete her bathing routine with min A.

−1: Kay will be able to complete her bathing routine with CGA.

0: Kay will be able to complete her bathing routine with SBA/set up.

+1: Kay will be able to complete her bathing routine with set up.

+2: Kay will be able to complete her bathing routine with modified I.

Baseline's score: −2

Highest score achieved to date: +1

Goal 2: Using energy conservation principles and adaptive equipment, Kay will be able to dress herself independently.

−2: Kay will be able to dress herself with min A.

−1: Kay will be able to dress herself with CGA.

0: Kay will be able to dress herself with SBA/set up.

+1: Kay will be able to dress herself with set up.

+2: Kay will be able to dress herself with modified I.

Baseline score: −2

Highest score achieved to date: +2

Cumulative baseline raw score for 2 goals: −4

Cumulative raw score after second session: +3

Baseline standardized score: 25

Second session standardized score: 69

Outcome change: +44

min A, Minimal assistance; *CGA,* contact guard assist; *SBA,* stand-by assist; *modified I,* modified independence.

With Kay meeting her goals, Tess considered discharging her, but then asked her if she would like to work on a legacy project—creating something that would enable her family to remember her and the things she valued. Kay was a bit taken aback. Tess asked, “With your great-granddaughter coming, would you like to leave her a message or tell her something about yourself? Or your children and grandchildren?” Tess went on, “Recently, I read about people writing letters to their children, sometimes just a couple of sentences, expressing their feelings and hopes for their future.” Kay said, “My parents never ‘talked.’ I guess they just assumed that as long as I was fed, I knew they cared for me.” Tess asked, “Did you ever wish that they had said, ‘I love you?’” Kay paused. Tess broke the silence. “How about writing a couple of letters to your family?” she asked.

Tess and Kay worked out a goal for the next 3 weeks (Box 49.3). Kay did not know if she would have the time and energy to write everyone a letter, so she decided to write a letter to each of her children first. Then, if she were able, she would write one letter to all her grandchildren and one letter to her great-grandchild. Over the next couple of weeks, Tess gave Kay prompts, such as, “How would you describe your son?” or “What do you admire most about your daughter?” to help her put her thoughts into words. By the end of 3 weeks, Kay had completed her letters and put them in a large envelope to be opened after she passed away.

Box 49.3

Kay's Revised Treatment Goals

Goal: Kay will write legacy letters to her family.

−2: Kay will decide whom she will write letters to.

−1: Kay will finish writing 1 or 2 letters.

0: Kay will finish writing 3 or 4 letters.

+1: Kay will finish letters to her children and 1 letter to her grandchildren.

+2: Kay will write letters to her children, grandchildren, and great-grandchild.

Baseline score: −2

Highest score achieved to date: +2

Baseline standardized score: 30

Three-week reevaluation score: 70

Change in outcome score: +40

min A, Minimal assistance; *CGA,* contact guard assist; *SBA,* stand-by assist; *modified I,* modified independence.

Upon completion of her letters, Kay felt that she had met her goals. She continued to dress and bathe relatively independently and expressed feeling at peace. Tess also thought that there were no other OT issues to address at the moment, but she urged Kay and her family to ask for OT again "when things change." Tess then discharged Kay from OT services.

About 1 month after Tess had discharged Kay, she received another consultation to train the family in body mechanics with caregiving. Tess knew that Kay was declining quickly and that it would be a few weeks to perhaps a month before Kay would pass away. She worked with designated family members who would be providing care and ordered additional equipment, such as a bedside commode, so Kay could toilet with assistance bedside instead of using diapers. She also ordered a wheelchair with a pressure-relieving cushion so that Kay could be taken outside. Kay was sleeping a lot more, but when Tess visited, she awoke, smiled, and asked Tess how her daughters were doing.

Tess subsequently made one more visit to check in with the family, to see if the equipment was sufficient and to offer support. The family was able to safely provide care for Kay without cueing. Because the family's goals had been met with positive outcomes (Box 49.4) and there were no other OT issues, Tess again discharged Kay from OT services.

Box 49.4

Family Goals

Goal: Family will safely and independently assist Kay with care.

−2: Family will verbalize understanding of good body mechanics.

−1: Family will demonstrate good body mechanics with 3 or 4 verbal cues during care.

0: Family will demonstrate good body mechanics with 1 or 2 verbal cues during care.

+1: Family will demonstrate good body mechanics with 1 verbal cue during care.

+2: Family will demonstrate good body mechanics with no cueing during care.

Standardized score after 2 sessions: 70

Change in outcome scores: +40

Targeting Intervention Outcomes

Outcomes determine whether OT intervention is effective. Important questions are:

- What are the recommended OT outcome measures in hospice and palliative care?
- What constructs do we measure with a population living with a life-threatening illness?
- How do we determine if our intervention has been effective with clients who are declining?

There is currently no accepted hospice and palliative care outcome measure that distinguishes OT-specific outcomes.[34,46,82] However, to accommodate the probable functional decline of hospice and palliative care clients, the literature suggests using reliable, valid, and individualized measures rather than one with preset performance levels on a traditional standardized measure.[73,82,112] Such client-centered measures may be more sensitive to subtle changes and more effective in capturing personal and meaningful outcomes.[112] For example, upon admission, a hospice client confined to bed with severe pain and inability to tolerate transfer to a wheelchair would be rated on the Functional Independent Measure (FIM) scale as 1, or dependent. The client's goal may be just to be able to tolerate being lifted into a chair and escorted outside. On the GAS, the client tolerating a lift transfer and getting outside may progress three levels, from −2 (much less than expected outcome) to 0 (expected outcome). Although the client would accomplish a major personal goal, the FIM is not sensitive enough to show this progress because the performance level for functional transfers remains 1 (dependent).

In the previously mentioned example, the GAS is measuring occupational engagement, whereas the FIM is measuring performance. This raises the question of what constructs we should measure to capture positive outcomes with clients who are functionally declining. With Kay, Tess measured occupational performance changes resulting from adaptations and modifications. **Occupational performance** (or functional performance) is often used in healthcare to determine efficacy[34]; however, with life-limiting disease, a focus on occupational performance does not accommodate functional decline and may cause emotional distress over limited functional improvement as the client's disease progresses.[34,94] As Kay became more debilitated, using an occupational performance outcome measure would be less ineffective. **Occupational engagement** outcomes strike a balance; change in participation in meaningful occupations is detected without focusing on performance outcomes. Occupational engagement is the involvement and interaction in a life situation[4] and does not necessarily require occupational performance.[123]

The purpose of hospice and palliative care is commonly said to be to increase **quality of life** (QOL). With medical advances, people are living longer but with chronic and incurable diseases.[32] Longevity cannot be assumed to correlate with wellness; consequently, the concept of quality of life arose to determine if treatments improve life rather than just prolonging it.[75] Quality of life shifts the focus on functional performance to the value of life and is conceptually aligned with the philosophies of occupational therapy.[75,96] However, the use of QOL as an outcome measure can be problematic with terminally ill clients because there is no universal definition of QOL; outcomes can be affected by subjective experience; and it may be impossible to ascertain QOL outcomes due to OT intervention versus the cumulative team effect.[34,75,96]

Environmental factors are not specifically cited in the literature as a hospice outcome measure; however, the environment can affect OT outcomes and must be addressed in hospice care.[9,97] In the end-stages of life, attention and modification of the environment may lessen the burden of functional problems, may affect OT outcomes more than functional status, and may be the only elements that can be varied as the client's status declines.[9,82,97] The context of dying can transform mundane occupations to highly significant life moments,[53] whereas cultural and personal contexts may conjure up taboos, fears, and inhibitions that isolate the client.[26] Focus on the physical environment may maximize a client's engagement in occupations and the caregiver's ability to provide safe and effective care.[9,97] Focus on the social environment can facilitate social engagement, enhance social support, connect the client and family to essential community and medical resources, and help facilitate closure in the end of life.[9,26,53,82,97]

Overall there is no consensus on what constructs we should measure with hospice and palliative care clients to capture positive OT outcomes. Selection of constructs relies on the clinician's clinical reasoning to discern outcomes appropriate to the client's status and stage in the dying process and whether chosen constructs will effectively distinguish OT outcomes from other disciplinary interventions.

In the end, a reliable and valid client-centered measure that has an appropriately chosen construct may determine whether OT intervention has been effective. Clinicians can use client-centered measures (eg, GAS and COPM) if they are conducive to the selected construct. For Kay, Tess was able to quantifiably capture Kay's improved occupational engagement and her family's occupational performance in caregiving with GAS. Further research, however, is needed to validate whether these measures effectively and accurately capture OT outcomes in hospice and palliative care.

The role of hospice and palliative occupational therapy is to promote occupational engagement throughout the lifespan. The clinician integrates knowledge of the dying and grieving process into the OTPF-3 domain and process to meet the unique needs of people living with life-threatening illness. While focused on the client's goals, the clinician draws upon clinical reasoning to adjust and accommodate evaluation, intervention, and selection of outcomes to the changing needs of the dying process. *This method serves the needs of the client, but how do clinicians take care of themselves to sustain ongoing quality care?*

Clinician Self-Care

Within 2 weeks of her last visit, Tess got a call from the case manager, who said that Kay had died peacefully with all her children at her bedside. People often asked Tess how she could work in hospice and palliative care, with constant loss, death, and sadness. Hospice and palliative care clinicians are at high risk of burnout, given the stress of working with dying clients and being constantly confronted with their own mortality.[115] Other contributing factors may include high workloads, lack of financial compensation, or lack of administrative support of palliative care programs.[41,115] To cope and sustain quality care, **clinician self-care** is essential. Research has found that setting strong work-home boundaries; spending time with loved ones; focusing on the satisfying aspects of one's job; maintaining self-awareness and good physical care; practicing a daily spiritual or meditative routine; having a personal philosophy about illness and death; and knowing one's role in life may provide healthy coping strategies and decrease the risk of burn-out.[41,115] For Tess, after that call, she took a moment to remember Kay's glow when she was able to “do what was important” and the privilege of working with such a vibrant person. How could she not do this job?

Summary

Regardless of the diagnosis or prognosis, people with a life-threatening illness need opportunities and support for occupational engagement to experience normalcy, purpose, well-being, and connectedness into the end of life. The hospice team appropriately consulted occupational therapy to enable Kay to “do what is important” within her limited life expectancy. Although Kay had ample help, attending to her own self-care was critical to her values and self-identity of self-sufficiency. With modifications, compensatory strategies, and adaptive equipment, Tess helped Kay maximize her occupational engagement in self-care for a finite but meaningful period of time. Tess also helped Kay remain active in her role as mother and grandmother, sharing words of wisdom in letters to her family and in her interactions with Tess. As Kay declined, Tess continued to work with her family and provided additional equipment, modifying Kay's environment to support her occupational engagement through the dying process. Using a client-centered outcome measure, Tess was able to quantifiably determine positive OT outcomes of occupational engagement until the end of life. However, seeing the sense of satisfaction on Kay's face truly confirmed to Tess that treatment was effective and worthwhile.

Epilogue

A month after Kay's death, Tess received a card from Liz. “I know you worked with Mom on writing letters to us all,” Liz wrote. “Per her wishes, I opened up mine the night she died. Mom wrote, ‘You have become what I always wanted to be. I love you.’ She had never told me that before … Thank you. The enclosed letter is for you from Mom.”

Tess slowly opened the letter and chuckled as she read, “Drink a cup of oregano tea. Thank you for everything. Kay”

Review Questions

1. How are hospice and palliative care interconnected yet differentiated?
2. What are five therapeutic benefits of occupational engagement for a person living with a life-threatening illness?
3. What are common grief reactions we may see in clients, families, and ourselves?
4. Identify four dying trajectories.
5. What occupations has research identified as common in the end of life?
6. How can the loss of role engagement affect quality of life, and how can roles be modified and adapted to sustain participation despite disease and decline?
7. If disease limits a client's occupational performance of a valued task, how can this limitation affect the client's self-esteem, and how can the OT validate the client beyond performance?
8. How can the OT help a client mourn loss if illness interrupts his or her life plan, and how can the OT help someone set new, meaningful, and realistic goals?
9. How does the context of incurable disease and dying affect the domain areas of OT?
10. How can the evaluation process accommodate a declining and dying client?
11. How can the intervention process foster occupational engagement in declining and dying clients?
12. Identify three possible hospice and palliative OT outcome measures.
13. Identify five coping strategies for preventing burnout.
