Funding for most community-based programs is derived from grants or contracts through local, state, or the federal government and also from foundations. Grants are funds that are awarded for a specific purpose and a specific period, usually for research or a service project, "based on a submission of a creative original proposal."[90] Contracts also provide funding for research or service projects; however, the funding agency defines the scope of the project and requests bids from competing organizations in the community. The majority of funding for community-based programs comes from foundations; "foundations are operated by philanthropic families, corporations, or community agencies that have reserved significant amounts of money for the purpose of supporting charitable organizations and programs to address specific community needs."[90] Many associations and civic groups, such as the United Way, American Head Injury Foundation, Kiwanis Club, and others, provide funding for community projects related to specific areas of interest. It is important to note that community-based programs should develop a broad financial base with multiple funding sources for programs to "survive and thrive" in the long run.

Community Rehabilitation Programs

There are almost 600 community rehabilitation programs (CRPs) with federal contracts under the Javits-Wagner-O'Day (JWOD) program, according to Source America (formerly NISH, the National Industries for the Severely Handicapped). These community-based nonprofit organizations train and employ individuals with severe disabilities (primarily developmental disabilities and blindness) and provide quality goods and services to the federal government. The CRPs subcontract work from various industries to allow individuals with severe disabilities the opportunity to be productive, earn a competitive wage, and contribute to society. (See the Source America website [http://www.sourceamerica.org] for more details.) These programs receive most of their funding from regional centers or the Office of Vocational Rehabilitation. Although most of these programs are run by individuals who are not OT professionals, this is an area that some occupational therapists may want to explore for future involvement. There is a great need for these types of programs for individuals with other severe, chronic disabilities (e.g., brain and spinal cord injuries), but creative funding needs to be obtained to support them.

Homeless Shelter Programs

An emerging practice area for occupational therapists is working with persons who are homeless. Because of the increasing number of persons experiencing homelessness, Congress enacted the Stewart McKinney Homeless Assistance Act of 1987 (Public Law 100-77).[34] This act was designed to meet the needs of those who are homeless by providing funds for emergency shelters, food, healthcare, housing, education, job training, and other community services. The act funded a Department of Labor project to plan, implement, and evaluate the effectiveness of a comprehensive spectrum of employment, training, and other support services to help persons who are homeless to locate and sustain employment. Based on the Job Training for the Homeless Demonstration Program (JTHDP), which consisted of 63 organizations across the United States that provided comprehensive services for persons who were homeless from September, 1988, to November, 1995, the Department of Labor created a best practices guide.[90] Box 14.6 lists the findings of the JTHDP, which recommended that a sponsoring agency provide the core services or that the agency develop linkages with other local human service providers to assist persons who are homeless in obtaining and sustaining employment.

Box 14.6

Core Services to Aid Underserved Community Members

The Job Training for the Homeless Demonstration Program has defined the following as necessary services to aid the underserved members of a community:

- Case management and counseling
- Evaluation and employability development planning
- Job training services (e.g., remedial education, basic skills training, literacy instruction, job search assistance, job counseling, vocational and occupational skills training, and on-the-job training)
- Job development and placement services
- Postplacement follow-up and support services (e.g., additional job placement services, training after placement, self-help support groups, mentoring)
- Housing services (e.g., emergency housing assistance, evaluation of housing needs, referrals to appropriate housing alternatives)
- Other support services (e.g., child care, transportation, chemical dependence evaluation, counseling, and referral to outpatient or inpatient treatment as appropriate)
- Mental health evaluation, counseling, and referral to treatment
- Other healthcare services
- Clothing
- Life skills training

From Herzberg GL, et al: Work and the underserved: homelessness and work. In Kornblau BL, Jacobs K, editors: *Work: principles and practice*, Bethesda, MD, 2000, American Occupational Therapy Association.

Occupational therapists have the skills to design and implement programs that incorporate the JTHDP recommendations for best practices. Client-centered job readiness and job training programs can and have been developed for community service agencies to address the concerns of persons who are homeless. This population desires intervention services that are "sensitive, respectful, and responsive to their self-identified needs."[10]

Occupational therapy practitioners work with those who are homeless, and with agencies providing services for people who are homeless, to build skills for accessing resources, solving problems by identifying strengths and assets, and learning to critically analyze situations for win-win situations for employers and the persons who are homeless.

Welfare-to-Work Programs

Congress passed the Personal Responsibility and Work Opportunity Reconciliation Act (Public Law 104-193) in 1996 to move people from welfare to work.[10] It required welfare recipients to find work after receiving 2 years of public assistance. The Balanced Budget Act of 1997 (Public Law 105-33) provided funds for welfare-to-work grants. These grants are for training long-term recipients of welfare or public assistance to enter the job market in unsubsidized jobs. People who are most difficult to place because of multiple barriers to work, such as low academic skills, poor work history, or those who need substance abuse treatment, are the target of these grants. A substantial percentage of welfare recipients have learning problems, mental health and substance use disorders, and issues of domestic violence that interfere with their sustained employability.[90]

Welfare-to-work programs are another innovative practice area for occupational therapists.

Therapists who are interested in entering this area of practice must find out which agencies within the local or state communities control the welfare-to-work funds. Occupational therapists can subcontract with these agencies and collaborate with them. This information can be accessed from the National Governors Association (NGA) Center for Best Practices welfare reform website.[64] Private foundations that are involved in the welfare-to-work programs may also be a source of entry for occupational therapists.

There are many barriers that a person receiving welfare must face to enter into competitive employment. Lack of transportation, lack of childcare, problems with domestic violence, illiteracy, lack of housing, substance abuse, and medical needs can interfere with a welfare recipient's ability to obtain and retain a job.[10] Successful welfare-to-work programs attempt to break these barriers down. For example, programs combine basic education and job development, provide refurbished cars for transportation to work, and provide one-on-one mentoring for improving self-sufficiency. Transitioning welfare recipients to the workplace presents a challenging practice area for occupational therapists to use their creativity to design and deliver effective services to help clients set goals, explore vocational options, and introduce them to different community resources to achieve successful and continued employment.[43]

Ticket to Work

The Ticket to Work and Work Incentives Improvement Act was enacted in December, 1999. This law created a voluntary program for recipients of Supplemental Security Income (SSI) and Social Security Disability Insurance (SSDI) to receive job-related support services and encourage beneficiaries to return to work and pursue their employment goals.[96] Those who have tickets can go to any Employment Network (EN), an organizational entity (state or local, public or private) that has contracted with the Social Security Administration (SSA) to coordinate and deliver employment services, vocational rehabilitation services, and/or other support services under the Ticket to Work Program. Interested individuals can contact the Ticket to Work Help Line at 1-866-968-7842 (V)/866-833-2967 (TTY) to verify eligibility and find out how the program works. The Ticket to Work Program can also be contacted via the website http://www.yourtickettowork.com or http://www.ssa.gov/work. The Ticket to Work Program creates opportunities for occupational therapists to serve on advisory panels, work as program managers, or provide employment support services.[43] Those who are interested in learning how this program will affect their Social Security benefits can register for free Work Incentive Seminar Events (WISE) at http://www.chooseworkttw.net.

Volunteerism

Some people may not be able to return to competitive employment due to the nature or extent of their disability, but they still may be interested in participating in some type of productive activity in the community. Occupational therapy practitioners can help people identify the type of work activities they can successfully do by practicing different skills that may be done by a volunteer at a hospital, school, community center, or any place of interest. Simulated clerical tasks, such as making photocopies, collating and stapling papers, making and receiving phone calls, and data entry, can be practiced. Customer service skills, hospitality and greeting skills, and providing directions and information can be practiced. Helping people identify their strengths will give them more confidence to advocate for themselves when applying and interviewing for a volunteer position. Additionally, occupational therapy practitioners can offer practical assistance to individuals in locating a suitable volunteer site in their local community by educating them on locating the various resources available on the Internet, such as the websites http://www.volunteermatch.org and http://www.idealist.org.

Future Trends

The population of older workers is increasing, whereas the population of younger workers between 25 and 44 is decreasing.[88] The Bureau of Labor Statistics projects that by 2020, 41.4 million workers will be age 55 or older, which is 25.2% of the total labor force.[9] It is predicted that there will be a shortage of younger workers to replace the baby boomers when they retire, thereby creating a gap in the labor market. One proposal to fill this gap would be to employ more people with disabilities.[88] Occupational therapists can work with human resource managers to educate and provide resources for workplace accommodations. The Society for Human Resource Management has recently partnered with the Office of Disability Employment Policy (ODEP).[88] This collaboration reveals that human resource professionals are seeking support and services for hiring and accommodating workers with disabilities.

Baby boomers represent one of the largest percentages of the working population.[88] As they age, employers may need to be sensitive to workers for whom multiple disabilities develop that eventually may have an impact on their job performance. Changes in the workplace offer new opportunities for occupational therapists to help aging workers stay employed with their functional limitations. As older workers retire, occupational therapists can help individuals plan for their retirement and explore ways to remain active in the community by participation in leisure pursuits or volunteer activities. Occupational therapists can help older individuals identify their strengths and abilities and provide community resources to allow meaningful participation in valued occupations.

Threaded Case Study

Joe, Lorna, and Henry, Part 2

Reflecting back on the introductory case scenarios, the reader sees opportunities for the application of these comprehensive work-related occupational therapy interventions. For example, Joe's occupational therapist could conduct a job demands analysis of the laundry attendant position and a worksite evaluation at the hotel and spa where he worked before his spinal cord injury. Then the occupational therapist would determine whether Joe could successfully carry out the essential functions of that alternative job. The occupational therapist could recommend any modifications that needed to be done to make the work area wheelchair accessible. A functional capacity evaluation may be helpful to determine whether Joe could carry out any of the specific physical demands of the job on an occasional or frequent basis. Based on the results, the occupational therapist could then make recommendations to the physician and the employer for any reasonable accommodations that may be necessary for Joe to successfully return to work, in addition to informing them of any concerns regarding Joe's ability to safely meet the physical demands of the job.

After Lorna, the upholsterer with the repetitive stress hand injury, obtains a general occupational therapy evaluation and intervention for her acute injuries in the clinic, she could similarly benefit from an ergonomic assessment and intervention at her workplace. The goal of an ergonomic assessment and intervention would be to eliminate the risk factors that contributed to her original injury and to avoid recurrence of future problems. The occupational therapist could communicate with Lorna's employer about developing an in-house ergonomics and injury prevention program at the company to reduce the number of work-related musculoskeletal disorders occurring at the workplace.

Finally, contemplate the third scenario, which involves Henry. Henry needs the assistance of an occupational therapy practitioner to help him discover what type of work that he would best be suited for, while taking into consideration his present physical and cognitive abilities and limitations. He could also benefit from a comprehensive vocational evaluation to assess his cognitive and physical abilities, work habits, work skills, and work tolerances, in addition to interests and attitudes, to determine whether he could return to any other type of work. Another alternative would be for Henry to participate in a work readiness program. The same areas assessed during a vocational evaluation would also be addressed in the work readiness program; however, Henry could also benefit from a discussion on work-related topics and could receive peer interaction and feedback on his work performance, work habits, and attitudes.

Summary

This chapter has provided an overview of the varying types of work programs in which occupational therapists are currently practicing; it also has identified and discussed areas for further involvement. There are tremendous opportunities for occupational therapists and certified occupational therapy assistants to expand their role and involvement in hospitals, schools, industrial settings, and the community in general in the area of work practice. Occupational therapy practitioners are challenged to take a proactive approach in advocating the need for and benefit of these types of work-related programs in all communities, to help restore the occupation of work and the worker role in many people's lives.

Review Questions

1. How has involvement of occupational therapy in work programs evolved over the years?
2. What is the role of occupational therapy in work programs?
3. Describe the difference between an FCE and a vocational evaluation.
4. What components are usually included in an FCE report?
5. Describe the difference between work hardening and work conditioning.
6. List the common applications of the results of a JDA.
7. What interventions are used to determine whether someone is capable of returning to a specific occupation after an injury?
8. Discuss the ergonomic design considerations for workstations, seating, visualizing job tasks, tools, and materials handling.
9. List and discuss the eight important elements of corporate injury prevention plans.
10. Why are occupational therapists good candidates for assisting companies in the development of injury management programs?
11. Name and describe some innovative types of work programs in which occupational therapists can be involved in the community.

Americans With Disabilities Act and Related Laws That Promote Participation in Work, Leisure, and Activities of Daily Living

Barbara L. Kornblau

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, the student or practitioner will be able to do the following:

1. Explain how the Americans with Disabilities Act (ADA) defines disability and how that definition may apply to clients seen by occupational therapists.
2. Compare and contrast definitions of discrimination and discuss how they may apply to clients served by occupational therapy.
3. Recognize and define specific terms used in the ADA, Fair Housing Act, and Air Carrier Access Act.
4. Discuss the roles that occupational therapy can play in advocating for clients under the ADA, Fair Housing Act, and Air Carrier Access Act.
5. Discuss the roles that occupational therapy can play in consulting with employers, places of public accommodation, airline carriers, and landlords.
6. Explain the process used to determine essential job function.
7. Analyze reasonable accommodations as an intervention strategy in occupational therapy and explain the decision-making process involved in making reasonable accommodations.
8. Outline the process for removing physical and other barriers to access in places of public accommodation and the steps necessary to perform an accessibility audit.
9. Prepare and train employers, coworkers, supervisors, airline employees, and those who work with the public to treat individuals with disabilities with dignity and respect.

KEY TERMS

Accessibility audit
Auxiliary aids
Direct threat
Discrimination
Essential job functions
Individual with a disability
Major life activities
Places of public accommodation
Qualified individual or person with a disability
Reasonable accommodations
Undue hardship

Threaded Case Study

Carlotta, Part 1

Carlotta is a 50-year-old woman with severe rheumatoid arthritis. Since her most recent exacerbation, she finds she must use a wheelchair for mobility. She has always prided herself on her independence and does not want to rely on her children or husband for assistance. She loves going to the movies, shopping, and traveling. Carlotta works as a Spanish teacher at a local high school.

She comes to the occupational therapist (OT) concerned about several things. How will she be able to participate in her work and leisure occupations from her wheelchair when some places (and people) in the community, including her classroom, are not wheelchair friendly or accessible? How will she manage airplane travel from a wheelchair? How can she independently participate in activities of daily living from a wheelchair when her landlord of 12 years will not allow her to make the changes needed in her apartment?

This chapter addresses Carlotta's concerns by expanding the concept of OT interventions to include advocacy as a key concept of intervention. As we address the occupations significant to Carlotta, we will look at three important laws for guidance and support in promoting occupational performance; we also will look to these laws to support our intervention plan. These laws are:

- The Americans with Disabilities Act (ADA),[81] including the Americans with Disabilities Act Amendments (ADAA)[82] and the 2010 ADA Standards for Accessible Design[113]
- The Air Carrier Access Act[78]
- The Fair Housing Act[94]

Each law provides an avenue for OT intervention that promotes the greater good for many individuals with disabilities. Each law also provides specific supports for our efforts to promote our client's desire to increase and improve her participation at work, at home, and in the community.

Carlotta's evaluation shows that as a person with a chronic disability, she is a very sophisticated player.[80] Over almost 25 years of living with arthritis, she has acquired many adaptive devices (eg, reachers, jar openers, bathtub benches) to make her life easier, facilitate independent participation, and prevent further damage to the joints of her hands. She requires the assistance of others for some tasks.

Her occupational profile shows that her job as a Spanish teacher at the large private school where she has worked for 18 years is very important to her.[80] She believes that she can do her job but will have some difficulty navigating the classroom in her wheelchair because of the presence of multiple levels. Her classroom is the former orchestra classroom. She also expresses concerns about continuing her weekly excursions to the movies. How can she navigate the old theater in town in which the old upstairs balcony was turned into a separate screen theater with a one-flight walk up?

Before she began to use a wheelchair herself, she saw wheelchair users at the local shopping mall struggling to get in the door, and she believes that this will present a barrier to her shopping or, as she puts it, “retail therapy.” How will she manage at the airport and aboard airplanes in her quest to find the perfect bed and breakfast (another hobby)? Finally, from her experience as an individual with a disability, she knows that she will need more adaptations in her bathroom to participate in activities of daily living. She is particularly concerned because her landlord has already told her she cannot widen the bathroom door or install grab bars in the bathtub. She is interested in finding alternatives so that she can take care of herself and not have to move. She also expressed concern about her difficulty carrying out a home aquatics program prescribed by her previous OT. She now requires assistance to get into the pool at her apartment complex, but the complex's rules do not allow guests on weekends.

Disability laws heavily influence the facilitation of participation in work, leisure, and the community. Ignoring disability laws can promote ineffective intervention plans.[80] To move forward with an intervention plan, Carlotta's OTs first must understand both the disability laws that affect the areas of concern to their client, and also the ways these laws can provide a basis for intervention.

Americans With Disabilities Act

To understand the protection the ADA affords Carlotta and the roles it provides for OTs and occupational therapy assistants (OTAs), one must first have a basic understanding of the ADA, its definitions, and how the courts have interpreted the law. Congress passed the ADA in 1990 in an effort to reduce **discrimination** against individuals with disabilities and promote their inclusion in the mainstream of society. The law's antidiscrimination provisions cover employment, certain state and local government services, public accommodations, communications, and public transportation. This chapter explores Title I (employment), Title II (state and local government services), and Title III (public accommodations) and how they affect OT practice.

Title I: Employment

Before the ADA became law, the Rehabilitation Act of 1973 prohibited discrimination against qualified individuals with disabilities in employment by three categories of employers: (1) the federal government, (2) employers who contract with the federal government to provide goods and service, and (3) employers who were recipients or beneficiaries of federal funding.[104]

Congress extended that protection by expanding it to private employers who are not dependent on federal funding by passing the ADA in 1990. Because one of Carlotta's concerns is her work and whether she can continue to participate in her work from a wheelchair, knowledge of Title I of the ADA can provide a foundation for OT intervention.

Title I of the ADA prohibits discrimination against individuals with disabilities in employment with private, nongovernment employers who have 15 or more employees. In a nutshell, the prohibition against discrimination in Title I states:

No covered entity shall discriminate against a qualified individual on the basis of disability in regard to job application procedures, the hiring, advancement, or discharge of employees, employee compensation, job training, and other terms, conditions, and privileges of employment.[74]

To understand this statement, one must understand the terms used by answering the following questions:

- Who is considered “an individual with a disability” under the ADA?
- What is a “qualified individual with a disability” under the ADA?
- What is considered “discrimination” under the ADA?

The ADA refers to “individuals with disabilities,” as opposed to “disabled individuals” to give voice to politically correct terminology that stresses the individual first, not the disability. It defines the phrase **individual with a disability** broadly under three umbrella categories, which are considered in the court cases discussed in the next section.

Changes in the ADA

When Congress passed the original ADA, it intended to create an inclusive society in which people with disabilities would work, engage in everyday community activities, and benefit from state and local benefits and services side by side and on the same basis as people without disabilities.[81] Looking back, on the 25th anniversary of the ADA, we see that individuals with disabilities have achieved success in gaining access to participation in the community and government benefits and services.

Employment under Title I has proved to be the biggest disappointment with the ADA. Greeted with great fanfare by the disability community, the courts took a civil rights bill intended to provide employment rights for people with disabilities and decimated its intent. Though originally given a broad mandate by Congress and intended to cover all who fit within the definition of “individual with a disability,” the Supreme Court and lower courts chipped away at these protections and narrowed the definition of “individuals with a disability.”

Ruling on three cases in one day, the Supreme Court severely restricted protection for individuals with disabilities in the employment arena.[79] For example, the Court ruled that individuals were not considered persons with disabilities if they used ameliorative measures to reduce the impact of their disabling condition.[101] The lower courts interpreted this to mean that someone with diabetes who took insulin was not considered a person with a disability.[93]

In *McClure v. General Motors Corp*., 75 Fed. Appx. 983 (5th Cir. 2003), the court held that Mr. McClure's fascioscapulohumeral muscular dystrophy, which prevented him from lifting his arms above his shoulders and required him to use an accommodation to perform his job as a mechanic, did not make him a person with a disability. The court stated, "But the evidence [of limitations from his fascioscapulohumeral muscular dystrophy] does not show that these differences rise to the level of severe restrictions."[98] Like Carlotta, Mr. McClure had many adaptive devices that "ameliorated the effects"[98] of his disability and its impact on everyday activities.

The lower courts also interpreted the Supreme Court's restrictions as imposing significant restrictions on individuals with intellectual disabilities. As presented in *Littleton v. Wal-Mart,*[97] Mr. Littleton had an intellectual disability and, with the assistance of a job coach, went for an interview with Wal-Mart for a shopping cart attendant position. Although arrangements were made in advance for the job coach to attend the interview, when they arrived, Wal-Mart's personnel would not allow the job coach to attend the interview. Mr. Littleton did not get the job. The court acknowledged that Mr. Littleton had an intellectual disability, which it referred to as "mental retardation," a term now considered offensive. In denying Mr. Littleton a trial and declaring that he was not an individual with a disability, the court said in its opinion, "He has pointed to no evidence which would create a genuine issue of material fact regarding whether he was substantially limited in the major life activity of learning because of his mental retardation [now referred to as intellectual disability]."[97] The Supreme Court refused to hear Mr. Littleton's appeal. (128 S.Ct. 302 [2007]0.

The court also said that episodic conditions, such as epilepsy, did not qualify as a disability. For example, in *Todd v. Academy Corp.*,[108] the court found that Mr. Todd was not an individual with a disability because the effects of his seizures were not substantial, since they lasted "only" 10 to 15 seconds and did not occur frequently enough.[108] In another case, *EEOC v. Sara Lee,*[92] the court held that the employee was not entitled to a reasonable accommodation from the employer because the employee took medications for seizures and therefore was not a person with a disability.[92]

The Supreme Court further limited the rights of people with disabilities when it reviewed what it means to be "substantially limited in a major life activity" in the case of *Williams v. Toyota Motor Mfg*.[115] Mrs. Williams had tendinitis and cumulative trauma syndrome. The Court declared that people with disabilities had to have multiple limitations in their everyday activities to be considered a person with a disability; one limitation was not enough.[115]

As a result of these decisions, the ADA faded into a hollow promise for people with disabilities in employment. Its definitions were meaningless. Its safeguards no longer provided protection for people with any disability. Veterans returning from the wars in Iraq and Afghanistan with limb loss feared that employers could discriminate against them and that the courts would not stand behind them because of the mitigating effect of their prostheses. Carlotta could have found herself without the ADA's protection because her wheelchair and adaptive aids mitigated the impact of her arthritis.

The disability advocacy community lobbied Congress to change the law to restore Congress' original intent to ensure that people with disabilities could work and not face unnecessary discrimination. These efforts led to the passage of the ADA Amendments Act (ADAAA), which specifically rejects the Supreme Court's decisions and broadens the definitions portion of the ADA to return the law to its original intent: a broad scope of protection under the ADA.[74] It also extended all of its changes to the Rehabilitation Act of 1973.[82]

The first definition states that with reference to individuals, disability means "(i) A physical or mental impairment that substantially limits one or more of the major life activities of such individual."[41] A physical or mental impairment includes "any physiological disorder or condition, cosmetic disfigurement or anatomical loss affecting one or more of the following body systems: neurological, musculoskeletal, special sense organs, respiratory (including speech organs), cardiovascular, reproductive, digestive, genito-urinary, hemic and lymphatic, skin, and endocrine."[44] The revised definition of physical or mental impairment included most of the traditional medical diagnoses seen by OTs in the individuals they treat; including, for example, individuals with multiple sclerosis, spinal cord injury, cerebrovascular accident (CVA), cerebral palsy, and arthritis—Carlotta's condition—which affects the musculoskeletal system. Mental or psychological impairments included "any mental or psychological disorder, such as an intellectual disability [formerly termed 'mental retardation'], organic brain syndrome, emotional or mental illness, and specific learning disabilities."[45]

The ADAAA broadened the meaning of the phrase "substantially limits" based on Congress' finding that the former regulation that defined "substantially limited" to mean "significantly restricted" was inconsistent with congressional intent because the standard was too high.[81,83] The ADAAA specified that the term "substantially limits" be interpreted consistently with the findings and purposes of the ADAAA enacted in 2008.[84]

The implementing regulations incorporated the policies that Congress outlined in the ADAAA into a series of rules to help define "substantially limiting." The closest one to an actual definition states:

An impairment is a disability within the meaning of this section if it substantially limits the ability of an individual to perform a major life activity as compared to most people in the general population. An impairment need not prevent, or significantly or severely restrict, the individual from performing a major life activity in order to be considered substantially limiting. Nonetheless, not every impairment will constitute a disability within the meaning of this section.[48]

The remaining rules explained how to interpret this general rule. As Congress intended, the rule was to be interpreted "broadly in favor of expansive coverage"[48] so that people such as Carlotta were covered by the ADA. Furthermore, the ADAAA required that lawsuits brought under the ADA focus on whether employers "complied with their obligations and whether discrimination has occurred, not whether an individual's impairment substantially limits a major life activity."[48] Accordingly, the threshold issue of whether an impairment "substantially limits" a major life activity should not demand extensive analysis.[48]

At the same time, the regulations say that the "determination of whether an impairment substantially limits a major life activity requires an individualized assessment."[47] This is an area where OTs can provide consultation. If Carlotta must prove that she is an individual with a disability, the OT can help provide the individualized assessment of her disability and specify the major life activities limited by her arthritis. The regulations reiterate that the standard used for this assessment is lower than the previous "substantially limited" standard.[47]

The regulations also say that the "comparison of an individual's performance of a major life activity to the performance of the same major life activity by most people in the general population usually will not require scientific, medical, or statistical analysis."[49] However, an individual with a disability, such as Carlotta, could present "scientific, medical, or statistical evidence" to show the comparison, which could include evidence from an OT assessment.[49]

The other rules governing "substantially limited" incorporated the specific concerns that Congress expressed in the law to address the problems created by the Supreme Court cases: mitigating measure, impairment that is episodic or in remission, and impairment in only one major life activity. Under the ADAAA, the ameliorative effects of mitigating measures would no longer play a role in the determination of whether an impairment substantially limited a major life activity.[50] Congress specified examples of mitigating measures as follows[84]:

1. "medication, medical supplies, equipment, or appliances, low-vision devices (which do not include ordinary eyeglasses or contact lenses), prosthetics including limbs and devices, hearing aids and cochlear implants or other implantable hearing devices, mobility devices, or oxygen therapy equipment and supplies"

2. "use of assistive technology"

3. "reasonable accommodations or **auxiliary aids** or services"

4. "learned behavioral or adaptive neurological modifications"

An episodic impairment or one that is in remission is considered a disability "if it would substantially limit a major life activity when active."[51] An impairment need limit only one major life activity to be considered a substantially limiting impairment.[52] For Carlotta, this means that none of the following circumstances—her use of assistive technology, a limitation only in walking, and remission of her arthritis—would prevent her from qualifying as substantially limited or a person with a disability.

Major life activities include many areas of occupation and functions related to activities of daily living (ADLs), including "but … not limited to, caring for oneself, performing manual tasks, seeing, hearing, eating, sleeping, walking, standing, sitting, reaching, lifting, bending, speaking, breathing, learning, reading, concentrating, thinking, communicating, interacting with others, and working."[46] Another category of major life activities includes "operation of a major bodily function, including functions of the immune system, special sense organs and skin; normal cell growth; and digestive, genitourinary, bowel, bladder, neurological, brain, respiratory, circulatory, cardiovascular, endocrine, hemic, lymphatic, musculoskeletal, and reproductive functions. The operation of a major bodily function includes the operation of an individual organ within a body system."[46]

Sometimes, when determining whether a person is limited in a major life activity, one may want to look at the condition under which individuals perform the activities, the manner in which they perform them, and/or how long it takes individuals to perform them.[48] However, the regulations give examples of certain disabilities that one could easily conclude will substantially limit at least the major life activity indicated in Box 15.1.

Box 15.1

Impairments That Substantially Limit Major Life Activities

- Deafness substantially limits hearing.
- Blindness substantially limits seeing.
- An intellectual disability (formerly termed mental retardation) substantially limits brain function.
- Partially or completely missing limbs or mobility impairments requiring the use of a wheelchair substantially limit musculoskeletal function.
- Autism substantially limits brain function.
- Cancer substantially limits normal cell growth.
- Cerebral palsy substantially limits brain function.
- Diabetes substantially limits endocrine function.
- Epilepsy substantially limits neurological function.
- Human immunodeficiency virus (HIV) infection substantially limits immune function.
- Multiple sclerosis substantially limits neurological function.
- Muscular dystrophy substantially limits neurological function.
- Major depressive disorder, bipolar disorder, posttraumatic stress disorder, obsessive compulsive disorder, and schizophrenia substantially limit brain function.

Adapted from 29 CFR §1630.2 (j)(3)(i-iii).

The OT evaluation provides the information the court will want to use to make a determination whether an individual is substantially limited in major life activities. OTs may find themselves assisting employers, attorneys, and others by providing this information, if requested.

The OT evaluation of Carlotta shows that she has arthritis, which substantially limits the major life activity of walking. Carlotta's arthritis also substantially limits her musculoskeletal function. She has difficulty participating in or is unable to participate in a variety of tasks related to everyday living. In light of these limitations, she probably falls under the first definition of disability.

The second definition of an individual with a disability under the ADA includes someone who has a record of having had such an impairment, as described in the first definition.[42] This category includes individuals with a history of a disabling condition, such as a person who had multiple sclerosis that is now in remission, or a person who has been cured of hepatitis C.

The third definition of an individual with a disability includes situations in which a person is regarded as having a substantially limiting impairment that is a perception of a disability based on myths, misperceptions, fears, and stereotypes.[43] For example, suppose a morbidly obese individual, Sue, seeks a promotion to a position that requires frequent trips out of town. The person empowered to decide whether Sue gets that promotion assumes that Sue will have difficulty managing the traveling because of her size. The manager is concerned that Sue will struggle with walking through the airports, breathing, and other nonsedentary aspects of her job. Sue has had a perfect attendance record and has always received excellent performance appraisals. The manager bases his failure to promote Sue on his assumptions about her supposed difficulty walking, breathing, and completing nonsedentary tasks, and these assumptions are simply not true. The manager regards Sue as being an individual with a substantially limiting impairment.

Individuals Not Covered by the ADA

The ADA provides protection against disability discrimination only for those who meet the criteria outlined earlier. This means that individuals with temporary impairments, such as a broken leg or a knee replacement that is likely or expected to heal normally, will not find that the ADA protects them. Individuals who have impairments that are not substantially limiting, such as a visual limitation correctable with eyeglasses, will not find benefits under the ADA.

Furthermore, the ADA enumerates specific exclusions in its definition of disability. It does not provide protection for individuals who fall into one of the following categories: transvestites, homosexuals, pedophiles, exhibitionists, voyeurs, gender disorders not caused by physical impairments, and other sexual behavior disorders.[63] The ADA further excludes from its protection illegal drug users, compulsive gamblers, kleptomaniacs, pyromaniacs, and alcoholics whose alcohol use prevents them from performing their jobs.[64] The ADA does provide protection against discrimination based on disability for recovering illegal drug users, as long as they participate in a rehabilitation program.

Qualified Individuals

Title I of the ADA does not protect all individuals with disabilities. It protects only those who are qualified individuals with a disability. The ADA specifies that “the term ‘qualified,’ with respect to an individual with a disability, means that the individual satisfies the requisite skill, experience, education and other job-related requirements of the employment position such individual holds or desires and, with or without reasonable accommodation, can perform the essential functions of such position.”[53] The first inquiry in deciding whether an individual with a disability meets the basic job requirements looks at the individual's amount of experience, level of education, and skills necessary to perform the job. Carlotta meets these requirements because the school hired her as a qualified teacher more than 18 years ago; therefore, she meets the basic education, skills, and experience requirement. The next inquiry is whether the individual can perform the essential functions of the job.

Essential Job Functions

The ADA defines **essential job functions** as job duties fundamental to the position that the individual holds or desires to hold, as opposed to functions that are marginal functions.[54] Essential functions are those that the individual who holds the position must be able to perform with or without the assistance of a reasonable accommodation. One may consider a function essential because the position exists to perform the particular function. These essential functions are usually obvious. For example, a typist must type, and a proofreader must proofread.

A function is essential because of the limited number of employees available who can share the particular function. For example, because there are only three Spanish teachers at Carlotta's school, Carlotta must collaborate with the other two Spanish teachers to write and direct the annual Spanish language pageant. If the school employed 20 Spanish teachers, it could divide responsibilities so that Carlotta did not have to participate in the annual Spanish language pageant.

An essential function is also one in which the function is so specialized that the employer hires the person in the position for his or her particular expertise or ability to perform that function. For example, the position of brain surgeon is a highly specialized one, and the person in this position is hired to perform highly technical surgery.

Whether a function is an essential function is determined on a case-by-case basis. Specific evidence will support whether a particular function is essential. The Equal Employment Opportunity Commission (EEOC), the federal agency that enforces Title I's provisions, and the courts look at seven factors[55] as evidence of whether a function is essential (Box 15.2).

Box 15.2

Seven Factors That Determine Essential Job Functions

- The employer's judgment of which functions are essential
- Written job descriptions prepared before the hiring process begins
- The amount of time spent performing the job function
- The consequences of not requiring the performance of a particular function
- The terms of the collective bargaining agreement
- The work experience of previous employees who held the job
- The current work experience of incumbents in similar positions

In some situations, essential functions are obvious. For example, the essential functions of a receptionist's position may include answering telephones, taking messages, and greeting and announcing visitors. Typing may be a marginal function for a receptionist in a very busy office where the receptionist has not had to type anything at all over the last 6 months. Essential job functions are determined on a case-by-case basis by looking at the facts of each situation. OTs can help determine essential job functions by looking at the job description, by conducting focus groups with employees, and by performing a job analysis as discussed in Chapter 14.

In determining essential job functions, the focus must be on the outcome or job tasks that employers expect employees to perform. The definition of essential job functions focuses on the concept of job duties or expected outcomes, not the physical demands required to perform a job duty. In other words, an essential function is a task that one must perform to perform the job, not a physical function. Essential functions are not bending, lifting, walking, climbing, or other physical demands. For example, being a mail clerk for a large corporation includes delivering mail as one of the essential functions. The essential function is not walking and carrying the mail, but rather the outcome of delivering the mail. A mail clerk who is not able to carry the mail could push the mail on a cart to accomplish the same result or outcome. Essential functions are what you do, not how you do it.

The job description, job analysis, and discussions with Carlotta about her job show that as a teacher, Carlotta must perform several essential functions, including grading papers and tests and recording their results, discussing student progress with parents, preparing lesson plans, motivating students, and maintaining order in the classroom. (Note that these essential functions are all specific job tasks and not physical functions, such as "hand manipulation skills for writing" or "walking around the classroom.") The OT evaluation shows that Carlotta is able to perform these functions for her position as a Spanish teacher. However, she may have difficulty maneuvering around the classroom to the desks of the individual students because of steps and multiple levels in the former band classroom in which she currently teaches Spanish. Carlotta will also have difficulty writing on the blackboard from a wheelchair. The key to facilitating Carlotta's continued participation in the workplace lies in making reasonable accommodations.

Reasonable Accommodations

The ADA defines **reasonable accommodations** as any change in the work environment or in the way that work is customarily performed that enables an individual with a disability to enjoy equal employment opportunity.[56] Not all employees are entitled to reasonable accommodation. Employers need to make reasonable accommodations only for employees with disabilities who are qualified (Box 15.3).

Box 15.3

Progression of Reasonable Accommodations Decision

Step 1: Is the Individual with a Disability Qualified (IWD)?

Does the individual meet one or more of the following criteria?

- A physical or mental impairment that substantially limits one or more major life activities
- A history of having had such an impairment
- Regarded as having such an impairment

If the worker is not an IWD, the employer does not have to accommodate.

Step 2: Is the Individual with a Disability Qualified?

Does the individual meet both of the following criteria?

- Individual satisfies the requisite skills, experience, education, and other job-related requirements of the job
- Individual can perform the essential functions of such position with or without reasonable accommodations

If the worker is not qualified, the employer does not have to accommodate.

Step 3: Is the Accommodation Reasonable?

- How much does the accommodation cost in relation to the size and budget of the business?
- Are there tax credits or deductions or outside funding sources to pay for the accommodation?
- Does the accommodation interfere with the operation of the business or the ability of other employees to perform their duties?

If it is not reasonable, the employer does not have to accommodate.

Courtesy Barbara L. Kornblau, ADA Consultants.

Reasonable accommodations include three subcategories. First, reasonable accommodations include modifications or adjustments in the job application process that enable consideration of a qualified applicant with a disability for employment in a position that the person wants.[57] This would include reading a job application to an individual with dyslexia or modifying the way a preplacement screening is performed to accommodate an individual with one hand. If Carlotta were to apply for another position, her potential employer would need to provide her with an accessible entrance to the human resources department so that she could obtain a job application.

The potential employer would also have to allow her to use a larger pen for filling out an application because she uses the larger pen to prevent joint changes in her hand. As an alternative, the potential employer can provide someone to assist her in filling out the application.

The modifications and adaptations that OTs most typically provide fall under the umbrella of the second category of reasonable accommodations. The second category includes modifications or adjustments to the work environment or to the manner or circumstances in which the position is customarily performed to enable an individual with a disability who is qualified to perform the essential functions of that position.[58] OTs have traditionally been involved in this area by modifying job sites, including raising or lowering work heights, making a jig, or having the individual with a disability use a piece of equipment (eg, a cart) to move objects rather than carrying them.

OT Practice Notes

OTs may help human resources personnel to understand how disabling conditions, and the limitations in performance skills and client factors that accompany them, can affect the hiring process. In addition, OTs can suggest appropriate, reasonable accommodations available for the application and interview process, which can prevent unintentional discrimination.

Carlotta's continued participation in her work environment will require reasonable accommodations in her intervention plan, in the form of changes in the way the work is performed. For example, Carlotta's employer could reasonably accommodate her by moving her to a different classroom, one that is on a single level and that does not have steps or risers; this would provide Carlotta physical access to the students at their desks. Carlotta could also benefit from a laptop computer with a projector that has a liquid crystal display (LCD), which will eliminate the need for her to write on the board—an impossible task from wheelchair level. (See Chapter 14 for a more detailed discussion of job modifications.)

OTs and OTAs working on the development of reasonable accommodations should note that employers must provide an effective reasonable accommodation—this means one that works, not the most expensive accommodation or the specific accommodation the employee wants. Although the employee suggests the specific type of accommodation, ultimately the employer gets to select the accommodation used. If a shoebox with some rubber bands wrapped around it works as well as the high-tech computerized gadget that the employee requests, the employer need only provide the shoebox with the strategically placed rubber bands.

The third category of reasonable accommodations includes modifications or adjustments that enable employees with a disability to enjoy equal benefits and privileges of employment as other similarly situated employees without disabilities enjoy.[59] For example, suppose the language department at Carlotta's school customarily holds an annual international fair for all the students and their families at the school. The teachers compete by class for the best food, costumes, and projects. The teacher of the winning class wins prizes supplied by the Parent-Teacher Association (PTA). Under the ADA, the school would be required to hold the fair at an accessible location so that Carlotta could participate. This would also apply to the school's annual holiday party and all other school functions for employees. OTs can improve awareness on the part of employers, assist them in making reasonable accommodations, and help sensitize them to the needs of individuals with disabilities in these situations.

According to the ADA, reasonable accommodations may include physical changes to make facilities accessible, in addition to other nonenvironmental changes. Depending on the individual circumstances, reasonable accommodations can include job restructuring; part-time or modified work schedules; reassignment to a vacant position; acquisition or modification of equipment or devices (eg, Carlotta's laptop computer and LCD projector); appropriate adjustment or modification of examinations, training materials, or policies; provision of qualified readers or interpreters; and other similar accommodations for individuals with disabilities.[57,58]

For example, an individual who needs to begin kidney dialysis may find that leaving work early 3 days a week reasonably accommodates his needs. Allowing a cashier with fatigue from multiple sclerosis to sit instead of stand while working may reasonably accommodate her needs. Because of their knowledge of the limitations of impairments and how to adapt the work environment to the individual, OTs can suggest and/or design many of these accommodations while working with the client. Carlotta has a good understanding of much of what she needs to reasonably accommodate her work needs, and her intervention plan should incorporate her insights and suggestions.

The most efficient way for employers to identify the reasonable accommodations that an individual employee may need is to initiate an informal, interactive process with the qualified individual with a disability in need of the accommodation.[86] Employers will find that individuals with a disability are often in the best position to determine which reasonable accommodations they may need to enable job performance. OTs may participate in this effort when the parties need additional expertise to make these accommodations. The EEOC recognizes the expertise of OTs in helping employers and individuals with disabilities make reasonable accommodations.[90]

The ADA provides an exception to the employer's requirement to provide reasonable accommodations for qualified individuals with disabilities. Employers need not provide reasonable accommodations when provision of the accommodation would cause an undue hardship to the employer. **Undue hardship** refers to any accommodation that would be unduly costly, extensive, substantial, or disruptive or that would fundamentally alter the nature or operation of the business.[60] For example, it would probably be an undue hardship for the school to fix Carlotta's classroom by ripping out the floor in the old band room to remove the risers and level the floor because this would eliminate the use of a very needed classroom for an extended period and might represent a significant expense. The alternative, to swap classrooms with another teacher, would be more cost-effective and less disruptive.

Determination of whether an accommodation presents an undue hardship to the employer involves looking at whether the proposed action requires significant difficulty or expense when the following factors are considered[61]:

- Nature and cost of the accommodation needed in light of tax credits and deductions and/or outside funding
- Overall financial resources of the facility, the number of people employed at the facility, and the effect on expenses and resources
- Overall financial resources, overall size of the business, and the number, type, and location of facilities
- Composition, structure, and functions of the workforce
- Impact of the accommodation on operation of the facility, including impact on the ability of other employees to perform their duties and impact on the facility's ability to conduct business

According to the Job Accommodations Network,[95] a federally funded program that has provided technical assistance in making accommodations for more than 25 years, data show that more than 50% of all accommodations cost nothing. The network's statistics also show that employers experience financial gains from the decreased costs of training new employees, a decrease in insurance costs, and an increase in worker productivity.

Discrimination Under the ADA

The ADA does not give one specific definition of discrimination. Instead, it specifies at least nine categories of activities considered discriminatory.

Limiting, classifying, or segregating.

The first prohibited activity includes limiting, classifying, or segregating the employee because of his or her disability.[65] For example, if Carlotta's school were to require all employees who use wheelchairs for mobility to work in one wing of the first floor, it would be segregating the employees with disabilities. This section also forbids employers from asking any questions about an applicant's worker's compensation history during the interview or on the employment application because employers can use this information to limit or classify individuals because of their disability.

Poor disability etiquette can lead to limiting, classifying, and segregating individuals with disabilities in the workplace. The way coworkers treat people with disabilities and the language they use to refer to individuals with disabilities can also make people feel bad or left out of the workplace culture. One method employers may use to avoid limiting, classifying, or segregating employees because of their disabilities is to sensitize supervisors and other employees to working with individuals with disabilities. Nondisabled individuals who lack familiarity in socializing with individuals with disabilities may not know how to shake hands with a person who does not have a right hand. They may shout at a person who is deaf, instead of speaking clearly and facing the person with the hearing impairment.

OT Practice Notes

OTs can assist employers in providing sensitivity training experiences similar to those used in some OT program classrooms to develop an understanding of the disability experience. Giving coworkers time in a wheelchair or with a blindfold during planned activities can help them experience functional limitations, if only for a brief time, that may encourage the development of some sensitivity to how it feels to have limitations in performance and participation. Using lay language free of confusing jargon during this kind of training makes it easier to get the message across to coworkers unfamiliar with OT lingo.

OTs can work with supervisors and coworkers on basic disability etiquette tips, such as using politically correct terminology in which, as mentioned earlier, the person comes before the disability. For example, using the phrase “a person who had a stroke” is better than calling someone a “stroke patient” or “stroke victim” because the word *victim* has negative connotations. Using the phrase “wheelchair user” is more appropriate than “wheelchair bound” because no one is physically bound to the wheelchair, as a book is bound to its binding. Box 15.4 gives more tips on disability etiquette, and Box 15.5 presents tips on conducting the interview process.

Box 15.4

Disability Etiquette Do's and Don'ts

- Do try to treat an individual with disabilities as you would treat any other person.
- Don't raise your voice at someone because he or she is in a wheelchair or has a visual or hearing impairment.
- Do address the person, not the wheelchair, interpreter, or guide.
- Don't trap yourself into thinking, “If I were disabled, how would I feel?”
- Do refer to an individual with a disability as “an individual with a disability.”
- Don't refer to an individual with a disability as “the quadriplegic” or “Mary is a diabetic or epileptic.”
- Do cleanse your vocabulary of offensive, outdated terms, such as wheelchair bound or stroke “victim” or as “afflicted with …” or “suffering from …”
- Don't refer to able-bodied persons as “normal.”
- Do avoid generalizations such as “People with epilepsy are unpredictable” or “People with learning disabilities are not very intelligent.”
- Don't apologize for comments such as “Let's take a walk” to an individual in a wheelchair or “Do you see my point?” to a person with a visual impairment.
- Do avoid statements such as “I admire your courage” or “You've done so much for a person in a wheelchair.”
- Don't use outdated terminology such as “handicapped,” “crippled,” “retarded,” “lame,” “the disabled,” or “the handicapped.”
- Do provide assistance only in the manner requested.
- Don't take hold of an individual's wheelchair or push his or her wheelchair unless asked to do so.
- Do put yourself on the same level as the individual in a wheelchair as soon as possible by sitting down during the conversation or interview.
- Don't turn away when conversing with an individual with a hearing impairment.
- Do speak directly to the person, not the interpreter.
- Don't complete the sentences of an individual with communication impairments.
- Do rid your thinking of stereotypes about disabilities.
- Don't perpetuate another person's insensitivity to an individual with a disability.

Box 15.5

Interview Do's and Don'ts

- Don't make notes about an individual's physical or mental condition.
- Do discuss reasonable accommodations when possible. The interviewee is an expert on accommodating his or her disability.
- Don't rely on body language as a measure during the interview process. Lack of eye contact or a mild grip handshake may be caused by an applicant's disability, not his or her lack of confidence.
- Do remember that individuals with disabilities may make poor interviewees if judged against many "traditional" interviewing standards.
- Don't try to put yourself in the applicant's place and ask yourself, "Could I do this job if I were disabled?"
- Do offer an applicant a job based on his or her abilities, not disabilities.
- Don't job stereotype.
- Do remember that communications skills are often an inaccurate measure of the intelligence, ability, or confidence of an individual with a speech or hearing problem.
- Don't patronize the applicant with a disability with your own body language.

Contractual relationships that discriminate.

The second prohibited activity includes participating in a contractual or other relationship that results in discrimination against qualified applicants or employees because of their disability.[66] This provision applies to collective bargaining agreements, contracts with employment agencies, and other contracts. For example, suppose Carlotta's employer contracted with an outside company to provide continuing education courses at her school. The continuing education company would have to comply with the ADA by offering reasonable accommodations when needed, such as allowing Carlotta to tape sessions or providing her with a note taker if she is unable to take notes during the classes. The OT could work with the continuing education provider to help develop other reasonable accommodations for Carlotta and other individuals with disabilities.

Using standards, criteria, and methods of administration that discriminate.

The third prohibited activity includes the use of standards, criteria, or methods of administration that are not job related and consistent with business necessity and that have the effect of discrimination based on the disability.[67] For example, an employer could not require that Carlotta have a driver's license for promotion to chair of the Spanish Department if driving is not an essential function of the position.

Employers may use a **direct threat** standard to exclude from employment individuals whose disabilities pose a direct threat to the health and safety of themselves or others in the workplace.[62] However, the direct threat must pose a significant risk for substantial harm to the health or safety of the individual or others that employers or others cannot eliminate or reduce to less than a significant risk by reasonable accommodation. Employers must consider the duration of the risk, the nature and severity of the potential harm, the likelihood that the potential harm will occur, and the imminence of the potential harm.[62]

For example, suppose Carlotta wanted to swap classrooms with a teacher whose classroom is on the second floor of the school, which has three stories and an elevator. The headmaster could not refuse to allow Carlotta to use this second-floor classroom because he fears that Carlotta, as a wheelchair user, would pose a direct threat in the event of a fire. The chance of a fire occurring is small; therefore, little likelihood exists that any harm will occur. Moreover, the school could develop an emergency plan in advance that would further lower the risk.

Employers must base the determination that an individual poses a direct threat on an individualized assessment of the person's present ability to safely perform the essential functions of the job. Employers must base the assessment on a reasonable medical judgment that relies on the most current medical knowledge and/or on the best available objective evidence.[62]

The regulations suggest that employers seek opinions from professionals who have expertise in the disability involved or direct knowledge of the individual with the disability. The EEOC recognizes that documentation of direct threat can come from OTs "who have expertise in the disability involved and/or direct knowledge of the individual with a disability."[90] Often a reasonable accommodation can reduce the risk. For example, say that a teenager with epilepsy has a seizure every time the buzzer goes off on the fryer while he is working at the local fast-food restaurant. The OT could suggest that the employer could reasonably accommodate him by changing the buzzer to a bell.

Discrimination based on association with an individual with a disability.

The fourth prohibited activity includes excluding or otherwise denying an equal job or benefits to a qualified individual because of a disability identified in an individual with whom the qualified individual is known to have a family, business, social, or other relationship or association.[68] For example, an employer could not refuse to hire Carlotta's husband because Carlotta has arthritis and is in a wheelchair, and the employer is worried that Carlotta's husband may have excessive absences because of Carlotta's condition. In fact, this principle prohibits the employer from asking any questions that may reveal information about his wife's disability.

Failing to make a reasonable accommodation.

The fifth prohibited activity includes failing to make a reasonable accommodation after a request for a particular accommodation for a known disability of a qualified individual or denying someone employment to avoid providing a reasonable accommodation, unless the employer can show that the accommodation would impose undue hardship on operation of the business.[69] As discussed previously, the OT can play a major role in assisting employers to determine reasonable accommodations. Carlotta's intervention plan includes her need for the following reasonable accommodations: a laptop computer with an LCD projector and a one-level classroom. Carlotta must request the specific accommodations that she wants. As part of the intervention plan, the OT may prepare a report for the school as documentation, explaining Carlotta's need for the particular accommodations, for submission with Carlotta's accommodation request. The OT may meet with the school's staff members to help them understand the needed accommodations. Should Carlotta's school fail to make the reasonable accommodations she requests, it would violate this provision of the ADA.

The employer must know that a prospective or actual employee is an individual with a disability before its obligation to make accommodations arises. Courts have found that an employer cannot discriminate based on disability if it does not know about the disability *(Morisky v. Broward County).*[100] Vague statements about one's limitations or past are not sufficient to put the employer on notice of a disability.[100] Disabilities such as multiple sclerosis, arthritis, learning disabilities, and mental health disorders may not be as obvious to an employer as the disability of a person in a wheelchair. To obtain reasonable accommodations for these hidden disabilities, employees or potential employees must disclose their disability to the employer. OTs can work with clients as employees or potential employees in determining whether to disclose the disability, when to disclose it, and how to disclose it.

Employment tests that screen out individuals with disabilities.

The sixth prohibited activity involves using employment tests that tend to screen out individuals with disabilities on the basis of their disability, unless the test is shown to be job related for the position in question and is consistent with business necessity.[70] The EEOC considers a test job related if it measures a legitimate qualification for the specific job in question.[90] A test is not consistent with business necessity if it excludes an individual with a disability because of the disability and is not related to the essential functions of the job.[90] For example, under this section of Title I, the private school where Carlotta works could not give a written, 12th grade–level reading test to an individual with a known learning disability who applies for a janitorial position. The janitorial position requires reading labels, which are on a fourth-grade reading level. The 12th grade–level test would screen out the applicant based on her disability and is neither job related nor consistent with business necessity.

Administering tests to measure physical attributes, not skills or aptitudes.

The seventh prohibited activity involves failing to administer tests in a manner to ensure that when administered to a job applicant or employee with a disability that impairs sensory, manual, or speaking skills, the test results accurately reflect the skill, aptitude, or whatever other factor of the applicant or employee that the test purports to measure rather than the sensory, manual, or speaking skills, except when such skills are the factors that the test purports to measure.[71] For example, in *Stutts v. Freeman*,[107] an individual with dyslexia was denied a heavy equipment job because he could not pass the written test required to enter a training program. The standard that he pass a written test had the effect of discriminating against the plaintiff as a result of his disability because the test was not meant to test the applicant's ability to read and write but rather his knowledge of heavy equipment operation. Had the employer administered the test orally, the potential employer would have focused on evaluation of the applicant's qualifications for the job, not his ability to read the material.

Retaliating against individuals who file discrimination claims.

The eighth prohibited activity prevents employers from retaliating against individuals who file claims for discrimination under Title I.[72] Before an applicant can file a lawsuit in court under Title I, he or she must file a complaint with the EEOC. This section prohibits an employer from firing, demoting, or otherwise retaliating against an employee who files a charge of discrimination with the EEOC or otherwise pursues his or her rights under this law.

Conducting preemployment medical exams or inquiries.

The ninth and final prohibited activity prevents employers from conducting preemployment medical examinations of an applicant or employee, or inquiring into whether the applicant is an individual with a disability or the nature and extent of the person's disability, before the employer extends an offer of employment to the applicant.[73] Under the ADA, a medical examination means a "procedure or test that seeks information about an individual's physical or mental impairments or health."[91] The EEOC considers a variety of factors in deciding whether a test is a medical exam. These factors include, among others, whether the test is administered or the results interpreted by a healthcare professional or someone trained by a healthcare professional; whether the test is designed to reveal an impairment; and whether the test measures the applicant's performance of a task or his or her physiological responses to performing the task.[91]

Preplacement Screenings and Functional Capacity Assessments

The preplacement screenings and functional capacity assessments provision of Title I affects the way OTs do business. OTs are often involved in preplacement screenings and functional capacity evaluations, which are sometimes considered under the category of fitness-for-duty exams. Employers often hire OTs to perform these tests (see Chapter 14). The ADA regulations outline the types of testing that employers (or those acting on their behalf) may perform and the stages at which they may perform them.

The hiring process involves two relevant stages. The first stage, the preoffer, occurs during the interview process, before an employer extends an offer of employment to an applicant or candidate. The second stage, the postoffer, occurs after the employer has made a hiring decision and extends an offer of employment to the applicant or candidate. We often speak of this offer of employment as a conditional offer of employment because it is subject to withdrawal under certain circumstances, which this chapter addresses later.

During the preoffer stage, an employer may conduct only a simple agility test. Employers and OTs acting on their behalf may not conduct medical examinations or inquiries, preemployment physical examinations, preplacement screening, or functional capacity assessments during the preoffer stage. An agility test is a simple test that looks at a person's physical agility. It is not a medical test. Agility tests do not involve medical examinations, physicians, or medical diagnoses. Employers may request clearance from the applicant's physician before administering an agility test.[90] The classic agility test for police recruits shows them running through tires, scaling a wall, and climbing ropes. Another example of a permissible agility test would include an employer asking an applicant to carry a piece of wallboard from one end of the construction site to the other.

Although employers may conduct these agility tests, the ADA rules govern their use. If an employer chooses to use an agility test, he or she must give the test to all similarly situated applicants or employees. If the agility test screens out individuals with disabilities, the employer must show that the test is job related, consistent with business necessity, and that the applicant could not perform the job with a reasonable accommodation.

During the postoffer stage, employers or those acting on their behalf may conduct agility tests, medical exams and inquiries, preemployment physicals, preplacement screenings, and functional capacity assessments. If the employer chooses to give medical exams, once a conditional offer of employment has been made, he or she must give the exam to all employees entering the same job category. The ADA does not require that a medical exam satisfy the job-related and consistent-with-business-necessity standards. However, if the employer withdraws a conditional offer of employment because of the results of the medical exam, he or she must be able to show (1) the reasons for the exclusion are job related and consistent with necessity, or the person is being excluded to avoid a direct threat to health or safety, and (2) no reasonable accommodation was available that would enable this person to perform the essential functions without a significant risk to health or safety, or the accommodation would cause an undue hardship.

As mentioned earlier, during the postoffer stage, employers and OTs acting on their behalf may perform preplacement screenings and functional capacity assessments. Both are subject to the same requirements as medical exams. In other words, although the tests need not comply with the job-related and business-necessity requirements, should the tests screen out individuals with disabilities, job related and business necessity become the required standard to meet. Reality dictates then that to comply with the ADA, the preplacement screening must be job related and test only the essential functions of the job. For example, assessing Carlotta's hand strength as part of the interview process for hiring her as a Spanish teacher would violate this provision of the ADA because hand strength is not job related and not related to an essential job function.

Employers and those acting on their behalf must keep the results of all medical exams and inquiries confidential, with some limited exceptions. These exceptions include work restrictions information, insurance purposes, government investigations of ADA complaints, and state worker's compensation and second injury funds, which are funds set up by some states to encourage employers to hire individuals with previous workers' compensation–related or other injuries.

This prohibition against inquiries into medical and disability-related information also extends to job applications and interviews. Employers cannot ask questions about a person's disability, or questions that will lead to information about a person's disability, during the job interview process. Box 15.6 shows examples of questions employers may not ask during the interview process.

Box 15.6

Questions Not Permitted Under the ADA

- How did you become disabled?
- Are you in good health?
- Have you recovered from your prior disability?
- How much can you lift?
- How far can you walk?
- Have you been in a wheelchair your whole life?
- Do you have a driver's license? (if the job does not require driving or if a reasonable accommodation cannot eliminate the driving)
- Does your wife, husband, child, or roommate have a disability?

- Who takes care of your disabled husband (or wife or child)?
- Have you ever been injured in an accident?
- Have you ever filed a claim for worker's compensation?
- How were you burned?
- Do you have any physical conditions that would prevent you from doing your job?
- Do you have a good back?
- Have you ever been hospitalized?

OTs can assist human resources professionals in the proper way to inquire into an individual's ability to perform the essential functions of a position without asking prohibited questions. Employers must base their interview questions on specific job functions, information that OTs gather from the job analysis (described in more detail in Chapter 14). Ideally, the interviewer should have a job description prepared from the OT's job analysis and ask interviewees questions about the match between their skills and abilities and the job's essential functions.

Role of the Occupational Therapist

OTs can work with individuals with disabilities, as part of their intervention plan, to identify needed accommodations that will enable participation in the workplace; they also can help the individual plan a strategy to obtain those accommodations from the employer. OTs can help their clients understand their right to reasonable accommodations under Title I of the ADA. This includes the requirement to request the specific accommodations needed and to furnish documentation of the need, which the OT can prepare for the client to provide to the employer. OTs may find themselves advocating for the accommodations to their client's employer.

For example, as described earlier, Carlotta's OT can play a major role in her employer's provision of the accommodations she needs. Carlotta and her OT identified the accommodations she needs as part of her occupational profile and intervention plan. If the employer refuses to provide the accommodations after Carlotta provides the OT's documentation and if Carlotta eventually files a lawsuit, the OT may find himself or herself testifying in court about Carlotta's need for the accommodations.

OTs can also provide consultation services for employers who want to avoid litigation and who seek advice on making reasonable accommodations for their employees with disabilities. If Carlotta's employer were proactive, he or she may have contacted an OT for advice on how to accommodate Carlotta.

This kind of consultation, in which the client is the employer, not the individual with a disability, usually begins with a job analysis (see Chapter 14) to see what the job requires. The therapist compares this information with the individual's limitations and tries to develop accommodations to enable performance. This accommodation development stage cannot proceed without input from the person with the disability.

For example, the author was hired by a hospital to look at whether a nurse affected by some post-polio weakness and arthritis could use a scooter (wheelchair substitute–type scooter) as her requested accommodation to cut down on the number of steps she took during the day. The nurse had filed a charge of discrimination with the EEOC, and the hospital's attorney suggested hiring an OT to see whether the requested accommodations were reasonable, so that a full-blown lawsuit could be avoided if possible. The head nurse could not imagine a nurse using a scooter. The author performed a job analysis and determined that the scooter was a reasonable accommodation. Convincing the head nurse that the scooter was reasonable took more work in the form of sensitivity training (an area in which OTs also make major contributions).

Suppose Carlotta decided she did not want to return to her teaching position because she wanted a career change from classroom teaching. An OT might suggest that Carlotta look for jobs with potential employers who are federal government contractors. Federal government contractors must develop affirmative action plans to recruit, hire, promote, and retain people with disabilities, with a workplace goal of 7%.[114] This recent workplace mandate also requires employers to evaluate their hiring practices and adjust them to achieve this goal.[115] In theory, this means that as a person with a disability, Carlotta would have preference in hiring if she applied for a job with a company that contracts with the federal government, as long as she is qualified for the position.

If Carlotta were out of work for a period of time and needed to transition from disability benefits to employment, many work incentive programs exist to help ease her transition. OTs can learn more about the return-to-work incentive programs designed for people with disabilities from the Social Security Administration's "Red Book."[106]

Title II: State and Local Government Services

Title II of the ADA prohibits state and local government entities, and those with whom they contract, from denying a qualified individual with a disability participation in or the benefits of services, programs, or activities provided to individuals without disabilities.[23] Title II's antidiscrimination protection in the employment of individuals with disabilities by state governments has been limited by cases decided by the U.S. Supreme Court. Individual state employees can no longer bring lawsuits for monetary damage in federal court when a state discriminates in its employment practices based on the disability.[88]

Title II's other requirements look similar to those of Title III, described in detail later for nongovernment entities. However, Title II goes farther in its requirement for state and local government services than for privately owned entities in one particular concept:

Title II requires that government agencies give qualified individuals with disabilities equal opportunity to participate in or benefit from the state or local government aid, benefits, or services.[24] This requires providing more access than in Title III's requirements to provide what is readily achievable, as described later in this chapter. Providing equal opportunity to state and local government services requires taking specific measures that allow access to equal services. These may include making facilities physically accessible, making policy changes, providing reasonable accommodations in the form of auxiliary aids and services, providing accessibility in public transportation, and supplying communication aids, such as 911 services for people with hearing impairments. It may include other accommodations described more fully under Title III later in this chapter. OTs can help state and local governments make some of the needed changes, as will be discussed further in this chapter.

Title II and Title III were amended through the rule-making process, and new regulations took effect March 15, 2011.[110-112] Most of the changes apply to both Title II and Title III. Several are specific to Title II. In particular, residential housing programs and detention and correctional facilities run by state and local governments must now comply with the applicable design requirements listed in the new 2010 Standards for Accessible Design, commonly called the 2010 Standards.[111,113]

Title III: Public Accommodations

Title III of the ADA prohibits discrimination against individuals with disabilities in **places of public accommodation (PPAs)**. This description may seem slightly misleading because despite its name, this section of the ADA covers privately owned entities that own or lease to others, places that affect commerce. In other words, PPAs are privately owned entities where business of some kind is transacted or affected. The term PPA covers 12 broad categories enumerated in the ADA (Table 15.1).[25] The U.S. Department of Justice, the federal government agency charged with overseeing and enforcing Title III, reports that more than 5 million PPAs exist in the United States.[109]

TABLE 15.1

Places of Public Accommodation Under Title III

Category	Examples
Places of lodging	Hotels, motels
Establishments serving food or drink	Restaurants, bars
Places of exhibition or entertainment	Movie theaters, stadiums
Places of public gathering	Convention centers
Sales or rental establishments	Bakeries, shopping malls
Service establishments	Laundromats, funeral homes, physician's offices
Public transportation terminals	Train stations
Places of public display or collection	Museums, libraries
Places of recreation	Parks, zoos, amusement parks
Places of education	Preschools, private schools, colleges
Social service establishments	Day care centers, senior centers
Places of exercise or recreation	Health clubs, bowling alleys, golf courses

The “super rule,” which forms the basis for Title III, prohibits discrimination as follows:

No individual shall be discriminated against on the basis of disability in the full and equal enjoyment of the goods, services, facilities, privileges, advantages, or accommodations of any place of public accommodation by any private entity who owns, leases (or leases to), or operates a place of public accommodation.[26]

Under Title III, PPAs must remove barriers to access, and if the PPA cannot remove the barriers, it must provide an alternative or reasonable accommodation to enable access to the goods and services it provides. Many think of the barriers that Title III addresses as architectural barriers or barriers in the physical environment, such as steps and curbs, that limit physical access to a place a person desires to go. However, although many view the requirements of Title III as a quasi–building code, removing barriers to access as described in the ADA refers to more than mere access through removal of physical barriers. It also refers to access caused by attitudinal barriers and rules and to policies based on myths, misperceptions, and fears about individuals with disabilities that act as barriers to their access to PPAs.

For example, before the ADA became law, some banks refused to allow individuals who are blind to have safe deposit boxes. The rationale behind this policy was that because individuals who are blind cannot see what is in their safe deposit boxes, how can they remove things that they need from the box? Only the safe deposit box holder can go into the viewing booth. Based on misperceptions, banks believed themselves at risk for accusations of theft from the boxes, and consequently, they disallowed individuals who were blind from benefiting from the services they provided to individuals who were not blind. This practice discriminated against individuals with visual impairments. The ADA prohibits these practices and seeks to break down these kinds of barriers.

To further its mission of breaking down physical and attitudinal barriers, Title III specifies three broad principles that provide the foundation for its philosophy of inclusion of individuals with disabilities in society. First, PPAs must provide individuals with disabilities an equal opportunity to participate in or benefit from the goods and services offered.[27] Furthermore, PPAs must give individuals with disabilities an equal opportunity to benefit from the goods and services that they offer.[27] Finally, PPAs must provide the benefits in the most integrated setting possible.[27,28]

PPAs can violate Title III's mandates against discrimination by doing the following, among other things.

- Refusing to admit an individual with a disability merely because he or she has a disability.[27] For example, a restaurant cannot refuse to admit and/or serve an individual with cerebral palsy because he or she drools.
- Failing to provide goods and services to individuals with disabilities in the most integrated setting appropriate to the individual's needs.[28] For example, a professional or college football team cannot segregate all wheelchair users in a “handicapped” section in the end zone. It must allow wheelchair users to sit with family members and disperse wheelchair seating throughout the stadium.
- Using eligibility criteria that screen out or tend to screen out individuals with disabilities from full and equal enjoyment of goods and services.[30] For example, retail stores located in a busy tourist area require that individuals using credit cards show a driver's license as proof of identification as a way of cutting down on the use of stolen credit cards. However, this practice screens out individuals with visual impairments or other disabilities who do not qualify for driver's licenses. The retail stores would have to accept state identification cards in place of a driver's license from individuals with disabilities who do not qualify for driver's licenses.
- Failing to make reasonable modifications in policies, practices, or procedures when the modifications are necessary to offer goods, services, or facilities to individuals with disabilities.[31] The example given earlier about bank policies for safe deposit boxes and individuals who are blind is a good illustration of a policy that discriminates on the basis of disability. As another example, Great Grocery Store has a policy whereby cashiers must place all checks in a specific column in the cash drawer. Carlotta's OT recommended that she use large-print checks because she can write more legibly with larger print. She attempts to give the cashier a large-print check. The cashier refuses to take the check because it does not fit in the cash drawer column for checks. She also tells Carlotta that their policy is to accept large-print checks only from blind people. Great

Grocery Store must modify its policies and accept Carlotta's check.

- Failing to take steps to ensure that individuals with disabilities are not excluded or denied services, segregated, or otherwise treated differently from individuals without disabilities because of the absence of auxiliary aids and services.[33] Auxiliary aids as used in the ADA include devices that OTs usually refer to as adaptive equipment or assistive technology. According to the regulations, auxiliary aids and services include, among other things, qualified interpreters on site or through video remote interpreting (VRI) real-time computer-aided transcription services, assistive listening devices, closed captioned decoders on televisions, Braille materials, taped texts, and "acquisition or modification of equipment or devices."[33]

For example, suppose Carlotta stays at a restored historic hotel in her quest for the perfect bed and breakfast. She finds that she can use the bathing facilities in her room only if she has a tub bench. The hotel would have to provide her with a bathtub bench as an auxiliary aid so that it will not exclude or deny her bathing services.

Two exceptions exist to the auxiliary aid provision requirement. The PPA need not provide an auxiliary aid that fundamentally alters the nature of the goods and services offered, or one that causes an undue burden.[33] An undue burden means that provision of the auxiliary aid would cause significant difficulty or expense. The impact on the PPA varies, depending on such elements as the size of the business and its budget. A major corporation should expect to spend more money on auxiliary aids and services than a neighborhood "mom and pop" operation. A fundamental alteration in the nature of the goods and services offered would occur, for example, if an individual with a visual impairment requested management to raise the lights in a bar in which the lights are customarily turned down low to create a particular ambiance or atmosphere.

The PPA need not provide personal devices and services such as individually prescribed devices (eg, eyeglasses) or services of a personal nature (eg, eating, toileting, or dressing).[37] However, it would probably be a reasonable auxiliary service should Carlotta request that the restaurant cut her meat in the kitchen before serving her steak if weakness in her hands prevents her from performing this task.

- Failing to furnish auxiliary aids and services when necessary to ensure effective communication, unless an undue burden or fundamental alteration would result.[33] For example, Bob is deaf and needs a sign language interpreter to converse with others. When seeking counseling services at a private mental health clinic, he requests a sign language interpreter to enable him to communicate with the mental health therapist. The mental health clinic must provide the sign language interpreter unless it is an undue burden.
- Refusing to remove architectural and structural communication barriers in existing facilities when

this is readily achievable.[34] Readily achievable means removal of barriers that can easily be accomplished and carried out without much difficulty or expense.[34] The ADA regulations provide 21 examples of steps PPAs can take to remove barriers (Box 15.7).

The ADA regulations recognize that not all changes are immediately readily achievable. In concert with input from members of the disability community, the Justice Department set forth four priorities in the ADA regulations that PPAs should follow to comply with the barrier removal requirements (Box 15.8).[33]

Box 15.7

Examples of Ways to Remove Barriers

- Installing ramps
- Making curb cuts in sidewalks and entrances
- Repositioning shelves
- Rearranging tables, chairs, vending machines, display racks, and other furniture
- Repositioning telephones
- Adding raised markings on elevator control buttons
- Installing flashing alarm lights
- Widening doors
- Installing offset hinges to widen doorways
- Eliminating a turnstile or providing an alternative accessible path
- Installing accessible door hardware
- Installing grab bars in toilet stalls
- Rearranging toilet partitions to increase maneuvering space
- Insulating lavatory pipes under sinks to prevent burns
- Installing a raised toilet seat
- Installing a full-length bathroom mirror
- Repositioning the paper towel dispenser in a bathroom
- Creating designated accessible parking spaces
- Installing an accessible paper cup dispenser at an existing inaccessible water fountain
- Removing high-pile, low-density carpeting
- Installing vehicle hand controls

Box 15.8

Four Priorities in Complying With Barrier Removal Requirements

Priority 1: Access Into a Place of Public Accommodation

First, the place of public accommodation (PPA) should try to provide access to and into the PPA from public sidewalks, parking, or public transportation. In other words, provide a way for individuals with disabilities to get into the building. For example, this includes, among other things as may prove necessary in individual circumstances, installing a ramp to the entrance, widening entrances, and providing accessible parking spaces.[34] Under this provision, the PPA is responsible for making sure that Carlotta can get from her parking space into the lobby of the movie theater.

Priority 2: Access to Areas Where Goods and Services Are Made Available

The second priority the PPA should focus on is providing access to areas of public accommodation where it makes goods and services available to the public. This step answers the following question: Now that individuals with disabilities can enter through our door, how do we get them to the actual part of the PPA where we provide the goods and services? This can include changes such as adjusting the layout of display racks, providing Braille and raised-character signage, widening doorways, providing visual alarms, and installing ramps.[33] The movie theater, under this section, would want to make sure Carlotta could get to the snack bar to purchase her popcorn and into the theater to watch the movie.

Priority 3: Access to Restrooms

The third priority for access is access to the restroom facilities. This may include modifications such as removing obstructing furniture or vending machines, widening doorways, installing ramps, providing accessible signage, widening toilet stalls, lowering paper towel dispensers and mirrors, and installing grab bars, usable faucet handles, and soap dispensers, to name a few. The movie theater would provide Carlotta access to the restrooms under this provision.[33]

Priority 4: Access to Goods and Services

The fourth and final priority for access is access to the goods, services, facilities, privileges, advantages, or accommodations offered at the PPA. This includes access to the actual goods or services that the PPA provides.[34] For Carlotta, the PPA needs to consider whether a place exists for her to sit in the movie theater so that she can watch the movie she wants to see. Can they remove seats to provide her a place to sit where she can sit with her family? Can they disperse the seats in the theater so that they do not have to segregate all of the wheelchair users in the back or front of the theater?

- Refusing to provide access to goods and services through alternative, readily achievable measures when removal of barriers is not readily achievable.[36] The ADA regulations give three examples of alternatives to removal of barriers, including, for instance, providing curb service or home delivery for an inaccessible restaurant, retrieving merchandise from inaccessible shelves or racks in the grocery store, and relocating activities to accessible locations.[36] For example, in pursuit of her movie hobby, Carlotta wants to see the latest popular art film. A multiscreen cinema is showing the film, but the particular theater the film is being shown in requires climbing a flight of steps. The theater must rotate the films to provide Carlotta access to the film that she wants to see.[36]
- Failing to provide equivalent transportation services and to purchase accessible vehicles in certain circumstances.[38] For example, Robby Rat's Fantasy Garden, a large amusement park, provides trams to take people to their cars in its enormous parking lots. On one of her trips, Carlotta takes her grandchildren to the Fantasy Garden. The Fantasy Garden must provide accessible transportation from the parking lot to the entry gates for Carlotta.
- Failing to maintain the accessible features of facilities and equipment.[29] For example, Streams Department Store must maintain its accessible ramped entrance into the store. This means shoveling snow in the winter and raking leaves in the fall so that Carlotta has access into the store on her trips to the city.
- Failing to design and construct new facilities and, when undertaking alterations, alter existing facilities in accordance with the ADA Accessibility Guidelines issued by the Architectural and

Transportation Barriers Compliance Board and incorporated in the final Department of Justice Title III regulations or the 2010 Standards, depending on the date of completion of the new or altered facilities.[35,39,40,113] This is where the "building code" flavor of the ADA comes in. Specific requirements dictate how builders should design and decorate buildings to provide access. The 2010 ADA Standards for Accessible Design (2010 Standards) requirements are available online (*http://www.ada.gov/2010adastandards_index.htm*).

Government agencies periodically update the accessibility guidelines and related standards. For example, the 2010 Standards allow PPAs to ask individuals to remove their service animal if it is out of control and the handler is not able to get it under control, or if it is not housebroken.[32] The 2010 Standards also adopt a two-tiered approach to mobility devices by distinguishing wheelchairs and "other power-driven mobility devices," to include mobility devices used by individuals with disabilities, but not necessarily developed for that purpose, such as a Segway PT.[112] Wounded soldiers returning from war often use adapted Segway PTs for mobility. The new rules allow access for these alternative mobility devices. Another change in the 2010 Standards provides that places of lodgings must allow individuals to make reservations for accessible guest rooms during the same hours and in the same manner as people without disabilities.[112]

Keep in mind that some state regulations differ from the 2010 Standards requirements. For example, Florida requires accessible parking spaces to have a 12-foot width (144 inches) and a 5-foot access aisle,[102] whereas the 2010 Standards require a width of 8 feet (96 inches) with a 5-foot access aisle.[76] The ADA regulations advise PPAs to follow the rule that provides the most access to individuals with disabilities.

Sometimes standards developed by government agencies exist only as recommended guidelines. For example, Carlotta may find it difficult to transfer from her wheelchair to an examination table for her annual Pap smear or to access mammography equipment from her wheelchair. Other wheelchair users may not have access to weight scales or other diagnostic equipment in their healthcare providers' offices. To address these needs, Section 4203 of the Affordable Care Act established Section 510 of the Rehabilitation Act.[77] This new section required the Architectural and Transportation Barriers Compliance Board (also known as the U.S. Access Board), in consultation with the Food and Drug Administration (FDA), to develop accessibility standards for medical diagnostic equipment.

The Architectural and Transportation Barriers Compliance Board (Access Board), published a "Notice of Proposed Rulemaking" in 2012 as a first step in developing accessibility standards for medical diagnostic equipment that would "allow independent entry to, use of, and exit from the equipment by individuals with disabilities to the maximum extent possible."[103] An advisory committee that included medical device manufacturers, healthcare providers, standards-setting organizations, organizations representing individuals with disabilities, federal agencies, and other stakeholders released recommended standards at the end of 2013.[98,99] At this point, these standards are recommendations only and are not required. However, OTs should consider these standards when advising clients with disabilities about access needs in medical settings. These standards are also important for OTs advising clients who seek OT consultation services for assistance in meeting their Title II and Title III access obligations in connection with the provision of medical services.

Role of the Occupational Therapist

Even though Congress passed the ADA more than 25 years ago, many examples point to a pervasive lack of compliance with access requirements.[85,96] OTs are in a unique position to promote Title III's access and inclusion mandates. With our knowledge of performance in occupations, performance skills, performance patterns, activity analysis, and client factors, we have the skills to look at how the physical environment can affect performance.[80] We know how to make adaptations in the environment, the task, or the person to enable performance despite the limitations an individual may have in performance skills. This knowledge base equips OTs to act as consultants, helping PPAs comply with Title III's access requirement, by looking at limitations to accessibility and making recommendations to PPAs to improve access, both physical and nonphysical (including attitudes, policies, and procedures).

OTs may find themselves working from two angles in providing access intervention. Their clients may include individuals with disabilities, such as Carlotta, who seek to increase their participation in the community by increasing their access and inclusion. Alternatively, OTs may find that their clients include proactive PPAs seeking to make their goods and services accessible to individuals with disabilities to avoid lawsuits and/or do the right thing.

When the individual with a disability is the client, the OT should perform an occupational profile that delves into the client's interests in the community, as was done with Carlotta.[80] The OT works with the client to determine what the barriers are to the client's participation in the community activities of his or her choice. In Carlotta's case, we know that movies and going to the mall are important to her. Part of our intervention plan will include problem-solving the changes that Carlotta needs to be able to participate in these occupations, explaining her right to accommodations under Title III, and suggesting ways to advocate to the PPA for the needed changes. If the PPA fails to make changes to provide access for Carlotta, she can file an administrative complaint with the Department of Justice in Washington (*http://www.usdoj.gov/crt/ada/enforce.htm#anchor218282*) or immediately file a lawsuit. The OT may serve as a witness in Title III litigation, should it come to that.

When the PPA is the client, the OT should look at the goods and services the PPA offers, the policies and procedures it uses (especially customer service–related policies), and the physical access offered, in the ADA-delineated priority order. Just as an employment-related ADA consultation with an employer usually begins with a job analysis, an access consultation with a PPA begins with an accessibility audit. An **accessibility audit** is a review of the access and inclusion practices of a PPA from a physical and policy perspective. The accessibility audit looks at the 2010 Standards requirements, the types of modifications the PPA can make to increase access, and the readily achievable changes the PPA can make according to the priorities set in Title III. Fig. 15.1 presents an accessibility audit that includes examination of physical and nonphysical barriers to access according to the 2010 Standards and follows the priorities specified in Title III. OTs can also provide consultation services for employers.

OT Practice Notes

Advocating for Employees With Disabilities

- Analyze physical functions to determine, for the employee, whether he or she can perform the essential functions of a given job with or without reasonable accommodations.
- Suggest specific reasonable accommodations, such as adaptive equipment, auxiliary aids, or modifications to the worksite, to enable the prospective or returning employee to perform the essential functions of his or her job.
- Obtain adaptive devices or auxiliary aids to facilitate performance in the workplace and in the community.
- Develop strategies to prepare the prospective employee to suggest reasonable accommodations to human resources personnel during the interview and hiring process.
- Teach adolescents with disabilities entering the job market for the first time how to manage the application, hiring, and interview processes.
- Expand access to public accommodations in the mainstream of independent living, such as theaters, conference centers, hotels, and restaurants, through focusing on mobility in the community; identification of equipment, aids, and services; and advocacy to obtain them.
- Provide information to clients so they can develop a basic understanding of their rights under the ADA.

OT Practice Notes

Consulting With Places of Public Accommodation

- Advise businesses that offer public accommodations, such as restaurants, movie theaters, hospitals, medical clinics, and hotels, how to make their facilities accessible to individuals with disabilities.

- Ensure that places of public accommodation are accessible to individuals with disabilities and make recommendations to remove architectural and other barriers.
- Assist in the acquisition of auxiliary aids to allow individuals with disabilities to have an equal opportunity to participate in or benefit from programs offered.
- Prevent lawsuits by performing accessibility audits and making recommendations for increased access and barrier removal on a proactive basis.
- Locate and/or acquire auxiliary aids and services for places of public accommodation.
- Train employees in how to make people with disabilities feel welcome in their facilities, how to use the auxiliary aids, and how to provide auxiliary services to individuals with disabilities.

OT Practice Notes

Consulting With Employers

- Analyze jobs to determine essential job functions and possible accommodations that one can easily make for a specific job.
- Develop or rewrite job descriptions based on job analysis that include specific descriptions of essential job functions.
- Modify job sites to make reasonable accommodations for individual employees with disabilities.
- Suggest specific devices and adaptive equipment that allow the employer to hire an individual with a disability who, with the assistance of the device, can now perform the essential functions of a given job.
- Sensitize coworkers and supervisors to interacting, supervising, and working effectively with individuals with disabilities.
- Train supervisors to develop reasonable accommodations for injured workers returning to the job, including worker's compensation claimants.
- Ensure that job sites are accessible to individuals with disabilities and make recommendations to remove architectural barriers when inaccessible features are found.
- Propose post-offer, job-related employee screenings and/or evaluations for positions associated with high risk for injury.
- Perform an individualized assessment of a worker's present ability to safely perform the essential functions of the job to determine whether the worker with a disability poses a direct threat to the health and safety of himself, herself, or others.
- Save businesses money by promoting cost-effective reasonable accommodations during the complaint or mediation process to avoid costly litigation.

How to Do an Accessibility Audit Under the ADA

A. Remember, Title III, Public Accommodations, is not limited to the physical accessibility of a building. Title III includes meaningful access and equal participation in all programs and services offered by the public accommodation.

1. Making something accessible is worthless if you do not identify its location. For example, public accommodations must include accessible signage to assist individuals in locating accessible bathrooms and building entrances.

B. Title III sets forth the following priorities for accessibility:

1. **Access to and into the place of public accommodation** from public sidewalks, parking, or public transportation. This includes installing a ramp to the entrance, widening entrances, and providing accessible parking spaces.

2. **Access to those areas of public accommodation where goods and services are made available to the public.** This includes adjusting the layout of display racks, providing Brailled and raised character signage, widening doorways, providing visual alarms, and installing ramps.

3. **Access to restroom facilities.** This includes removing obstructing furniture or vending machines, widening doorways, installing ramps, providing accessible signage, widening toilet stalls, lowering paper towel dispensers and mirrors, and installing grab bars.

4. **Access to the goods, services, facilities, privileges, advantages, or accommodations offered at the place of public accommodation.** This includes access to the actual goods or services themselves.

C. **The Accessibility Audit should follow the priorities set forth in Title III.**

STEP ONE: According to the first priority, look at the access to and into the place of public accommodation from public sidewalks, parking, or public transportation:

		YES	NO
1.	Are parking spaces 96 inches wide with an adjacent access aisle of 60 inches?	________	________
2.	Is one in every eight parking spaces served by a 96-inch access aisle marked "van accessible"?	________	________
3.	How many parking spaces are designated for individuals with disabilities? ________ (________% of spaces) (compare with chart at ADAAG § 4.1.2(5)(a); 10% of total number provided for outpatient units or facilities should be accessible.)	________	________
4.	If covered parking is provided, is the ceiling at least 114 inches high to allow access to high-top vans?	________	________
5.	Are all curb ramps (curb cuts) from the parking spaces at a gradient of 1:20 with a textured, non-slip surface?	________	________

6. Are parking area and building separated by a street? ________ ________

7. Are the accessible parking spaces located on the shortest accessible route of travel from the parking area to the accessible building entrance? ________ ________

8. Is the surface of the accessible route smooth (no sand, gravel, or utility hole covers)? ________ ________

9. Are all ramps along the accessible route at a gradient of at least 1:12 (1:16 - 1:20 preferred)? ________ ________

10. Do ramps have 5-foot level landings at the bottom and top that are as wide as the ramp itself? ________ ________

11. Do all ramps have handrails with top handrail, non-slip, gripping surfaces mounted between 34 inches and 38 inches above the ramp surface? ________ ________

12. Is the accessible route walkway at least 48 inches wide? ________ ________

13. Is the accessible route marked with appropriate signage? ________ ________

14. Is there a passenger loading and unloading zone? ________ ________

15. The accessible entrance is located ________________ ________________________________ ________ ________

16. Is the accessible door marked with appropriate signage? ________ ________

17. Is the entrance door a minimum of 32 inches wide? ________ ________

18. Is the door automatic? ________ ________

19. Is the door-opening mechanism set to less than ________ pounds of pressure (as measured by a push then pull scale, although no specific requirements are set for exterior doors at this time)? ________ ________

20. If there are two doors in series at the entrance, do the doors open in the same direction or away from the space between the two doors and is the space at least 48 inches plus the width of any door opening into the space? ________ ________

21. Is there an alternative to a revolving door? ________ ________

22. Is door hardware shaped so as to require one hand to open and not to require tight grasping, tight pinching, or twisting of the wrist to operate? ________ ________

23. Are thresholds less than ½ inch high? ________ ________

24. If the primary entrance has steps, is there a proper sign directing patrons to the accessible entrance? ________ ________

STEP TWO: Look at access to those areas of public accommodation where goods and services are made available to the public. This includes adjusting the layout of display racks, providing Brailed and raised character signage, widening doorways, providing visual alarms, and installing ramps.

A. List all areas in the facility where goods, services, and programs are provided to the public. (Remember, this includes areas in places that are not normally considered places of public accommodations, but parts of those facilities where members of the public would go, i.e., the showroom of a factory not open to the general public but where outside buyers and salespersons might go.)

B. Are all areas where goods, services, and programs are located accessible?
(This section should be repeated for all goods, services, and programs offered at the location.)

Goods/Service/Program and Location

		YES	NO
1.	Is the width of the pathway to the area, including corridors and aisles, at least 32 inches of usable space?	______	______
2.	Is the pathway free of protruding telephones, water fountains, or other items?	______	______
3.	Is the pathway flooring covered with high-density, low-pile (½ inch) carpeting, non-slip tile, or vinyl?	______	______
4.	Are doorways at least 32 inches wide?	______	______
5.	If there are steps along the pathway, is the area also served by an elevator?	______	______
6.	Are steps covered with non-slip surfaces, provided with adequate lighting, and designed with curved nosers and sloped risers?	______	______
7.	Do all stairways have handrails positioned at both sides of the stairs with top handrail, non-slip, gripping surfaces mounted between 34 inches and 38 inches above the stair nosing?	______	______
8.	Do the handrails extend 12 inches beyond the top riser and 12 inches plus the width of one thread beyond the bottom riser?	______	______
9.	Are thresholds at ½ inch high or less for interior doors?	______	______
10.	Is the door-opening mechanism set to 5 pounds of pressure or less?	______	______
11.	Is door hardware shaped so as to require one hand to open and not to require tight grasping, tight pinching, or twisting of the wrist to operate?	______	______
12.	If doorways have two independently operated door leaves, is one leaf at least 32 inches wide?	______	______
13.	If there are two doors in series along the pathway, do the doors open in the same direction or away from the space between the two doors and is the space at least 48 inches plus the width of any door opening into the space?	______	______
14.	Are elevator call buttons centered at 42 inches above the floor and at least ¾ inch in diameter?	______	______
15.	Do objects mounted below the elevator call button protrude more than 4 inches into the elevator lobby?	______	______
16.	Are visible and audible signals provided at each elevator entrance to indicate which car is answering the call and the direction the car is going (once for up and twice for down)?	______	______

17. Are raised and Braille characters at least 2 inches high, provided on both jambs of the elevators, and centered 60 inches above the floor? ________ ________

18. Are elevators provided with an automatic reopening device? ________ ________

19. Is the minimum amount of time the elevators remain open in response to a call at least 3 seconds? ________ ________

20. Are control buttons inside the elevator designated by Braille and raised letters? ________ ________

21. Are floor buttons 54 inches or less above the floor for a side wheelchair approach and 48 inches or less for a front approach? ________ ________

22. If public telephones are provided, are they on an accessible floor at an accessible location? ________ ________

23. Is at least one telephone mounted so that its operable parts are no more than 54 inches or less above the floor for a side wheelchair approach and 48 inches or less for a front approach? ________ ________

24. Is there a clear floor or ground space of at least 30 inches by 48 inches under the telephone absent bases, enclosures, fixed seats, and protruding objects of more than 4 inches? ________ ________

25. Is at least one telephone equipped with an amplifier for individuals with hearing impairments and located near an electrical outlet for portable TTDs? ________ ________

26. Is the telephone cord at least 29 inches long? ________ ________

27. Is at least one text telephone provided? ________ ________

28. Where are the accessible telephones located? ________ ________

29. Are accessible telephones marked with appropriate signage? ________ ________

30. Are water fountains mounted so that spouts are no higher than 36 inches from the floor? ________ ________

31. Are fire alarms and other warning signals provided in both a visual and audible manner? ________ ________

32. Are room numbers, directional signs, emergency directions, and other signs and markings indicated in large, block letters and numerals, using contrasting colors so they can be read by individuals with visual impairments? ________ ________

33. Are signs provided in raised and Braille letters and numbers? ________ ________

If the answer to any of the above questions is no, what reasonable accommodations may be made to allow access to the area where the goods, services, and programs are provided?

____

____

STEP THREE: Look at access to restroom facilities.

		YES	NO
1.	Where are the accessible restrooms located? ____________ ______________________________	______	______
2.	Is the accessible restroom designated with appropriate signage?	______	______
3.	Is the restroom on an accessible pathway?	______	______
4.	Can one use the restroom without going up or down steps?	______	______
5.	Is the width of the pathway to the restrooms, including corridors, and aisles, at least 32 inches of usable space?	______	______
6.	Is the pathway to the restrooms free of protruding telephones, water fountains, or other items?	______	______
7.	Is the pathway flooring to the restrooms covered with high-density, low-pile (½ inch) carpeting, non-slip tile, or vinyl?	______	______
8.	Are the doorways to the restrooms at least 32 inches wide?	______	______
9.	Do doorways to the restrooms require 5 pounds or less of pressure to open?	______	______
10.	Is the entrance to the toilet stall at least 32 inches wide?	______	______
11.	Is the top of the seat of the accessible toilet between 17 inches and 19 inches from the floor?	______	______
12.	Does the toilet paper dispenser allow for the continuous flow of toilet paper without delivery control?	______	______
13.	Does the toilet stall have a minimum depth of 56 inches where toilets are wall mounted and 59 inches where toilets are floor mounted?	______	______
14.	Is at least one stall a minimum of 36 inches wide with an outwardly opening, self-closing door?	______	______

15. Are there a minimum of two grab bars at least 36 inches long in the accessible toilet stall with one grab bar mounted behind the toilet? ________ ________

16. Are grab bars between 33 inches and 36 inches from the floor? ________ ________

17. Are urinal rims at a maximum of 17 inches from the floor? ________ ________

18. Is there a clear space in front of the urinal of 30 inches by 48 inches to allow a front approach? ________ ________

19. Are soap dispensers, paper towel dispensers, hand dryer, and feminine product dispensers within 48 inches of the floor? ________ ________

20. Are mirrors mounted so that the bottom edge is within 40 inches of the floor? ________ ________

21. Are sinks mounted so that the rim or counter surface is within 34 inches of the floor and a 29-inch clearance space is provided from the floor to the bottom of the apron? ________ ________

22. Is there a clear space in front of the sink of 30 inches by 48 inches to allow a front approach? ________ ________

23. Are hot water pipes insulated or configured to avoid contact? ________ ________

24. Are sink faucets lever-operated, push-type, electronically controlled, or otherwise operable with one hand without requiring tight grasping, pinching, or twisting of the wrist? ________ ________

25. Do self-closing faucets remain open for at least 10 seconds? ________ ________

STEP FOUR: Look at access to the goods, services, facilities, privileges, advantages, or accommodations offered at the place of public accommodation.

This step answers the question, "Can people use or take advantage of the goods, services, facilities, or programs provided at the place of public accommodation?"

Look back at the goods, services, facilities, or programs identified in **STEP TWO** and determine whether they are usable. **For example:**

	YES	NO
1. Are printed materials provided in alternative formats where needed?	________	________
2. Are items in racks or on walls within reach?	________	________
3. Are special listening devices provided for individuals with hearing impairments in theaters, conference centers, and concert halls?	________	________

4. Can individuals in wheelchairs reach the microfilm machines at the library? ____________ ____________

5. Is there an integrated location for individuals in wheelchairs to sit at the football stadium without having to transfer out of one's chair? ____________ ____________

6. Can individuals with disabilities reach the items on the grocery store shelves? ____________ ____________

STEP FIVE: If STEPS ONE through FOUR identify goods, services, facilities, or programs that are not usable by individuals with disabilities, can an accommodation be made to enable the individual to take advantage of the goods, services, facilities, or programs?

Are there policies that need to be changed to enable participation by individuals with disabilities?

FIG 15.1 How to do an accessibility audit to check for compliance with ADA requirements.[113] (Courtesy Barbara L. Kornblau, ADA Consultants, 1992, 2002, 2011.)

Air Carrier Access Act

Carlotta's occupational profile shows that travel is a meaningful occupation for her. To pursue that occupation now that she uses a wheelchair for mobility, she will need to know what to expect while traveling and how she can advocate for herself. The key is the Air Carrier Access Act of 1986 (ACAA). The ACAA, as amended,[78] prohibits discrimination against qualified individuals with physical or mental impairments in air transportation by foreign and domestic air carriers. The ACAA applies only to air carriers that provide regularly scheduled services for hire to the public. As with the ADA and Fair Housing Act, the ACAA lists specific actions that it considers discriminatory.

Discrimination Prohibited Under the ACAA

Airline carriers may not refuse to transport qualified individuals with disabilities on the basis of their disability.[3] The definitions of disability are similar to the definitions found in the ADA. A qualified individual with a disability in the airline travel context means that he or she seeks to purchase or has a ticket to fly. The ACAA would protect Carlotta because she has arthritis and an airline ticket. By federal statute, carriers may exclude anyone from a flight if carrying the person would pose a direct threat to the health and safety of others.[4] This parallels the direct threat criteria under the ADA. If the airline carrier excludes persons with disabilities on safety grounds, the carrier must provide a written explanation of the decision within 10 days of the refusal, including the specific basis for the refusal.[6]

Airline carriers may not deny transportation to a qualified individual with a disability "because the person's disability results in appearance or involuntary behavior that may offend, annoy, or inconvenience crewmembers or other passengers."[5] Airline carriers cannot limit the number of people with disabilities they will allow on flights as a means of refusing transportation based on disability.[2] The ACAA prohibits airlines from requiring a person with a disability to accept special services, such as preboarding, if the passenger does not request them.[1] Similarly, air carriers cannot segregate passengers with disabilities, even if separate or different services are available to them.[8]

Under the ACAA, airline carriers cannot require qualified individuals with a disability to provide advance notice of their intention to travel or of their disability as a condition of receiving transportation or of receiving services or required accommodations.[7] Carlotta would not have to notify the airline in advance that she planned to fly. A limited exception to this rule exists, however. An airline carrier may require up to 48 hours' notice for certain specific accommodations that require advance preparation. These include, for example, medical oxygen use, transportation of an electric wheelchair in a plane with fewer than 60 seats, travel with a service animal on a flight longer than 8 hours or an emotional support or psychiatric service animal, and provision of an onboard wheelchair in an aircraft that lacks an accessible lavatory.[8]

Airlines cannot exclude a passenger with disabilities from a particular seat, or require him or her to sit in a certain seat, except to comply with safety regulations established by the Federal Aviation Administration (FAA), such as exit row seating, which requires that passengers have specific abilities to open the exit door in case of an emergency.[15] Airlines must accommodate passenger seat assignments if they are required, based on the person's disability, and requested 24 hours in advance. For example, if Carlotta traveled with a service animal that assisted her in tasks such as pulling her wheelchair and picking up items from the floor, the carrier would have to assign them to a bulkhead seat or another seat that could accommodate the service animal.[14]

Airline carriers may not require a person with a disability to travel with an attendant except in certain limited circumstances.[9] Such limited circumstances include, among others, those in which a person with an impairment in mobility is unable to assist in his or her own evacuation and in which a person with a mental disability cannot understand or respond to the crew's safety instructions.[9] If the person with a disability and the carrier disagree about whether the individual's circumstances meet the ACAA's criteria, the carrier may require the attendant but may not charge for the attendant's transportation cost.[9]

Airline Carriers' Obligations

Airline carriers must provide assistance in boarding and deplaning by providing personnel, ground wheelchairs, boarding wheelchairs, and ramps or mechanical lifts.[16] If entry-level boarding is unavailable, airlines must provide boarding assistance through lifts or ramps.[17] Exceptions exist for certain small airplanes and low-volume airports. OTs should review with Carlotta how to explain to airline personnel the safest way to transfer her. Carlotta should also know that the carrier cannot leave her unattended in a ground or boarding wheelchair for more than 30 minutes if she cannot independently operate that wheelchair.[18] The carrier must also accept her wheelchair as carry-on baggage if a place exists to store it on the plane or as gate-checked baggage, which the airline returns to her as soon as possible and as close to the airplane door as possible if she wishes.[20] She can also choose to have it delivered to her in the baggage claim area.[20]

The ACAA requires airlines to provide other assistance to individuals with disabilities as outlined in Box 15.9.[19] Carriers cannot charge for providing these services.[10]

Box 15.9

Services Airlines Must Provide if Requested

- Assistance moving to and from seats during boarding and deplaning
- Assistance in preparation for eating, such as opening cartons (but not assistance in eating)
- Assistance to and from the lavatory if the aircraft has an onboard wheelchair (but no assistance in the lavatory)
- Assistance moving to and from the lavatory for a semiambulatory person, not involving lifting or carrying
- Assistance loading and retrieving carry-on items, including mobility aids stored on board

Wide-bodied aircraft must have accessible lavatories, and those with 100 seats or more must have priority space for storing wheelchairs in the cabins.[12,13] This information may help Carlotta select her flights based on the services that the plane provides. In addition to services and access on the airplanes themselves, airlines must make sure that their terminals are accessible.[11]

The ACAA requires airline carriers to train their employees in awareness and appropriate response to persons with a disability, "including persons with physical, sensory, mental, and emotional disabilities, including how to distinguish among the differing abilities of individuals with a disability."[21] This could provide opportunities for advocating for a particular client such as Carlotta or for consulting with the airline to provide sensitivity training and disability awareness.

Each airline must designate a complaint resolution official at each airport that it serves to receive and make efforts to resolve complaints. If it cannot resolve the complaint, it must give the passenger a written summary of the problem and outline the steps that the carrier will take to solve it. It must also notify the passenger of his or her right to pursue the complaint with the U.S. Department of Transportation (DOT).[22] Information about filing a complaint with the DOT is available online at *http://airconsumer.ost.dot.gov/ACAAcomplaint.htm*.

The DOT takes the ACAA very seriously. In February, 2011, one airline agreed to a $2 million settlement with the DOT for failing to provide adequate and prompt enplaning and deplaning wheelchair assistance to passengers with disabilities, failing to provide dispositive responses to written complaints alleging ACAA violations, and failing to properly categorize and accurately report its disability-related complaints.[75]

Role of the Occupational Therapist

OTs can work with their clients to help them understand what their needs will be for air travel and also to help them develop a strategy to follow for meeting their needs. They can also play a key role in informing clients of the rights to which they are entitled in air travel and how to advocate for those rights for themselves.

Ethical Considerations

As OTs we are in a unique position to facilitate an understanding of disabilities and the impact they have on everyday activities and functions. OTs can use this knowledge to work directly with airlines as consultants and conduct the training mandated by law to promote a culture of sensitivity and awareness.

Fair Housing Act

Congress passed the Fair Housing Amendments Act of 1988 to add "handicaps" (hereafter referred to as individuals with disabilities, a more politically correct term with the same legal meaning[89]) to the list of those protected against discrimination in housing. Before passage of the Fair Housing Act Amendments, the Fair Housing Act (FHA) prohibited discrimination based only on race, color, religion, sex, familial status, or national origin.[94]

Generally, the FHA prohibits discrimination in the sale, rental, or advertising of housing dwellings, in the provision of brokerage services, or in other residential real estate–related transactions, such as the provision of mortgage loans. The FHA covers private housing, housing that receives federal government assistance, and state and local government housing. Some exceptions exist to the FHA. For example, the FHA does not apply to owner-occupied apartment buildings with four or fewer units, or to private homes when the owner owns fewer than three single-family homes and is not in the business of selling or renting dwellings.

The FHA uses the same definition of individuals with disabilities as the ADA. Discrimination means denying or making a sale or rental unavailable because of the disability of a buyer or renter, the disability of an intended resident, or the disability of any person associated with a person with a disability. Landlords may not inquire whether a person applying to buy or rent housing is an individual with a disability, and they cannot charge a higher price or provide different services because a renter or purchaser of a dwelling unit is an individual with a disability.

Passage of the Fair Housing Act Amendments gave individuals with disabilities certain additional rights to use and enjoy their dwellings. These additional rights play a significant role in promoting independent living and participation for individuals with disabilities. Under the FHA, it is illegal to refuse to permit reasonable modification of existing premises occupied or to be occupied by individuals with disabilities if the proposed modification is necessary to allow the person with the disability full use and enjoyment of the dwelling. However, unlike the ADA, which requires businesses to pay for modifications that provide access, the FHA does not require landlords to pay for modifications; it requires only that the landlord allow the tenant to make modifications, at the expense of the person with a disability who needs them.

The landlord may condition permission for modification on the renter's agreeing to restore the interior to its condition before the modification, if this is reasonable. If the renter plans to make a modification in the dwelling, the landlord may not increase a security deposit. The landlord may, however, condition permission for modification on provision of a reasonable description of the proposed modification and assurances that the work will be properly performed by licensed professionals with permits, in addition to other stipulations.

The FHA also makes it illegal for any person to refuse to make reasonable accommodations in rules, policies, practices, or services, when needed, to afford a person with a disability equal opportunity to use and enjoy a dwelling unit, including public and common use areas. For example, an apartment building management company would have to make an exception to a "no pets" policy so that an individual with a spinal cord injury could keep a service dog. Another often-disputed example involves parking. A person with a disability may need an assigned parking space close to his or her apartment in a development that prides itself on unassigned parking. It would be a reasonable accommodation to modify the parking policy to allow assignment of a parking space to the person with the disability.

Research shows that interventions based on home assessments, such as providing bath benches and recommending grab bars, help prevent falls in the home and encourage safe and independent participation in everyday home life.[87,105] Carlotta's intervention plan would include a home assessment. Applying the provisions of the FHA to Carlotta's case affords her some assistance in her quest for independent participation. First, the landlord would have to allow Carlotta to install the grab bars that her OT recommended for her bathtub, as long as this was done in a workmanlike manner with permits and all necessary requirements. The landlord would probably have to allow Carlotta to widen her bathroom door, as the OT recommended, so that Carlotta could wheel her wheelchair into the bathroom. With these modifications and others developed by the OT in collaboration with Carlotta, Carlotta can independently participate in her ADLs.

The second issue for Carlotta involves her need for assistance to carry out her aquatics home program. To do this, she must be able to use the pool, an amenity to which she is entitled, as are all residents of the apartment complex. Carlotta has no access to the pool unless her friend can help her get into and out of the pool each day. The landlord would probably have to modify the “no guests in the pool on weekends” policy to allow Carlotta access to and use of the pool on weekends.

What if the landlord does not want to allow Carlotta to make these accommodations? Even the most wonderful suggestions for accommodation made by the OT and/or OTA are worthless if the client cannot use them. Because the success of the OT intervention plan may rest on provision of these accommodations, the OT and/or OTA should steer Carlotta to the website for the U.S. Department of Housing and Urban Development (HUD) —*http://www.hud.gov/complaints/housediscrim.cfm*—where Carlotta can file an administrative complaint to encourage the landlord to allow her to make the needed accommodations. Remember, under the FHA the landlord is not responsible for making the accommodations, but must allow the tenant to make needed reasonable accommodations. HUD staff members will contact the landlord and/or property management company, mediate the situation by encouraging them to follow the law, and try to resolve the issues without the need for filing a lawsuit.

OTs and OTAs will also find the FHA helpful in other, very commonly encountered situations. For example, OTs who make home visits to patients' and clients' homes before hospital discharge will appreciate the support of the FHA. During these home visits, OTs customarily evaluate the individual's ability to function in the home as independently as possible. This assessment includes making recommendations about adaptive equipment and other modifications to the home to promote independent participation. The FHA gives the therapist's recommendations clout should the landlord refuse to allow the modifications to the dwelling unit. Clients in need of grab bars and other accommodations in their homes have an alternative route to take should the landlord say “no” to the accommodations needed.

Advocacy as Intervention

OTs promote participation in work, leisure, and ADLs. As shown earlier, sometimes barriers to participation exist despite the efforts of OTs and their clients. For example, the client may successfully transfer from the wheelchair to the toilet and bath bench in the clinic, but cannot get into the bathroom at home if the landlord will not allow modifications to the apartment. Carlotta can do her job from a wheelchair, but the headmaster will not transfer her to an accessible classroom.

To promote participation in these instances, the OT may have to include advocacy as an intervention strategy. The OT may need to act as an advocate, or he or she may have to guide the client through a self-advocacy process.

Ethical Considerations

Eight Rules of Advocacy

- Know the laws.
- Read the regulations.
- Believe that you or your client has a right to what you seek.
- Organize yourself, document your efforts, get everything in writing, and keep copies of all correspondence.
- Start with the source of the problem.
- Be specific; tell them exactly what you want.
- File a complaint with the administrative agency that oversees the matter.
- Follow through.

Summary

The ADA, ACAA, and FHA exist to provide individuals with disabilities certain rights. These laws, in concert with OT intervention, have the potential to open many avenues to participation for individuals with disabilities. By familiarizing themselves with these laws and sharing that information with clients, OTs can play a major role in ensuring that those whom they serve have more opportunities to participate in work, leisure, and ADLs.

With the assistance of the ADA, ACAA, and FHA, Carlotta should be able to continue in her job as a teacher with the reasonable accommodations provided by her employer under Title I of the ADA. Carlotta can continue traveling by airplane to find the perfect bed and breakfast with accommodations provided to her under the ACAA. She can continue shopping and going to movies with the protection afforded her under Title III of the ADA. The FHA will provide the legal tools Carlotta needs to stay in her current apartment and care for herself independently, with cooperation from her landlord for the accommodations she needs.

Leisure Occupations[a]

Sheama Krishnagiri, Megan Chang

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, the student or practitioner will be able to do the following:

1. Discuss the benefits of leisure for adults.
2. Describe the key areas in which humor can be used.
3. Understand the different leisure needs of people in different stages of life.
4. Identify specific strategies to promote leisure activity for people with disabilities.

KEY TERMS

Humor
Leisure
Leisure exploration
Leisure participation
Modeling
Play

Threaded Case Study

Jeri, Part 1

Before she was involved in a traffic accident, Jeri, a 29-year-old newly married woman, lived a full and happy life. She was employed as an interior designer; spent time with her husband, friends, and family; and participated in leisure occupations. She particularly enjoyed scrapbooking, going to a nearby lake to boat and fish, playing with and caring for her dogs, and shopping. As Jeri was driving home from running errands one evening, a drunk driver hit her car. It rolled over, and she was trapped inside. She was taken by paramedics to the local hospital, where she was found to have a traumatic brain injury, a broken wrist, and a broken leg. Jeri was transported to the regional brain trauma center for rehabilitation. She recovered over a period of months and returned home.

Jeri continues rehabilitation as an outpatient for residual problems from her brain injury and for continuing problems using her dominant hand because of the wrist fracture. Jeri receives occupational therapy twice weekly and is demonstrating significant improvement; she has progressed from needing maximum assistance for activities of daily living (ADLs) to minimum assistance. Jeri has no apparent cognitive deficits; she uses a walker to ambulate; and she still needs a family member or aide at home on a full-time basis because she has poor balance, which impairs her safety when moving around in her environment. The occupational therapist (OT) is ready to discharge Jeri because her ADL goals have been met. However, during the intervention review before discharge, Jeri tells her OT that she spends most of her days hanging out at home, watching TV, that she feels lonely and disengaged from her friends, and that she will miss occupational therapy because it is her only activity outside the home.

Critical Thinking Questions

1. Is Jeri ready to be discharged from occupational therapy?

2. Why is Jeri dissatisfied with her current lifestyle?

3. What intervention could the OT provide to improve Jeri's quality of life?

Participating in meaningful leisure occupations is vital to a healthy, balanced lifestyle.[6,52,62] As one of eight categories of occupation in the domain of occupational therapy, **leisure** is defined in the current version of the occupational therapy Framework (the “Occupational Therapy Practice Framework,” third edition [OTPF-3]) as “a nonobligatory activity that is intrinsically motivated and engaged in during discretionary time, that is, time not committed to obligatory occupations such as work, self-care, or sleep”[4] (OTPF-3, p. S21). Key phrases in the definition are that these activities are intrinsically motivated and that they are not obligatory. In other words, people participate in leisure occupations that they choose and enjoy. For instance, for some people cooking may be a chore, whereas for others it is a pleasure.

Leisure time may be spent in a variety of ways indicative of an individual's unique interests. Examples of leisure occupations are reading, playing games, participating in sports, doing arts and crafts, engaging in outdoor activities (biking, hiking, fishing), cooking, taking a yoga class, exercising at the gym, going to concerts, watching movies, and so on. Because of the uniqueness of individuals, this list is as long as there are people who participate in leisure occupations.

Leisure and Life Satisfaction for People With Physical Disabilities

When adults sustain injuries (eg, traumatic brain injury, stroke, spinal cord injury, carpal tunnel syndrome), have health conditions (eg, multiple sclerosis, Parkinson's disease, arthritis, Alzheimer's disease), or experience life transitions (eg, empty nest syndrome, menopause, retirement) that disrupt normal habits and routines, they face devastating losses. Loss of work, social activities, and meaningful leisure activities may contribute to depression, and the self must be redefined.[47,78]

Occupational therapists are skilled in collaborating with people with physical disabilities to assist them in resuming a full life.[76] It has been suggested that one method of measuring whether a person is fully engaged in life is to consider the individual's participation in leisure activities.[10,63] This is especially important because research indicates that the perception of leisure satisfaction by adults with physical disabilities is the most significant predictor of life satisfaction.[39,42] Depressive symptoms have also been shown to diminish when the number and variety of pleasant activities increase.[24,33,68] Engaging in familiar or novel leisure activities provides a receptive environment for opportunities for socializing and making friends, in which people with physical disabilities have a chance to demonstrate their occupational skills to others who might not otherwise view those with a disability as capable or as a candidate for friendship.[65] Subsequent studies of people with multiple sclerosis and those with Parkinson's disease have demonstrated similar findings about social participation.[18,31]

OT Practice Notes

Benefits of Leisure Activities

Participation in leisure activities can offer many psychosocial and physical benefits.

Psychosocial Benefits

- Increased sense of self-worth
- Release of hostility and aggression
- Shared control of self and environment
- Experience of choice
- Increased socialization
- Development of leadership
- Practice in adaptive behavior and coping skills
- Increased attention span
- Improved emotional well-being
- Adjustment to living arrangements
- Increased tolerance of groups and other people
- Experience of intellectual stimulation

Physical Benefits

- Increased circulation
- Promotion of gross, fine, bilateral, and eye-hand coordination

- Provision of vestibular stimulation
- Provision of sensory stimulation
- Promotion of motor planning
- Improvement or maintenance of perceptual abilities
- Maintenance or improvement of adaptive and coping skills
- Increased strength, range of motion, and physical tolerance
- Improved balance
- Provision of opportunity to grade activities

OT Practice Notes

The Therapist's Role in Encouraging Leisure Activities

If therapists provide interventions aimed only at physical rehabilitation (eg, strengthening, range-of-motion exercises) and improving performance in activities of daily living and instrumental activities of daily living, the recovering individual may never experience the opportunity of resuming old leisure interests or developing new ones. Leisure skills are integral to redefining one's identity, self-worth, and self-efficacy.

Leisure also has been shown to contribute to individual development and well-being and to provide a significant mechanism of coping.[4] Unfortunately, studies indicate that most leisure activities are abandoned after the onset of a physical disorder such as rheumatoid arthritis or stroke.[63,88] Adults with physical disabilities seem to relinquish activities that are purely for enjoyment, especially community-based social activities, and focus their effort and time on ADLs and work.[63,67]

The emphasis on the physical model of recovery is most likely due to healthcare professionals who deliver treatment with a focus on mobility and independence in ADLs and also the fact that rehabilitation outcome measures are commonly based on these factors.[63] Occupational therapists need to recognize that people often experience difficulty adapting their interests and activities by themselves after a physical or neurological disorder.

Drummond and Walker[24] conducted a randomized, controlled study of stroke survivors, and the findings of that study affirmed the need for occupational therapists to address the leisure area of occupation to encourage clients to engage in leisure interests and activities after therapy is discontinued. In the study, 65 clients were randomly assigned to three groups—leisure rehabilitation, conventional OT treatment, and control. The baseline number and frequency of leisure activities in the three groups demonstrated no significant difference between the groups on admission to the hospital.

After discharge from the hospital, the leisure rehabilitation group and the conventional OT treatment group were treated by the same occupational therapist for 30 minutes one time per week for 3 months, and then for one 30-minute session every 2 weeks for 3 months. Each person in the leisure rehabilitation group was given an individualized program that included "advice and help … in the following broad categories: treatment (eg, practice of transfers needed for leisure pursuits); positioning; provision of equipment; adaptations; advice on obtaining financial assistance and transportation; liaison with specialist organizations, and providing physical assistance (eg, referral to voluntary agencies)."[24]

The conventional OT treatment group received individualized treatment by the same therapist for the same amount of time. Interventions included "transfers, washing and dressing practice, and, where appropriate, perceptual treatments …. No reference was made to the importance of continuing previous interests, and no help or advice was offered to encourage participation in leisure pursuits."[24]

At 3 and 6 months after discharge, an independent assessor readministered the leisure questionnaire, which showed that the leisure rehabilitation group had significantly higher leisure scores than did the conventional OT treatment group and the control group.[24]

Thus, adults with physical disabilities may give up leisure activities because they are not aware of ways to adapt valued activities so they can participate in them again, or they may not know about new hobbies or crafts that they might enjoy. Occupational therapists have an important role in helping people both explore and plan engagement in leisure occupations so that they can participate in activities that bring joy to life.[11,55,70,76,78] Engagement in "serious leisure" (a term used in the literature to indicate fulfilling leisure activities that engage the individual's special skills, knowledge, and experience) has been associated with positive effects on affect,[39,51] quality of life, and mood.[23] Additionally, it can serve as a mechanism for upholding identity and for helping the individual remain engaged in a fulfilling life with the disability.[31,34,40]

Benefits of Play and Laughter in Leisure Occupations

When talking about participating in leisure occupations, people often use the word *play:* play golf, play the piano, play sports, play cards, play board games, and so on. Other types of leisure occupations involve being creative, such as dressing uniquely, preparing original recipes, writing poetry, and such. **Play** allows adults to escape the reality of everyday life and immerse themselves in a world of carefree spontaneity that provides meaning to their existence and sometimes an avenue for self-expression.[12] Play suggests fun, and fun is often accompanied by laughter.

Many physical health benefits of laughter have been demonstrated through numerous research studies. For example, immune cells increase and stress hormones decrease, thereby possibly preventing illness or aiding recovery.[9,66,77] Some people experience relief from pain and a sense of well-being after hearty laughter.[1,22,46] Laughter also benefits people psychologically and psychosocially.[26,69,73,85] Laughing together facilitates bonding, reduces anxiety, and improves coping[35,48]—all important factors in a therapeutic alliance between the occupational therapist and the client (Box 16.1).

Box 16.1

Health Benefits of Laughter

Physical Health Benefits of Laughter[26,69]

- Stress hormones decrease (eg, cortisol and noradrenaline).[9]
- Immune functions increase (eg, immunoglobulin A and natural killer cells).[9,77]
- Muscle tension relaxes.
- Blood pressure drops, and cardiovascular functions improve; blood flow increases to aid healing.
- Respiratory airways are cleared (through laughing and coughing).
- Pain relief may be attained after hearty laughter and may last for several hours as a result of release of opioids and endorphins.[66]
- “Feel good” hormones (eg, beta-endorphins and serotonin) are released.

Psychological and Psychosocial Health Benefits of Laughter[46,69,73]

- Facilitates bonding—laughter occurs more often with others than when alone
- Improves ability to cope with problems[1]
- Increases well-being and promotes hope and optimism[48]
- Diverts negative thoughts—it is hard to maintain destructive thoughts when laughing[22]
- “Saves face” in embarrassing situations
- Facilitates mental clarity, creativity, and brainstorming because the two brain hemispheres communicate better during humor, and the limbic system is aroused[48]
- Adds vibrancy to facial tone and sparkle to the eyes

Facilitating psychosocial and physical adaptations is integral to occupational therapy, and given the current healthcare climate of high productivity and short hospital and rehabilitation stays, it is imperative that occupational therapists be able to quickly form a therapeutic alliance with their clients. **Humor** and laughter are natural ways that therapists and clients connect. Recent studies have found that all of the occupational therapists who were interviewed or surveyed agreed that humor has a place in occupational therapy.[44,50,73]

In a national, cross-sectional, randomized survey of 283 occupational therapists that examined their attitudes and use of humor in interacting with adult clients with physical disabilities, humor was classified into four key areas: building relationships, helping clients cope with adversity, promoting clients' physical health, and facilitating compliance with treatment.[73] Although therapists reported positive attitudes about humor in all four of these areas, most were actually using humor only to build relationships and to help clients cope. The majority of therapists felt comfortable using spontaneous humor with clients as part of the therapeutic use of self rather than using planned humor as a therapeutic intervention.

People who are disabled may need to learn ways to adapt to their new circumstances. Humor is a skill that can be learned and may provide the client with the ability to manage concerns related to his or her health and life situations. Within a larger relational context, humor may be modeled by occupational therapists to teach coping skills. Bandura[7] described four essential factors for **modeling** to be an effective intervention: (1) the client must have an adequate attention span that allows him or her to focus on the modeled behavior; (2) the client must be able to cognitively form and retain a mental image of the behavior; (3) the client must be able to recall the image and then produce the behavior; and (4) and perhaps most important, the client must have the motivation to engage in the behavior.

Ethical Considerations

Establishment of trust through the bond of a therapeutic relationship may provide the encouragement clients need to try new behavior, such as humor and laughter.[38]

The intimacy that humor presumes may provide the client with a sense of connection with the therapist. This connection, which occurs on conscious and unconscious levels, has many benefits for clients. When the therapist is able to demonstrate professionalism and empathy with a touch of humor, a client may feel less alone and more cared for as an individual.[73] An improved sense of equality with the healthcare provider may occur that could increase the client's active involvement in her or his treatment.[2,26]

Although laughter has been shown to be beneficial, there are times when humor may not be a good choice and must be used with caution or avoided altogether. Seizures and cataleptic or narcoleptic attacks may follow a laughter episode in a small number of people.[32] In addition, because laughing increases abdominal and thoracic pressure, people with recent abdominal surgery, upper body fractures, acute asthma, or “preexisting arterial hypertension and cerebral vascular fragility”[32] should not be encouraged to laugh.

Ethical Considerations

Occupational therapists also need to be aware that humor can have destructive elements and may be used intentionally or unintentionally to hurt a person. Following the “AT&T principle”[71] (**a**ppropriate, **t**imely, and **t**asteful) can help OTs determine the proper use of humor. As Klein[44] pointed out, this principle means that the therapist must be attuned to the patient's humor style, culture, and current status (physical, emotional, and cognitive) before introducing humor and facilitating laughter.

Leisure exploration is defined in the OTPF-3 as “identifying interests, skills, opportunities, and appropriate leisure activities,” and **leisure participation** is “planning and participating in appropriate leisure activities; maintaining a balance of leisure activities with other areas of occupation; and obtaining, using, and maintaining equipment and supplies as appropriate”[4] (OTPF-3, p. S21). In exploring leisure options with the client, the occupational therapist must evaluate the appropriateness of an occupation with respect to the client's age and gender, the cultural fit, and the meaning of the occupation to the specific individual. These concerns are addressed in the next section.

Meaningful Leisure Occupations: Age, Cultural Issues, and Gender

Clients choose the leisure occupations they want to pursue.[4,76] Choices may be based on past experiences or on a desire to explore something new. As people move through the developmental stages of adulthood, the occupation of leisure may vary in intensity and time allotted. The continuity theory of aging suggests that personality plays a major role in adjustment to aging. Because personality does not radically change throughout life, preferences, lifestyle, and activities remain relatively the same in individuals who age successfully.[5,14,56,80,81]

Age and Leisure

It is crucial that occupational therapists have a knowledge of the typical progression through adulthood, the common life-stage choices of leisure activities, and the ways physical disabilities can disrupt participation in leisure activities. Armed with this information, OTs are able to discover gaps in developmental stages and to assist clients in the mastery of valued and meaningful occupations.[27]

Young Adulthood (20 to 40 Years)

Young adults are typically healthy, active, working, and engaged in relationships. Erikson's sixth stage of psychosocial development, intimacy versus isolation, describes young adulthood as a time in life when people know who they are and are ready to form intimate relationships with others.[61] Inability to make commitments on an intimate level may lead to isolation. Levinson views this age period as a time of becoming independent from parents, choosing and beginning a career, and imagining one's dream future.[61] Young adults typically settle down and choose interests that encompass family, work, and leisure activities.

Examples of leisure activities in which young adults engage may include social and family group activities, sports (eg, basketball, off-road biking), exercise (eg, zumba and yoga), travel, computer games, social networking on the Internet, hobbies and crafts (eg, scrapbooking), outdoor activities, dancing, dating, and sex. In addition, the popularity of outdoor adventure sports continues to grow at a rapid pace. Many outdoor adventure sports are fully accessible, even if the individual has limited arm movement. These include paragliding, flying a sailplane, hang gliding, sky diving, surfing, white water rafting, and zip lining (Fig. 16.1).[83]

FIG 16.1 Wheelchair user zip lining in Costa Rica. (From Vogel B: Outdoor recreation: you can do it, New Mobility 26(263):32–42, 2015.)

Accidents or physical disorders that affect an individual's areas of occupation, performance skills, and body functions can severely impede progress through the normal activities of young adulthood and may delay the development of age-related roles such as spouse, parent, employer/employee, social participant, participator in leisure occupations, and sexual being. Individuals at the beginning stage of adulthood who sustain an irreversible injury may need to redefine themselves to successfully navigate the aging process. Leisure problems may include social isolation and changes in relationships, lack of ability to perform favorite sports, difficulty traveling, and decreased knowledge of how to creatively express the self.[36,42,78] A sense of incompetence may ensue that could lead to depression.

Middle Adulthood (40 to 65 Years)

People in this age group are typically immersed in work and family life. They have usually developed expertise in their chosen field of employment and may have risen to supervisory levels. Financial independence is attained as people purchase homes and cars and build a nest egg. Some adults in this age group experience a midlife review of self and career and may change careers or retire. This is the stage of generativity versus stagnation (Erikson's seventh stage of psychosocial development) in which the person enjoys developing the skills and talents of younger people (eg, serving as a sports coach or work mentor).[61] Lack of generativity may lead to stagnation in life, disappointment, and burnout.[27]

Examples of leisure activities typical of this age group are friend and family activities, sports (eg, golf, bowling, coaching [Fig. 16.2]), card games, Internet surfing, socializing and shopping, travel, pet care, gardening, movies, attending plays and concerts, boating, fishing, reading, television, bike riding, dating, and sexual activity with a spouse or partner.

FIG 16.2 Middle-aged man coaching a baseball player at third base. (Courtesy iStock.com)

Disruption caused by a physical disability can impair the individual's ability to engage in cherished leisure occupations. Spouses or significant others are called on to be caregivers, and the relationship may undergo changes. Leisure occupations such as travel and fishing may be put aside for the more immediate concerns of learning to cope with self-care, rehabilitation exercises, and therapeutic equipment.[74,88] Friend relationships often change as well. For example, if two men had a friendship based on golfing every Saturday and one of them experiences a stroke and needs to use a wheelchair, either they will have to be proactive and figure out a way to enjoy each other's company in a new way (eg, playing golf with adapted equipment or trying out a new activity that they both enjoy), or they may drift apart. Finally, changes caused by life transitions such as menopause and empty nest syndrome are ameliorated many times by engagement in leisure occupations. For example, a qualitative study of women experiencing menopause indicated that leisure activities not only gave the women a sense of familiarity, security, and continuity, but also provided them opportunities to develop new interests and to focus on themselves.[64]

Late Adulthood (65 Years or Older)

Occupational roles typically go through transformations during this age span. Some changes seen in older adults include a shift of emphasis from parent to grandparent and from worker to retiree or volunteer. As time spent in work/career diminishes, free time increases, and leisure occupations come into full bloom. The interests and activities that were put aside during career attainment can now be given full rein.[27] Erikson's last stage of psychosocial development (stage 8, ego integrity versus despair) is described as the time when people review their lives and hopefully accept the life cycle as being complete and satisfying.[61] The "use it or lose it" principle is particularly important as people age. If activity levels are not maintained, strength, coordination, and skills may deteriorate rapidly.[61] Some aspects of aging considered fairly normal include diminishing hearing and eyesight, arthritis, and decreased sensory abilities, in addition to general aches and pains.

Examples of leisure activities in which older adults engage are dining with or cooking for friends and family, social activities, card games, bingo (Fig. 16.3), travel, sports (eg, golf, or attending games or watching them on TV), walking, exercise at the gym, swimming, boating, sexual activity with a spouse or partner, reading, television, pet care, gardening, and hobbies (eg, crafts, genealogy, collecting, scrapbooking).[13,47]

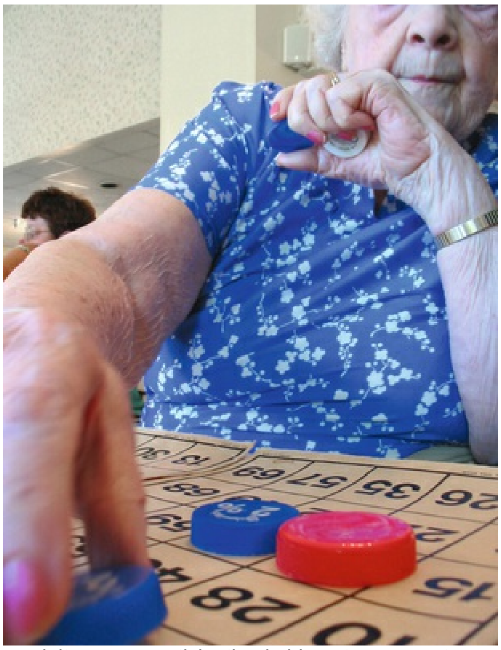

FIG 16.3 Older adult woman participating in bingo tournament. (Courtesy iStock.com)

If a physically disabling event or disease progression occurs, spouses or significant others may be called on to assist their partners in performing ADLs, including leisure. This can be problematic because the caregiver may also be advanced in age and may not be well suited to provide the care needed.[53] Consequently, leisure activities may be forgotten except for sedentary activities, such as watching television.[88]

For some in late adulthood, isolation and depression could set in and diminish the person's quality of life. A quantitative study of 383 retirees indicated that leisure plays a significant role in achieving a high level of life satisfaction, which the authors propose is equivalent to successful adaptation to retirement.[56] In a study of 324 older Swedes living in the community, Silverstein and Parker[71] discovered that people who increased participation in leisure activities reported being more satisfied with life. The researchers stated, "The results suggest that maximizing activity participation is an adaptive strategy taken by older adults to compensate for social and physical deficits in later life."[71] Mental acuity may also be strengthened or preserved by engaging in novel activities. Engagement with life is vital to successful aging.[47,72]

Culture and Leisure

Because of the increasing diversity of the U.S. populace, occupational therapists must know how culture affects the choices and performance of leisure activities for clients. The U.S. Census Bureau (*www.census.gov*) reports that although the white population is still the majority (63%), by the year 2050, whites and minority groups overall will be roughly equal in size. Ethnic groups are currently concentrated in various areas of the country (Table 16.1). Thus, depending on where occupational therapy is delivered, therapists should make themselves familiar with leisure activities related to the culture of their clients.

TABLE 16.1

Population Estimates for Ethnic Groups in the United States (2013)

Ethnic Group	Percentage of the Population	Population Centers
White	62.6	Midwest and Northeast
Hispanic or Latino	17.1	Southwest and California
Black or African American	13.2	Southeast and Mid-Atlantic
Asian American	5.3	West and Northeast
American Indian and Alaskan Native	1.2	Northwest, West, Southwest, and Midwest
Native Hawaiian and other Pacific Islanders	0.2	Hawaii and West
Two or more races reported	2.4	

Data from US Bureau of the Census: 2013 population estimates. http://www.census.gov.

Leisure Occupations Related to Culture

Games and leisure occupations instruct, inspire, and reflect the values and beliefs of the parent cultures. For people who immigrate to a new country (eg, Hispanics to the United States), leisure activities can be used to maintain connections with their heritage. Other possible uses of leisure that aid community integration are to gain pleasure from the new environment and people and learn their language and customs.[43] Watching television and reading are two ways newcomers use leisure to improve their conversational skills and to understand cultural features.[3] Depending on the interest of the client involved, occupational therapists may offer leisure occupations that reflect the client's traditional background, thus fostering security in a new country, or provide leisure experiences of the new country to increase learning, comfort, and integration. Keeping the leisure interventions client centered is the critical element for a successful outcome. Table 16.2 presents ideas for leisure resources.

Leisure-Time Physical Activity by Gender, Age, and Racial/Ethnic Groups

Physical inactivity has been associated with various health risks, such as obesity; cardiovascular disease, including stroke; diabetes; some cancers; and premature mortality.[19] Occupational therapists can help clients live a healthy lifestyle by encouraging them to participate in some type of leisure-time occupation that involves physical exercise at least several times a week. Some examples of leisure occupations that provide physical exercise but that could be more attractive alternatives to some people are dancing, swimming, boating, bowling, golfing, gardening, and yoga.

To discover trends in physical activity levels, researchers at the Centers for Disease Control and Prevention conducted a randomized telephone survey of 170,423 people from 35 states and the District of Columbia. They asked, "During the past month, other than your regular job, did you participate in any physical activities or exercise such as running, calisthenics, golf, gardening, or walking for exercise?" Analysis of the data revealed that women, older adults, and the majority of racial/ethnic groups participated the least in leisure-time physical activities.[37] African Americans, Hispanics, Native Americans, and Alaskan Natives more often reported fair or poor health, obesity, diabetes, and lack of leisure-time physical activity than did whites, Asians, or Pacific Islanders. Women in all cultures surveyed engaged in the least amount of physical activity.[28,60]

Some barriers to leisure-time physical activity have been identified. Although many people of different cultures and ages believe that movement (eg, exercise, gardening, walking) yields positive benefits, such as improved health and appearance, they do not engage in physical activities because of "self-consciousness and lack of discipline, interest, company, enjoyment and knowledge."[21] Additional barriers to activity were identified, such as lack of transportation, prohibitive cost, and perceived lack of safety.[47] Social issues, such as gender roles for activity and poor support from the family, were identified by minority women. As barriers to activity, these women additionally reported problems with language, isolation in the community, and lack of childcare because of lack of relatives in the area. In planning interventions, occupational therapists can collaborate with clients to address these problems, find community resources, and develop strategies to improve participation in leisure-time physical activities.

OT Practice Notes

Barriers to Leisure Participation

Incurring any type of disability or health condition may result in barriers to leisure engagement, such as the following.[10,29]

- Perception of constraint
- Loss of interest, motivation
- Lack of facilities/support, lack of physical access
- Reduced ability/limited tolerance of activity
- Lack of time
- Attitude of others (caregivers may not value leisure)
- Attitudes of fellow participants (awkwardness displayed by able bodied)
- Challenging behaviors (eg, in those with neurologic disability)
- Communication issues (eg, in those with cognitive deficits)
- Increased expense (as a result of adaptations, career support, equipment)

Leisure Occupations: Evaluation and Intervention

The OTPF-3 focuses on a client-centered approach, and as the first step in the therapy process, the OTPF-3 requires the OT to work collaboratively with the client and family/caregivers to develop an occupational profile.[4] The profile includes the client's occupational history, past and current interests, performance, and values. A knowledge of the problems and goals the client and family/caregivers consider important gives the therapist a basis for a meaningful intervention plan. Evaluation includes formal and informal assessments, conducted initially and over the course of the therapy process, to guide the therapist in providing an individualized intervention program that meets the client's expressed needs and desires. Examples of possible assessments that address the leisure area of occupation and a description of each are presented in Table 16.3.

OT Practice Notes

Evaluation and Intervention for Leisure Activities

To ensure successful performance of leisure activity, the OT practitioner needs a comprehensive approach to evaluation. Important components are:

- Demographic material
- Social information, including family context
- Educational history
- Occupational history
- Military involvement
- Community and church involvement
- Typical daily routine
- Interests and hobbies
- Meanings assigned to occupations, including leisure occupations
- Mealtime interests
- Abilities
- Sensorimotor components
- Cognitive components
- Psychosocial components

TABLE 16.3

Standardized and Nonstandardized Leisure Assessments and Descriptions Used by OTs

Assessment	Descriptions
Activity Card Sort (second edition)[8]	Picture cards of adults performing instrumental, social-cultural, and leisure activities. Client sorts them into piles, depending on his or her interest level. Provides a “retained activity level” score indicating engagement levels of performance of past and current activities. Standardized.
Canadian Occupational Performance Measure (fifth edition)[49]	Interview conducted before and after interventions to describe problems, level of satisfaction in performing activities, and level of perceived performance abilities in areas of self-care, productivity, and leisure. Available in multiple languages. Standardized with Web-based scoring.
Leisure Attitude Scale—Short Version for adolescents and young adults (LAS-SV)[79]	Measures leisure attitudes using 18 self-report items, comprising three subscales, that address cognitive, affective, and behavioral components of attitude. Rated on a 5-point Likert scale from 1 (strongly disagree; very unfavorable or negative attitude) to 5 (strongly agree; favorable or positive attitude). Standardized.
Leisure Satisfaction Scale (LSS—Short Form)[82]	Measures whether personal needs are met through leisure activities. Scale of 24 items scored on a 5-point Likert scale from 1 (almost never true for me) to 5 (almost always true for me). Higher scores indicate greater satisfaction. Standardized.
Nottingham Leisure Questionnaire (shortened version)[25,84]	Measures declination of leisure participation in clients with stroke. Questionnaire of 30 items scored on a 3-point Likert scale (regularly, occasionally, never). Standardized.

Ohio Functional Assessment Battery: Standardized Tests for Leisure and Living Skills[59]	Designed for use in cognitively impaired individuals. Structured interview/questionnaire assessing interests, resources, participation, motivation, and barriers to therapy. Three test options: Functional Living Skills Assessment, Quick Functional Screening Test, and Recreation and Leisure Profile. Standardized.
Physical Activity Scale for the Elderly (PASE)[86]	Ten-item self-report assessment measures physical activity, including leisure, household, and physical activities over the preceding 7 days. Standardized.
Physical Activity Scale for Individuals with Physical Disabilities (PASIPD)[87]	Modification of the PASE specifically for individuals with physical disabilities; 13 items consist of leisure, household, and occupational activity components. Standardized.
Quality of Life Scale[15,16,30,88]	Perceived quality of life on a scale of 16 items (eg, material comforts, expressing oneself creatively, socializing, participating in active recreation). Rated on a Likert scale from "very dissatisfied" to "very satisfied." Standardized.
Occupational Profile[48]	Interview with the client (and family/caregivers if appropriate), along with observations to gather information about demographics, language, health status, and social and medical history. Questions address why the client needs OT services, what his or her concerns are, the client's occupational history (eg, values, meanings associated with life experiences), and the client's priorities. Nonstandardized.
Modified Interest Checklist (*http://www.cade.uic.edu/moho/*)	Checklist of 68 activity items that assesses the client's level of interest (casual, strong, or no interest). Includes many leisure-time activities. Available in multiple languages. Nonstandardized.
Role Checklist[57] (*http://www.cade.uic.edu/moho/*)	Interview to discover past, present, and future occupational roles (including leisure roles) and their value to the client. Available in multiple languages. Nonstandardized.

Intervention: Where There's a Will, There's a Way

Based on information gathered during the evaluation process, an intervention plan incorporating leisure occupations is developed; this plan must be one that the client and family/caregivers view as important to improving quality of life. Clients (including family members or caregivers, as necessary) and therapists develop goals and plan interventions together, thus ensuring that the client is motivated to engage in therapy sessions to the best of his or her ability.[4] In occupational therapy, leisure occupations can be a means and an end. As a means of intervention, the client is provided with the therapeutic use of leisure that is motivating because it is chosen and fun. Leisure as an end is seen when the client voluntarily engages in leisure occupations after therapy intervention stops.[4] As stated by Taylor and McGruder,[78] when developing discharge plans that include leisure, the therapist should consider "attributes of novelty and challenge, meaningful use of time, and identity construction," which are imperative to the continued growth, adaptation, and quality of life of clients. Occupational therapists may offer a variety of leisure activities that are delivered to individuals or groups, depending on the relevance to the client's interests, abilities, and activity demands. In the case of Kris (see the following case study), individual activities need to be mastered before group activity can be considered.

Case Study

Kris

Kris, a 22-year-old man with a spinal cord injury (paraplegia), has an avid interest in playing wheelchair basketball. To prepare him for this sport, the occupational therapist works with him individually to order the correct wheelchair, strengthen his upper extremities, develop skill in dribbling, catching and throwing the ball, making baskets from the wheelchair, finding appropriate sports apparel (eg, to hide his leg bag; shirts that can stay down in back when he is reaching for the basket; push cuffs or golf gloves to protect his hands), and learning how to get back into the wheelchair when he falls out on the court. Referral is then made to a recreational therapist, who helps Kris incorporate these basic skills into an existing team of players. By developing his individual skills before entering the group activity, his potential to successfully participate in his leisure activity of choice is increased.

Balloon volleyball is a fun and social activity. For example, in a long-term care facility, residents with appropriate cognitive and motor skills can be organized into two teams, seated and facing each other. A real or simulated volleyball net is erected between the two teams, and a balloon is hit back and forth. Music adds to the enjoyable atmosphere. This game can meet several OT goals, such as improving eye pursuit, upper extremity range of motion, socialization, and cognition (keeping track of the score). In addition, because joking and laughing often occur, physical, social, and psychological benefits may be gained (see Box 16.1). The therapist must ensure that clients are interested in participating and that each person is safe, with wheelchairs locked and, if necessary, seat belts attached. Cardiac patients may not be appropriate to include because of the upper extremity workout and increased respiration, heart rate, and blood pressure that could occur.

Adapting the Activity for Success

Occupational therapists are uniquely qualified to adapt the activity, including the equipment, the environment, or the nature of the activity, to make leisure occupations accessible to clients. By participating in leisure occupations that are meaningful, clients are able to continue to make positive adaptations that lead to greater life satisfaction. Table 16.4 describes some leisure occupations and possible adaptations.

TABLE 16.4

Examples of Adapted Leisure Occupations

Leisure Occupation	Possible Adaptations	
Gardening	Raised beds for flower or vegetable gardens that are accessible from a chair or wheelchair. Nonskid surface under pots to prevent sliding during potting.	 (Courtesy iStock.com.)
Bowling	Wheelchair specially designed for bowling, on which the wheels are set under the chair for ease of bowling action. Bowling ball can be made with handles for people with arthritis or hand dexterity problems.	 (Courtesy Innovative Bowling Products, Jacobus, PA.)
Golf	Adapted golf clubs (eg, constructed to be used from a seated or wheelchair position or to be used one handed), lower extremity prosthetics specially made for golf.	 (Courtesy David B Windsor, PGA, Georgia State Golf Association Adaptive Golf; Adaptive Golf Academy and Adaptive Golf Association.)
Playing cards	Card shuffler, card holder, large-print or Braille cards	

		 (Courtesy iStock.com.)
Computer activities or Internet surfing	Large monitor screen, large-print font, voice-activated controls or software (eg, Dragon NaturallySpeaking).	 (Courtesy iStock.com.)
Cooking	Energy conservation techniques, sliding instead of lifting heavy pots, nonskid surface to prevent slippage, rocker knife, perching stool.	 (Courtesy iStock.com.)
Pets	Canine companions to manage daily tasks (eg, open drawers and doors, acknowledge phone ringing, obtain objects) and to provide love and licks. Therapy dogs to visit clients in hospitals, skilled nursing facilities, and homes to bring joy and opportunities for touch. Pets such as fish, cats, dogs, and others provide companionship and may promote motivation for engagement in caring activities.	 (Courtesy iStock.com.)
Bike riding	Handcycles for those with lower extremity weakness or paralysis. These bikes are propelled and controlled by arm strength and coordination.	

		

Level of Functioning

Occupational therapists view the client as a whole person with myriad dimensions (eg, physical, cognitive, spiritual, psychological). Leisure occupations are self-enhancers that add joy and pleasure to life. For effective implementation, activities must be analyzed according to the individual's level of functioning (eg, performance skills, performance patterns, client factors, activity demands, and context). Examples of clients by level of function, along with leisure occupations that are meaningful to the individual, are presented in the case studies of Tina, John, and Miguel.

Case Studies

Tina, John, and Miguel

Tina

Level of Function: Maximum Assistance Needed

Tina, a 41-year-old mother of two, had a severe stroke that left her unable to smoothly coordinate movement. She enjoys listening to tapes of her son playing the guitar.

Leisure Occupation

OT assessment revealed that when Tina was positioned correctly, her left hand could be guided to hit a large-button switch (Fig. 16.4). Stephanie, the OT, connected the button switch to a tape player, which held a tape of her son's recent musical accomplishments. Her family members were instructed in how to assist Tina so that they could all participate in a valued leisure activity together.

FIG 16.4 Tina, with her husband, Scott, using a large-button device to turn on a tape player so she can listen to her son playing the guitar.

John

Level of Function: Moderate Assistance Needed

John, a 50-year-old man, suffered a traumatic brain injury 3 years earlier. He demonstrates poor dynamic balance, short-term memory deficits, and weakness on his right side. He uses a three-wheeled walker for ambulation. John lives with his wife and is independent in the majority of activities of daily living. His passion is bowling.

Leisure Occupation

After assessing his satisfaction and perceived bowling performance using the Canadian Occupational Performance Measure (COPM), DeShawn, John's occupational therapist, accompanied John, his wife, and their adult son to the bowling alley. DeShawn called ahead to make sure the bowling alley was accessible and had accommodations for people with disabilities. The lanes were set up with gutter bumpers and a bowling ball ramp. Using a gait belt and moderate assistance, John was able to place a lightweight ball on the ramp, set up his shot, release the ball, and knock down some of the pins. When he, his wife, and his son saw that bowling was possible again, they set up a family night once a week to resume a cherished fun activity.

Miguel

Level of Function: Independent

Miguel, a 25-year-old single man, was in a skiing accident 5 years earlier and incurred a spinal cord injury that resulted in paraplegia. He progressed through rehabilitation and is independent in ADLs and instrumental activities of daily living (IADLs). He uses a power wheelchair, drives, and has a job as a police dispatcher. Miguel has come to occupational therapy to upgrade his wheelchair and discuss leisure occupations. He reports that his free time is boring and he wants to return to a sport.

Leisure Occupation

Wheelchair sports abound in variety. Miguel's occupational therapist, Eric, began by helping Miguel explore the many options for people who want to participate as a wheelchair athlete, including basketball, mountaineering, hunting, rugby (the fastest-growing wheelchair sport), weightlifting, racing (including handcycle racing), tennis, javelin throwing, and snow skiing. When Miguel indicated that he might be interested in resuming his previously loved leisure occupation of camping, Eric showed him how to locate helpful resources, such as magazines, journals, websites, catalogs, and other related publications. For example, an article in the *British Journal of Occupational Therapy*[17] reviewed sports wheelchairs, and that article might also provide information on the chairs' suitability for use on camping trails.

Miguel was further directed to *New Mobility*, a magazine written for and by people with physical disabilities, which had an excellent article on accessible campgrounds and suggestions for making a trip successful. Eric also recommended other magazines, such as *Adapted Physical Activity Quarterly* and *Sports'n Spokes*, so that Miguel could read about others' experiences and stories and broaden his ideas of equipment and gadgets for wheelchair users. Eric was thrilled to hear from Miguel a few months later that he had indeed gone camping (Fig. 16.5) and that it was a "super experience!"

FIG 16.5 Miguel, in his power wheelchair, is able to enjoy the experience of forests and camping. (Courtesy iStock.com)

Threaded Case Study

Jeri, Part 2

Reconsider the questions posed about Jeri, a 29-year-old newly married woman whose case study opened the chapter.

1. Is Jeri really ready to be discharged from occupational therapy?

Probably not. Although the occupational therapist has done a thorough job of teaching Jeri how to be competent in ADLs, we now know that there is more to life for occupational therapists to consider than just instructing clients in personal care techniques. OT assessments of Jeri's leisure attitudes, interests, skills, and abilities need to be undertaken and a further intervention plan developed that addresses her quality of life issues.

2. Why is Jeri dissatisfied with her current lifestyle?

Jeri is leading a restricted life, compared with her life before the accident. She has lost many of the activities that brought joy to her life. She is unable to do scrapbooking because she still lacks the fine motor coordination in her dominant hand to manipulate scissors and small decorative paper pieces. She wants to drive again and misses working as an interior designer, shopping, meeting friends for lunch, and running errands. Her husband treats her as though she will break and is unsure whether she is capable of boating and fishing again. Jeri is no longer engaging in leisure activities that reaffirm her age-related competencies.

3. What interventions could the OT provide to improve Jeri's quality of life?

To improve Jeri's ability to resume her cherished hobby of scrapbooking, the occupational therapist could provide fine motor activities that incorporate scrapbooking materials. Manipulation of materials can be improved by gluing small pieces of paper onto sturdy cards to make them easier to hold and using adapted scissors for cutting. A predriving assessment and perhaps driver training may help Jeri resume her outside activities, or the assessment may determine that driving is not advisable at this time. If Jeri is unable to drive, the occupational therapist may determine that an intervention aimed at accessing and using public transportation may be the first step in increasing community independence.

A collaborative session with Jeri's husband can be set up to talk through his concerns and to instruct him in the use of adaptive equipment, transfers, and other means of assisting her in resuming former life roles, such as fishing. Jeri, her husband, and the occupational therapist could discuss Jeri's missed social roles and need for emotional expression. They may set mutual goals that encourage Jeri and her husband to invite friends and family over for a few hours for socializing. She may also be interested in joining a brain injury support group that the OT department runs to provide her with needed peer interaction; her husband may also wish to be included in a support group for families. Sexual and sensual expression may be brought up in this meeting, and the occupational therapist could offer suggestions regarding communication of perceived changes, use of touch, and positions to enhance intimacy. The occupational therapist may also indicate referrals, as necessary. All of these leisure-related accomplishments will help reestablish 29-year-old Jeri's perception of herself as a whole human being.

Summary

Occupational therapists assist clients in attaining life satisfaction through a variety of occupations that are meaningful to the individual. Engaging and reengaging in leisure occupations, which may include social interactions, movement, playfulness, and pleasure, are important aspects of a balanced lifestyle. Realizing that lack of leisure activities may lead to isolation and depression and detrimentally affect an individual's recovery and joy in life, occupational therapists need to include leisure evaluation, intervention planning, and implementation for people with physical disabilities. Consideration of the client's age, gender, culture, interests, and environment is paramount when investigating or implementing leisure so that the intervention is client centered. A skilled occupational therapist can facilitate participation in meaningful leisure occupations that may lead to improved psychological and physical well-being, social relationships, and quality of life.

Review Questions

1. What can the absence of a meaningful leisure occupation lead to for people with a physical disability?
2. List five psychosocial benefits and five physical benefits of leisure activities.
3. Why is the client's cultural background important when considering leisure occupations?
4. When should humor and laughter be used with caution?
5. What four factors are essential for modeling behavior to be an effective intervention?
6. Why is it important for the client to be involved in setting his or her own goals?

Assistive Technology

Denis Anson

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, the student or practitioner will be able to do the following:

1. Describe the range of assistive technology options currently available for people with physical disabilities.
2. Explain the human interface assessment (HIA) model.
3. Identify common solutions for enabling control of daily living devices through technology.
4. Discuss options for augmentative and alternative communications.
5. Analyze input and output options for assistive technologies and match them to the needs of clients.

KEY TERMS

Assistive technologies
Augmentative and alternative communications (AAC)
Electronic aids to daily living (EADLs)

Graphic communications
Human interface assessment (HIA) model
Message composition system
Message transmission system
Modifier keys
Pointing systems
Power switching
Rehabilitation technology
Universal design
User control system

Threaded Case Study

Gianna, Part 1

Gianna, who is 26 years old, has completed her undergraduate degree and wants to apply to law school. Her path to the legal profession is challenged by a complete spinal cord injury at the C4 level, which she sustained 12 years previously in an automobile accident that killed her parents. Gianna is bright, articulate, and exceptionally popular in her rural community. She recently received a new wheelchair with sip-and-puff controls, which allows her mobility in her home and community, and she would now like to attend law school. Ultimately, Gianna would like to specialize in disability rights to support the civil rights of others with profound disabilities. She believes that her insider perspective on the issues might make her arguments more compelling when disabled workers are seeking reasonable accommodations.

The admissions office at the nearby university, where Gianna wants to apply for law school, suggested that Gianna may have a difficult time completing the required work. As a law student, she will have to research legal precedence in case law and write briefs. She can get into the library, which meets many of the requirements of the Americans with Disabilities Act (ADA), but will need to be able to navigate the legal records, take notes on her findings, and write formal responses to legal challenges. The admissions counselor believes that Gianna, who has no movement below her neck, may find that the challenge of the legal profession exceeds her capabilities.

Gianna does have full-time attendant care, and the attendant would be allowed to sit with Gianna in the classroom and act as a note taker for her. (The school also provides lecture notes to disabled students within 3 days of a class session, if requested.)

However, because Gianna's attendant must constantly monitor Gianna's physical needs, the ability of the attendant to focus on the lecture may be impaired. In addition, because the attendant does not have the interest or background to study law, her ability to identify and record what is important in the lecture is limited. Finally, because of the required hours and hourly wage, Gianna is often faced with attendants quitting after 6 months or so. The new attendant would not have a complete background to help in interpreting the material Gianna is studying.

In her home life Gianna would like to be able to adjust the lights in the room, the room temperature, and the music playing (she prefers to study with music in the background) without interrupting her attendant. She knows that she will always be dependent on others for bathing, dressing, meal preparation, and many other aspects of her activities of daily living. However, she thinks that if she were able to make fewer demands on her attendants, they might be able to remain in her employ longer.

Gianna is seeking an assistive technology consultation to explore technological aids that could help her reach her life goals.

Critical Thinking Questions

1. Which of Gianna's areas of occupation might be improved through the application of assistive technology?

2. What types of assistive technologies might assist Gianna in pursuing her activities and

occupations?

3. What control strategies might be appropriate for Gianna?

4. Would Gianna benefit from output enhancement technologies?

What Is Assistive Technology?

A discussion of assistive technology should begin with a description of the general limits of this modality. This is made difficult because the legal definitions of assistive technology are not uniform. Assistive technologies are sometimes included in the category of rehabilitation technology.[12] In other cases, rehabilitation technology is considered an aspect of assistive technologies.[8] A third type, universal design technologies, does not seem to fit into either category.[11] For the purposes of this discussion, the author presents a set of definitions that are within the current definitions, but not necessarily congruent with any particular statute.

Rehabilitative, Assistive, and Universal Technologies

The category into which an enabling technology falls depends largely on its application, not on the specific device. What is for some people a convenience may be an assistive technology for another.

Rehabilitation Technology

To *rehabilitate* is to restore to a previous level of function. To be consistent with general usage, therefore, the term **rehabilitation technology** should be used to describe technologies that are intended to restore an individual to a previous level of function after the onset of pathology. When an occupational therapist (OT) uses a technological device to establish, restore, or modify function in a client, he or she is using a rehabilitative technology. Physical agent modalities, such as ultrasound, diathermy, paraffin, and functional electric stimulation, are examples of rehabilitative technology. Broadly, whenever an OT uses a technology, be it diathermy or a traditional OT activity (eg, leather working) with the primary goal of restoring strength, mobility, or function, the technology is rehabilitative. When these technologies have done their job, the client will have improved intrinsic function, and the technology will be removed.

Assistive Technology

Central to occupational therapy is the belief that active engagement in meaningful activity supports the health and well-being of the individual. When an individual has functional limitations secondary to some pathology, he or she may not have the cognitive, motor, or psychological skills necessary to engage in a meaningful activity and may require assistance to participate in the desired task.

Ethical Considerations

Rehabilitative technologies are generally intended to be used in a therapy setting by trained professionals and for a short period. Because these technologies are intended to be used by trained professionals, they can have fairly complex or cryptic controls. The expectation is that the professional will have had significant training before using the technology. The professional guiding the use of such technologies is expected to ensure correct application of the technology and to protect the safety of the individual using the device.

To *assist* is to help, aid, or support. There is no implication of restoration in the concept of assistance. **Assistive technologies**, therefore, are technologies that assist a person with a disability to perform tasks. More specifically, assistive technologies are technologies, whether designed for a person with a disability or designed for mass market and used by a person with a disability, that allow that person to perform tasks that an able-bodied person can do without technological assistance. It may be that an able-bodied person prefers to use a technology to perform a task (eg, a television remote control), but the device does not rise to the level of assistive technology as long as it is possible for the individual to perform the task without the technology.

Assistive technologies replace or support an impaired function of the user without being expected to change the native functioning of the individual. A wheelchair, for example, replaces the function of walking but is not expected to teach the user to walk. Similarly, forearm crutches support independent standing but do not, of themselves, improve strength or bony integrity and thus will not change the ability of the user to stand without them.

Because they are not expected to change the native ability of the user, assistive technologies have different design considerations. These devices are expected to be used over prolonged periods by individuals with limited training and possibly with limited cognitive skills. The technology, therefore, must be designed so that it will not inflict harm on the user through casual misuse. The controls of the device must be readily understood, such that although some training may be required to use the device, constant retraining will not be. The device should not require deep understanding of its principles and functions to be useful.

A significant difference between rehabilitation technology and assistive technology can be seen at the end of the rehabilitation process. At this point the client no longer uses rehabilitation technologies but may have just completed training in the use of assistive technologies. The assistive technologies go home with the client; the rehabilitation technologies generally remain in the clinic. Some technologies do not fit neatly into these categories because they may be used differently with different clients. For some clients, the practitioner may use assisted communication as a tool to train unassisted speech. For other clients, assisted communication may be used to support or replace speech. In the first case, the technology is rehabilitative; in the second, the same technology may be assistive.

Universal Design

Universal design is a new category of technology. The principles of universal design were published by the Center for Universal Design at North Carolina State University in 1997,[11] and their application is still very limited. The concept of **universal design** is very simple: if devices are designed with the needs of people with a wide range of abilities in mind, they will be more usable for all users, with and without disabilities.

In some cases this design philosophy could make assistive technology unnecessary. A can opener that has been designed for one-handed use by a busy housewife will also be usable by a cook who has suffered a cerebrovascular accident (CVA) and now has the use of just one hand. Because the two individuals are using the same product for the same purpose, it is just technology, not assistive technology. Electronic books on dedicated e-readers (eg, Kindle, iPad) include features to allow them to be used as talking books. The goal here is to provide a hands-free, eyes-free interface so that the books can be used by commuters while driving. However, the same interface will meet the needs of an individual who is blind and cannot see the screen or who has limitations in mobility and cannot operate the manual controls. No adaptation is necessary because the special needs of the person with a disability have already been designed into the product.

Role of Assistive Technology in Occupational Participation

The Occupational Therapy Practice Framework[7] defined the appropriate domain of occupational therapy as including analysis of the performance skills and patterns of the individual and the activity demands of the occupation that the individual wants to perform.

Human Interface Assessment

The **human interface assessment (HIA)** model, developed by Anson et al.,[5] provides a detailed look at (1) the skills and abilities of humans in the areas of motor output, cognitive processing, and communication/interaction and (2) the demands of an activity (Fig. 17.1A). The HIA model suggests that when the demands of a task do not exceed the skills and abilities of an individual, no assistive technology is required, even when a functional limitation exists (Fig. 17.1B). Conversely, when a task makes demands that exceed the native abilities of the individual, the individual will not be able to perform the task in the prescribed manner (Fig. 17.1C). In these cases an assistive technology device may be used to bridge the gap between demands and abilities (Fig. 17.1D).

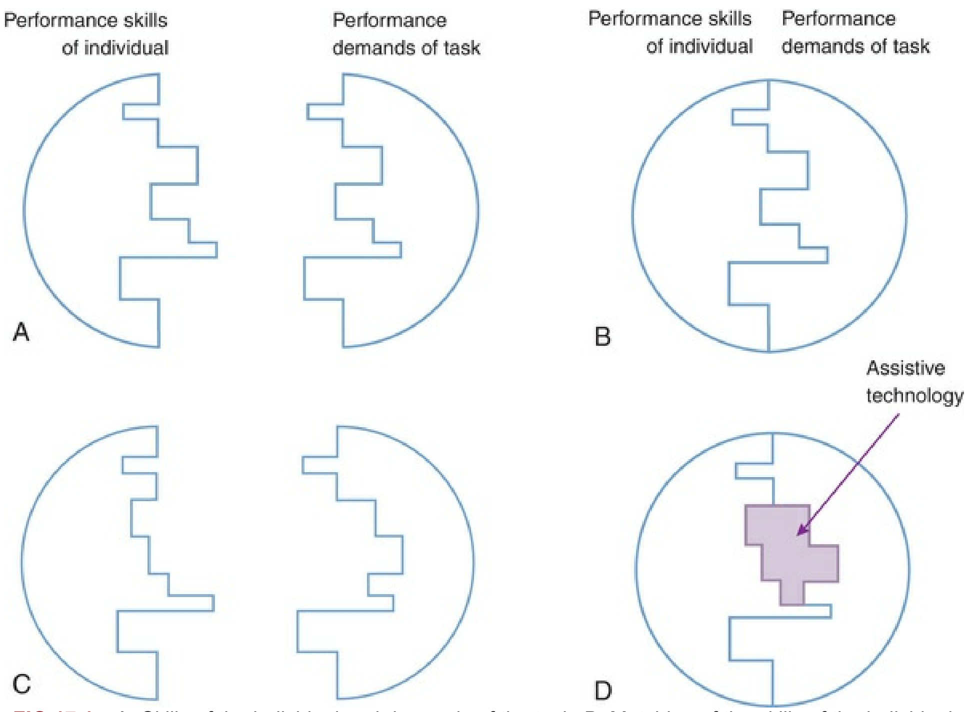

FIG 17.1 A, Skills of the individual and demands of the task. B, Matching of the skills of the individual with the demands of the task. C, Mismatching of the skills of the individual and demands of the task. D, Assistive technology used to bridge the gap between the skills of the individual and the demands of the task.

Although an assistive technology must be able to assist the individual in performing the desired task, it also presents an interface to the individual that must match his or her needs. A careful match between the abilities of the human in sensory perception, cognitive processing, and motor output and the input and output capabilities of assistive technologies is necessary for assistive technologies to provide effective interventions.

Types of Electronic Enabling Technologies

Even though modern technology can blur some of the distinctions presented in this section, it is useful to consider assistive technologies in categories defined by the application for which the technologies are used. This chapter deals only with electronic assistive technologies, which in terms of their primary application may be considered to fall into three categories: electronic aids to daily living, augmentative and alternative communications, and general computer applications.

Electronic Aids to Daily Living

Electronic aids to daily living (EADLs) are devices that can be used to control electrical devices in the client's environment. Before 1998 a device in this category was generally known as an environmental control unit,[31] although technically this terminology should be reserved for furnace thermostats and similar controls. The more generic EADL applies to control of lighting and temperature, in addition to control of radios, televisions, telephones, and other electrical and electronic devices in the environment of the client (Fig. 17.2).[9,10,13]

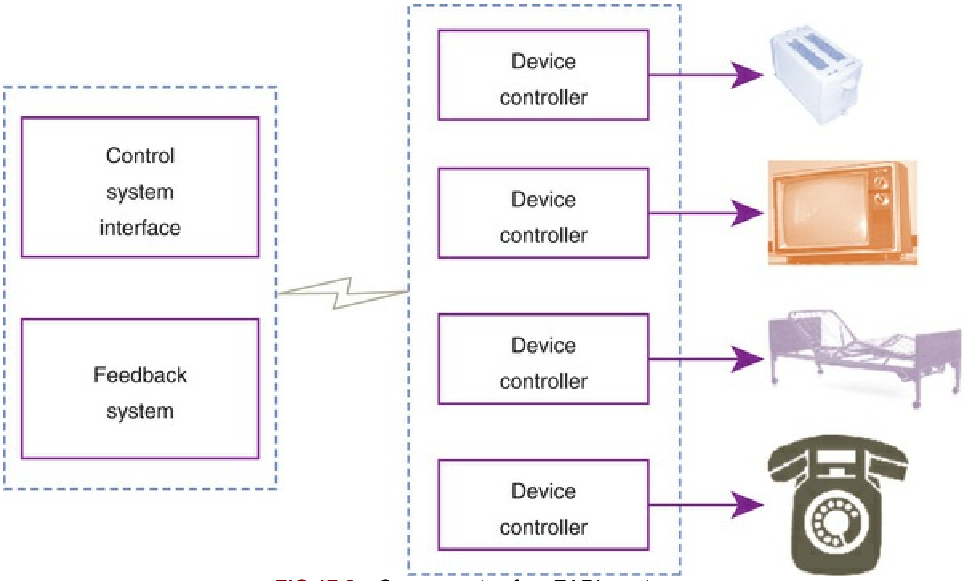

FIG 17.2 Components of an EADL system.

As described by the HIA model, EADLs bridge the gap between the skills and abilities of the user and the demands of the device to be controlled. Within this context, EADL systems may be thought of in terms of the degree and types of control over the environment that they provide to the user. These levels of control are simple **power switching**, control of device features, and subsumed devices (Fig. 17.3).

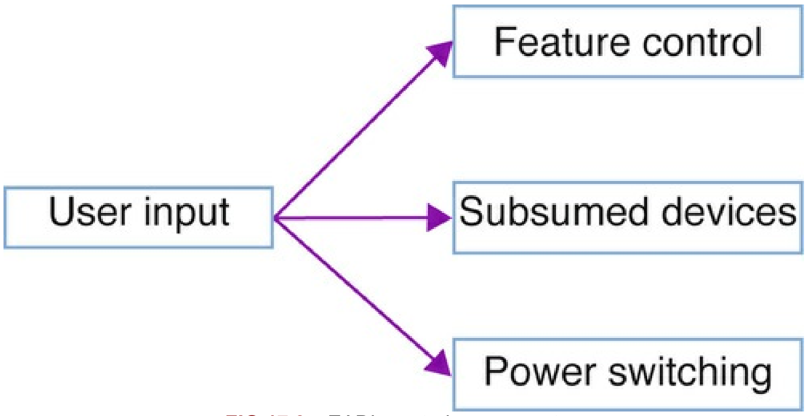

FIG 17.3 EADL control components.

Power Switching

The simplest EADLs provide simple switching of the electrical supply for devices in a room. Though not typically considered EADLs, the switch adaptations for switch-adapted toys provided to severely disabled children would formally be included in this category. Primitive EADL systems consisted of little more than a set of electrical switches and outlets in a box that were connected to devices in a room by extension cords (eg, Ablenet PowerLink 3). These devices are limited in their utility and safety because extension cords pose safety hazards to people in the environment through the risks of both falls (tripping over the extension cords) and fires (overheated or worn cords). The limitations of extension cords drove EADL technology to use remote switching technologies.

Second-generation EADL systems used various remote control technologies to remotely switch power to electrical devices in the environment. These strategies included the use of ultrasonic pulses (eg, TASH Ultra 4), infrared light (eg, infrared remote control), and electrical signals propagated through the electrical circuitry of the home (eg, X-10). All these switching technologies remain in use, and some are used for much more elaborate control systems. However, we will be considering only power switching.

The most prevalent power-switching EADL control system is produced by the X-10 Corporation. The X-10 system uses electrical signals sent over the wiring of a home to control power modules plugged into wall sockets in series with the device to be controlled. (In a series connection, the power module is plugged into the wall, and the remotely controlled device is plugged into the power module.) X-10 supports up to 16 channels of control, with as many as 16 modules on each, for a total of up to 256 devices controlled by a single system.

The signals used to control X-10 modules will not travel through a home's power transformer, so in single-family dwellings, there is no risk the devices will interfere with systems in a neighbor's home. However, this is not necessarily true in an apartment setting, where two X-10 users may inadvertently control each other's devices. The general setup for early X-10 devices was to control up to 16 devices on an available channel so that such interference would not occur.

In some apartments or homes, the power in a single unit may be on different phases of the power supplied to the building. (These phases are required to provide 220-volt power for some appliances.) If this is the case, the X-10 signals from a controller plugged into one phase will not cross to the second phase of the installation. A special “phase crossover” is available from X-10 to correct this problem. In addition to switching power on and off, X-10 modules can be used with special lighting modules to dim and brighten room lighting. These modules work only with incandescent lighting, but they add a degree of control beyond simple switching. Models are being developed for halogen bulbs. For permanent installations, the wall switches and receptacles of the home may be replaced with X-10–controlled units. Because X-10 modules do not prevent local control, these receptacles and switches work like standard units, with the added advantage of remote control.

When they were introduced in the late 1970s, X-10 modules revolutionized the field of EADLs. Before X-10, remote switching was a difficult and expensive endeavor, restricted largely to industry and to applications for people with disabilities. However, the X-10 system was intended as a convenience for able-bodied people who did not want to walk across a room to turn on a light. Because the target audience was able to perform the task without remote switching, the technology had to be inexpensive enough to make it more attractive to pay the cost of the device than to get out of a chair. X-10 made it possible for an able-bodied person to remotely control electrical devices for under $100, whereas most disability-related devices cost several thousand dollars. Interestingly, the almost universal adoption of X-10 protocols by disability-related EADLs did not result in sudden price drops in the disability field; consequently, many practitioners continue to adapt mass-market devices for individuals with disabilities.

The currently developing Internet of Things (IoT) will likely bring new power control options. Just as smart televisions are not "off" when switched off, so that they can "listen" for control signals, IoT devices in the near future will not be truly off when not in use. Rather, they will be in a sleep mode, listening for signals to turn themselves on arriving over the Internet. Such devices can be controlled from any Internet-connected device. For example, Philips' Hue light bulbs can be switched on and off, and can change the color of light being provided, through the user's smart phone or tablet. Similarly, television set-top boxes, streaming radio services, and other entertainment services can be controlled either by a dedicated remote control, a personal computer, or a cell phone.

Feature Control

As electronic systems became more widely used in the home, simple switching of lights and coffee pots failed to meet the needs of individuals with disabilities who wanted to control the immediate environment. With wall current control, a person with a disability might be able to turn radios and televisions on and off, but would have no control beyond that. Yet, a person with a disability would want to be able to surf cable channels as much as an able-bodied person with a television remote control. When advertisements are blaring from the speakers, a person with a disability might want to be able to turn down the sound or change to another radio station. Nearly all home electronic devices are now delivered with a remote control, which generally uses infrared signals. However, most of these remote controls are not usable by a person with a disability because the devices require fine motor control and good sensory discrimination.

EADL systems designed to provide access to the home environment of a person with a disability should provide more than on/off control of home electronics; they should also provide control of the features of home electronic devices. For this reason, EADL systems frequently have hybrid capabilities. They incorporate a means of directly switching power to remote devices, often using X-10 technology. This allows control of devices such as lights, fans, and coffee pots, in addition to electrical door openers and other specialty devices.[37] They also typically incorporate some form of infrared remote control, which allows them to mimic the signals of standard remote control devices. This control is provided either by programming in the standard sequences for all commercially available DVD players, televisions, and satellite decoders (as is done for cable or satellite television remote controls to also control the connected television) or by "teaching systems," in which the EADL learns the codes beamed at it by the conventional remote.

The advantage of teaching systems is that they can learn any codes, even, subsequently, those not yet invented. The disadvantage of these systems is that the controls must be taught, which requires more setup and configuration time for the user and caregivers. Because the infrared codes have been standardized, it is entirely possible for an EADL to include the codes for the vast majority of home electronics. As with "universal remote controls" for able-bodied users, the setup process then requires only that the individual enter simple codes for each device to be controlled.

Infrared remote control, as adopted by most entertainment systems controllers, is limited to approximate line-of-sight control. Unless the controller is aimed in the general direction of the device to be controlled (most have wide dispersion patterns), the signals will not be received. This means that an EADL cannot directly control, via infrared, any device not located in the same room. However, infrared repeaters (eg, the X-10 Powermid) can overcome this limitation by using radio signals to send the control signals received in one room to a transmitter in the room with the target device. With a collection of repeaters, a person would be able to control any infrared device in the home from anywhere else in the home.

One problem shared by EADL and able-bodied consumers is the proliferation of remote control devices. Many homes are now plagued with a remote control for the television, the cable/satellite receiver, the DVD player, the home stereo/multimedia center, and other devices, all in the same room. Universal remote controls can be switched from controlling one device to another but are often cumbersome to control.

Some hope is on the horizon for improved control of home audiovisual devices with less difficulty. In November, 1999, a consortium of eight home electronics manufacturers released a set of guidelines for home electronics called Home Audio Video Interoperability (HAVi). The HAVi specification would allow compliant home electronics to communicate so that any HAVi device can control the operation of all of the HAVi devices sharing the standard. A single remote control could control all of the audiovisual devices in the home through a single interface. (As of summer 2016, eight major manufacturers were identified: http://documents.mx/documents/home-audio-video-interoperability.html#)

The Infrared Data Association (IrDA) is performing similar specifications work focusing purely on infrared controls. The IrDA standard will allow an infrared remote control to control features of computers, home audiovisual equipment, and appliances with a single standard protocol. In addition to allowing a single remote control to operate a wide range of devices, the IrDA standard will allow other IrDA devices (eg, personal digital assistants [PDAs], personal computers, and augmentative communications systems) to control home electronics. Having a single standard for home electronics will allow much easier design of EADL systems for people with disabilities.

A more recent standard, V2,[23] offers a much higher level of control. If fully implemented, V2 will allow a single EADL device to control all the features of all electronic devices in its vicinity, such as the volume of the radio, the setting of the thermostat in the hall, or the "push to walk" button on the crosswalk.

One of the issues preventing adoption of these universal remote standards comes from marketing departments. General Electric does not want its devices to be controlled by a device labeled Samsung. We may see product lines that all use the same remote controls (Samsung television remotes, for example, can also control Samsung's DVD players and stereo systems), but standardization across manufacturers does not appear likely in the near future.

An interesting aspect of feature control by EADLs is the relationship between EADLs and computers. Some EADL systems, such as the Quartet Simplicity, include features to allow the user to control a personal computer through the EADL. In general, this is little more than a pass-through of the control system of the EADL to a computer access system. Other EADLs, such as the PROXi, were designed to accept control input from a personal computer. The goal in both cases is to use the same input method to control both a personal computer and the EADL. In general, the control demands for an EADL system are much less stringent than those for a computer. An input method that is adequate for EADL control may be very tedious for general computer controls. On the other hand, a system that allows fluid control of a computer will not be strained by the need to also control an EADL. The "proper" source of control will probably have to be decided on a case-by-case basis (this issue appears again in the discussion of augmentative communication systems, later in the chapter).

Subsumed Devices

Modern EADLs frequently incorporate some common devices that are more easily replicated than controlled remotely. Some devices, such as telephones, are so widely used that an EADL system can assume that a telephone will be required. Incorporating telephone electronics into the EADL is actually less expensive, because of the standardization of telephone electronics, than inventing special systems to control a conventional telephone. Other systems designed for individuals with disabilities are so difficult to control remotely that the EADL must generate an entire control system. Hospital bed controls, for example, have no provisions for remote control, but they should be usable by a person with a disability.

Many EADL systems include a speakerphone, which allows the user to originate and answer telephone calls by using the electronics of the EADL as the telephone. Because of the existing standards, these systems are generally analog, single-line telephones, electronically similar to those found in the typical home. Many business settings use multiline sets, which are not compatible with home telephones. Some businesses are converting to digital interchanges, or "Voice Over IP" (VOIP), which are also not compatible with conventional telephones. As a result, the telephone built into a standard EADL may not meet the needs of an individual with a disability in an office setting. Before recommending an EADL as an access solution for a client's office, therapists should check that the system is compatible with the telecommunications systems in place in that office.

Many homes no longer are connected to a hard-wired telephone line and depend exclusively on cell phones for communication. In the United States, there are two competing standards for cell communications, each of which is used in different frequency ranges for different carriers. As a result, providing telephone communication in EADL systems may require matching the local carrier, further complicating the choice.

Because the target consumer for an EADL often has severe restrictions in mobility, the manufacturers of many of these systems believe that a significant portion of the customer's day will be spent in bed; therefore, they include some sort of control system for standard hospital beds. These systems commonly allow the user to adjust the bed's head and foot height independently, thereby extending the time the individual can be independent of assistance for positioning. As with telephone systems, different brands of hospital beds use different styles of control. It is essential that the practitioner match the controls provided by the EADL with the input required by the bed to be controlled.

Controlling Electronic Aids to Daily Living

EADL systems are designed to allow individuals with limited physical capability to control devices in the immediate environment. Consequently, the method used to control the EADL must be within the capability of the client. Because these controls have many features in common with other forms of electronic enablers, control strategies are discussed next.

Augmentative and Alternative Communications

The term **augmentative and alternative communications (AAC)** is used to describe systems that supplement (augment) or replace (alternative) communication by voice or gestures between people.[30] Formally, AAC incorporates all assisted communication, including tools such as pencils and word processors or computers, as used to communicate either over time (as in leaving a message for someone who will arrive at a location after you leave) or over distance (sending a letter to Aunt May). However, as used in assistive technology, AAC is considered the use of technology to allow communication in ways that an able-bodied individual would be able to accomplish without assistance. Thus, using a pencil to write a letter to Aunt May would not be an example of an AAC for a person who is unable to speak because an able-bodied correspondent would be using the same technology (pencil and paper) for the same purpose (social communication). However, when a person who is nonvocal uses the same pencil to explain to the physician that she has sharp pains in her right leg, the pencil becomes an AAC device because an able-bodied person would communicate this by voice.

The causes of a communication disorder fall into two very different categories: language disorders and speech disorders. After a brain injury that affects Wernicke's area on the left cerebral hemisphere, an individual may exhibit a language disorder; that is, the person may have difficulty understanding language (sometimes referred to as receptive aphasia). An individual who sustains damage to the frontal cortex region involved with speech production (Broca's area) would have problems speaking (referred to as expressive aphasia, although no aphasia is purely receptive or expressive), regardless of the means of production.

Although there are degrees of aphasia, ranging from mild to severe/profound, in most cases a person with a language disorder will not benefit from AAC. In contrast, with a brain injury (from birth, trauma, or disease) that affects the speech motor cortex (Broca's area), an individual may be perfectly able to understand and formulate messages but unable to speak intelligibly because of difficulty controlling the oral musculature. Such a person has no difficulty with language composition, only with language transmission. (In cases of apraxia, the motor control of writing can be as impaired as that of speaking without affecting language.) In other cases the physical structures used for speech generation (eg, jaw, tongue, larynx) may be damaged by disease or trauma. Although the person has intact neural control, the muscles to be controlled may not function properly. This person may well benefit from an AAC device. In recent years it was discovered that, for many individuals with autism, the sound of their own voice interferes with the process of composing a message. For these individuals, the separation between composition of a message and voicing of a message provided by an AAC device can be an effective aid to communication.

AAC devices range from extremely low technology to extremely high technology. In hospital intensive care units (ICUs), low-tech communication boards can allow a person maintained on a respirator to communicate basic needs (Fig. 17.4). A low-tech communication board can allow a client to deliver basic messages or spell out more involved messages in a fashion that can be learned quickly. For a person with only a yes/no response, the communication partner can indicate the rows of the aid one at a time and ask whether the desired letter or word is in the row. When the correct row has been selected, the partner can move across a row until the communicator indicates the correct letter. This type of communication is inexpensive and quick to teach but very slow to use. In settings in which there are limited communication needs, it is adequate but will not serve for long-term or fluent communication needs.

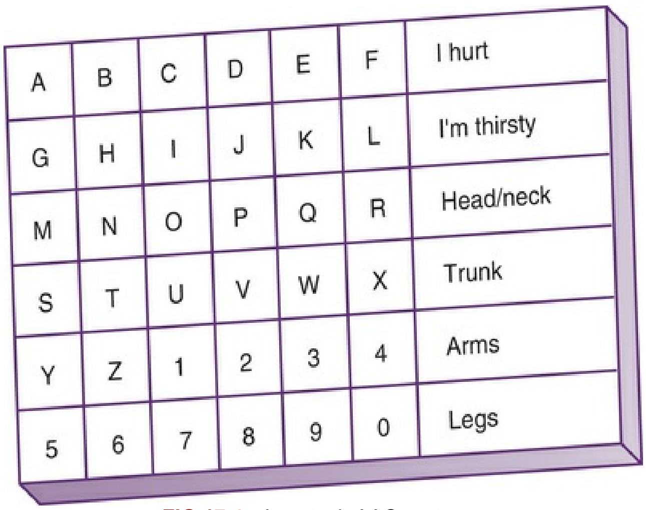

FIG 17.4 Low-tech AAC system.

To meet the communication needs of a person who will be nonvocal over a longer period, practitioners frequently recommend electronic AAC devices (Fig. 17.5).

OT Practice Notes

In selecting a communication device, the practitioner must consider the type of communication the individual will use, in addition to the settings in which the communication will take place.

FIG 17.5 High-tech AAC system (Accent). (Courtesy Prentke Romich, Wooster, OH.)

Light[29] described four types of communication that humans use: (1) expression of needs and wants, (2) transfer of information, (3) social closeness, and (4) social etiquette. In the ICU setting noted earlier, most communication occurs at the first two levels. The communicator wants to express the basic needs of hunger, thirst, and relief of pain. He or she wants to communicate with the physician providing care, convey information about where it hurts, and determine whether treatment seems to be working. In work or school settings, communication is often intended to convey information.

When participating in a classroom discussion, a student may want to be able to describe the troop movements in the battle of Gettysburg, for example. In math class, the student may need to present a proof involving oblique angles and parallel lines. Such exchanges of information may be spontaneous (as when a student is called on in class) or planned (as in a formal presentation).

In a social or an interpersonal setting, communication has a markedly different flavor. Teenagers may spend hours texting, exchanging very little "information" but communicating shared feelings and concerns. At a faculty tea, much of the communication is very formulaic, such as "How do you do?" Such queries are not intended as questions about medical status, but simply a recognition of the other person's presence and an indication that the speaker wishes him or her well. (Historically, this query was originally expressed as, "I hope I see you well today." This phrasing more accurately expresses the sentiment but is somewhat longer. The proper response to "How do you do?" was not "Fine, thank you," but a reciprocal "How do you do?").

The planning and fluency of communication in each domain are substantially different, and the demands on AAC systems in each type of communication are likewise very different. An AAC system used solely for expression of needs and wants can be fairly basic. The vocabulary used in this type of communication is limited, and because the expressions tend to be fairly short, the communication rate is not of paramount importance. In some cases the entire communication system may be an alerting buzzer to summon a caregiver because the individual is in need. Low-tech communication systems such as those just described can meet basic communication needs for individuals whose physical skills are limited to eye blinks or directed eye movement.

Low-tech devices also may enable expression of more complex ideas. For example, a therapist became aware that his client with aphasia wished to communicate something. Because no AAC was available to this client, the therapist began attempting to guess what the client wanted to communicate. After exhausting basic needs ("Do you need a drink?" "Do you need to use the bathroom?"), the therapist was floundering. Over the next 20 minutes, the client, in response to a conversation between another therapist and client in the same treatment room, was able to communicate that his ears were the same shape as Cary Grant's! Even a basic communication aid, such as the ICU aid described earlier, would have allowed much faster transfer of this information.

Most development in AAC seems to be focused on the level of communicating basic needs and transfer of information. Information transfer presents some of the most difficult technological problems because the content of information to be communicated cannot be predicted. The designer of an AAC device would probably not be able to anticipate the need to discuss the shape of Cary Grant's ears during the selection of vocabulary. To meet such needs, AAC devices must have the ability to generate any concept possible in the language being used. This is referred to by AAC practitioners as spontaneous novel utterance generation (SNUG). Making these concepts available for fluent communication is the ongoing challenge of AAC development.

Social communication and social etiquette present significant challenges for users of AAC devices. Although the information content of these messages tends to be low, because the communication is based on convention, the dialog should be both varied and spontaneous. AAC systems, such as the Dynavox, have provisions for preprogrammed messages that can be retrieved for social conversation, but providing both fluency and variability in social discourse through AAC remains a challenge.

One aspect of social communication that has recently been addressed is "phatic communication." When participating in a conversation, the listener sends messages that indicate continued attention and interest. These may include smiles, head nods, or short expressions of agreement (eg, "Yes!"). Such phatic content has not generally been available to AAC users. Recently, the Fat Cat Chat products have provided an enjoyable means of phatic communication. Although not intended as full communication solutions, products such as Fat Cat Pirate Chat (Point and Read, Inc. *http://www.piratechat.us*) allow a person with severe communication limitations to indicate his or her participation in a conversation.

Current devices allow somewhat effective communication of wants. They are not nearly as effective in discussing dreams.

Parts of AAC Systems

In general, electronic AAC systems have three components (Fig. 17.6): a **user control system**, which allows the user to generate messages and control the device; a **message composition system**, which allows the user to construct messages to be communicated to others; and a **message transmission system**, which allows the communication partner to receive the message from the user. The issues of user control of AAC devices are essentially the same as those for other electronic assistive technologies and are discussed with access systems in general.

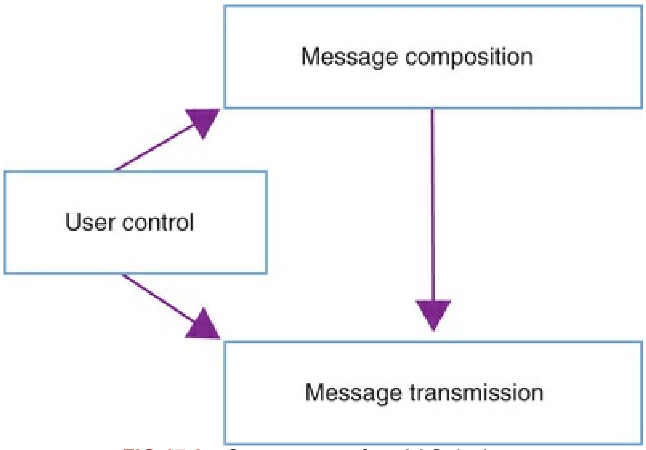

FIG 17.6 Components of an AAC device.

Message composition.

Most of the time both individuals with disabilities and able-bodied people plan their messages before speaking. (Many of us can remember the "taste of foot" when we have neglected this process.) An AAC device should allow the user to construct, preview, and edit communication utterances before they become apparent to the communication partner. This gives the AAC user the ability to think before speaking. It also allows compensation for the difference in rate between message composition via AAC and communication between able-bodied individuals.

Able-bodied individuals typically speak at a rate of 150 to 175 words per minute.[35] Augmentative communication rates are more typically on the order of 10 to 15 words per minute, resulting in a severe disparity between the rate of communication construction and the expected rate of reception. Although input techniques (discussed later) offer some improvement in message construction rates, the rate of message assembly achieved with AAC is such that many listeners lose interest before an utterance can be delivered. If words are spaced too far apart, an able-bodied listener may not even be able to assemble them into a coherent message!

The message construction area of an AAC device allows the individual to assemble a complete thought and then transmit it as a unit. A typical AAC device includes a display in which messages can be viewed before transmission. This area allows the communicator to review and edit the message being composed prior to transmitting it to the communication partner. This has two beneficial effects: the communicator can select words with care before communicating them, and the communication partner is relieved of the need for constant vigilance in conversation. The Atkinson-Shiffrin model of human memory suggests that human sensory memory retains spoken information for only 4 or 5 seconds before it fades.[1] Communication between able-bodied people generally takes place quickly enough for a complete sentence to be held in sensory memory at once. When an able-bodied person is communicating with a person using an AAC device, the time between utterances may be too long to allow the communication to remain in memory. The able-bodied person loses focus and may not be able to maintain attention to the conversation. If messages come as units, the communication partner can respond to a query and then busy himself or herself with another activity while the communicator composes the next message. This is not unlike having a conversation via e-mail or chat.

Message transmission.

When the communicator has finished composing a message, it can be transmitted to the communication partner. The means of transmission varies with the device and the setting. Some AAC devices use exclusively printed transmission. One of the first true AAC devices, the Canon

Communicator, was a small box that included an alphanumeric keyboard. The box was strapped to the user's wrist, and the user tapped out messages that were printed on paper tape (message composition). When the message was completed, it was removed from the communicator and passed to the communication partner (message transmission).[20] With devices such as the Zygo LightWRITER, the message may be shown on an electronic display that is made visible to the communication partner. Other systems use auditory communication in which the message is spoken out loud via speech synthesis. There is a tendency to think of voice output as more appropriate than text since able-bodied people generally communicate by voice.[20] In activities such as classroom discussion, voice communication may be the most appropriate method of communication. In other settings, such as a busy sidewalk or a noisy shop, voice output may be drowned out or unintelligible, and printed output may result in more effective communication. In a setting where verbalization may disturb others, printed output may, again, be the transmission method of choice.

In settings in which voicing is the preferred method of communication, voice quality must be considered. Early AAC devices used voices that to novice listeners were only slightly more understandable than the communicator's unassisted voice. As speech synthesis technology has improved, AAC voices have generally become more intelligible. The high-quality voices of modern speech synthesizers have vastly improved intelligibility but continue to provide only a narrow range of variation and vocal expression. It is a mark of the improved state of speech synthesis that AAC users can now discuss *who* they would like to sound like rather than *what* they would like to sound like.

Communication Structure

Communications to be augmented may be categorized in terms of their intent, in addition to their content, as proposed by Light.[29] At the top level, with the conditions discussed earlier, communication may be divided into primarily verbal and primarily written. In these cases the categorization would be based on the mode of communication that would typically be used by an able-bodied person, not on the form being used by the augmented communicator.

Verbal communications.

One category of verbal communication is conversation. Conversation implies a two-way exchange of information. This includes face-to-face communication with a friend, oral presentation when question and answer sessions are included, small group discussions, and a conversation on a telephone. In all these cases, rapid communication is required and the user is expected to compose and respond immediately. If the composition rate is too slow, communication breaks down and the conversation stops. The augmented communicator may use “telegraphic” speech styles, but this results in a primitive style of language (“want food”) that may be taken to indicate poor cognition.

Another form of verbal communication is an oral presentation in which no question and answer component is included or cases in which such a component is considered separately. In these cases the augmented communicator has ample preparation time to generate communications before delivery, and an entire presentation may be stored in a communication device before the time of delivery. In such cases, even though the time taken to prepare the message may be long, delivery of the message is not inhibited as long as the device has adequate storage for the entire presentation. Stephen Hawking, through the use of an AAC device, is able to orally present formal papers at conferences just as well as his colleagues. His ability to respond to questions, however, is severely constrained. Nonetheless, because he is Stephen Hawking, colleagues wait as long as necessary for his answers to questions. Less eminent augmentative communicators may find this more constraining.

Graphic communications.

The category of **graphic communications** includes all forms of communication mediated by graphic symbols. This includes writing using paper and pencil, typewriter, computer/word processor, calculator, or a drawing program. In this form of communication, the expectation is that there is a difference between the time to create the message and the time to receive it. In the realm of graphic communications, there is a wide range of conditions and intents of communication that may influence the devices selected for the user.

Historically, graphic communication did not allow conversation in the traditional sense, other than the note passing that friends sometimes engage in when not attending to a presentation. Today, however, technologies such as instant messaging and texting allow real-time conversations via written (typed) communication. The same need for fluency and immediacy of communication applies as for verbal conversations.

One specialized type of graphic communication is note taking. Note taking is a method of recording information as it is being transmitted from a speaker so that the listener can recall it later. The intended recipient of this form of communication is the person who is recording the notes. Because it is a violation of social convention to ask the speaker to speak more slowly to accommodate the note taker, a note-taking system must allow rapid recording of information. Note taking differs from merely recording a presentation in that it is a cognitively active process. Because spoken language is typically highly redundant, the note taker must attend to the speaker and listen for ideas that should be recalled later. Only key points need to be recorded. However, because the listener is also the intended recipient, notes can be very cryptic and may be meaningless to anyone other than the note taker. The special case in which notes are taken for a student with a disability changes the process to one of recording a transcript rather than simply taking notes, which is a different type of communication.

Modern assistive technologies and mainstream applications offer aids to help the student with limited note-taking ability keep up. Products such as Microsoft's One-Note (*http://www.microsoft.com*) and Ginger Labs' Notability (*http://gingerlabs.com*) are able to make an audio recording of a lecture as the individual makes notes. When a note is selected, the portion of the audio that was recorded at the time the note was written can be played back. With this system, notes can be particularly cryptic ("Interesting" or "Test!") because they are keyed to the information being referenced.

Messaging is a form of graphic communication that shares many characteristics with note taking. Although the intended recipient is another person, shared abbreviations and nongrammatical language are common in messaging. The language that is common in adolescent e-mail is very cryptic and only barely recognizable as English (Fig. 17.7), but it is a form of graphic messaging that communicates to its intended audience. In general, messaging does not demand the speed of input of note taking because encoding and receiving are not linked in time. However, instant messaging, which has become nearly ubiquitous, blurs the lines between messaging and conversation. The expectation generally is an immediate response, as in conversation. Social networking tools such as Twitter apply a different set of constraints. Because a Twitter feed may be followed by many people, obscure abbreviations cannot be used. However, because a single tweet can have no more than 140 characters, messages must balance between being cryptic and informative.

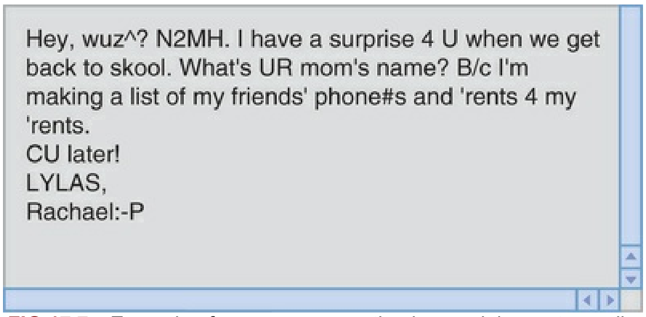

FIG 17.7 Example of message encryption in an adolescent e-mail.

The most language-intensive form of graphic communication is formal writing. This includes writing essays for school, writing for publication, and writing a book chapter, such as this one. Formal writing differs from the previously discussed forms of graphic communication in that it must follow the rules of written grammar. It is expected that the communicator will spend significant time and effort in preparing a formal written document, and the abbreviations used in note taking and messaging are not allowed.

The most difficult form of formal communication may be mathematical notation. The early target of AAC devices was narrative text as used in messaging and written prose. Such language is commonly linear and can be composed in the same order that it is to be read. Mathematical expressions, on the other hand, may be two dimensional and nonlinear. Simple arithmetic, such as 2 + 2 = 4, is not excessively difficult. However, algebraic expressions, such as:

$$x = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a}$$

can be much more difficult for an AAC device to create. A relatively basic calculus equation such as:

$$\sum_{n=1}^{+\infty} \frac{(-1)^{n+1} \cdot 1 \cdot 3 \cdot 5 \mathrm{L}\, (2n-1)}{2 \cdot 4 \cdot 6 \mathrm{L}\, 2n} x^n$$

can be impossible to write, much less solve, for the user of an AAC device. Although current technology allows prose construction with some facility, an AAC user will have marked difficulty with higher mathematics. Because similar issues are experienced on the World Wide Web, new communication protocols (eg, MathML[17]) have been developed, and if these are incorporated into augmentative communication devices, they may provide improved access to higher mathematics for AAC users. Unfortunately, MathML is a visually descriptive language and is not intended to be read or written by people. The user selects options from menus or drags elements into position, and a MathML interpreter generates the language that allows the result to be printed. Thus, MathML allows access to higher math but requires a great deal of motor control to produce.

General Computer Access

Computers play an interesting double role in the field of assistive technology. In some cases using the computer is the intended activity. Browsing on the Web, for example, does not imply looking for specific information; it is a process of following links of immediate interest to see what is out there. The “Stumble-Upon” extension for the Firefox browser, for example, takes the browser to a random page that fits the interests declared by the user. Hobby computer programmers may use the computer simply to find out what they can make it do. Using a computer can provide an individual with a disability a degree of control that is missing in much of the rest of life. In other cases, the computer is a means of accessing activities that would not be possible without it, so the computer can be considered in the same category as any other assistive technology. A student with a high-level spinal cord injury may need a computer to take notes in class. A businessperson with mild cognitive limitations may use computer technologies to organize and record information. A person with severe limitation in mobility may use social networks to remain in contact with friends and family. In these cases and many others, the computer is the path, not the destination.

As with the television remote control, the status of the computer in assistive technology depends on the status of the user, not on the type of computer. If a person with a disability is using a computer in the same way and for the same purposes as an able-bodied person would, it is not assistive technology. When a person with paraplegia accesses an online database of movies being shown at local theaters, this is not an assistive technology application because the same information is available without the computer. However, when a blind individual accesses the same database using the installed screen reader, it is an assistive technology because the printed schedule is not accessible. For a person with a print impairment, the computer can provide access to printed information either through electronic documents or through optical character recognition (OCR) of printed documents, which can convert the printed page into an electronic document. Once a document has been stored electronically, it can be presented as large text for a person with limited visual acuity, or it can be read aloud for a person who is blind or profoundly learning disabled. Computers can allow the manipulation of “virtual objects” to teach mathematical concepts and constancy of form and to develop spatial relationship skills that are commonly learned by manipulation of physical objects.[22] Smart phones and PDAs may be useful for a busy executive, but they may be the only means available for a person with attention deficit/hyperactivity disorder (ADHD) to get to meetings on time.[39] For the executive, they are conveniences, but for the person with ADHD, they can be assistive technologies.

Individuals using computers can locate, organize, and present information at levels of complexity that are not possible without electronic aids. Through the emerging area of cognitive prosthetics, computers can be used to augment attention and thinking skills in people with cognitive limitations. For example, ThoughtQ from Quillsoft (*http://www.thoughtq.com/*), can assist a person with cognitive limitations in researching a topic by suggesting related search terms. By narrowing the suggestions or casting a wider net, the suggestions can assist in identifying topics for inclusion in a report. These ideas and concepts can be organized using a mind-mapping tool, such as SimpleMind (*http://www.simpleapps.eu/simplemind/desktop*), which can assist the individual in arranging the individual concepts into an organized report. Computer-based biofeedback can monitor and enhance attention to task. Research involving individuals with temporal processing deficits has led to the development of computer-modified speech programs that can be used to enhance language learning and temporal processing skills.[33,38]

Beyond such rehabilitative applications, the performance-enhancing characteristics of the conventional computer can allow a person with physical or performance limitations to participate in activities that would be too demanding without the assistance of the computer. An able-bodied person would find having to retype a document to accommodate editing changes frustrating and annoying. A person with a disability may lack the physical stamina to complete the task without the cut-and-paste abilities of the computer. For the able-bodied person, the computer is a convenience. For the person with a disability, it is an assistive technology because the task is impossible without it. The applications of the computer for a person with a disability include all of the applications of the computer for an able-bodied person.

Over time, applications that started as assistive technologies can become mainstream and thus no longer considered assistive technology. Curb cuts on sidewalks, for example, were originally mandated to allow wheelchair users to move in the community. As they became more common, they were used primarily by delivery persons or able-bodied people with rolling luggage or strollers. Electronic reminders were originally developed for people who, because of brain injury, needed constant reminders to manage their time. They became mainstream as Personal Data Assistants and now are in virtually all cell phones; so, for funding purposes, they are now arguably not assistive technologies.

Control Technologies

All these electronic enabling technologies depend on the ability of the individual to control them. Although the functions of the various devices differ, the control strategies for all of them share characteristics. Because the majority of electronic devices were designed for use by able-bodied people, the controls of assistive technologies may be categorized in ways that are adapted from the standard controls. Electronic control may be divided into four broad categories: input adaptations, performance enhancements, output adaptations, and cognitive aids.

Input to Assistive Technologies

Although there is a wide range of input strategies available to control electronic enablers, they can be more easily understood by considering them in subcategories. Different authors have created different taxonomies for the categorization of input strategies, and some techniques are classified differently in these taxonomies. The categorization presented here should not be considered uniquely correct, but merely as a convenience. Input strategies may be classified as those using physical keyboards, those using virtual keyboards, and those using scanning techniques.

Physical Keyboards

Physical keyboards generally supply an array of switches, with each switch having a unique function. On more complex keyboards, **modifier keys** may change the base function of a key, usually to a related function.[2] Physical keyboards are found in a wide range of electronic technologies, including typewriters/computers, calculators, telephones, and microwave ovens. In these applications, sequences of keys are used to generate meaningful units, such as words, checkbook balances, telephone numbers, or the cooking time for a baked potato. Other keyboards may produce immediate action when a key is pressed. For example, the television remote control has keys that switch power or raise volume when pressed. Other keys on the remote control may, like other keyboards, be used in combinations. Switching to channel 152 requires sequential activation of the "1," "5," and "2" keys.

Physical keyboards can be adapted to the needs of an individual with a disability in a number of ways (Fig. 17.8). Most alphanumeric keyboards, for example, are arranged in the pattern of the conventional typewriter. This pattern was intentionally designed, for reasons related to mechanical limitations, to slow the user down. Most individuals with disabilities do not require artificial restraints to slow them down, so this pattern of keys is seldom optimal for assistive technologies. Alternative keyboard patterns include the Dvorak Two Handed, Dvorak One Handed, and Chubon (Fig. 17.9).[2] These patterns offer improvement in the efficiency of typing that may allow a person with a disability to perform for functional periods of time.[4]

FIG 17.8 Physical keyboard with adaptive features. (Courtesy Kinesis Corp., Bothall, WA.)

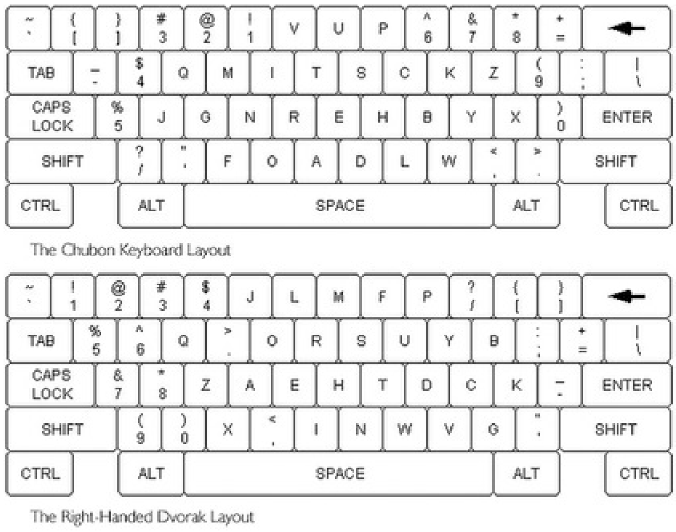

FIG 17.9 Alternative keyboard patterns.

The standard keyboard is designed to respond immediately when a key is pressed and, in the case of computer keyboards, to repeat when held depressed. This behavior benefits individuals with rapid fine motor control but penalizes individuals with delayed motor response. Fortunately, on many devices the response of the keyboard can be modified. Delayed acceptance provides a pause between the instant that a key is pressed and the instant that the key press takes effect. Releasing the key during this pause prevents the key from taking effect. This adaptation, if carefully calibrated, can allow a person to type with fewer mistakes, thereby resulting in higher accuracy and, sometimes, higher productivity. However, if not carefully calibrated, it will slow the typist without advantage.

The scale of the standard keyboard provides a balance between the fine motor control and range of motion (ROM) of an able-bodied individual. The "optimum keyboard," modeled after the IBM Selectric typewriters of the 1960s, was scaled to match the hands of women typists. However, a client with limitations in either ROM or motor control may find the conventional keyboard difficult to use. If the client has limitations in motor control, a keyboard with larger keys and/or additional space between the keys may allow independent control of the device. This adaptation may also assist people with a visual limitation because larger keys provide space for larger labels on the keys. This applies to computer keyboards, but it also applies to such suboptimal keyboards as those of television remote controls, which are available in large scale from a number of vendors. However, providing an equivalent number of options with larger keys increases the size of the keyboard, which may make it unusable for a person with limitations in ROM.

To accommodate limitations in ROM, the keyboard controls can be reduced in size. Smaller controls, placed closer together, allow selection of the full range of options with less demand for joint movement. However, smaller controls are more difficult to target for people with limited motor control. A mini-keyboard is usable only by a person with good fine motor control and may be the only scale of keyboard usable by a person with limited ROM. However, as many users of net books have discovered, smaller keyboards are often not as usable for able-bodied typists.

To accommodate both limited ROM and limited fine motor control, a keyboard can be designed with fewer options. Many augmentative communication devices can be configured with 4, 8, 32, or 64 keys on a keyboard of a single size. Modifier, or "paging," keys can allow access to the full range of options for the keyboard, but with an attendant reduction in efficiency. In this approach the person uses one or more keys of the keyboard to shift the meanings of all of the other keys on the keyboard. Unless this approach is combined with a dynamic display, the user must remember the meanings of the keys.

Physical Pointing Systems

In addition to keyboards, many electronic systems use some sort of pointer to select or activate controls and files. Because humans are good at recognizing shapes, and almost uniquely good at pointing to things of interest (most animals, when you point at something, will look at your finger, rather than in the direction pointed), a pointing interface requires much less cognitive processing than the memory-intensive command line of early computer systems. But, as with all engineering, gaining ease of use in one area usually increases the load in another. In the case of **pointing systems**, the increased demand is in vision and visual processing and in the motor control required to move a pointer to the desired target. To able-bodied individuals who grew up with it, the computer mouse seems a simple, intuitive control system. For a person with limited vision, the challenge of locating the pointer on the screen belies the simplicity. Similarly, a person with tremor would argue that pointing at a very small target is far from simple.

Fortunately, the field of assistive technology includes a wide range of accommodations for pointing systems. When the number of selections is limited, such as the adjustments available on a car radio or in a television guide, selection can occur by turning a knob, pressing Up or Down keys, or pushing a joystick to indicate the desired direction of movement. For systems in which access to any point on the screen is desired, a mouse or track pad is the common access method.

Limited control systems can generally be adapted by moving from one to another of the available access methods. If the current system requires turning a knob and the individual finds knob-turning difficult, adaptations can change the control to up/down buttons or a joystick. Mouse emulation, while more demanding, can also be provided fairly simply in most cases. Touch screens allow a person to point to controls on the screen rather than slide a mouse over the desktop. For tablets and short-term use, touch screens are good solutions, but for long-term work on the desktop, they are less usable. Try holding your arm in front of you for five minutes, and you will see that prolonged shoulder flexion is not physiologically ideal.

Any body part that can move smoothly through a range of motion can be used to drive a mouse emulator. Most commonly, such systems first use head movement as a control point. In currently available systems, a small infrared reflector is mounted on the individual's forehead, glasses, or even on a pen placed behind the ear. A camera shines infrared light on this reflector, then tracks where the reflection lies in the camera's field of view. When the user moves her head, the mouse pointer moves in the same direction. Although these systems are commonly controlled by head movement, they can, in fact, be controlled by any body part that provides sufficient range in two dimensions of movement. Individuals have used these systems to move the mouse with a fingertip or a toe.

When the individual lacks the motor control to select points on the screen with free movement, mouse access can be provided, with less fidelity, by other means. Switch joysticks or even individual switches can be used to move the mouse in the cardinal directions (up, down, left and right). Although this may require some fine tuning as the pointer approaches the target, directional control does provide access to any point on the screen. For the individual who lacks the ability to operate multiple switches, single-switch scanning can also be used. Mouse scanning can be done either as Cartesian, in which the mouse pointer scans vertical and then horizontal, or as radial, in which the mouse projects a “beam” that sweeps the screen like a radar display. When the desired beam sweeps over the target, activating the switch, it moves along the path until stopped by another action. In both cases, a broad path may be the first selector, which is then swept by a narrower beam when stopped.

The ultimate pointing system to date is eye-tracking input. Eye-tracking systems are generally based on reflected infrared light from the surface of the eye. In general, these systems require extreme stability of the physical location of the eye and the camera observing the reflections.[28] Most approaches to eye tracking have depended on the precise relationship of the camera and the user's eye. Traditionally, this has meant that the user must hold his or her head extremely still for the system to be usable. Because of cost considerations, this method of input has not been a reasonable option for a person who can produce head movements, so the requirement for head stabilization has not been a major issue.

For a time it appeared that eye tracking would become part of mainstream products, as EADLs have done, with a resulting decrease in pricing. The first mainstream products that incorporated eye tracking were handheld camcorders, which had eye tracking built into the viewfinder. By tracking the portion of the screen being focused on, eye tracking allowed the camera to focus on the part of the display of special interest to the person taking the video. As with military applications of eye tracking, in which eye-tracking systems are mounted on the helmet of the user, this worked because the camera eyepiece was held against the eye, so the geometry was stable. However, as image analysis became more efficient, it became easier to identify faces in the field of view than to try to determine where the camera user was looking, and eye gaze in the mainstream appears to have receded from common usage.

Virtual Input Techniques

When an individual lacks the motor control to use an array of physical switches, a virtual input system may be used in its place. For language, virtual input systems can be classed as virtual keyboards (systems that act like keyboards, without physical switches for each key), switch encoding systems (patterns of switch closures are used to emulate keyboard input), and speech-based systems (dictation or command-and-control systems driven by the user's native speech).

One type of virtual input system is the on-screen keyboard. An on-screen keyboard is an image of a keyboard, displayed on the device screen, that can be activated by a pointer, such as the mouse or fingertip. Whereas physical keyboards have a rigidly defined layout, an on-screen keyboard can be created with any desired number of rows of keys, with each row having few or many keys. An on-screen keyboard need not be rectangular, and rearranging the keys to a more efficient pattern can be easy (depending on the keyboard). It is even possible for the keyboard to change size and shape, depending on the program to which it is sending characters.

Before smart phones and tablets became widely used, on-screen keyboards were rare in consumer electronics, but they now are part of everyday life. In assistive technology, on-screen keyboards are either added devices when the usual physical keyboard cannot be used, or a keyboard with enhanced features used to improve individual productivity. Historically, keyboards with word prediction (discussed later) were used only as assistive technology, but today many mainstream keyboards include this feature.

One advantage of having a technology go mainstream is the new ideas that influence it. Throughout the time that on-screen keyboards have been used, various methods have been tried to improve accuracy. When on-screen keyboards became mainstream, new approaches were provided. The iOS on-screen keyboard, for example, enlarges the active area around probable keys and shrinks the active area around unlikely keys of the keyboard, making it easier to type the correct letter and more difficult to type inappropriate keys—a very clever idea that was never tried in disability-related keyboards, although similar (and less transparent) approaches have been tried.

Several augmentative communication systems now use dynamic displays, in which the graphic keyboard can be changed as the user makes selections so that the meaning of each location of the keyboard changes as a message is composed. Dynamic displays free the user from having to either remember the current meaning of a key or decode a key with multiple images on it.

Switch-Encoding Input

An individual who lacks the ROM or fine motor control necessary to use a physical or graphic keyboard may be able to use a switch-encoding input method. In switch encoding, a small set of switches (from 1 to 9) is used to directly access the functionality of the device. The meaning of the switch may depend on the length of time it is held closed, as in Morse code, or on the immediate history of the switch set, as in the Tongue Touch Keypad (TTK).

In Morse code, a very small set of switches is used to type. In single-switch Morse, a short switch closure produces an element called a dit, which is typically written as *. A long switch closure produces the dah element, which is written as −. Formally, a long switch closure is three times longer than a short switch closure, but this can be adjusted to fit the needs of the individual. Patterns of switch closures produce the letters of the alphabet, numbers, and punctuation. Pauses longer than five times the short switch closure indicate the end of a character. Two-switch Morse is similar, except that two switches are used: one to produce the dit element and a second to produce the dah. Because the meaning of the switches is unambiguous, it is possible for the dit and dah to be the same length, thereby potentially doubling typing speed. Three-switch Morse breaks the time dependence of Morse by using a third switch to indicate that the generated set of dits and dahs constitutes a single letter.

Morse code is a highly efficient method of typing for a person with severe limitations in motor control and has the advantage over other virtual keyboard techniques of eventually becoming completely automatic.[5,32] Many Morse code users indicate that they do not “know” Morse code; they think in words, and the words appear on the screen, just as in touch typing. Many Morse code users type at speeds approaching 25 words per minute, which makes this a means of functional writing. The historical weakness of Morse code is that each company creating a Morse interface for assistive technology has used slightly different definitions of many of the characters. To address this issue and to promote the application of Morse code, the Morse 2000 organization has created a standard for Morse code development.[36]

Another variety of switch encoding involves switches monitoring their immediate history for selection. The TTK, from newAbilities Systems, uses a set of nine switches on a keypad built into a mouthpiece that resembles a dental orthotic.

Early versions of the product used an “on-screen keyboard” called MiracleTyper (Fig. 17.10). With this input method, the first switch selection selects a group of nine possible characters, and the second switch action selects a specific character. This approach to typing is somewhat more physically efficient than Morse code but does require the user to observe the screen to know the current switch meaning. Later versions of the TTK used the keypad only as a mouse emulator to allow the user to select any on-screen keyboard desired for text entry.

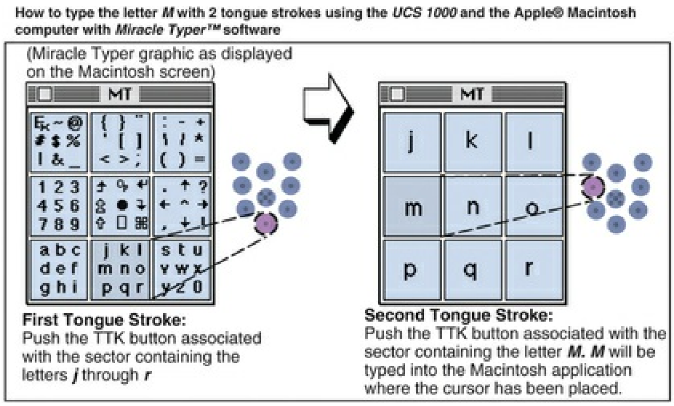

FIG 17.10 MiracleTyper enables character selection by the selection history.

A different approach to switch encoding is provided by the T9 keyboard (Fig. 17.11), which is included in most cell phones with standard keypads. In this novel interface, each key of the keyboard has several letters on it, but the user types as though only the desired character were present. The keyboard software determines from the user's input what word might have been intended. The disambiguation process used in the T9 keyboard allows a high degree of accuracy in determining which character the user intended, in addition to rapid learning of the keyboard. This input technology is potentially compatible with pointing systems, described earlier, and can provide an excellent balance of target size and available options.

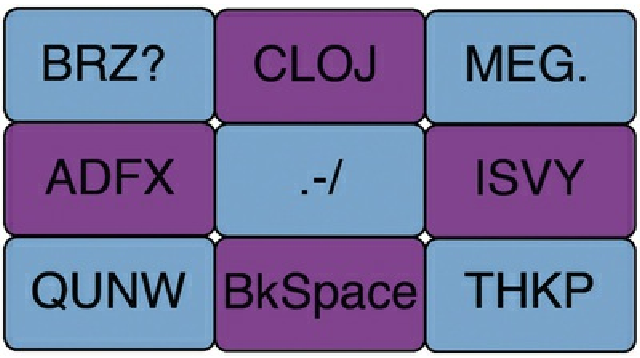

FIG 17.11 T9 keyboard.

Speech Input

For many, speech input has a magical allure. What could be more natural than to speak to an EADL or computer and have one's wishes carried out? When first introduced by Dragon Systems in 1990, large-vocabulary speech input systems were enormously expensive and, for most, of limited utility. Although highly dedicated users were able to type via voice in 1990, almost no one with the option of the keyboard would choose to use voice for daily work. These early systems required the user to pause between each word so that the input system could recognize the units of speech. Technology has evolved to allow continuous speech, with a recognition accuracy greater than 90%.[24,26] (The companies producing speech products claim accuracy greater than 95%.) Even though this advance in speech technology is remarkable, it does not mean that speech input is the control of choice for people with disabilities, for a number of reasons.

Speech recognition requires consistent speech. Although it is not necessary that the speech be absolutely clear, the user must say words the same way each time for an input system to recognize them. Consequently, the majority of people with speech impairments cannot use a speech input system effectively. Slurring and variability in pronunciation results in a low recognition rate.

Speech input requires a high degree of vigilance during training and use. Before current speech technology can be used, it must be “trained” to understand the voice of the intended user. To do this, the system presents text to the potential user, which must be read into the microphone of the recognition system. In Windows 7, the speech system uses responses to a tutorial to learn the individual user, disguise the training process, and provide the user with an overview of the system at the same time. If the user lacks the cognitive skills to respond appropriately to the cues presented, the training process will be very difficult. A few clinicians have reported success in training students with learning disabilities or other cognitive limitations to use speech input systems, but in general, the success rate is poor. Even after training, the user must watch carefully for misrecognized words and correct them at the time the error is made. Modern speech recognition systems depend on context for their recognition. Each uncorrected error slightly changes the context, and eventually the system can no longer recognize the words being spoken. Spell checking a document does not find misrecognized words because each word on the screen is a correctly spelled word. It just may not be the word that the user intended!

Speech input is intrusive. One person in a shared office space talking to a computer reduces the productivity of every other person in the office. If everyone in the office were talking to their computers, the resulting noise levels would be chaotic. Speech input is effective for a person who works or lives alone, but it is not a good input method for most office or classroom settings.[25]

Recently, Internet-based speech recognition has become available on cell phones, tablet computers, and even desktops. Where the local processor might not be powerful enough to perform the complex calculations of speech recognition, vast “server farms” in the cloud can do the hard work. With such systems, an audio recording of the user's speech is transmitted to the server, and recognized text is returned. Because of the vast power of the server farms and the number of users, these systems do not require any training to use. However, they also do not learn the idiosyncratic speech patterns of the individual. In addition, both the audio and the text are sent unencrypted to the servers, so these systems cannot be used for sensitive information (eg, medical records).

The type of speech system used depends on the device being controlled. For EADL systems, discrete speech (short, specific phrases, such as “light on”) provides an acceptable level of control. The number of options is relatively small, and there is seldom a need for split-second control. Misrecognized words are unlikely to cause difficulty. Text generation for narrative description, however, places higher demands for input speed and transparency and may call for a continuous input method. Other computer applications may work better with discrete than with continuous input methods. Databases and spreadsheets typically have many small input areas, with limited information in each. These applications are much better suited to discrete speech than to continuous speech.

The optimum speech recognition program would be a system that would recognize any speaker with an accuracy of better than 99%. Developers of current speech systems say that based on advances in processor speed and speech technologies, this level of usability should be possible within about 5 years. However, they have been making the same prediction (within 5 years) for the past 20 years! Modern speech recognition systems are vastly better than those available 10 years ago and are also available at less than 1% of the cost of the early systems. However, even with these improvements, they are still not preferable to the conventional keyboard for most users.

Scanning Input Methods

For an individual with very limited cognition and/or motor control, a variation of row-column scanning is sometimes used.[2,14,20] In scanning input, the system to be controlled sequentially offers choices to the user, and the user indicates affirmation when the correct choice is offered. Typically such systems first offer groups of choices, and after a group has been selected, the items in the group are offered sequentially. Because in early systems the items were presented as a grid offered a row at a time, such systems are commonly referred to as row-column scanning, even when no rows or columns are present.

Scanning input allows the selection of specific choices with very limited physical effort. Generally, the majority of the user's time is spent waiting for the desired choice to be offered, so the energy expenditure is relatively small. Unfortunately, the overall time expenditure is generally relatively large. When the system has only a few choices to select among, as in most EADL systems, scanning is a viable input method. The time spent waiting while the system scans may be a minor annoyance, but the difference between turning on a light now versus a few moments from now is relatively small. EADL systems are used intermittently throughout the day rather than continuously, so the delays over the course of the day are acceptable in most cases. For AAC or computer systems, however, the picture is very different. In either application, the process of composing thoughts may require making hundreds or thousands of selections in sequence. The cumulative effect of the pauses in row-column scanning slows productivity to the point where functional communication is very difficult and may be impossible. Certainly, when productivity levels are required, the communication rate available by scanning input will not be adequate.

Integrated Controls

One area of current development is the long advocated idea of integrated controls.[16] An individual with a profound disability is likely to require more than one type of control device. A person with severe motor involvement from cerebral palsy, for example, may require an augmentative communication system for interpersonal communication, an EADL for control of the local environment, a computer access system to complete job-related tasks, and a powered mobility device to navigate the community. Historically, each of these systems had their own control systems, with slightly different control strategies. The user of these multiple systems would have to move from control system to control system and have to learn how to control each of the systems.

With an integrated control system, the user would have a single interface that could control each assistive technology device. Because both AAC and computer access commonly involve language, the ability to use an AAC device to control a computer was an early goal. The 1994 standard for the general input device emulating interface (GIDEI)[18] defined characters to be sent from an AAC device to a supporting computer to provide control equivalent to the keyboard and mouse. With GIDEI, an AAC user could use the same control interface to communicate with friends in the same room or to write a business proposal.

Because many devices can be used with a moving pointer, the joystick control of a powered wheelchair may offer another avenue to integrated controls. The same joystick could be used to move a selection icon on the display of an EADL or AAC device or the mouse pointer of a computer screen. Ideally the communication between devices would be wireless, and the current Bluetooth standard for short-range, wireless communications offers to make such controls possible. (Bluetooth is a consortium of electronics companies whose goal is to develop a flexible, low-cost wireless platform capable of short-distance communication.)

For the practitioner, the question will be whether the advantages of a single, generic control that is not optimal for any particular device would outweigh the costs of learning individual, optimal control strategies for each device. Because the demands of controlling a powered wheelchair are significantly different from those for writing a formal proposal, changing channels on a television, or answering a question in a classroom, different control strategies might be necessary for each device. Whether a single control interface can support the optimal strategy for each device remains to be seen.

Rate Enhancement/Efficiency Options

For EADL systems, the rate of control input is relatively unimportant. As noted earlier, the number of control options is relatively limited, and selections are rarely severely time constrained. However, for AAC and computer control systems, the number of selections to be made in sequence is high, and the rate is frequently very important. Because a person with a disability cannot generally make selections at the same rate as an able-bodied person, rate enhancement technologies may increase the information transmitted by each selection. In general, language can be expressed in one of three ways: letter-by-letter spelling, prediction, and compaction/expansion. The latter two options allow enhancement of language generation rates.

Letter-by-Letter Spelling

Typical typing is an example of letter-by-letter representation and is relatively inefficient. In all languages and alphabets, there is a balance between the number of characters used to represent a language and the number of elements in a message. English, using the conventional alphabet, averages about six letters (selections) per word (including the spaces between words). When represented in Morse code, with only two symbols, the same text will require roughly 18 selections per word. By comparison, the basic Chinese vocabulary can be produced by selecting a single ideogram per word; however, thousands of ideograms exist. In general, having a larger number of characters in an alphabet allows each character to convey more meaning but may make selection of each specific character more difficult.

Many AAC systems use an expanded set of characters in the form of pictograms or icons to represent entire words that may be selected by the user. Such semantic compaction allows a large vocabulary to be stored in a device but requires a system of selection that may add complexity to the device.[13] For example, a device may require the user to select a word group (eg, food) before selecting a specific word (eg, hamburger) from the group. Using subcategories, it is theoretically possible to represent a vocabulary of more than 2 million words on a 128-key keypad with just three selections.

Prediction

Because messages in a language tend to follow similar patterns, it is possible to produce significant savings of effort with prediction technology. Two types of prediction are used in language: word completion and word/phrase prediction.

In word completion, a communication system (AAC or computer based), after each keystroke, presents a number of options to the user representing words that might be typed. When the appropriate word is presented by the prediction system, the user may select that word directly rather than continuing to type the entire word out. Overall this strategy may reduce the number of selections required to complete a message.[21] However, it may not improve typing speed.[27] Anson[3] demonstrated that when a person types from copy using the keyboard, typing speed was reduced in direct proportion to the frequency of use of word prediction. The burden of constantly scanning the prediction list overwhelms the potential speed savings of word completion systems under these conditions. However, with an on-screen keyboard or scanning system, for which the user must scan the input array in any case, word completion does appear to increase typing speed and reduce the number of selections made.

Because most language is similar in structure, in some cases it is also possible to predict the word that will be used after a specific word. For example, after a person's first name is typed, the surname frequently is typed next. When this prediction is possible, the next word may be generated with a single selection. Combined with word completion, next-word prediction has the potential to reduce the effort of typing substantially. However, in many cases this potential goes unrealized. Although provided with next-word prediction, many users become so involved in spelling words that they ignore the predictions, even when they are accurate. The cognitive effort of switching between “typing mode” and “list scanning” mode may be greater than the cognitive benefit of not having to spell out the word.[19]

Compression/Expansion

Compression/expansion strategies allow limited sets of commonly used words to be stored in unambiguous abbreviations. When these abbreviations are selected, either letter by letter or through word completion, the abbreviation is dynamically replaced by the expanded form of the word or phrase.[2,14]

Because the expansion can be many selections long, this technology offers an enormous potential for energy and time savings. However, the potential savings are available only when the user remembers to use the abbreviation rather than the expanded form of a word. Because of this limitation, abbreviations must be selected carefully. Many abbreviations are already in common use and can be stored conveniently. Most people refer to the television by the abbreviation TV, which requires just 20% of the selections to represent it. With an expansion system, each use of TV can automatically be converted to “television” with no additional effort from the user. Similarly, TTFN might be used to store the social message “Ta-ta for now.”

Effective abbreviations will be unique to the user rather than general. An example of an effective form of abbreviations would be the language shortcuts commonly used in note taking. These abbreviations form a shorthand generally unique to the individual and allow complex thoughts to be represented on the page quickly in the course of a lecture. A clinician should work carefully with the client to develop abbreviations that she or he finds useful and can remember easily.

Another form of "abbreviation" that is less demanding to create involves corrections of common spelling errors. For individuals such as students or adult writers who have cognitive deficits that influence spelling skills, expansions can be created to automatically correct misspelled words. In these cases the "abbreviation" is the way the client generally misspells the word, and the "expansion" is the correct spelling of the word. Once a library of misspelled words has been created, the individual is relieved of the need to worry about the correct spelling. Some maintain that this form of adaptation prevents the individual from ever learning the correct spelling. If the client is still developing spelling skills, this is probably a valid concern, and the adaptation should not be used. However, for individuals with an irremediable cognitive deficit, accommodation through compression/expansion technology is a desirable choice.

None of these technologies will allow a person with a disability to produce messages at the same rate as an able-bodied person. However, individually and collectively, they can make generation of the message significantly more efficient than it would be without them. The techniques are not mutually exclusive; icons can be predicted by using next-word techniques, and abbreviations can be used in conjunction with word completion and word prediction technologies.

Output Options

Control of assistive technologies involves a cycle of both human output and human input matched to technology input and technology output. Individuals who have sensory limitations may have difficulty controlling assistive technologies (or common technologies) because they are unable to perceive the messages sent to them by the technology. For these individuals, adaptations of the output of the technology may be required. These adaptations generally depend on one of three sensory modalities: vision, hearing, or tactile sensation.

Visual Output

The default output of many types of electronic technology is visual. Computer screens are designed to resemble the printed page. AAC systems have input that looks like a keyboard and, generally, a graphic message composition area. EADLs use display panels and lighted icons to show the current status of controlled devices. Perception of all these controls depends on the user having visual acuity at nearly normal levels. When the client has some vision but it is limited, some adaptations may be required.

Colors and contrast.

Many types of visual impairment affect the ability to separate foreground and background colors. In addition, bright background colors (including white) can produce a visual glare that makes the foreground difficult to perceive. In accommodating visual deficits, the clinician should explore the colors that are easily perceived by the individual and those that are difficult. For most people, background colors should be muted, soft colors that do not produce a strong visual response. Icons and letters, in contrast, may be represented in colors that provide visual contrast with the background. Very bright or strident colors should be avoided in both cases, and the specific colors and contrast levels required by the user must be selected on an individual basis. For many people with color and contrast issues, simply changing the display to white text on a black background provides a functional accommodation.

Image size.

Visual acuity and display size present difficulty in output display that closely mirrors the issues that ROM and fine motor skills present in keyboard design. A person with 20/20 vision can generally easily read text that is presented in letters about $\frac{1}{6}$ of an inch high. (Because a printing "point" is $\frac{1}{72}$ of an inch, this is equivalent to a page printed in a 12-point font.) On a typical display this allows the presentation of 100 to 150 words of text at a time or a similar number of icons for selection. If the user has lower visual acuity, the letter/icon size must be increased to accommodate the loss of acuity. Larger icons, however, require either fewer letters shown at a time or increased display size. For people with severe visual limitations, as with individuals with severe fine motor limitations, it would be impractical to display all choices at once.

Screen enlargement programs[2] typically overcome this limitation by showing a part of the full screen at a time and moving the portion that is expanded to the area most likely to be of interest to the user. The visual effect is similar to viewing the screen through a magnifying glass that the user moves over the display. Most programs can be configured to follow the text insertion point, the mouse pointer, or other changes on the display. Navigation is a serious problem with all such programs. When the user can see only a small portion of the screen at a time, the landmarks that are normally available to indicate the layout of the text on a page may be invisible because they are not in the field of view. Any screen enlargement program must provide a means of orienting to the location on the screen that is usable by the client.

AAC systems can accommodate the needs of a user with low visual acuity by using precisely the same techniques that are used for a person with limited fine motor control. The keyboard of the device can be configured with fewer, larger keys, each of which has a larger symbol to represent its meaning. However, as with keyboards for those with physical limitations, the result is either fewer communication options or a more complex interface for the user. In addition, these accommodations do not adapt the size of the message composition display, which may be inaccessible to a user with visual limitations.

Speech Output

It is very important to keep the difference between voice input and voice output clearly in mind. In voice input, the user speaks and the spoken word is converted into commands in the assistive technology. In voice output, the device communicates with the user through auditory means and converts printed words or commands into voice. Voice output technology has been in existence for much longer than voice input and is a more mature technology—not perfect, but more mature.

The demands of voice output are very different, depending on the application and the intended listener. In general, voice output can be divided into systems in which a second person is the listener or the user is the listener.

Second person as listener.

When used in AAC applications, voice output is almost always intended to be understood by a person who may have little experience with synthetic voices. For example, if an AAC user is at the corner market buying 2 pounds of hamburger for dinner, the butcher most likely has very little experience with a synthetic voice. When an AAC user asks for directions on the street corner, not only will the listener have little previous experience, but the AAC's voice will be competing with the sounds of trucks and buses.

To be understandable by novice listeners in real-world environments, a synthetic voice should be clear and as human sounding as possible. The voice will be easily understood to the extent that it sounds like what the listener expects to hear. Ideally, the voice should provide appropriate inflection in the spoken material and be able to convey emotional content. Current AAC systems do not convey emotional content well, but high-end voice output systems do sound very much like a human speaker. The state of the art in speech output is the Alex voice of the Apple OS X operating system. Alex sounds very nearly human and can even be heard to inhale intermittently. Its ability to correctly pronounce words with abnormal spellings is uncanny. Unfortunately, the Alex voice alone is as large as all the rest of OS X, including all the other voices provided in the system. Under adverse conditions, synthesized voices remain less understandable than a human speaker because the facial and lip movements that provide additional cues to the sounds being produced do not accompany synthetic voices. Until lifelike facial avatars can be provided that match the lifelike voices, noisy environments will remain an issue.

User as listener.

When voice output is used for computer access or EADLs, voice quality need not be as human sounding. In either case, the user has the opportunity to learn to understand the voice during training. In EADL applications, there will be relatively few utterances that must be produced, and they can be designed to sound as different as possible so that there is little chance of confusion. General voice output for an entire language is somewhat more difficult, though, because many words sound similar and can easily be confused.

For general text reading, however, the primary issue is voicing speed. As noted earlier, humans generally talk at a rate of 150 to 175 words per minute. However, most humans read 300 to 400 words per minute. A person who depends on a human-sounding voice for reading printed material will be limited to reading at less than half the speed of able-bodied readers. To be an effective text access method, synthetic voice output must be understandable at speeds in excess of 400 words per minute. This obviously requires significant training because untrained people without disabilities cannot understand speech at such speeds. However, with training, speech output is a very useful way for a person with a visual limitation to access printed material.

Speech is a useful tool in two cases: (1) when it replaces voice for a person with a disability and (2) when the user is not able to use vision to access the technology. AAC devices using voice provide the most "normal" face-to-face communication available. In most conditions, able-bodied people communicate by voice. People with disabilities generally want to communicate in similar fashion. The other application of voice is "eyes free" control. In the mass market for able-bodied consumers, these applications include presenting information over the telephone, while driving, or in other settings in which a visual display might be difficult to use. All these situations also are important for people with disabilities. In addition, assistive technologies using voice output may be intended for use by people with print impairments. The category of print impairments includes conditions that result in very low vision and/or blindness, in addition to conditions that result in an inability to translate visual stimuli to language and those that make manipulation of printed material difficult.

The one weakness of voice output technologies lies in its use for people who are developing language skills. Because English is an irregular language, with many letter combinations making similar sounds, it is almost impossible to learn spelling by listening to the sound of words. Accordingly, children who are blind from birth may not be good candidates for speech output as the primary language access method because the structure of words is lost when converted to speech. For these children and for many others, tactile access is a better tool and in fact is required by the Individuals with Disabilities Education Act (IDEA).[40]

Tactile Output

The oldest method for individuals with visual deficits to access printed material is Braille. In 1829 Louis Braille developed the idea of adapting a military system that allowed aiming artillery in darkness and writing secret messages to provide a method of reading for students at the National Institute for the Young Blind in Paris.[9] Over time, this original system has been extended to allow communication of music, mathematics, and computer code to readers without vision. Basic Braille uses an array of six dots to represent letters and numbers. Traditional Braille, however, is usable only for static text, such as printed books. Dynamic information cannot be represented by raised dots on a sheet of paper.

Technology access requires the use of refreshable Braille. Refreshable Braille displays use a set of piezoelectric pins to represent Braille letters. In a conventional computer display, changing electrical signals cause individual pixels to show light or dark (or intermediate colors) to show a portion of a document. With refreshable Braille, changing electrical signals to the display moves the tactile pins up and down, thereby allowing a single display to represent different portions of a longer document.

Braille is not widely used by individuals who are blind.[9] By some estimates only 10% of the blind population know and use Braille. For example, it is not usable by those who have limited tactile sensation in addition to blindness. Because the largest group of blind individuals in the United States consists of those with diabetic retinopathy, which is frequently matched to peripheral neuropathy affecting touch, a large proportion of blind individuals cannot use Braille. Nonetheless, Braille is a skill that should probably be taught to a person who is blind, provided the person has adequate sensation. Most Braille readers are employed. Most people who are blind but do not read Braille are not employed. Although Braille may not be an essential skill for employment, the ability to learn Braille certainly correlates with the ability to hold a job.[9]

Threaded Case Study

Gianna, Part 2

Gianna has difficulty in her current areas of occupational performance in instrumental activities of daily living (IADLs), education, and social participation, which might be addressed through assistive technology. She will continue to have deficits in her ADLs that will not be addressed through assistive technology. Through the use of an EADL, Gianna can gain control over her immediate environment. She will be able to control the temperature of her home, the radio, and/or television; control the lighting; and open doors as desired. Her verbal communication skills are excellent, but her ability to write letters to friends (graphic communications) would benefit from the same technologies (primarily mobility [not addressed in this chapter] and computer access) that will allow her to pursue her education. Although Gianna can write and print papers, she will not be able to hand them in without assistance unless her professors allow electronic submission.

In view of Gianna's level of motor control, she might consider head pointing, Morse code, or speech recognition as a means of controlling her assistive technology. All of these technologies can be applied to computer control and to her EADL. Careful assessment by her therapist would determine which control strategy best meets her needs and whether the same control strategy would work for all of her assistive technology applications.

Depending on the input method selected, Gianna might benefit from word prediction and abbreviation expansion for her text input. Because her vision and hearing are not affected, no changes in the output systems of her computer would be necessary.

Through the application of appropriate assistive technology, it will become possible for Gianna to have more control over her life in terms of both her immediate surroundings and her future occupations. Gianna will be able to access online resources, write papers for college, and ultimately, if she has the cognitive skills, become a successful lawyer. Her assistive technology does not guarantee that Gianna will succeed, but it does give her the same opportunities to succeed or fail that her peers without functional limitations have.

Summary

An OT should always keep in mind that disability makes few things impossible. It does make many things harder, and some sufficiently difficult that they are "not worth it." Assistive technology can make many things easier for the person with a disability. Because they are easier, many things that were previously not worth the effort can become reasonable activities for a person with a disability. In the terminology of the disability model, assistive technology will never remove a functional limitation. However, it can prevent that functional limitation from resulting in a disability.

Review Questions

1. Compare and contrast rehabilitative and assistive technologies.
2. In what way do devices using universal design assist individuals with disabilities? Why aren't they considered assistive technologies?
3. According to the HIA model, why might a person with a disability not require any assistive technology for the completion of some tasks?
4. In pediatric applications, complex EADL devices might not be considered appropriate. What sort of EADL might be used with a very young child?
5. Some EADL devices allow control of the features of devices in the environment. Discuss the benefit of providing such control. What additional load does this place on the user?
6. AAC devices can be used to provide alternative or augmentative communication. Discuss the difference between these two strategies. Might an AAC device be a rehabilitation technology in some applications?
7. What is the value of having a message composition area that is independent of the message transmission feature of an AAC device? Discuss the value for the communicator and for the communication partner.
8. Discuss the difference between "conversation" and "formal presentation." How might each of these be important in an educational setting? What are the dominant demands of each type of communication?
9. How does a language disorder differ from a communication disorder? What sort of AAC device would help a person with a language disorder?
10. If an individual is able to use a physical keyboard but can only use one hand, what keyboard options might help him or her with text production?
11. Consider the keypad providing control for a microwave oven. How might the keypad present difficulty to an individual who is blind? How might it be modified by an OT to improve its usability?
12. Word prediction and word completion are often touted as means to improve typing speed, yet research suggests that they do not improve speed. What advantage might these technologies offer to improve productivity for a person with a disability?
13. Abbreviation expansion is generally considered a means of typing long words and phrases with only a few keystrokes, although this requires the user to remember the abbreviation. How else can this technology be used for individuals with learning disabilities in ways that do not require memorization of keystroke sequences?
14. Refreshable Braille is expensive, whereas text-to-speech is quite inexpensive. Yet Braille training is mandated by the IDEA. What factors support the teaching of this old technology to individuals who are blind?
15. Integrated control systems allow a single control device to serve as the interface for a range of assistive technologies. What are the advantages of integrated control systems? Why might an integrated control system not be desirable for an individual user?

PART IV

Performance Skills and Client Factors: Evaluation and Intervention

OUTLINE

18

Performance Skills

Definitions and Evaluation in the Context of the Occupational Therapy Practice Framework

Mark Kovic, Winifred Schultz-Krohn

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, the student or practitioner will be able to do the following:

1. Explain the difference between a performance skill and a client factor.
2. Develop an understanding of client-centered, occupation-based performance.
3. Relate how improvements in performance skills may affect habits, roles, and routines.
4. Define impairment, strategy, and function.
5. Identify principles that may affect client outcomes.
6. Explain how a skilled intervention with clients facilitates cortical reorganization.

KEY TERMS

Adaptive plasticity
Client factor
Contrived
Control parameter
Cortical reorganization
Function
Impairment

Motor control theory
Neuroplasticity
Occupational performance
Performance skill
Plateau
Strategy
Task-oriented approach (TOA)

Current Occupational Therapy Practice Framework (OTPF-3)

The current version of the OT Framework, the "Occupational Therapy Practice Framework: Domain and Process," third edition (OTPF-3), was published in 2014. The revisions in this document were designed both to guide occupational therapy (OT) practice and to convey to others the domain and process of the profession.[1] The Framework is meant to be an "ever-evolving document," and the current revisions were offered to "build on a set of values that the profession has held since 1917"[1] (OTPF-3, p. S3). This chapter reviews the roles of performance skills and client factors as applied to a client case presentation.

Threaded Case Study

John, Part 1

John is a 50-year-old construction worker who has been out of work for a year. He has taken on a new role, keeping the house clean while his wife continues to work full time. He lives with his wife and two children, ages 10 and 15.

John sustained a right middle cerebral artery (MCA) cerebrovascular accident (CVA). The resultant client factor deficits from this CVA include mild impairment in his left lower extremity and moderate impairment in his left upper extremity, with greater impairment in distal motor control compared to proximal motor control. His movement patterns in his left upper limb include lifting his shoulder and bending his elbow to position his hand so that it is better able to pick up items, but he is only able to use gross grasp and has limited precision for release of objects with his left hand. He presents with a left visual field deficit and decreased sustained attention to tasks regardless of environment. He requires occasional indirect verbal cues to attend to tasks and activities. He benefits from the use of strategies to compensate for his deficits. He is currently able to complete all basic self-care activities, with occasional to minimal physical assistance required. Much of the physical assistance required is for starting the activity and the quality of performance. He is medically stable and taking antiseizure medications. He is right-hand dominant.

John lives in a one-story ranch home without any steps inside the house. He is currently walking with the use of a large-based quad cane. He and his family live in an urban setting with access to public transport. He has numerous friends and family members who live nearby. His children participate in several after-school activities, and this requires a parent to pick them up and bring them home. His wife has been picking up the children over the past year because her work is near the children's school.

John wants to improve his home management skills and continue to maintain his role as a homemaker in support of his wife. He has asked that the occupational therapy (OT) practitioner focus on his being able to complete his morning routine, take his medications, and manage the home. He is currently unable to do stovetop cooking activities, and he has difficulty vacuuming the carpet and sweeping the floors in the house. He is unable to perform shaving activities as he did before the CVA. Previously John had used a safety razor with his right hand while holding part of his face with his left hand to allow the safety razor to glide smoothly over the skin, without cuts or nicks. Since the CVA John has used an electric razor, which he holds in his right hand; however, he does not like the poor results, and he often has razor irritation after shaving. He is unable to use his left hand to assist in the shaving process.

Critical Thinking Questions

1. What performance skills would potentially negatively affect John's ability to engage in desired occupations?

2. Given John's stated concerns, what additional occupations may be compromised?

3. What evidence is available to support services designed to improve John's occupational performance?

Role of Performance Skills and Client Factors in Occupational Performance

Performance skills and client factors affect a client's occupational performance. **Occupational performance** is the engagement in meaningful and purposeful activities that relate to habits, routines, and roles. Active client engagement in occupation-based evaluation and intervention can facilitate changes in performance skills and performance patterns, and this may influence habits, roles, routines, and ultimately occupational performance. This chapter addresses how these elements relate to any client throughout the lifespan. It also describes how neuroscientific research supports an occupation-based approach to facilitate changes in the central nervous system (CNS) that directly correlate with improvements in occupational performance and client-centered outcomes.

The importance of client-centered interactions in selecting specific occupations that will help clients progress through their course of occupational therapy (OT) is a concept endorsed by the American Occupational Therapy Association (AOTA)[1] and several leaders in the OT profession.[7,9,16,26] There are several variations of how this process may occur; however, regardless of whether the Assessment of Motor and Process Skills (AMPS),[7] the occupational functioning model,[26] or the task-oriented approach (TOA)[17] is used, the message is similar—analysis of client performance provides the OT practitioner with a means of understanding what is observed.

These authors identify with a common thread, consistent with the World Health Organization's definition and classification of disability,[26] that performance analysis is important. This analysis may be formal or informal. Yet, one particular caution is to make sure that during any informal analysis, the intended outcome is specifically identified. This allows the OT practitioner to anchor what was expected with what is actually performed and observed. Thus, the focus remains on the tasks and corresponding performance skill, rather than on the client factor serving as the key determining variable in the OT process.

Occupation-Based Approaches and Neuroscientific Evidence

Connecting occupation-based approaches to the neuroscientific realm provides a framework to consider these concepts as they relate to learning. Learning, as defined in this context, theoretically occurs as a result of neuroplasticity and assumes that new neuronal connections and axonal sprouting occurs within the central nervous system through multi-sensory input.[24] Application of this concept may be seen with clients who have sustained upper motor neuron (UMN) injuries. Current trends in occupational therapy to ameliorate upper extremity hemiparesis as a result of UMN lesions are varied, yet research indicates that a potentially beneficial way to achieve a successful client-centered outcome is to include those interventions which address how the client interacts with the task and the environment. This particular approach is supported by basic and applied neuroscience concepts which imply that skilled interaction among a client's task performance in an environment may direct cortical changes and facilitate neuromuscular recovery. Consequently, this type of approach may improve completion of ADLs through improvements in performance skills[11] via engagement in occupational performance-based activities. Occupational performance, as such, often arises from a person performing a particular task in a particular environment. This dynamic interaction among the individual, the task, and the environment is consistent with the foundational framework provided by the **task-oriented approach**.[17] The TOA is one of a variety of approaches to evaluation and intervention which incorporates an underlying understanding of a variety of concepts. Among these is the ecologic approach to the performance of functional tasks (and purposeful movements). This approach emphasizes the interaction among the person, environment, and task performance.[17] Within this approach, the term “task” is not equivalent to “occupation.”[7] Although several definitions of the term occupation have been offered, the elements that distinguish occupations from tasks include the specific meaning to the occupational performance and the occupational performance within a context or environment.[6] A task is often a small portion of an occupation, such as the task of cutting with a knife and fork within the occupation of self-feeding. The performance skill in this task may be grasping the fork. Yet, an appreciation for the task-oriented approach can be seen with understanding the potential impact the task has upon occupational engagement. The OT practitioner may then apply motor learning concepts, adapt, modify, or otherwise facilitate successful completion of an occupation-based goal.

Application of the TOA directs occupational therapy practitioners to address the performance skill[11] deficits that their client's experience while simultaneously incorporating current understanding of neuroscience concepts. Both the process and outcome are important with regard to this approach. The net result of this approach is that the client may benefit from improved activity of daily living (ADL) performance. Ultimately, this may support habits and routines and eventually facilitate return to desired, client-centered roles.

Performance Skills and Client Factors

The OTPF-3 identifies client factors and performance skills as separate elements and describes how they impact and are impacted by client interaction with task and the environment in the process of performance of ADLs.[1] Fisher[7] provided a background to the process of how to formally and informally assess performance skills and patterns in relation to occupations. She stated that in order to understand how the client factors impact occupational performance, it is important to thoroughly determine how these components impact performance skills during occupational performance. Thus, it could be inferred that any attempt to assess this relationship without an appreciation and understanding for this dynamic process may lead to potentially "misdirected" conclusions. There will be a mismatch between client need and OT practitioner choice of intervention. In other words, the OT practitioner may make clinical decisions which are not in the best interests of the client and will not reflect "best practice."

Table 18.1 lists the performance skills from the OTPF-3.

TABLE 18.1

Performance Skills in the OTPF-3

Performance Skills	Definition
Motor skills	Skills observed as a person interacts with and moves task objects and herself or himself around the environment
Process skills	Skills observed as a person selects and uses tools and materials, carries out actions and steps, and modifies performance when problems are encountered
Social interaction skills	Skills observed during a social exchange

In what way could the occupational therapy practitioner evaluate John in order to identify what assets and deficits this client may be able to utilize?

It is necessary to understand current client abilities relative to specified task performance. This can be understood with measurement of particular client factors such as John's left upper limb active ROM and strength. As discussed in the chapter, this is important to have an understanding of particular deficit areas prior to the initiation of occupational therapy services. This should then be combined with observation of John participating in certain activities. The activities may occur in a structured or unstructured manner. They could include performance of his morning routine. This may include dressing, brushing his teeth, or shaving. The OT practitioner would observe what specific strategies are utilized. If John turned his body to the side in order to position his left arm across his lap to then place his left arm into the sleeve of a shirt, it is likely that this particular strategy maximizes his performance skill. The evaluation process would be a combination of the client factor measurement with the occupational performance and would most likely reflect what John is able to do for these activities of daily living (ADLs).

Client factors related to body and structure function are important as they inform the OT process and ultimately contribute to understanding of how these functions (or lack thereof) contribute to the evaluation process and development of an intervention plan. Additionally, values, beliefs and spirituality are included as client factors in the OTPF-3.[1] Within the OTPF-3,[1] client factors are differentiated at the person, organization, and population level; this chapter will primarily address client factors applied to the level of the person. Some of the specific client factors identified at the level of the person are: neuromusculoskeletal functions related to strength, muscle tone, motor reflexes, and voluntary and/or involuntary movement. Global and specific mental functions are important client factors which support incorporation of the input from one's interaction with a task within an environment. These mental functions, collectively termed cognition, are required for a person to make sense of sensorimotor input from the environment. These functions are important to overall functional ability. Also, the degree to which the central nervous system is intact following damage or a lesion, will impact a client's occupational performance.

As it relates to upper motor neuron (UMN) cortical lesions, these client factors may result in peripheral soft tissue changes, hypertonia, spasticity, and changes in range of motion. Any combination of these changes will likely impact how a client participates in a particular task. These client factors remain relevant and supportive in their role in the overall OT process. In other words, they are a means to understanding an end which focuses upon performance skills as these skills support performance of occupations.

Client factors differ from performance skills in that they represent the responses to system control. Client factors can often be measured and quantified—strength, range of motion, visual acuity, muscle tone, attention. **Client factors** represent bodily functions and what the body "does," rather than what the person does. This distinction is made clear by Fisher[7] where client factors are the actual body structures and basic body functions. Additionally, client factors represent what a person can utilize to perform a particular task. Thus, client factors facilitate performance skills but merely assessing available client factors is not predictive of occupational performance.[1]

Performance skills include the motor, process, and communication/social interaction skills required to perform specific tasks (ie, ADLs, IADLs, work). Fisher[7] described performance skills as "small units of action [that] are always goal-directed because they are enacted in the context of carrying out and completing a daily life task." Therefore, performance skills are not assessed in the absence of occupational performance but must be assessed while the client is engaged in an occupation. For example, John would like to be able to complete a dinner that includes cooking on the stove, specifically cooking pasta and spaghetti sauce. Although assessment of specific body functions may reveal limited isolated active range of motion (AROM) of his left arm, making it difficult to hold the handle of the sauce pan while stirring the sauce with his right hand, during the actual task performance the OT practitioner would also notice the difficulties with positioning his body appropriately to the stove and poor pacing of the actions which are in the performance skill category of motor and process skills. Motor and process skills are required in adequate and appropriate amounts to interact with an object in the environment during performance of a task in an accurate and efficient manner. This process can be quite dynamic and complex, and understanding this interaction informs and directs the OT evaluation and intervention. The ability to judge and respond to task demands is an aspect of the cognitive performance skills linked to overall occupational performance. Returning to the example of John cooking pasta and spaghetti sauce for dinner would require him to sequence the task appropriately by starting spaghetti sauce, then placing the water on the stove for the pasta, and as the sauce simmers, adding the pasta to the boiling water. These aspects of the task may require reaching, manipulation, and calibration. All of these are motor performance skills. He would need to time all these events appropriately for dinner to avoid serving cold pasta with over-cooked sauce. He needs to endure and pace his performance. With John's difficulties in attention (a client factor) an OT practitioner may assume the complex task of cooking spaghetti and sauce would be a challenge. Without observing the actual performance, the therapist may have suggested a checklist as an intervention method and not understand how the motor and process performance skills interact with cognitive skills during the occupation of meal preparation. Thus, a person presents with specific deficits (client factors) which impact performance skills which relates to occupational performance. Significant changes/impairments with these client factors may sufficiently impact a client's performance patterns and skills and eventually (adversely) impact occupational roles. Research indicates that the TOA is more likely to impact and positively influence outcomes when compared to treatment which only addresses client factors.[20] Neuroscientific research is pointing toward the possibility that the central nervous system is organized in such a way that tasks can be addressed through interaction with the environment rather than specific muscle groups meant to perform specific tasks. This is consistent with the TOA. Thus, understanding a client's roles and routines will guide an OT practitioner's ability to address performance skills as they relate to occupational performance. In summary, performance skills are required for interaction with task, object, and environment.[22]

How would John benefit most from occupational therapy intervention with a focus on performance skills to support improvements in client chosen activities?

John is motivated to improve his self-care and home management skills at home. He is able to complete his morning routine and self-care activities with limited physical assistance from another person. He has a supportive family who provides assistance as needed. He stated that he wants to be able to improve his ability to complete his morning routine, self-care activities, and home management. If the OT practitioner were to focus on prioritizing these activities, it would be possible to determine the best way to address re-acquisition of these abilities. Although there are multiple control parameters (a control parameter refers to the motor element that influences performance) that influence successful task completion, it is likely that in any particular activity, at least one key parameter may be the most limiting factor to successful task completion. For example, with the shaving activity; John's impaired movement in his left hand compromises bilateral task performance and serves as the control parameter. This impairment, as described in the case illustration, comes from the inability to have sufficient distal control. It is important to observe the actual performance of the shaving activity when possible in order to avoid any contrived situations. Merely having John use a safety razor with the cover in place to simulate the act of shaving would not accurately replicate the actual performance of shaving. In this instance, it needs to be determined if focusing on how the performance skill of bilateral control can be achieved will improve shaving or if the task needs to be adapted to maximize independence. The OT practitioner can validate these approaches by observing John with the actual task of shaving. This same approach may be taken with each activity to be addressed.

Motor Control Theory

Interaction among the task, person, and environment represents important aspects of motor control. **Motor control theory** (ie, the ability to make dynamic changes/responses of body and limb to complete a purposeful activity[24]) has undergone much development in recent years. This development has expanded our knowledge base, answered some questions, introduced other questions, and has permitted a further appreciation of the complexity of cortical function as it relates to motor performance.

A variety of sources indicate that multisensory input will provide the nervous system with input which will ultimately lead to improved quality of movement performance, decreased error, and support more efficient movement patterns.[4,20,21] These multiple sensory inputs to learning (or re-learning) will attempt to work together to contribute to understanding interaction with the environment whether they are intact or not intact. When one sensory input (or system) is impaired, others may need to compensate. When one part of a system is impaired, the performance pattern is affected. For example, if a person presents with impaired ability to perform dynamic distal (hand and finger) movements due to decreased motor control, then he or she may move the proximal upper limb in such a manner as to compensate for this impairment. The net result of this compensatory movement may present as “shoulder hiking” and may include other movements such as lateral trunk flexion or even shortening of the lever arm (ie, elbow flexion) to control degrees of freedom.[23]

John “hikes” (abnormally elevates) his left shoulder as movement is initiated with his left arm as he attempts to reach for objects such as his razor or toothbrush. Doing so allows him to be able to move his left arm to a position where he can then access these items. It may be possible that John is aware of the fact that he may have reached differently before the CVA. The OT practitioner may ask John to reach for these items with his right hand for comparison (recall that John is right-hand dominant). This serves as an informal task analysis. If the position of the items and how John interacts with the objects in the environment is changed, it can also be analyzed as to how this may affect the strategy, given available skills.

It is possible that this inefficient movement pattern could then be repeated and eventually develop into a new adapted or maladapted pattern. However, unless this process is properly analyzed, the client is more likely to “learn” and repeatedly use this inefficient movement pattern to accomplish a task. Poor and ineffective patterns may emerge, overuse syndromes may occur, and the net result is potentially poor self-efficacy and extra energy expenditure with occupational performance.

Repetition alone as part of a neuromuscular rehabilitation approach is insufficient to create and reinforce cortical reorganization.[2,12,23] This statement is neither novel nor groundbreaking in its meaning, yet its intent is shared by multiple researchers in a variety of arenas from basic neuroscience to the field of occupational therapy.[2,12,13,19] It is a well-established hallmark of occupational therapy to work with the client to develop an occupational profile and to engage the client in meaningful and purposeful activities. Additionally, intense task-oriented training of the sensorimotor cortex is believed to lead to cortical reorganization. Bayona et al.[2] found that rehabilitation outcomes have greater success when the tasks are meaningful to the patient. Volpe et al.[27] shared this same conclusion.

Yet, client-centered, therapist-driven task-oriented approaches may not directly translate to anecdotal or clinically measurable/significant pre-, post- changes. Motor learning concepts[26] indicate that the degree to which a task is learned is positively correlated with the “depth” of the “well” in which it is kept. In other words, the more ingrained a task is to a person, the more challenging it may be to change or transition the movement or behavior. The key point where that transition occurs may also be influenced by control parameters.

Control parameter is a motor control term that could be anything that shifts a motor behavior from one manner of performance to another type of performance. Control parameters can be internal to the person (strength, vision—for example, John's left visual field deficit) or external (location of an object, lighting). Consider the task of washing your back, the length of your arm, size of your back, established habits from training, all serve as control parameters—do you attempt to wash your left scapular area with your right hand or left? When the control parameter is a client factor, this may be an appropriate instance where the occupational therapy practitioner may attempt to address/remediate the client factor.[17] This approach to the OT process, often termed a "bottom-up" approach, assumes that addressing the fundamental client factors will allow the OT practitioner to interact with the client in order to impact and improve client occupational performance. Yet, doing so may not translate to improved performance skills or occupational performance. In fact, it is likely that the further the intervention for the client factor is from the actual occupational activity, the less likely there will be a positive correlation between these two items. Ultimately, the degree to which the client factor is impaired will impact the end result and how there is compensatory or adaptive interventions by the OT practitioner and the client. These concepts could be at least part of the explanation as to why there have been improvements measured in clinical outcome measures in some well-developed studies in this arena, but that there are limited long-term improvements. Consequently, it may be challenging to overcome (sometimes poorly) practiced performance skills and patterns. Return to the example of John cooking dinner. He has a left visual field cut which compromises his ability to obtain visual information and when the pot with pasta (located on the left side of the stove) begins to boil over John is not receiving that visual input. He could be trained to visually scan the environment to compensate for the visual field cut and it would be most appropriate to provide this training within a natural environment and with preferred occupations.

Fundamentals of experience-driven **neuroplasticity** include the adaptive capacity of the central nervous system to make fundamental changes and alterations on the cellular and eventually the systems level which can then lead to new learned/adapted behaviors. There are key critical "signals" which can facilitate such recovery.[11] Additionally, the brain continually reorganizes itself, with or without damage.[11,13] This process of learning will occur spontaneously—without any explicit learning or formal rehabilitation. Lack of skilled therapeutic intervention may lead to maladaptive behavioral responses. It is the skilled learning which occurs through the use of strategies and adaptation to facilitate this adaptive response. This has been shown to occur with the use of the TOA and task-specific techniques. Focus upon the performance skill in therapy allows the opportunity for skilled learning to occur. A person may present with compensatory movements or adaptations to control parameters such as decreased agonist strength. The TOA, with a focus upon the person interacting with the task in the environment, can address this limiting performance client factor (compensation), in part, by guiding the performance skill via skilled management of the dynamic interaction of these items. Compensatory behavioral changes are a regular part of this process.[13]

John has been attempting to move his left arm as much as possible since the CVA. He tells family and caregivers frequently that he wants to do as much as possible for himself. He is motivated to make improvements. When he attempts to complete self-care activities on his own, he does not make adjustments in the environment. He interacts with objects with poorly coordinated movement patterns. His performance skills are relative to how he uses objects. The OT practitioner can maximize the quality of the performance skills with a focus upon how John brushes his teeth or shaves. This would then serve as the foundation for how to modify the task or the environment.

Kleim and Jones[12] identify ten principles which fit this process: (1) use it or lose it, (2) use it and improve it, (3) specificity, (4) repetition matters, (5) intensity matters, (6) time matters, (7) salience matters, (8) age matters, (9) transference, and (10) interference. These principles come from basic and applied neuroscience research concepts which have shown evidence that they can impact outcomes. These principles can support evaluation and treatment.

Effective evaluation of the client who presents with upper limb hemiparesis as has been described in this chapter should then include an understanding of the specific impairments (client factors) which impact the performance of occupation-based, client-centered tasks. Although addressing specific client factors may be a part of treatment, this may not necessarily reflect changes in occupational performance. A client may need to improve bicep strength in order to complete a hand-to-mouth pattern, yet improving the bicep strength to a point where the strength is sufficient to facilitate the movement does not guarantee that the task can be completed successfully. Thus, the focus should be upon the performance skills and patterns. Observation of the client strategy with use of remaining abilities as it relates to overall function is an important part of the evaluation process. This should occur with respect for current understanding of how skilled interventions by the occupational therapy practitioner may direct learning/re-learning and lead to neuroplastic cortical changes. These changes in performance skills can lead to improvements in occupational performance.

Comprehensive evaluation with respect for the TOA requires a thorough assessment of impairment, strategy, and function. As stated earlier in this chapter, the specific impairments are those which result as a consequence of the UMN lesion. These impairments may include but are not limited to: weakness (of the agonist), decreased coordination, decreased in-hand manipulation, inability to manage agonist and agonist efficiently, impaired/absent sensation, proprioception, impaired vision, and decreased overall cognitive ability. These impairments may be measured with traditional assessment approaches utilized by OT practitioners: manual muscle testing, range of motion testing, sensation testing, vision testing, strength (grip) testing via a dynamometer (for example), coordination testing via the 9-Hole Peg Test (for example), and so on. The appropriate standardized test may be, in part, determined by the site/setting. The benefit of these assessments is that they provide a pre-test foundation from which to measure progress. Yet, these client factors remain relevant in so much as they impact occupational performance via performance skills. Thus, it is important for the OT practitioner to have an appreciation of the strategies and performance patterns utilized by the client.

John has less than five pounds of grip strength in his left hand as measured by the dynamometer. He has impaired sensation on his left hand. He does not visually attend to the environment in his left peripheral visual field. These are client factors. John grasps objects such as eating utensils with insufficient strength and has difficulties when he attempts to use his left hand to hold a fork while cutting foods with the knife in his right hand. He is unable to judge the water temperature from a faucet on his left hand prior to shaving. He does not always attend to the left side of his environment when he is attempting to cook. These are performance skills. He requires assistance and verbal cues to complete his morning routine with good quality. This is occupational performance.

Ultimately, it is the occupational performance that arises from performance skills and patterns supported by clinical observations and leads to clinical decisions for "best practice." The benefit from use of the TOA with respect for current neuroscientific concepts such as cortical neuroplasticity is that the OT practitioner addresses a client's needs from a "top-down" approach rather than from a "bottom-up" approach. The top-down approach directs the OT practitioner to work with the client from the view of actual occupational performance. Fisher[7] describes these approaches along with the benefits and potential pitfalls of each of these approaches. It is possible to complete the impairment-based measurements and progress to function or to start with functional performance and to utilize these observations to guide assessment and treatment, yet caution is suggested when a "motor behavior perspective"[8] is solely utilized.

John has decreased strength and range of motion throughout his left upper limb. This impairment is observable and measurable. Sole measurement of these items is insufficient to create a client-centered occupation-based treatment plan. It might be possible to measure these client factors. Improvement with strength or range of motion may not reflect improvements with John being able to raise his left arm to apply shaving cream to his face. It is important to understand the deficits as they relate to real performance of some client-identified, clinician-driven approach.

Neuroscience Research Related to Practice

Recent research relating neuroscientific concepts from the animal model (rodent and primate) to the human model provide evidence of the potential benefits of provision of skilled learning opportunities to direct cortical reorganization.[19,20,22] **Cortical reorganization** is the concept that the adult brain has a neuroplastic ability to alter or modify its synaptic connections in the context of performance of a skilled activity—whether the brain and central nervous system is intact or not intact. Nudo and Milliken[19] and Nudo et al.[20] completed groundbreaking research which demonstrated that through skilled learning principles, it is possible to create topographical cortical map changes which directly correspond to specific "pellet retrieval" (distal forelimb) tasks after induced focal cortical lesions in these particular representative areas in squirrel monkeys. Task-specific training can lead to increased cortical representation of the trained areas along with a decreased representation of the previously post-infarct compensatory areas. The net result of performance skill in these primates was improved quality of movement. Most of the "improved performance patterns" occurred via observation of and interpretation of behavior by the researcher pre- and post-intervention assessment. This demonstrates the ability of the cortical region to reorganize when demands are placed upon it to function. Of course there are limits to the process of reorganization, particularly if large sections of the cortex are damaged.

It is suggested that the OT practitioner utilize these principles from the animal models with caution, as there are variables which are yet to be clarified. Animal (primate) model research in this area has provided invaluable information, yet these conclusions have resulted from specific, focally induced lesions[23] with clear boundaries as to the lesioned area. In many instances, adjacent tissue is undamaged.[23] In humans, research has demonstrated that peri-infarct (cortical) reorganization may occur. Additionally, in humans, the "edges" of the lesioned area are not always clear.[22] Aside from the clinical implications of these variances, there are other potential issues which may arise from more complex cortical damage. These may include medical complexity, family/caregiver support, comorbidity, cultural expectations, or other client-specific variables. These challenges have not been the focus of nor have they been addressed in the animal model.

What would be the best fit for treatment interventions for John, given the current evidence available and understanding of neuroscience to facilitate occupational performance?

Current research indicates that it may be most beneficial to observe how John participates in particular daily activities. This allows the OT practitioner to understand what repeated behaviors are used and where new strategies may be effective in assisting John in his desired occupational outcomes. In doing so, it may be possible to better fit treatment to his needs. This allows the possibility to focus upon activities which are of interest to John and utilize concepts related to the task-oriented approach (TOA). This approach is both client-centered and occupation-based. The specific treatment activities will focus upon matching the client performance patterns.

Data from both animal and human models lead to the likelihood that client-centered, client-specific intervention plans and approaches may be "best practice." This, of course, may introduce challenges to how to implement such approaches into the current standard of care. Regardless, the distinction between animal and human models will likely continue to be a topic of discussion. This discussion is relevant when we attempt to consider what defines the aforementioned "best practice." Birkenmeier et al.[3] attempted to address this translation from neuroscientific concepts to animal model research to clinical research implementation. Their description of how they made these decisions is one of the most comprehensive presentations of this issue. Lang and Birkenmeier collaborated on a resource book which aligns animal model research with a parallel human model treatment regimen. These examples are comprehensive in nature and include dozens of examples. Additionally, there are suggestions to guide the OT practitioner to upgrade and downgrade (modify) specific interventions.[15]

Research sponsored Northstar Neuroscience Phase III Clinical Trial[14] has taken these neuroplastic concepts and knowledge from animal models and applied them to a treatment protocol based on occupational therapy concepts of client-centeredness. This randomized controlled trial included nearly 150 subjects in close to twenty sites. The study intended to investigate the potential benefits of sub-threshold cortical stimulation in combination with "skilled" (already defined in this chapter) learning via a therapy protocol grounded in the TOA.

Similar investigations have identified that there may be potential benefits from sub-threshold (ie, non-evoked action potentials) cortical stimulation to support synaptic connections, dendritic density, and to facilitate overall cortical reorganization.[22] Although the exact dosage of the stimulation and whether specific cortical stimulation to the region responsible for post-lesion upper limb (distal) control or another approach such as transcranial magnetic stimulation (TMS) remains unclear at this time, this area holds potential future benefits.[22]

The treatment protocol for the Northstar Neuroscience Phase III Clinical Trial[14] study incorporated the approach of evaluation (and corresponding intervention) of **impairment**, **strategy**, and **function** in the realm of the TOA. The impairment corresponds to the client factor. The strategy corresponds to how the person attempts to perform a task as it relates to occupation, given specific impairments. Function corresponds to how the impairment and corresponding strategy relates to performance skills and patterns. Ultimately, subjects in this clinical trial were evaluated and treated with this framework. The research therapists evaluated and treated the subjects with a focus upon performance skills. This focus arose from client-centered occupation-based tasks which were determined by each participant via the Canadian Occupational Performance Measure (COPM).[16] Clients' self-perceived changes in the performance patterns for ADL's were measured by the COPM. Other assessments were utilized as outcome measures which included the Fugl-Meyer[8] and Arm Motor Ability Test.[13] These latter two are well-established and validated clinical measures and were primary outcome measures for this particular study and are focused upon limb movement (Fugl-Meyer) and contrived activity performance (Arm Motor Ability Test). Clients demonstrated improvements in COPM outcome measures but significant changes were not noted in the other two measures. The evaluation of the clients occurred according to the principles outlined by the TOA. The treating therapists were trained and followed standardized procedures to focus with the client on the client-centered goals. Once an individual improved on a client factor or performance skill, the treating therapist reviewed how that change affected the performance pattern and what this represented in the occupational performance. The changes in performance skills with participants in this study—addressed through the utilization of client-centered functional activities focused on the use of strategies related to task performance—corresponded to changes in client factors. This treatment approach and protocol is consistent with neuroscience concepts of skilled learning supporting cortical changes which may lead to changes (improvements) in occupational performance, performance patterns, habits, routines, and roles. A portion of this protocol included evaluation of and understanding of the impact of client factors upon performance skills. Consistent with this chapter, caution was heeded as to how the client factor was a means to understanding its relevance to performance skills and overall occupational performance.

Muscle strength, range of motion, sensation, and a variety of other client factors are necessary to engage in functional activities and therefore important to measure in a quantifiable manner. An adequate amount of strength, for example, is necessary to grip an eating utensil or sufficient active range of motion is necessary to complete a hand-to-mouth pattern. Yet, the key with this protocol was that neuroplastic concepts were utilized to link client factors to performance skills to facilitate adaptive plasticity. Isolated work on the client factors of muscle strength or range of motion was not part of the protocol.

Adaptive plasticity (the innate ability of the central nervous system to adapt or modify behavioral responses after exposure to a challenge to the system) implies that by addressing the performance skill, direct change toward improved quality of occupational performance will occur. As defined, the performance skill occurs in the process of engaging in the occupation and cannot be separated from the occupation.

The examples provided in this chapter reflect neuroscientific knowledge as it relates to how OT practitioners work with the neurologically impaired client, and these same fundamental concepts can guide clinical interventions with a variety of other clients across the lifespan.

Although the approach discussed in this chapter may relate to any client, a few other examples have been provided for consideration. This list is not exhaustive. In this chapter, the focus is upon adults. For example, a client who has cancer, chronic obstructive pulmonary disease (COPD), total knee replacement (TKR), or Parkinson's disease may benefit from the approach discussed in this chapter. The condition will inform the OT practitioner as to etiology, clinical and medical presentations, prognosis, and other valuable information. The client factors impacted by any condition, such as the ones previously listed, may impact performance skills. This may impact performance patterns. Ultimately, this leads to the possibility that habits, routines, and roles may be impacted. Observation and assessment of performance skills may still guide the OT practitioner to a client-centered occupation-based intervention.

Threaded Case Study

John, Part 2

John has sustained a right MCA CVA. This condition informs the OT practitioner that it is likely that he has left upper limb motor impairment. Additionally, there may be other consequences from the CVA. John may have decreased attention and decreased visual attention to the left side. Yet, it remains important to be aware that John is also a parent and a housekeeper. He wants to return to these roles. Thus, mere measurement of the specific client factors which have resulted from the

CVA will not explicitly return him to these roles and routines.

The older client with the TKR may present with decreased bilateral upper extremity strength, not as a result of the TKR but due to deconditioning from diminished activity secondary to knee problems. This decreased bilateral upper extremity strength will limit the ability to efficiently utilize a walker for functional mobility around the home. This client may also have a history of cognitive impairments that affect the ability to learn new concepts. The OT practitioner may need to consider these items to develop a client-centered intervention plan. Relating this example to the framework provided in this chapter, the OT practitioner will likely assess upper limb strength and range of motion. Part of the OT intervention may even include exercises and activities which may improve these client factors. Yet, this does not mean that in doing so, the client will improve the performance skill of (for example) a morning routine. Nor does it imply that engaging a client with a purposeful activity will translate to improved occupational performance. How a task is practiced in the clinic may not translate to the home environment. Thus, the formal or informal occupational profile and analysis will provide the foundation from which the OT practitioner may link the current status to desired outcomes.

Best Practice Occupational Therapy Service

It is important to bring this discussion back to clients who have acquired neurological deficits in order to identify how this particular group of clients can best be treated by occupational therapy practitioners. As occupational therapy practice for the adult neurological practice moves further from an "expert opinion" approach to one which is grounded in evidence (whether that evidence supports or refutes traditional practice approaches), there is much more to be learned in order to determine "best practice." There have been attempts to identify both current trends and task-specific training in order to identify what defines "best practice." In support of this comment, Carter et al.[5] describe that much of the effort in rehabilitation research is going toward the direction of "motor restoration." Additionally, they state that the quality of the research is more rigorous than it has ever been in the past. There is no doubt that these efforts will continue and may involve other novel means to address these deficits such as post-stroke bilateral upper limb training interventions.[25]

When it comes to measuring performance and improvements in clients with neuro-insults, it may be that previous outcome measures used to identify improvements are insufficient at this point in time. For example, some standardized and validated measures which address activities of daily living do so with contrived ADLs. **Contrived** activities are those which are artificially created in an attempt to recreate real scenarios. Although there are potential benefits gained from using a standardized ADL assessment as a common, consistent approach to measuring performance and conveying performance information that is clearly recognized due to the standardization process, if this standardization lacks the fundamental elements of the task or is too "contrived," then it may affect performance and the corresponding measurement of performance. An example of a contrived situation would be having a client "spread" butter on bread by having the client use a knife on a plate in the spreading motion without the actual bread or butter. In this example, the client may possess the motor control needed for the task but in the actual task (real world experience) of spreading butter on the bread the client may fail to notice that all the butter is located on one corner of the bread or may use excessive force and tear the bread. These observations would not be possible using a contrived activity but would be immediately noticed if the client was given an actual piece of bread and butter. Wu et al.[29] describe that "real" performance of activities results in different and "better" results than imagined or contrived activities. Additionally, there is a variety of means to measure performance including time to complete portions of a task, time to complete the entire task, and subjective observations of quality of performance. Further research may advance newer ways to measure performance skills and occupational performance. This does not mean that we, as occupational therapy practitioners, should not attempt to incorporate current trends, concepts, measures/assessments, and techniques.

There are other considerations to make with the impact of how we intervene with clients such as John. Timing, dosage, and method of delivery are important variables to control for in clinical studies and these variables should also be considered in clinical practice. Although evidence-based practice is expected, using data from an investigation which did not attempt to control these factors needs to be considered with some caution,[5] Given the competition for space in the cortex after UMN damage,[19] it is necessary for OT practitioners to respond immediately and effectively to client needs. This clinical reasoning process may affect how performance "plateaus" are determined in clinical practice.

Plateau is a term which is all too common in the realm of current rehabilitation practice with persons with upper limb hemiparesis as well as other conditions across the lifespan. Page et al.[21] suggest that the way in which therapists frame the upper limb hemiparetic population may need to be reconsidered. They state that what defines: (1) "motor recovery plateau," (2) "ability to recover motor function," and (3) when to "use different modalities…" may need to be reconsidered. "Traditional" expectations of most (motor) recovery occurring in 6 to 12 months often guides insurance and is tied into clinical practice. This chapter identifies the reasons as to why this may not necessarily be the case. Immediately following a CVA some clients may be able to participate in a rehabilitative approach designed to foster self-care skills, whereas where other clients may be far too ill. The timing, intensity (dosage), and method of delivery for these two clients will most likely vary, but a similar functional outcome may ultimately be met. Hubbard et al.[11] summarize principles which should be considered for incorporation of task-specific interventions. These suggestions may serve as a guide for "best practice" while addressing the potential for improvements in performance skills. They suggest that such training/intervention should "be relevant to the patient/client and to the context; be randomly assigned; be repetitive and involve massed practice; aim towards reconstruction of the whole task; and be reinforced with positive and timely feedback."[12] They further conclude that, although as noted in this chapter, there is much evidence pointing toward the benefit of task-oriented or task-specific training techniques, "common" practice approaches are grounded in "accepted practice or custom" and may be beneficial at specific points in time. An appreciation for this conclusion and the current state of neuroscience as it relates to this population can serve to transform clinical practice. Given the complexity of human beings, it may ultimately prove that what emerges as "best practice" may incorporate a multifactorial approach to guide client-centered evaluation and treatment and maximize outcomes and facilitate client habits, routines, and roles.

Summary

It is possible to address client-centered, occupation-based needs with a focus on performance skills. Neuroscientific research indicates that this approach can be applied with the use of certain methods, such as the TOA. The TOA emphasizes a dynamic interaction between the person, the task, and the environment. OT practitioners are educated and trained to address control parameters and complete performance analyses to maximize overall occupational performance.

Review Questions

1. What are the advantages of using real situations when assessing clients rather than contrived situations?
2. What are the advantages of using contrived situations when assessing clients instead of real situations?
3. What does the term *plateau* mean in reference to clients who have sustained neurological insults?
4. What is the difference between a client factor and a performance skill?
5. Using the task of brushing your teeth as part of your morning routine, identify two client factors and two performance skills that influence the way you engage in this task.
6. What does the term *control parameter* mean with regard to working with clients who have sustained neurological insults?
7. Explain the term *neuroplasticity*.
8. Explain the term *cortical reorganization*.
9. How do the meanings of the terms *neuroplasticity* and *cortical reorganization* support occupation-based interventions?
10. Explain how the TOA was used with the case of John.

Evaluation of Motor Control

Linda Anderson Preston

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, the student or practitioner will be able to do the following:

1. Differentiate between upper and lower motor neuron pathological conditions.
2. State the principles of neuroplasticity, and explain to clients the potential for recovery after a neurological injury or cerebrovascular disorder.
3. Describe four types of rigidity and the ways each affects movement.
4. Clinically differentiate between spinal and cerebral hypertonia.
5. Rate hypertonia on the Modified Ashworth Scale or the mild-moderate-severe scale.
6. Name standardized assessments designed to evaluate function after a cerebrovascular accident.
7. List the components of the postural mechanism.
8. Describe at least four types of cerebellar disorders.
9. List and describe at least four extrapyramidal disorders.
10. Choose a coordination assessment that objectively assesses function.
11. Name three current medical or surgical treatment options for the management of spasticity.
12. List at least three conservative occupational therapy interventions for spasticity.
13. Describe a conservative, evidence-based, client-centered OT program for treating Parkinson's disease.

KEY TERMS

Clonus
Coordination
Decerebrate rigidity
Decorticate rigidity
Flaccidity
Hypertonicity

Hypertonus
Hypotonus
Intrathecal baclofen pump
Motor control
Movement disorders
Nerve blocks
Neuroplasticity
Paresis
Plegia
Postural mechanism
Rigidity
Serial casting
Spasticity
Spinal hypertonia
Todd's paralysis

Threaded Case Study

Daniel, Part 1

Daniel, a 54-year-old salesman who is right-hand dominant, had an embolic cerebrovascular accident (CVA) 2 months ago that weakened the right side of his body. He has just completed 3 weeks of inpatient rehabilitation services that included occupational therapy, and he is starting outpatient occupational therapy today. His 70-year-old mother must drive him to therapy, and he finds this quite frustrating because he values his independence. His goal is to start his car ignition with his right hand and eventually resume driving. His vision and visual fields were not compromised by the CVA, as assessed by an ophthalmologist and the inpatient occupational therapist. Daniel is concerned about the future, and he wants to return to full-time employment. The occupational therapist knows very well that one-third of the 15 million people affected by a stroke each year are left permanently disabled.[36]

Daniel's right upper extremity (RUE) shows hypertonia in a flexion synergy, with moderate spasticity in his shoulder internal rotators, elbow flexors, forearm pronators, wrist and finger flexors, and thumb adductors. Daniel does not have active range of motion of the right shoulder external rotation or right forearm supination. His active finger extension on his right hand is emerging and is a 2− on the strength grade scale. He is currently at stage 4 of the Modified Brunnstrom Motor Recovery Scale (Table 19.1; also Figs. 19.1 to 19.5). He has only 1 pound of lateral pinch strength in his right hand. His range of motion losses and impairments, coupled with RUE spasticity, prevent him from starting his car ignition with his right hand. He needs OT rehabilitation services to regain the performance skills of holding a steering wheel, releasing a steering wheel, and turning on the ignition with his right hand.

TABLE 19.1

Modified Brunnstrom Stages of Motor Recovery[a]

Stage	Modified Brunnstrom Motor Recovery of Arm and Hand	Interdisciplinary Spasticity Management Options
0	Flaccidity with no active movement.	• Prevent contractures with PROM and consider splinting • Functional electrical stimulation
1	Spasticity developing. Trace muscle contraction in elbow flexors and scapular retractors (see Fig. 19.1).	• Same as stage 0
2	Weak synergistic movement of scapular retractors, scapular elevators, elbow flexors, and forearm pronators. Promote active movement in gravity-reduced planes. Eccentric, side-lying, and supine exercises are good ways to start facilitating movement. Functional electric stimulation may speed up motor recovery. Clients tend to use trunk lateral flexion to substitute for weak shoulder/scapular muscles (see Fig. 19.2).	• Prevent contractures with PROM and consider splinting. Risk for shoulder, elbow, forearm, and finger flexion contractures. • Blocks[b] and surgery generally are not indicated at this stage.
3	Spasticity increasing. Synergy patterns and their components can be performed voluntarily to almost full ROM. Gross grasp is developing; however, there is no active finger release. Lateral pinch is possible via thumb adduction tone and flexor pollicis longus tone. Synergy pattern may be useful for carrying objects (eg, envelopes with lateral pinch, or grocery bags in client's affected hand with finger flexion tone). Clients in this stage also tend to substitute with trunk lateral flexion to make up for shoulder weakness (see Fig. 19.3).	• *Acute:* Client is a good candidate for nerve or motor point blocks to prevent contractures. Recovery may be facilitated by unmasking movement in antagonists if spastic agonists are weakened by blocks. See text for OT treatment suggestions. • *Chronic:* After all conservative measures have failed, orthopedic surgery may be performed to release contractures so as to improve hygiene in the

		hand and ease UE dressing.
4	Spasticity declining, movement combinations from synergies are now possible. Elbow extension and wrist and finger extension are emerging but are not to full range. Occupational therapy should incorporate functional tasks that promote extension of the elbow, wrist, fingers, and thumb (see Fig. 19.4).	• *Acute:* Client is a good to excellent nerve block candidate. Better chance of gaining motor control of antagonists with blocks to the spastic agonists. • *Chronic:* Ongoing blocks three or four times per year if the risk/benefit ratio for orthopedic surgery is not acceptable to client. Orthopedic surgery options include procedures to gain function and to ameliorate contractures.
5	Synergies are no longer dominant. Finger extension is full range. Isolated finger extension is possible. Three-jaw chuck pinch and tip pinches are possible, but motor control is only fair. Emergence of intrinsic function. Occupational therapy should focus on purposeful fine motor activities (see Fig. 19.5).	• Client is an excellent candidate for fine-tuning motor control via blocks (eg, neuromuscular blocks to the extrinsic flexor pollicis longus supports the goal of improved intrinsic motor control of the thumb by allowing action of the opponens pollicis, abductor pollicis brevis, and flexor pollicis brevis to be unmasked). It should be noted that reducing hypertonia does not always result in improved dexterity.[33]
6	Isolated joint movements are performed with ease. Intrinsic function is normal. All types of prehension are possible with normal motor control.	• Client is not a candidate for blocks or surgery. Discharge from occupational therapy if all goals have been met.

[a]These stages may be used as a guideline for OT intervention and interdisciplinary spasticity management in clients with hemiplegia or hemiparesis. *Note:* Upper extremity recovery is variable owing to varying degrees of paralysis. Some clients may never progress through all the stages.

[b]The term *blocks* refers to chemical denervation with botulinum toxin type A or type B; neurolysis; or motor point blocks with phenol or alcohol.

CVA, Cerebrovascular accident; *PROM,* passive range of motion; *ROM,* range of motion; *UE,* upper extremity.

Critical Thinking Questions

1. What performance skills or standardized assessments would you select as part of your initial evaluation to assess Daniel's motor function?

2. What activities or intervention would you plan for Daniel to reduce the spasticity in his right arm?

3. What home exercises or activity program would you prescribe to help him reach his goals of using his right hand to insert the key into the car ignition and then drive with both hands on the steering wheel?

Motor control is the ability of the central nervous system (CNS) to direct or regulate the musculoskeletal system in purposeful activity.[102] The components necessary for motor control include normal muscle tone, normal postural tone and postural mechanisms, selective movement, and coordination. Complex neurological systems (ie, the cerebral cortex, basal ganglia, and cerebellum) collaborate to make motor control possible. A neurological insult, such as a CVA (stroke), brain injury, or disease such as multiple sclerosis or Parkinson's disease, affects motor control. Functional recovery depends on the initial amount of neurological damage, prompt access to medical treatment to (hopefully) limit the extent of neurological damage, the nature of the neurological damage, whether it is static or progressive, and therapeutic intervention that can facilitate motor recovery.

Plasticity is an important concept in neurological rehabilitation because it helps explain why recovery is possible after a brain injury or lesion. The term *plasticity* simply means the ability to change. **Neuroplasticity** is defined as the capacity for anatomic and electrophysiological changes in the CNS. According to Umphred,[101] neuroplasticity can be viewed as a progression from short-term changes in the "efficiency or strength of synaptic connections to long-term structural changes in the organization and numbers of connections among the neurons."[101]

In some instances the CNS is able to reorganize and adapt to functional demands after injury. Motor relearning can occur through the use of existing neural pathways (unmasking) or through the development of new neural connections (neural sprouting) (Fig. 19.6). With unmasking, it is believed that seldom-used (secondary) pathways become more active after the primary pathway has been injured. Adjacent nerves take over the functions of damaged nerves.[26] With sprouting, dendrites from one nerve form a new attachment or synapse with another. Axonal sprouting also occurs and allows for flexible synaptic connections to be formed. Neural sprouting is believed to be the primary process for neuroplasticity, leading to improvement in function.[61]

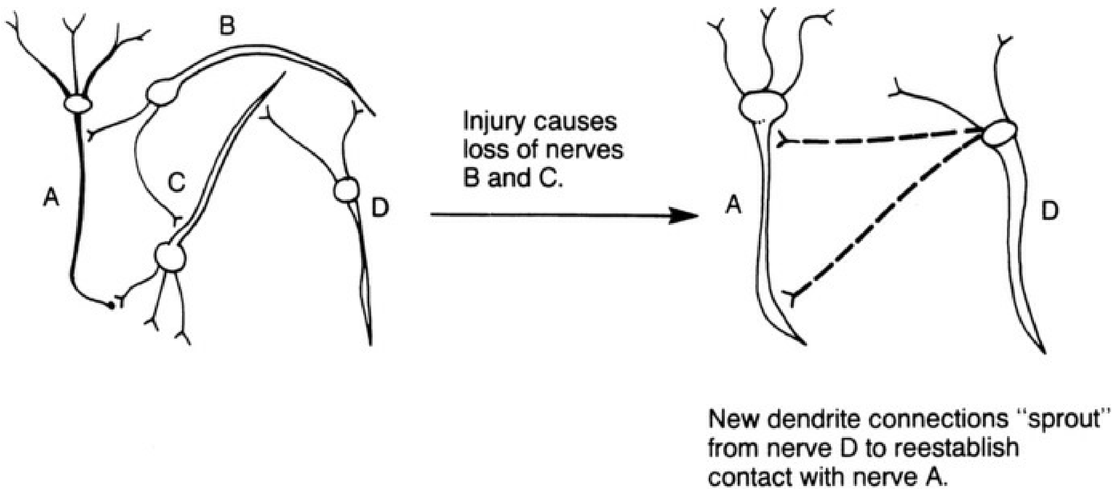

FIG 19.6 Sprouting theory of nerve cell replacement. Injury causes loss of nerves B and C. New dendrite connections "sprout" from nerve D to reestablish contact with nerve A. (From DeBoskey DS, et al: *Educating families of the head injured,* Rockville, MD, 1991, Aspen.)

Observing movements during occupational performance is a way to assess motor control. Then, after occupational performance has been evaluated, it may be necessary to evaluate the specific components that underlie motor control. These components include muscle tone, postural tone and the postural mechanism, reflexes, selective movement, and coordination.

The Upper Motor Neuron and Lower Motor Neuron Systems

This chapter focuses on the functional effects of lesions in the upper motor neuron system (UMNS). The UMNS includes any nerve cell body or nerve fiber in the spinal cord (other than the anterior horn cells) and all proximal structures. These structures include the brainstem, the descending nerve tracts, and the brain cells of both gray and white matter that serve motor function. UMN "signs" often seen after damage has occurred include hyperreflexia, a positive Babinski's sign, and spasticity.[33] Weakness, paralysis, and fatigue often accompany UMN syndrome. CVA and traumatic brain injury (TBI) can lead to UMN dysfunction. The results of electromyography and nerve conduction studies are normal with UMN dysfunction.

The lower motor neuron system (LMNS) includes the anterior horn cells of the spinal cord, the spinal nerves, the nuclei and axons of the cranial nerves, and the peripheral nerves. LMN dysfunction results in diminished or absent deep tendon reflexes and muscle weakness, atrophy, or flaccidity. An example of an LMN disease is Guillain-Barré syndrome. Individuals who have sustained a spinal cord injury can show both UMN and LMN signs if the anterior horn cells have been damaged. The findings of electromyography and nerve conduction studies are abnormal with LMN dysfunction.[4] Fig. 19.7 illustrates the influence of the UMNS on the LMNS.[25]

OT Practice Notes

These questions may help guide evaluation of motor control dysfunction.

1. Is the client having difficulty with sitting or standing balance?
2. Is trunk control adequate to perform the activity?
3. Do changes in body position affect muscle tone (eg, more hypertonia when standing than supine, more hypertonia when walking than standing)?
4. Are primitive reflexes evoked during performance?
5. Is spasticity limiting antagonist movement?
6. Are spatial or temporal sequencing problems interfering with coordinated movement?
7. Does weakness prohibit antigravity activity?
8. Is tremor present?
9. Is incoordination apparent (ie, overshooting or undershooting the target)? Are there extraneous movements?

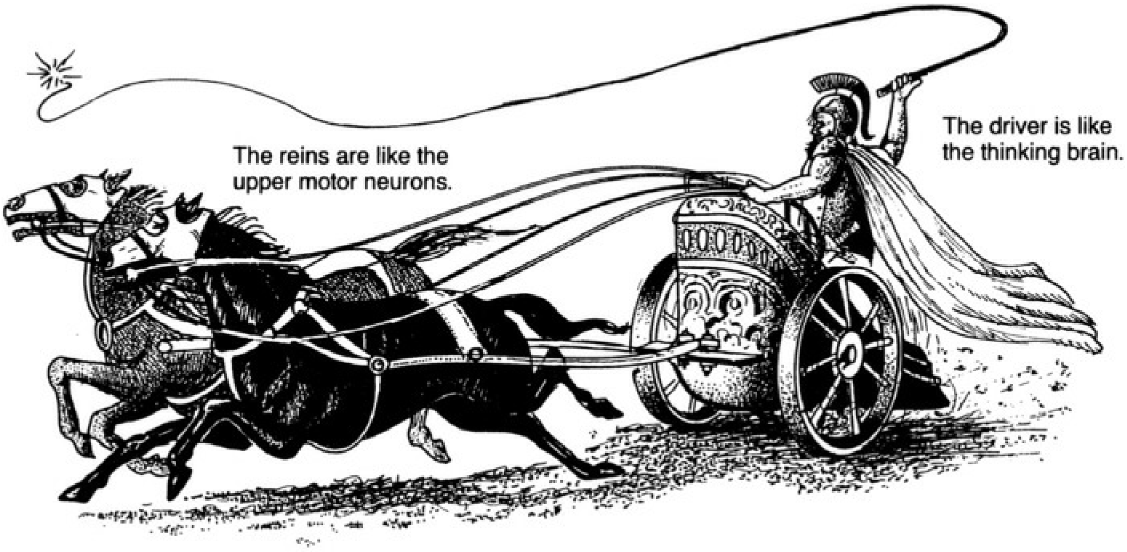

FIG 19.7 The control of movement works much as does a chariot driver with a team of horses. Remember, the upper motor neuron system facilitates or inhibits the lower motor neuron system. Therefore, think of the driver as the brain; the reins as the upper motor neurons; and the horses as the lower motor neurons and muscles. (From DeBoskey DS, et al: *Educating families of the head injured,* Rockville, MD, 1991, Aspen.)

Client-Centered Performance Interviews to Detect Problem Areas in Motor Control

The occupational therapist faces the challenge of maximizing the client's ability to return to purposeful and meaningful occupation in his or her physical, cultural, and social environment. Therefore, evaluating functional performance is primary in helping clients set realistic goals. A simple method of goal setting is to ask the client to name the top two or three things he or she would like to be able to resume doing. The Canadian Occupational Performance Measure (COPM), an assessment tool, is a more structured interview that ensures client-centered therapy.[67] It helps prioritize the client's functional activity goals in the areas of self-care, leisure, and productivity.

Two other noteworthy, client-centered, quality of life surveys frequently are used in interdisciplinary settings with clients who have been diagnosed with a CVA. The Stroke Impact Scale (SIS) version 3.0 contains 59 items grouped into eight domains that include items addressing strength, hand function, activities of daily living (ADLs), instrumental activities of daily living (IADLs), mobility, communication, emotion, memory, thinking, and social participation.[28] The Stroke Specific Quality of Life Scale consists of 49 items divided into 12 domains: energy, family roles, language, mobility, mood, personality, self-care, social roles, thinking, upper extremity function, vision, and work/productivity.[105] Both scales are scored on a 5-point Likert scale.

The occupational therapist (OT) can observe the client for motor control dysfunction during assessment of ADLs and IADLs, and of productive and leisure activities. The therapist must observe how problems in motor control affect occupational performance while considering the client's sensation, perception, cognition, and medical status.

Standardized Activities of Daily Living Assessments for Motor Control

Many standardized ADL tests are available for assessing occupational performance and are useful for observing motor control. The Test d'Évaluation des Membres Supérieurs de Personnes Âgées (TEMPA) is an upper extremity functional activity performance test developed to help therapists distinguish between "normal and pathologic[al] aging in upper extremity performance."[27] Test items include picking up and moving a jar, writing on an envelope, tying a scarf, and handling coins, among others.

Several assessments have been designed to assess function after a CVA. These can be used to observe for motor control problems.

1. The Graded Wolf Motor Function Test[75] (GWMFT) was developed to measure functional gains after a hemiparetic event from a CVA or TBI. This test was based on the Wolf Motor Function Test.[16] It is called "graded" because there are two levels of difficulty for each task; level A is more advanced, and level B is easier. Gorman[45] investigated the interreliability and intrareliability of the GWMFT with a sample of eight physical therapists and three subjects. Intrarater and interrater reliability was .935 on the timing scores. Intrarater reliability was .897, and interrater reliability was .879 on the functional ability scores. This is a very useful test that can be used with a wide variety of clients with hemiparesis who have varying degrees of motor recovery. More research is needed to confirm the validity and reliability of this test.

2. The Wolf Motor Function Test (WMFT) has been and continues to be widely used to quantify the motor abilities of clients with chronic and persistent high levels of upper extremity dysfunction after a CVA or TBI.[1,91,107] It has an interrater reliability range of .95 to .97 (Fig. 19.8).

WOLF MOTOR FUNCTION TEST
DATA COLLECTION FORM

Subject's Name: ______________________________ Date: ________________

Test (check one): Pre-treatment ______ Post-treatment ______ Follow-up ______

Arm tested (check one): More-affected ______ Less-affected ______

Task	Time	Functional Ability	Comment
1. Forearm to table (side)		0 1 2 3 4 5	
2. Forearm to box (side)		0 1 2 3 4 5	
3. Extend elbow (side)		0 1 2 3 4 5	
4. Extend elbow (weight)		0 1 2 3 4 5	
5. Hand to table (front)		0 1 2 3 4 5	
6. Hand to box (front)		0 1 2 3 4 5	
7. Weight to box	______________	______________lbs.

A

FUNCTIONAL ABILITY SCALE

0 – Does not attempt with upper extremity (UE) being tested.

1 – UE being tested does not participate functionally; however, attempt is made to use the UE. In unilateral tasks the UE not being tested may be used to move the UE being tested.

2 – Does, but requires assistance of the UE not being tested for minor readjustments or change of position, or requires more than two attempts to complete, or accomplishes very slowly. In bilateral tasks the UE being tested may serve only as a helper.

3 – Does, but movement is influenced to some degree by synergy or is performed slowly or with effort.

4 – Does; movement is close to normal,* but slightly slower; may lack precision, fine coordination or fluidity.

5 – Does; movement appears to be normal.*

*For the determination of normal, the less-involved UE can be utilized as an available index for comparison, with pre-morbid UE dominance taken into consideration.

B

FIG 19.8 Wolf Motor Function Test score sheet (A) and functional ability scale (B). (From Taub E, Morris DM, Crago J: *Wolf Motor Function Test [WMFT] manual,* revised 2011, University of Alabama at Birmingham CI Therapy Research Group. http://www.uab.edu/citherapy/.)

3. The Functional Test for the Hemiplegic/Paretic Upper Extremity[106] assesses the client's ability to use the involved arm for purposeful tasks. This test provides objective documentation of functional improvement and includes tasks ranging from those that involve basic stabilization to more difficult tasks requiring fine manipulation and proximal stabilization. Examples include holding a pouch, stabilizing a jar, wringing a rag, hooking and zipping a zipper, folding a sheet, and putting in a light bulb overhead.[106]

4. The Fugl-Meyer Assessment[62] (FMA) is based on the natural progression of neurological recovery after a CVA. Low scores on the FMA have been closely correlated with the presence of severe spasticity. Fugl-Meyer et al. developed a quantitative assessment of motor function after a stroke by measuring such parameters as range of motion (ROM), pain, sensation, and balance.[41a] Scores on the FMA correlate with ADL performance, and this tool is widely used to document upper extremity (UE) recovery after a CVA.[1,57,91,107]

5. The Arm Motor Ability Test[65] (AMAT) is a functional assessment of UE function. Cutting meat, making a sandwich, opening a jar, and putting on a **T**-shirt are some of the tasks included in this test. It has high interrater and test-retest reliability.

6. The Motricity Index[23] (MI) is a valid and reliable test of motor impairment that can be performed quickly. The test assesses the client's ability to pinch a cube with the index finger and thumb, in addition to elbow flexion, shoulder abduction, ankle dorsiflexion, knee extension, and hip flexion.

7. The Assessment of Motor and Process Skills (AMPS)[12] is a standardized test that assesses the quality of performance in ADLs, in addition to motor and process skills in ADLs and IADLs. The test was created by occupational therapists. Although this test is not diagnosis specific, it has been widely used with clients who have had a CVA. OT practitioners can become certified in the use of this test by completing a 5-day training course.[12]

As mentioned, after observing functional performance, the occupational therapist usually finds it necessary to assess the performance components that underlie motor control: muscle tone (normal/abnormal), the postural mechanism, muscle tone assessment/reflexes, sensation, and coordination.

Muscle Tone

Muscle tone is the resistance felt by the examiner as he or she passively moves a client's limb.[94] It is dependent on the integrity of peripheral and CNS mechanisms and the properties of muscle. It should be high enough to resist gravity, yet low enough to allow movement. The tension is determined partly by mechanical factors (eg, the connective tissue and viscoelastic properties of muscle) and partly by the degree of motor unit activity. When passively stretched, normal muscle offers a small amount of involuntary resistance.

Normal muscle tone relies on normal function of the cerebellum, motor cortex, basal ganglia, midbrain, vestibular system, spinal cord, and neuromuscular system (including the mechanical-elastic features of the muscle and connective tissues) and on a normally functioning stretch reflex. The stretch reflex is mediated by the muscle spindle, a sophisticated sensory receptor that continuously reports sensory information from muscles to the CNS.

Normal muscle tone varies from one individual to another. Within the range considered normal, the degree of normal tone depends on such factors as age, gender, and occupation. Normal muscle tone is characterized by a number of factors:

1. Effective coactivation (stabilization) at axial and proximal joints

2. Ability to move against gravity and resistance

3. Ability to maintain the position of the limb if it is placed passively by the examiner and then released

4. Balanced tone between agonistic and antagonistic muscles

5. Ease of ability to shift from stability to mobility and to reverse as needed

6. Ability to use muscles in groups or selectively with normal timing and coordination

7. Resilience or slight resistance in response to passive movement

Hypertonicity (increased tone) interferes with the performance of normal selective movement because it affects the timing and smoothness of agonist and antagonist muscle groups (see Chapters 31, 32, and 33). Normalization of muscle tone and amelioration of **paresis** (incomplete paralysis/weakness) are desirable when striving for selective motor control. Some function can be achieved even though tone may not be normal. **Plegia** is defined as complete paralysis.

Abnormal Muscle Tone

Abnormal muscle tone usually is described with the terms *flaccidity, hypotonus, hypertonus, spasticity,* and *rigidity.* To plan the appropriate intervention, the OT practitioner must recognize the differences among these tone states and must be able to identify these states during the clinical assessment.

Flaccidity

Flaccidity refers to the absence of tone. Deep tendon reflexes (DTRs) and active movement are absent. Flaccidity can result from spinal or cerebral shock immediately after a spinal or cerebral insult. With traumatic UMN lesions of cerebral or spinal origin, flaccidity usually is present initially and then often, but not always, changes to hypertonicity within a few weeks, depending on the location and amount of brain damage.

Flaccidity also can result from LMN dysfunction, such as peripheral nerve injury or disruption of the reflex arc at the alpha motor neuron level. The muscles feel soft and offer no resistance to passive movement. If the flaccid limb is moved passively, it will feel heavy. If moved to a given position and released, the limb will drop because the muscles are unable to resist the pull of gravity.[4]

Hypotonus

Hypotonus is considered by many to be a decrease in normal muscle tone (ie, low tone). DTRs are diminished or absent. Van der Meche and Van der Gijn[102] suggested that hypotonus could be an erroneous clinical concept. They performed electromyographic (EMG) analysis on the quadriceps muscles in "hypotonic" clients (eg, those with peripheral neuropathy, cerebral infarction, and other diagnoses) and in relaxed normal subjects in a lower leg free-fall test. They concluded that if a client's limb feels hypotonic or flaccid, this is the result of weakness, not of long-latency stretch reflexes.

Hypertonus

Hypertonus is increased muscle tone. Hypertonicity can occur when a lesion is present in the premotor cortex, the basal ganglia, or descending pathways. UMNs tend to have an inhibitory influence on LMNs. Damage to the UMNS has the effect of increasing stimulation of the LMNs, with resultant increased alpha motor activity. Any neurological condition that damages and compromises the function of the UMN pathways can directly or indirectly facilitate alpha motor neuron activity, which may result in hypertonicity. Other spinal or brainstem reflexes may become hyperactive, which leads to hypertonic patterns, such as flexor withdrawal or the dominance of primitive reflexes during movement activities.[33]

Hypertonicity often occurs in a synergistic neuromuscular pattern, particularly when seen after a CVA or TBI. Synergies are defined as patterned movement characterized by co-contraction of flexors or extensors. A typical synergy seen in the upper extremity after a CVA or TBI is a *flexion synergy*. The flexion synergy is shoulder adduction; internal rotation; elbow flexion; forearm pronation; wrist, finger, and thumb flexion; and thumb adduction. In contrast, an extension synergy is seen in the lower extremity.

For the client who has sustained damage to the UMNs, the energy cost of moving against hypertonicity is considerable. It takes a great deal of effort for clients with moderate to severe hypertonicity to move against this force. Antagonist power may be insufficient to overcome the spastic agonist muscle groups. Daniel, in the case study, had problems overcoming the pull of his spastic finger flexors with his weak finger extensors. Even clients with mild hypertonicity report frustration during functional activities. Loss of reciprocal inhibition is noted between spastic agonists and antagonists.[4] Clients are unable to rapidly and efficiently coordinate the activity between agonist and antagonist groups of muscles. The client with a UMN lesion will have dysfunction in spatial and temporal timing of movement. This makes his or her movements uncoordinated. This frustration, coupled with the fatigue, decreased dexterity, and paresis associated with UMNS, can influence therapy participation. Furthermore, the architecture of hypertonic muscles changes over time. The muscles lose their ability to lengthen and shorten because of viscoelastic changes that result from the hypertonia.[87]

Not everyone recovers full UE motor function after a CVA or TBI. Table 19.1 can help the OT practitioner to explain the stages of motor recovery to families, and to clarify that not all clients will progress through all seven stages. The table can be used for preparation for discharge, allowing the therapist to explain to the client and family that the client has reached a plateau in motor recovery.

Hypertonicity can increase as a result of painful or noxious stimuli. These stimuli often can be reduced with appropriate medical care. Stimuli that can increase tone include pressure sores, ingrown toenails, tight elastic straps on a urine collection leg bag, tight clothing, an obstructed catheter, a urinary tract infection, and fecal impaction. Other triggering factors include fear, anxiety, environmental temperature extremes, heterotopic ossification, and sensory overload. These triggering factors are seen in both cerebral and spinal hypertonicity; however, they are more pronounced in spinal hypertonia. Therapeutic intervention should be designed to reduce, eliminate, or cope with the various external factors.[77]

Clients with hypertonicity often have difficulty initiating movement, especially rapid movement. Although hypertonic muscles appear to be able to resist substantial external force (as in manual muscle testing), they do not function as normal, strong muscles. Through the mechanism of reciprocal inhibition, hypertonic muscles inhibit the activity of their antagonists and thus can mask potentially good or normal function of antagonists.[77] Four types of hypertonia are described in the following sections: cerebral hypertonia, spinal hypertonia, spasticity, and rigidity.

Cerebral Hypertonia

Cerebral hypertonia is caused by TBI, stroke, anoxia, neoplasms (brain tumors), metabolic disorders, cerebral palsy, and diseases of the brain. In multiple sclerosis, hypertonia is produced from both spinal and cerebral lesions. With cerebral hypertonia, muscle tone fluctuates continuously in response to extrinsic and intrinsic factors. Cerebral hypertonia usually occurs in definite patterns of flexion or extension, causing the limb to frequently assume and remain in a specific position (Fig. 19.9). Typically, these patterns occur in the antigravity muscles of the upper and lower extremities (eg, flexors of the upper extremities, extensors of the lower extremities).

FIG 19.9 A client with dystonia in his right index finger (extension). His left wrist shows severe hypertonicity. Tone abnormalities are the result of a traumatic brain injury.

The dominance of primitive reflexes and associated reactions alters postural tone. When an individual is supine, muscle tone is less than when the individual is sitting or standing. Tone is highest during ambulation. Thus, attention to postural tone is important when positioning a client for splinting or casting. A cast or splint fabricated on a client in a supine position may not fit when the client is sitting up because of the influence of gravity and posture on increasing muscle tone.[87]

Spinal Hypertonia

Spinal hypertonia results from injuries and diseases of the spinal cord. In slow-onset spinal disease (eg, spinal stenosis, tumor), there is no period of spinal shock. With a traumatic spinal cord injury, spinal shock occurs and is characterized by initial flaccidity. Over time (weeks or months), the flaccidity diminishes and hypertonia develops. The affected extremities first develop flexor and adductor tone. Over time, extensor tone develops and becomes predominant in the lower extremities. Spinal hypertonia can lead to muscle spasms severe enough to cause an individual to fall out of a wheelchair, off a gurney, or out of bed. The degree of hypertonicity in incomplete spinal lesions varies, depending on the degree of damage to the spinal cord. Tone tends to be more severe in individuals with incomplete spinal cord lesions than in those with complete lesions.[87]

Spasticity

According to Nance et al.,[77] the most commonly cited definition of **spasticity** is from the American Academy of Neurology: “Spasticity is a motor disorder that is characterized by a velocity dependent increase in tonic stretch reflexes (muscle tone) with exaggerated tendon jerks, resulting from hyperexcitability of the stretch reflex, as one component of the upper motor neuron syndrome.”[7]

Spasticity has two characteristics:

- *Velocity dependence:* The stretch reflex is elicited only by the examiner's rapid passive stretch.
- *Clasp-knife phenomenon:* When the examiner takes the extremity through a quick passive stretch, a sudden catch or resistance is felt, followed by a release of the resistance. What actually happens is that the initial high resistance felt by the therapist is due to spasticity and then the hypertonia is suddenly inhibited, allowing the extremity to be moved through the full passive range of motion.

One of the main CNS tracts involved in the pathophysiology of spasticity is the corticospinal tract. It is a major motor tract that originates from many areas in the cerebral cortex, including the cells of the prefrontal region, the cingulate gyrus, and the postcentral gyrus of the parietal lobe.[33]

Clonus.

Clonus is a specific type of spasticity. This condition often is present in clients with moderate to severe spasticity. Clonus is characterized by repetitive contractions in the antagonist muscles in response to rapid stretch. Recurrent bursts of Ia afferent activity result in a cyclical oscillation of phasic stretch reflexes. Clonus is seen most commonly in the finger flexors and ankle plantar flexors. The occurrence of clonus can interfere with participation in purposeful activity, transfers, and mobility. Therapists should educate clients and their families in how to use weight bearing actively because this usually stops the clonus. Therapists and physicians record clonus by counting the number of beats elicited after a quick stretch to an extremity, such as a quick stretch of the ankle plantar flexors or finger flexors. A 3-beat clonus can be rated as mild and is less likely to interfere with ADLs than a clonus of 10 beats or more. Clonus may be elicited during quick stretch tone evaluation or may become apparent during assessment of occupation (eg, grasping, ambulation, pushing the involved foot into a shoe). If clonus greatly interferes with ADLs, the client may be referred to a physiatrist or neurologist for oral medication, Botox[16] injection, Myobloc[76] injection, or phenol motor point block.[87]

Daniel is going to have a Botox injection in his flexor carpi ulnaris and ring finger flexor digitorum profundus to help reduce the spasticity in these muscles; this will help him work on finger and wrist extension ROM and strength.

Rigidity

Rigidity is a simultaneous increase in muscle tone of agonist and antagonist muscles (ie, muscles on both sides of the joint). Both groups of muscles contract steadily, leading to increased resistance to passive movement in any direction and throughout the ROM. Rigidity signals involvement of the extrapyramidal pathways in the circuitry of the basal ganglia, diencephalon, and brainstem. It occurs in isolated forms in disorders such as Parkinson's disease, TBI, some degenerative diseases, encephalitis, and tumors, and also after poisoning with certain toxins and carbon monoxide. Rigidity also is seen in conjunction with spasticity in individuals with stroke and TBI. Rigidity is not velocity dependent (ie, the tendon reflexes are not exaggerated, and no catch is felt upon quick stretch).[2]

Rigidity is evaluated during muscle tone evaluation and can be rated as mild, moderate, or severe. Four types of rigidity are commonly seen:

- Lead pipe rigidity
- Cogwheel rigidity
- Decorticate rigidity
- Decerebrate rigidity

Both lead pipe and cogwheel rigidity can occur in Parkinson's disease. In lead pipe rigidity, constant resistance is felt throughout the ROM when the part is moved slowly and passively in any direction, not unilaterally, as in spasticity. This rigidity feels similar to the bending of solder or a lead pipe (thus its name). In cogwheel rigidity, a rhythmic give in resistance occurs throughout the ROM, much like the feeling of turning a cogwheel. It is thought that cogwheel rigidity is lead pipe rigidity with concomitant tremor, which results in the ratchety pattern of movement.[73] DTRs are often normal or are only mildly increased in clients with Parkinson's rigidity.

Decerebrate and decorticate rigidity can occur after severe TBI with diffuse cerebral damage or anoxia. These abnormal postures occur immediately after injury and can last a few days or weeks if recovery occurs, or can persist indefinitely if there is little or no recovery.

Decerebrate rigidity results from lesions in the bilateral hemispheres of the diencephalon and midbrain. It appears as rigid extension posturing of all limbs and the neck. Bilateral cortical lesions can result in **decorticate rigidity,** which appears as flexion rigidity in the upper extremities and as extension rigidity in the lower extremities. Supine positioning increases the abnormal tone, and with either type of rigidity, it may be extremely difficult to position clients in a sitting position.

Seizures and Todd's Paralysis

OT practitioners will encounter clients with seizures. **Todd's paralysis** sometimes occurs after a seizure (postictal). It usually occurs on one side of the body and can affect speech and vision. It can last anywhere from 30 minutes to 36 hours. Occupational therapists may be asked to complete an ADL assessment and discharge recommendations if the paralysis/paresis has not completely resolved before the client is discharged. Physicians need to differentiate Todd's paralysis from a CVA, which it resembles, because a CVA requires different treatment.[100]

Muscle Tone Assessment

Objective assessment of muscle tone in the client with cerebral spasticity is difficult because the tone fluctuates continuously in response to extrinsic and intrinsic factors. The postural reflex mechanism, the position of the body and head in space, the position of the head in relation to the body, synergies, the presence of primitive reflexes, and associated reactions all influence the degree and distribution of abnormal muscle tone.[92]

Guidelines for Muscle Tone Assessment

The following steps describe correct procedures for assessing muscle tone.

1. It is helpful to rate spasticity and hypertonia with the client in the same position, preferably at the same time of day, to enhance reliability because the body and head position influence cerebral hypertonia. The client's upper extremity muscle tone usually is evaluated with the client sitting on a mat table when possible. Remember that the client's trunk posture (eg, seated, bearing weight symmetrically rather than slumped or leaning to one side) will affect the results of the tone evaluation. Tone fluctuates from hour to hour and from day to day because of intrinsic and extrinsic factors that influence it. This fluctuation makes accurate measurement difficult, particularly for cerebral hypertonia. Nevertheless, rating tone is still worthwhile, especially in the managed care environment, in which objective measures of progress are needed to justify the continuation of therapy.

2. Grasp the client's limb proximal and distal to the joint to be tested and move the joint slowly through its range to determine the free and easy ROM available. Note the presence and location of pain. If there is no active movement and if the limb feels heavy, record that the limb is flaccid or “0” in strength. If the limb has some active movement and no evidence of increased tone, the affected muscle or muscle group may be labeled “paretic” instead of “hypotonic.” The paretic antagonist muscle can then be graded in strength (usually the strength grade will fall between 1 and 4−). Grading the paretic antagonist muscles provides more objective clinical information than merely labeling the muscles as hypotonic. Strength-grading antagonists can help the occupational therapist triage candidates for phenol block and botulinum toxin type A or type B injection who have the potential to improve function; for example, a client with an elbow extension strength grade of 2− (in the presence of elbow flexor tone) would be a better block candidate than a client with a triceps strength grade of 0.

3. Hold the limb on the lateral aspects to avoid giving tactile stimulation to the belly of the muscle being tested.

4. Clinical assessment of spasticity involves holding the client's limb as just described and moving it rapidly through its full range while the client is relaxed. The easiest scale to use is the mild/moderate/severe scale. Some physicians find goniometric measurement of the location of the first tone helpful before and after long-acting nerve block. Record the findings for various muscle groups (see the tone rating scales in the next section.)

5. Clinical assessment of rigidity involves moving the limb slowly during the range, noting the location of first resistance to movement in degrees; label it mild, moderate, or severe.

OT Practice Notes

It is important to note the client's overall posture during evaluation of muscle tone. Is the client's posture symmetric, with equal weight bearing on both hips (if sitting) or on both feet (if standing)? Note how the client moves in general. Is the head aligned or tilted to one side? Is one shoulder elevated? Does the client have a forward head posture? Is the trunk rotated or elongated on one side and shortened on the other? Such postural deviations affect the client's ability to move the limbs functionally. Current intervention focuses heavily on quality of movement, achieving as normal motor control as possible during occupation.

Manual Rating Scales for Spasticity and Hypertonicity

Ashworth Scale

The Ashworth Scale[8] (Box 19.1) and the Modified Ashworth Scale[15] (MAS) are the two scales most widely used to manually rate spasticity. The literature reflects some controversy over the validity and reliability of these scales. Fleuren et al.[39] studied 30 clients with elbow flexion spasticity, correlating the Ashworth Scale with EMG studies, and concluded that the Ashworth Scale is not a reliable measure of spasticity.[39] Pandyan et al.[80,82] noted that the Ashworth Scale and the Modified Ashworth Scale should be used as an ordinal scale of resistance to passive movement, but that they are not valid for assessing spasticity.

Box 19.1

Ashworth Scale

0 = No increase in muscle tone

1 = Slight increase in muscle tone; "catch" when limb moved

2 = More marked increase in muscle tone, but limb easily flexed

3 = Considerable increase in muscle tone; passive movement difficult

4 = Limb rigid in flexion or extension

From Ashworth B: Preliminary trial of carisoprodol in multiple sclerosis, *Practitioner* 192:540, 1964.

Four studies have demonstrated that the MAS is a reliable scale for the assessment of spasticity[15,49,50]; four other studies have reported that it is not reliable.[5,13,38]

Therapists familiar with the Ashworth Scale or the MAS can help physicians evaluate candidates for neurosurgical procedures. For example, some of the selection criteria for implantation of the Synchromed Intrathecal Baclofen Pump (ITB)[72] are based on the occurrence of a point reduction, on either of the aforementioned scales, after administration of a test dose of medication; a 2-point reduction is required in spinal spasticity, and a 1-point reduction is required in cerebral spasticity.

Tardieu Scale

Both the Modified Tardieu Scale (MTS)[17] and the Tardieu Scale[53] measure spasticity.[40] The Tardieu Scale is written in French and has been shown to have excellent test-retest and interrater reliability, when used with inertial sensors, in assessing elbow flexor tone in patients with a CVA.[83] The MTS had an interrater reliability coefficient of .7 and was shown to be more reliable than the MAS.[47]

Mild/Moderate/Severe Spasticity Scale

Some therapists and physicians find a mild/moderate/severe scale easier to use than the scales just discussed. The scale in Box 19.2 is suggested as a guide for estimating the degree of spasticity.[36] The scale in Box 19.3 is suggested as a guide for estimating the extent of hypertonia.[85]

Box 19.2

Mild/Moderate/Severe Spasticity Scale

Mild: Stretch reflex (palpable catch) occurs at the muscle's end range (ie, the muscle is in a lengthened position).

Moderate: Stretch reflex (palpable catch) occurs in midrange.

Severe: Stretch reflex (palpable catch) occurs when the muscle is in a shortened range.

Farber S: *Neurorehabilitation: a multisensory approach*, Philadelphia, 1982, Saunders.

Box 19.3

Preston's Hypertonicity or Rigidity Scale

0	No abnormal tone is detected during slow, passive movement.
1 (mild)	First tone or resistance is felt when the muscle is in a lengthened position during slow, passive movement.
2 (moderate)	First tone or resistance is felt in the midrange of the muscle during slow, passive movement.
3 (severe)	First tone or resistance occurs when the muscle is in a shortened range during slow, passive movement.

Mechanical and Computer Rating Systems for Spasticity and Hypertonicity

Mechanically determined parameters for assessing hypertonia may be more reliable than the manual methods. McCrea et al.[70] concluded that using a linear spring-damper model to assess the hypertonic elbow was reliable and valid. This model is not widely used in clinical practice, nor even in research practice, because of time constraints and difficulty accessing certain muscle groups (eg, it is easier to set up and measure elbow hypertonia than hip hypertonia in a mechanical tone rating device).

Leonard et al.[68] investigated the construct validity of the Myotonometer (Neurogenic Technologies, Missoula, Montana), a computerized electronic device with a probe (resembling an ultrasound transducer) that is placed on top of the skin over the muscle belly. Measurements were taken over the biceps brachii at rest and during maximum voluntary muscle contraction. They revealed a significant difference between affected and unaffected extremities in subjects with UMN spasticity. The authors concluded that the Myotonometer could provide objective data about the tone reduction efficacy of various tone-reducing procedures.

Clearly, more research is needed in the areas of manual, mechanical, and computer rating systems for the assessment of hypertonia. Identification of a uniformly acceptable, reliable, and valid measure of spasticity continues to confound clinicians.

Range-of-Motion Assessment in Evaluation of Tone

Assessment of passive ROM (PROM) supplements and often correlates with tone assessment. For example, if a client with an acute CVA (1 month after onset) has a wrist ROM measurement of 20 degrees extension (normal, 70 degrees) and if orthopedic causes have been ruled out (eg, arthritis, fixed contracture), the therapist should assess the tone in the wrist flexors and the extrinsic finger flexors. Spasticity of any of these muscles can inhibit full wrist extension. Assessment of PROM can reveal possible signs of joint changes (eg, subluxation, dislocation, and contracture) resulting from chronic hypertonia, such as proximal interphalangeal joints (PIPs) that measure −45 degrees (extension) to 125 degrees (flexion) instead of 0/100 degrees (the norm). Some physicians find PROM measurements useful for documenting the location of the first tone, or resting position, before and after Botox[16] or Myobloc[76] injections.

Other Considerations in Tone Assessment

Changes in bone or other peripheral structures can lead to ROM limitations. For example, heterotopic ossification can limit joint ROM. Heterotopic ossification is the formation of new bone in soft tissue or joints, which can lead to pain and/or joint contracture. Heterotopic ossification can occur in individuals with TBI and spinal cord injury, along with severe spasticity, or with other types of severe injuries. Conversely, the presence of fixed contractures may be incorrectly labeled as hypertonia. Physiatrists and other physician specialists can aid in the diagnosis of contractures through the use of diagnostic short-term nerve blocks, EMG, and/or radiographs.[87]

Assessing Movement and Control

Along with the assessment of muscle tone, the occupational therapist performs an assessment of UE movement and control. The therapist identifies where and how much the client's motor control is dominated by synergies, and where selective, isolated movement is present. The degree to which abnormal tone interferes with selective control is identified. Also, identifying in which direction of movement spasticity occurs and how it affects function helps in determining the need for intervention.

Manual muscle testing usually is not appropriate for clients who show moderate to severe spasticity or rigidity because the relative tone and strength of the muscles are not normal, and movement is not voluntary or selective. Tone and strength are influenced by the position of the head and body in space, and by abnormal contraction, deficits in tactile and proprioceptive sensation, and impaired reciprocal inhibition. However, if hypertonia is mild and selective movements are possible, it is helpful to grade the strength of the antagonists to measure progress objectively.[87]

Sensation

The sensibility tests recommended for clients with CNS damage include static two-point discrimination, kinesthesia, proprioception, pain, and light touch using the Semmes-Weinstein monofilament test.[5] The therapist can assess light touch more accurately with the Semmes-Weinstein monofilaments because they provide better pressure control than a cotton ball (see Chapter 23 for the procedures for administering these sensory tests). If a client has a significant sensory impairment (ie, is unable to detect deep pressure or pain), the therapist must instruct the individual to watch his or her limb to help compensate for the sensory loss. Sensory impairment is one of the main reasons clients do not automatically use their neurologically impaired hand during ADL tasks. Another reason is unilateral neglect, also known as hemi-inattention.

Medical Assessment of Muscle Tone

Physiatrists, orthopedic surgeons, and neurologists are some of the physicians who may specialize in assessment of muscle tone. They may use static or dynamic surface or percutaneous (needle) EMG. Multiple channels are used in dynamic EMG to evaluate the hypertonicity of many contributing muscles. EMG helps the physician determine abnormal, excessive electrical activity in muscles. EMG can help physiatrists and neurologists plan and implement short- and long-acting nerve blocks to treat hypertonia.[87]

Normal Postural Mechanism

The **normal postural mechanism** is composed of automatic movements that provide an appropriate level of stability and mobility. These automatic reactions develop in the early years of life and allow for trunk control and mobility, head control, midline orientation of self, weight bearing and weight shifting in all directions, dynamic balance, and controlled voluntary limb movement. Components of the normal postural mechanism include normal postural tone and control, integration of primitive reflexes and mass movement patterns, righting reactions, equilibrium and protective reactions, and selective movement.

In clients with UMNS damage, the normal postural mechanism has been disrupted. Abnormal tone and synergistic patterns of movement dominate clients' movements, and these clients have impaired balance and stability. Movements are slow and uncoordinated. Therapists must assess the extent of damage to the postural mechanism in clients with CNS trauma or disease.

Normal postural tone allows automatic and continuous postural adjustment to movement. Postural control is the ability to control "the body's position in space for the dual purposes of stability and orientation."[4] It is important to assess the automatic righting, equilibrium, and protective reactions, which are part of the postural mechanism, in clients with CNS trauma or disease.

Righting Reactions

Righting reactions direct the head to an upright position. They help a person assume a standing position. Automatic reactions maintain and restore the normal position of the head in space and the normal relationship of the head to the trunk, in addition to the normal alignment of the trunk and limbs. Without effective righting reactions, the client will have difficulty getting up from the floor, getting out of bed, sitting up, and kneeling.[4]

Equilibrium Reactions

Equilibrium reactions help the individual sustain or keep a position. According to Ryerson,[92] they are the "first line of defense against falling." Equilibrium reactions, which are elicited by stimulation of the labyrinths in the inner ear, are used to maintain and regain balance in all activities. These reactions ensure sufficient postural alignment when the body's center of gravity is altered by a change in the supporting surface. Without equilibrium reactions, the client will have difficulty maintaining and recovering balance in all positions and activities.

Protective Reactions

Protective reactions are the second line of defense against falling if the equilibrium reactions cannot correct a balance perturbation. They consist of protective extension of the arms and hands, which is used to protect the head and face when an individual is falling. Stepping and hopping are examples of lower extremity protective reactions. Without protective reactions, the client may fall or may be reluctant to bear weight on the affected side during normal bilateral activities.[91]

Assessment of Righting, Equilibrium, and Protective Reactions and Balance

Formal testing of the righting, equilibrium, and protective reactions may be difficult because of the cognitive and physical limitations of the client or time constraints of the therapist. The therapist can evaluate righting reactions, however, during transfers and ADLs. Equilibrium and protective reactions can be observed when the client shifts farther out of midline than necessary during functional activities, such as lower extremity dressing.

Postural stability is also known as balance. Balance depends on normal equilibrium and protective reactions. Balance is the ability to maintain the center of mass over the base of support.[95] Balance involves the complex interaction of many systems, including the vestibular, proprioceptive, and visual systems, in addition to motor modulation from the cerebellum, basal ganglia, and cerebral cortex. Occupational and physical therapists must also observe the client's ankle, hip, and step strategies and note areas of breakdown in the kinetic chain.

When assessing a client with CNS dysfunction, the therapist should assess the client's static and dynamic balance before leaving the client unattended on a mat table, in a wheelchair, or during ambulatory ADLs. Dynamic balance involves maintaining balance while moving, and static balance involves maintaining equilibrium while stationary.

The Physical Performance Test assesses physical function during activity. Seven of the nine items in this assessment involve static and dynamic balance.[104] The test takes only 10 minutes to complete.[89] Fig. 19.10 shows the test form and test protocol. Four other noteworthy balance assessments are the Tinetti Balance Test of the Performance-Oriented Assessment of Mobility Problems[98] and the Berg Balance Scale.[11] The Berg Balance Scale is a good assessment for lower functioning clients (eg, those who are less ambulatory). Shumway-Cook[92] developed the Dynamic Gait Index (DGI) to assess balance with changes in task demands in ambulatory patients. It has been widely used with ambulatory clients who have been diagnosed with vestibular disorders, CVA, multiple sclerosis, or Parkinson's disease, and in the geriatric population. It is a reliable and valid test.[30] The Functional Gait Assessment (FGA) is another reliable and valid balance assessment.[109]

PHYSICAL PERFORMANCE TEST SCORING SHEET

Primitive Reflexes

Dominance of primitive reflex movement patterns can interfere with the client's occupational performance. Difficulties that may be encountered are described in the following sections.

Observation of these motor behaviors is a way of evaluating for the presence of primitive reflexes.

Brainstem-Level Reflexes

Asymmetric tonic neck reflex.

The asymmetric tonic neck reflex (ATNR) is tested with the client positioned supine or sitting.

- *Stimulus:* Actively or passively turn the client's head 90 degrees to one side.
- *Response:* An increase in the extensor tone of both extremities (upper and lower) on the face side, and an increase in the flexor tone of both extremities (upper and lower) on the skull side.[44]

Symmetric tonic neck reflex.

The symmetric tonic neck reflex (STNR) is tested with the client positioned sitting or quadruped.

- *Stimulus 1:* Flex the client's head and bring the chin toward the chest.
- *Response:* Flexion of the upper extremities and extension of the lower extremities.
- *Stimulus 2:* Extend the client's head.
- *Response:* Extension of the upper extremities and flexion of the lower extremities.[64]

Tonic labyrinthine reflex.

The tonic labyrinthine reflex (TLR) can be tested with the client supine with his or her head in midposition.

- *Stimulus:* The test position.
- *Response:* An increase in extension tone or extension of the extremities.

The TLR can also be tested with the client prone with the head in midposition.

- *Stimulus:* The test position.
- *Response:* An increase in flexor tone or flexion of the extremities.

Positive supporting reaction.

The positive supporting reaction is caused by pressure on the ball of the foot.

- *Stimulus:* Pressure on the ball of the foot.
- *Response:* Rigid extension of the lower extremities due to co-contraction of the flexors and extensors of the knee and hip joints. The practitioner may also see internal rotation of the hip, ankle plantar flexion, and foot inversion.[64]

Spinal-Level Reflexes

Spinal reflexes can occur after an UMN lesion. They appear because of lack of integration with higher centers. Some examples of exaggerated spinal reflexes are hyperactive DTRs, Babinski's sign, and the flexor withdrawal, crossed extension, and grasp reflexes.[58]

Crossed extension reflex.

The crossed extension reflex causes increased extensor tone in one leg when the other leg is flexed. Therefore, if the client with hemiplegia who is influenced by this reflex flexes the unaffected leg for walking, a strong extensor hypertonicity occurs in the affected leg and interferes with the normal pattern of ambulation.

Flexor withdrawal reflex.

The client with a flexor withdrawal reflex shows flexion of the ankle, knee, and hip when the sole of the foot is touched (swiped heel to ball of foot). This reflex clearly interferes with gait pattern and transfers.

Grasp reflex.

The client with a grasp reflex will not be able to release objects placed in the hand, even if active finger extension is present.

The flexor withdrawal, crossed extension, and grasp reflexes are rarely seen in isolation.[64]

Trunk Control Assessment

Collin and Wade[23] designed a quick and easily administered test of trunk control that is valid and reliable in clients with a diagnosis of CVA. It involves four timed tests: (1) rolling to the weak side, (2) rolling to the sound side, (3) moving from supine to sitting, and (4) sitting on the side of the bed with the feet off the floor for 30 seconds.

To accurately assess trunk control, the therapist must evaluate strength and control in four muscle groups—the trunk flexors, the extensors, the lateral flexors, and the rotators. For all the tests, the client should be sitting upright on a mat table with the feet supported. Remember that the client should not be left unattended on the mat table until the therapist determines that he or she has adequate trunk control and sitting balance. The procedures described in the following sections are condensed from Gillen's *Stroke Rehabilitation: A Function-Based Approach.*[42]

Trunk Flexors

The examiner asks the client to sit upright, to slowly move his or her shoulders behind the hips (eccentric control), and to hold the end-range posture (isometric control) (Fig. 19.11A). The client then is asked to move forward (concentric control) to resume the initial upright posture (Fig. 19.11B).

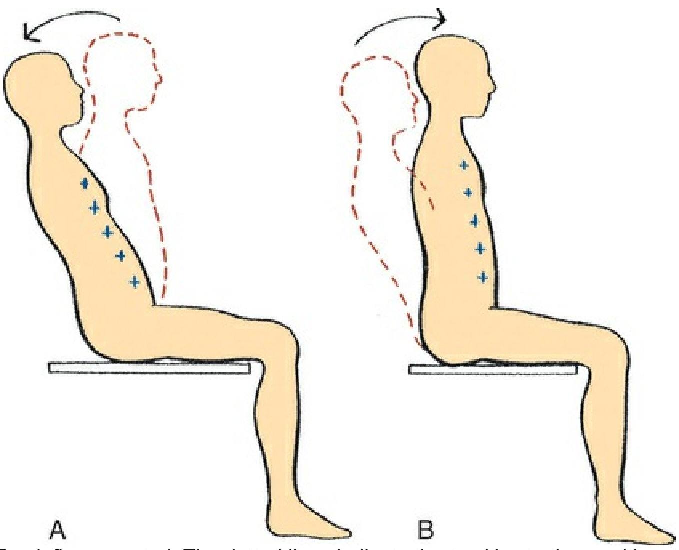

FIG 19.11 Trunk flexor control. The dotted lines indicate the trunk's starting position; the solid lines indicate the trunk's final position. The arrows indicate the direction of movement, and the plus symbols indicate the muscle groups primarily responsible for control of the pattern. Skeletal muscle activity occurs on both sides of the trunk (reciprocal innervation). (From Gillen G, Burkhardt A: *Stroke rehabilitation: a function-based approach,* ed 4, St Louis, 2015, Elsevier/Mosby.)

The examiner should observe for evidence of unilateral weakness, potential for falls, and symmetry of weight shift. A functional test for trunk flexor control is to observe the client move from supine to sitting.

Trunk Extensors

Test 1.

The client sits in a position of spinal flexion with a posterior pelvic tilt and moves into trunk extension while simultaneously moving the pelvis into neutral or into a slight anterior tilt. This test assesses concentric trunk extensor control, which is a prerequisite for lower extremity dressing and forward reach (Fig. 19.12A).

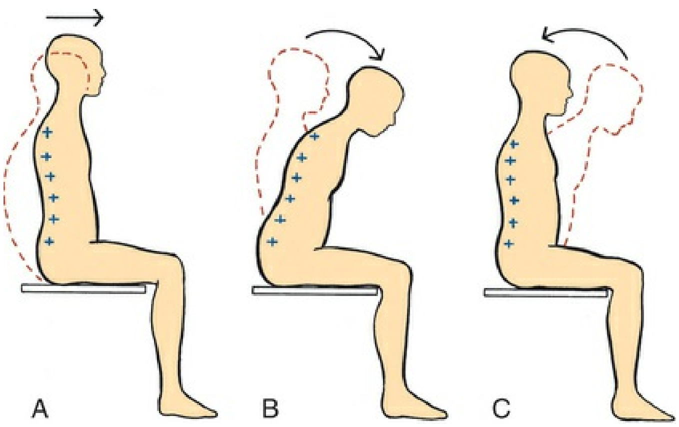

FIG 19.12 Trunk extensor control. The dotted lines indicate the trunk's starting position; the solid lines indicate the trunk's final position. The arrows indicate the direction of movement, and the plus symbols indicate the muscle groups primarily responsible for control of the pattern. Skeletal muscle activity occurs on both sides of the trunk (reciprocal innervation). (From Gillen G, Burkhardt A: *Stroke rehabilitation: a function-based approach,* ed 4, St Louis, 2015, Elsevier/Mosby.)

Test 2.

The client is seated in an upright posture. The examiner asks the client to maintain an erect spine and lean forward. This test evaluates eccentric trunk extensor control (Fig. 19.12B).

For both trunk extensor tests, the examiner should observe for signs of unilateral weakness and note end-range control.

Test 3.

The client is asked to move his or her shoulders back to assume a seated, aligned, upright position. The trunk extensors are contracting concentrically (Fig. 19.12C).

Lateral Flexors

The client sits in an upright posture. The pelvis is stationary, and the upper trunk laterally flexes toward the mat table. Fig. 19.13 shows eccentric contraction of the left side and muscle shortening of the right side. The client is asked to return to the original test position (concentric control of the left side) (Fig. 19.13).

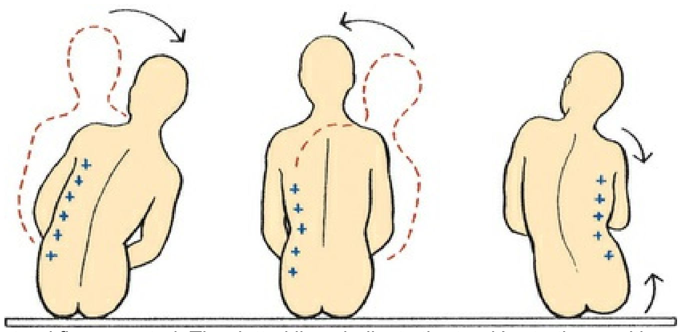

FIG 19.13 Lateral flexor control. The dotted lines indicate the trunk's starting position; the solid lines indicate the trunk's final position. The arrows indicate the direction of movement, and the plus symbols indicate the muscle groups primarily responsible for control of the pattern. Skeletal muscle activity occurs on both sides of the trunk (reciprocal innervation). (From Gillen G, Burkhardt A: *Stroke rehabilitation: a function-based approach*, ed 4, St Louis, 2015, Elsevier/Mosby.)

Fig. 19.13 shows assessment of trunk and pelvis lateral flexion, in which movement is initiated from the lower trunk and pelvis. The end position is one of trunk elongation on the weight-bearing side and shortening on the non-weight-bearing side, which involves concentric contraction of the right side.

Lateral flexion is needed for fall prevention when a client is reaching to the side (eg, shutting a car door).[36]

Trunk Rotation

The primary muscles responsible for rotation are the obliques. When a person rotates the trunk to the left, the right external and the left internal obliques are recruited. Rotational control is a prerequisite for upper extremity dressing and reaching across the midline. Three movement patterns are evaluated.

1. The client sits upright with the pelvis in a neutral, stable position. The client reaches with his or her right arm, across the body, in the direction of the floor. This motion helps in assessment of concurrent flexion and rotation. The motion tests concentric control of the obliques and the back extensors (particularly the thoracic region). Both sides need to be tested.

2. The second movement pattern involves trunk extension with rotation. The upper trunk remains stable, and the lower trunk and pelvis move forward on one side (ie, shifting forward). Again, both sides are tested.

3. The client is positioned supine for the third movement. Farber[36] described this as the client initiating a "segmental roll by lifting the shoulders from the support surface and toward the opposite side of the body. This pattern is controlled by a concentric contraction of the abdominals (obliques)."

Coordination

Coordination is the ability to produce accurate, controlled movement. Characteristics of coordinated movement include smoothness, rhythm, appropriate speed, refinement to the minimum number of muscle groups needed, and appropriate muscle tension, postural tone, and equilibrium. Coordination of muscle action is under the control of the cerebellum and is influenced by the extrapyramidal system.

For coordinated movement, all elements of the neuromuscular mechanism must be intact. Coordinated movement depends on contraction of the correct agonist muscles with simultaneous relaxation of the correct antagonist muscles, together with contraction of the joint fixator and synergist muscles. Other functions that must be intact include proprioception, body scheme, and the ability to judge space accurately and to direct body parts through space, with correct timing, to the desired target.

Incoordination

Many types of lesions can produce disturbances in coordination. Disturbances in coordination often stem from cerebellar and extrapyramidal disorders. Noncerebellar causes include diseases and injuries of muscles and peripheral nerves, lesions of the posterior columns of the spinal cord, and lesions of the frontal and postcentral cerebral cortex.[32]

Cerebellar Disorders

Cerebellar dysfunction can cause incoordination that may affect any body region and cause a variety of clinical symptoms. For example, the client may have postural difficulties that include slouching or leaning positions (caused by bilateral lesions) or spinal curvature (caused by unilateral lesions) and wide-based standing. Eye movements, both voluntary and reflexive, may be affected, as may the resting position of the eye.[73] One interesting fact about the cerebellum is that lesions or disease in one cerebellar hemisphere show signs of impairment on the same side of the body (ipsilateral).[3] Common signs of cerebellar dysfunction that the therapist may encounter include ataxia, dysdiadochokinesis, dysmetria, dyssynergia or asynergia, nystagmus, and dysarthria.

Ataxia

Ataxia is manifested as delayed initiation of movement responses, errors in range and force of movement, and errors in the rate and regularity of movement. Poor coordination is noted between the agonist and antagonist muscle groups. This results in jerky, poorly controlled movements. When a client with ataxia reaches for an object, it is apparent that the shortest distance between the client and the object is not a straight line. The client with gait ataxia has a staggering, wide-based gait with reduced or no arm swing. The person is unable to tandem walk (heel to toe); step length may be uneven; and the client may have a tendency to fall.[34] The client with cerebellar dysfunction isolated to one cerebellar hemisphere will have a tendency to fall on the side of the lesion or dysfunction because of the ipsilateral (same side) influence of the cerebellum on the lower motor neurons.

Many ataxias are hereditary and are classified by chromosomal location and type of inheritance: autosomal dominant, in which the affected client inherits a normal gene from one parent and a faulty gene from the other parent; or autosomal recessive, in which both parents pass on the faulty gene. Two of the more common inherited ataxias are Friedreich's ataxia and Machado-Joseph disease. Ataxia can also be acquired. Conditions that can cause acquired ataxia include stroke, multiple sclerosis, tumors, alcoholism, peripheral neuropathy, metabolic disorders, and vitamin deficiencies.[79]

Dysdiadochokinesis

Dysdiadochokinesis is an inability to perform rapid alternating movements, such as pronation and supination or elbow flexion and extension. There is a breakup and irregularity that happens when the client attempts to perform these movements.[34] This author tests this by counting how many cycles a client can perform in a 10-second time frame. A cycle consists of one full repetition of supination and pronation. It is best to test the unaffected (or lesser affected) side first. The affected side is then compared with the unaffected side.[84]

Dysmetria

Dysmetria is an inability to estimate the ROM necessary to reach the target of movement. The target is missed. The two types of dysmetria are hypermetria, in which the limb overshoots the target, and hypometria, in which the limb undershoots the target.

Dyssynergia or Asynergia

Literally, dyssynergia is a decomposition of movement in which voluntary movements are broken up into their component parts and appear jerky. Dyssynergia is one of the main clinical signs of cerebellar dysfunction or lesions involving pathways to and from the cerebellum.[34]

Nystagmus

Nystagmus is an involuntary movement of the eyeballs in an up-and-down (vertical), back-and-forth (horizontal), or rotating direction. It interferes with head control and fine adjustments required for balance. Nystagmus can be induced by specific procedures, but induced nystagmus is typically brief in neurotypical clients (eg, nystagmus is observed for a few seconds after quickly spinning the person around several times and then stopping the motion). Nystagmus can also occur as a result of vestibular system, brainstem, or cerebellar lesions or dysfunction.[3] When nystagmus occurs after a CNS lesion or dysfunction, it is typically sustained for a longer time and with a larger excursion or movement range of the eyeball in the socket. This can significantly disrupt an individual's functional performance.

Dysarthria

Dysarthria is explosive or slurred speech caused by incoordination of the speech mechanism. The client's speech may also vary in pitch or may seem nasal and tremulous, or both.[26]

Extrapyramidal Disorders

Extrapyramidal disorders are characterized by hypokinesia (small movement) or hyperkinesia (exaggerated movement). Hypokinesia examples are discussed first. Parkinson's disease is characterized by hypokinesia, bradykinesia (slow movement), cogwheel and lead pipe rigidity, a decrease in or loss of postural mechanisms, and a resting, pill-rolling tremor.[35]

Parkinson's plus is the name given to a group of **movement disorders** that have signs of Parkinson's disease with concomitant neurological deficits. Progressive supranuclear palsy (PSP) is an example of a Parkinson's plus disorder. Clients affected with PSP have loss of vertical ocular gaze, balance dysfunction, rigidity of the neck and trunk muscles, dementia, and usually absence of tremor. The life expectancy is shorter than in Parkinson's disease; death often occurs within 6 to 10 years.[48]

Chorea

Chorea is characterized by irregular, purposeless, quick movements. They are not movements that occur in a regular pattern, such as the alternating movement seen with clonus, nor is chorea as quick as clonus. The jerky movements randomly flow from one muscle to another. Chorea usually stems from disorders in the caudate nucleus.[34] These movements may occur during sleep.[26] Two diagnoses often present with chorea: tardive dyskinesia (TD) and Huntington's disease. TD is a drug-induced disorder, often associated with neuroleptic drug use. Occupational therapists may see clients who have TD in psychiatric settings. It also can occur as a side effect of certain medications for Parkinson's disease. Huntington's disease is an inherited, autosomal dominant disease. Clients with Huntington's disease have chorea that compromises functional movement (eg, walking) or tasks that require fine coordination of movements. As the disease progresses, rigidity develops.

Athetoid Movements

Athetoid movements are continuous, slow, writhing, arrhythmic movements that primarily affect the distal portions of the extremities. These movements are not present during sleep. Adult athetosis can occur after cerebral anoxia and with Wilson's disease. Movement patterns include alternating extension and flexion of the arm, supination and pronation of the forearm, and flexion and extension of the fingers. Athetosis that occurs with chorea is called *choreoathetosis.*

Dystonia

Dystonia results in sustained muscle contraction of the extremities (eg, hyperextension or hyperflexion of the wrist and fingers), often with concurrent torsion of the spine and associated twisting of the trunk.[34] Dystonic movements are often continuous and often seen in conjunction with spasticity. The client in Fig. 19.14 sustained a TBI, and his right wrist and fingers show dystonia. Dystonia can be primary or secondary, the latter occurring with other CNS disorders (eg, hypoxic brain injury, tumor). Segmental dystonia involves two or more adjacent body parts. Generalized and multifocal types of dystonia also exist. Focal dystonia involves only one limb, as is seen in writer's cramp, musician's cramp, and spasmodic torticollis.[32]

FIG 19.14 A client with right upper extremity dystonic posturing of the wrist and finger extensors. His left wrist shows severe hypotonicity. Tone abnormalities are the result of a traumatic brain injury.

Ballism

Ballism is a rare symptom produced by continuous, abrupt contractions of the axial and proximal musculature of the extremity. Ballism causes the limb to fly out suddenly, with a much greater amplitude than chorea. It occurs on one side of the body (hemiballism) and is caused by lesions of the opposite subthalamic nucleus.

Tremor

Tremors stem from alternating contractions of opposing muscle groups. They are rhythmic. oscillatory movements. There are three common types of tremor.

- *Action tremor,* formerly known as intention tremor associated with cerebellar disease, occurs during voluntary, intentional movement. It is intensified at the termination of the movement and is often seen in multiple sclerosis. The client with action tremor may have trouble performing tasks that require accuracy and precision of limb placement (eg, drinking from a cup, inserting a key into a lock).
- *Resting tremor* occurs at rest and subsides when voluntary movement is attempted. It occurs as a result of damage to or disease of the basal ganglia and is seen in Parkinson's disease.[34]
- *Essential familial tremor* is inherited as an autosomal dominant trait. It is most visible when the client is carrying out a fine precision task, such as writing or pouring liquids. The pathophysiology is not known. This is the most common movement disorder.[32]

Assessment of Coordination

Medical Assessment of Coordination

Incoordination consists of errors in rate, rhythm, range, direction, and force of movement. Therefore, observation is an important element of the clinical examination. The neurological examination for incoordination may include the nose-finger-nose test; the finger-nose test; the heel-knee test; the knee pat (pronation-supination), hand pat, and foot pat tests; finger wiggling; and drawing a spiral. Such tests can reveal dysmetria, dyssynergia, adiadochokinesis, tremors, and ataxia. Usually the neurologist or the physiatrist performs these examinations. Magnetic resonance imaging (MRI) and computed tomography (CT) scans also may be ordered. Infrequently EMG is used to better characterize the frequency and pattern of the tremor. For example, the rate of the resting tremor often seen in a client with Parkinson's disease is 3 to 5 per second. A faster or slower tremor effectively rules out this condition.[51]

Occupational Therapy Assessment of Coordination

Selected activities and specific performance tests can reveal the effects of incoordination on function. The occupational therapist can observe for coordination difficulties during ADL assessment by observing the client write, open containers, or button a garment. The therapist should observe for irregularity in the speed of movement. Movement during the performance of various activities may appear irregular and jerky and may overreach the mark. The following general guidelines and questions can be used when evaluating incoordination.

1. Assess muscle tone and joint mobility first in a sitting position.

2. Observe for ataxia, proximal to distal, during functional upper extremity movement. Are movements away from or toward the body more difficult for the client?

3. Stabilize joints proximally to distally during the functional task, and note differences in client performance compared with performance without stabilization. (Stabilization can be attained by splinting, holding the wrist stable with the other hand, or stabilizing the affected body part against a wall.) Weighted cuffs may be applied to the extremity during task performance to determine whether weighting or resistance reduces the tremor. Note the amount of resistance provided. Observe whether the cuff weights make the coordination worse because sometimes the use of weights increases tremor.

4. Observe for tremor. Are the head and speech affected by the tremor?

5. How do the client's ataxia and coordination problems affect participation in occupation?

Perform an occupational profile, in addition to a performance patterns interview, to ask about the client's roles, routines, goals, and environment to determine which activities are important for the client.

Numerous standardized tests of motor function and manual dexterity are available and can be administered to evaluate coordination. These tests include the Purdue Pegboard,[88] the Minnesota Rate of Manipulation Test,[74] the Bennett Hand Tool Test,[10] the Jebsen-Taylor Hand Function Test,[60] and the 9-Hole Peg Test.[69]

Standardized functional assessments for a CVA (eg, the WMFT), mentioned earlier, may be useful for measuring the efficacy of OT intervention for impaired coordination.[14]

Occupational Therapy Intervention

Intervention for Hypertonicity and Spasticity

Hypertonicity is only one part of the UMNS. It is very important to treat other performance deficits of the UMNS, such as paresis, fatigue, and decreased dexterity. These deficits can impede function to a greater extent than hypertonia.[32]

Before treating hypertonia, the therapist and physician need to closely evaluate the function of the tone. Hypertonicity can have beneficial effects, such as aiding in standing and transfers, maintaining muscle bulk, and preventing deep vein thrombosis, osteoporosis, and edema. Intervention is necessary when spasticity interferes with ADLs, gait, sleep, or wheelchair positioning, or when it causes severe pain and limits hygiene (eg, the client is unable to wash the hand or axilla) or leads to contractures or decubitus ulcers. Hypertonicity or spasticity may be treated with conservative therapeutic interventions, pharmacologic agents, or surgery.[32,87]

Conservative Treatment Approaches

Weight bearing.

For hypertonicity reduction and paresis remediation in the upper extremity, therapists have been using weight-bearing skills and activities for many years with clients who have UMN lesions, but evidence of treatment efficacy has not been fully established.

Brouwer and Ambury[18] concluded that corticospinal facilitation of motor units occurred during upper extremity weight bearing. They believed that afferent input from weight bearing increased motor cortical excitability. Chakerain and Larson[21] studied the effects of upper extremity weight bearing on hand opening and prehension in children with spastic cerebral palsy. Computer calculations of clients' hand surface area were performed. An increase in surface area was noted after weight bearing, along with an increase in the maturity of movement components needed for prehension. McIlroy and Maki[71] demonstrated that if the affected arm is used when weight bearing, postural responses occur throughout the weight-bearing extremity and during other perturbations of posture.

Despite the fact that few well-controlled studies document how and why weight bearing works physiologically, it certainly is a requirement for improving functional performance. Seated clients who reach to the floor to pick up an object need upper extremity postural support to prevent them from falling. Standing clients who reach into a high cabinet need upper extremity weight bearing to facilitate balance.[42]

Traditional Sensorimotor Approaches

Proprioceptive neuromuscular facilitation (PNF) has been shown to be effective in gaining motor control for clients with a variety of diagnoses (see Chapter 31).[92] The Neuro-Developmental Treatment (NDT) Association[56a] has stated that therapists who follow an NDT approach:

- Perform an in-depth analysis of the intricacies of movement and of how the details relate to the whole to allow for functional movement in a wide variety of environments.
- Believe that control of movement is based on a complex interaction of many body systems, which are plastic and adaptable, and on the tasks presented and the environments in which the tasks are performed. Therefore, function can be altered by changing one or more of these elements.
- Implement an understanding of the development of atypical movement, in addition to the compensations, to help minimize the impact of CNS pathology and prevent the emergence of contractures and deformities, which contribute to the functional problems.

Another OT objective is to have the client manage muscle tone to engage in and complete basic ADLs (BADLs) and IADLs. Positioning and movement in patterns opposite to hypertonic or synergistic patterns are important to expand the motor repertoire and develop movement that is as close to normal as possible. At times it is appropriate to facilitate synergistic movements in the client with chronic disease, or if the client does not recover beyond stage 3 of the Modified Brunnstrom's Stages of Motor Recovery (see Table 19.1 and Fig. 19.3). The synergy patterns can be facilitated to improve lateral pinch or elbow flexion function. The client should also be taught how to incorporate the affected upper extremity as much as possible into BADLs and IADLs. (See Chapter 10 for a more detailed review of traditional treatment strategies.)

Even when motor control is adequate for participation in occupation, the sensory, cognitive, and perceptual abilities of the client may affect the achievement of functional goals. Perceptual dysfunction may alter the client's abilities, requiring the therapist to focus on perceptual training concurrently.

Casting.

In some cases unilateral hypertonicity is severe enough to necessitate serial inhibitive casting or splinting. Casting in inhibitive postures has been shown to be effective in tone reduction.[44] The beneficial effect of casting on hypertonia and upper extremity contractures has been well documented in the literature.[13,33]

Casting in inhibitive postures is effective because it provides neutral warmth, maintained pressure, and constant joint positioning with static lengthening of muscle. **Serial casting** is most successful when a contracture has been present for less than 6 months. The cast may be bivalved (cut in half) and worn as a splint. This helps protect the skin and allows the therapist to work with the extremity out of the cast. However, many clinicians believe that a nonbivalved cast is more effective and actually causes less skin breakdown. A dropout cast, which can be used as part of the serial casting process, includes a cutout area, allowing movement of the joint in the desired direction. For example, for an elbow with flexor hypertonicity, the dorsal upper arm portion of a long arm cast can be cut out to allow the triceps to be facilitated to extend the arm.

Serial casting should stop when the desired position has been achieved and tone is manageable with the last cast or splint. If no evidence of increased PROM is seen after two or three casts have been removed, serial casting must stop; however, the last cast should be kept, bivalved, and used as a "retainer" splint to prevent additional contractures, similar to retainer use in orthodontics.

Many innovations have occurred in commercially available spasticity reduction splints that are used to place the wrist and hand in inhibitive postures. The client and the family need to be educated on continuing to incorporate the extremity in occupation and on bearing weight on the extremity as much as possible to retain the ROM gains achieved during casting.[43,87]

Physical Agent Modalities

Physical agent modalities, such as cold, superficial heat, ultrasound, and neuromuscular electrical stimulation, can be used as preparation for or in conjunction with purposeful activity and muscle reeducation, provided the OT practitioner has the appropriate training and meets the license criteria for his or her state or country. Ultrasound can help inhibit or reduce hypertonicity temporarily and can increase tendon and muscle extensibility. It is helpful to provide concurrent stretch during the ultrasound procedure. Even though neuromuscular electrical stimulation has been shown to strengthen paretic muscles,[20,54] more research needs to be done. Quandt and Hummel[89] reached this conclusion after completing a comprehensive review on the effect of functional electrical stimulation on hand motor recovery after a CVA.

Distal-to-Proximal Approach

The Functional Tone Management (FTM) Arm Training Program (Saebo, Charlotte, North Carolina) was developed to address the weaknesses of therapeutic interventions currently applied to the neurologically impaired upper extremity and hand. The occupational therapists who founded Saebo theorized that because grasp and release capabilities are pivotal to reintegrating the UE into daily activities, a paradigm shift for UE neurological rehabilitation was needed. Although traditional therapeutic interventions such as Bobath-based (NDT) programs are based on a proximal-to-distal recovery pattern, Saebo developed the FTM Arm Training Program on the basis of a distal activation model, which focused on the key point of early initiation of UE movements that incorporate grasp and release. To incorporate the hand into the FTM Arm Training Program, Saebo developed a dynamic orthosis for the hand and elbow, called the SaeboReach (Fig. 19.15).

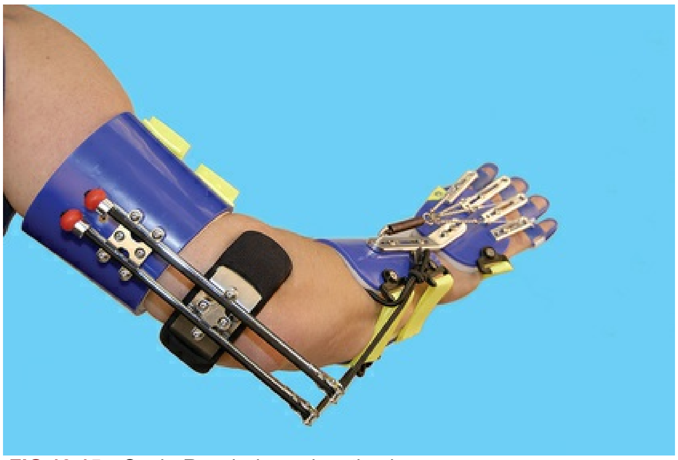

FIG 19.15 SaeboReach dynamic orthosis. (Courtesy Saebo, Charlotte, NC.)

The SaeboReach orthosis assists an individual with hypertonia in the hand to place the hand in an open, functional position. This positioning is accomplished by means of a fixed wrist support and a finger and thumb spring system of variable strength. Once the hand is open, the client can begin to retrain the finger flexors for improved motor control of the hand. While wearing the SaeboReach, the client relearns to produce a graded muscle contraction of the finger flexors to grasp an object. The finger and thumb spring system, coupled with the client's own efforts to relax muscle activation, allows the hand to open enough for the object held in the hand to be released while assisting the elbow extensors.

The SaeboGlove's lightweight, low-profile design assists with finger and thumb extension in clients with neurological or orthopedic problems. The SaeboGlove positions the wrist and fingers into extension in preparation for functional activities. The client grasps an object by voluntarily flexing the fingers. The extension system assists with reopening of the hand to release the object (Fig. 19.16).

FIG 19.16 SaeboGlove. (Courtesy Saebo, Charlotte, NC.)

Once the client is comfortable using the SaeboReach, the FTM Arm Training Program can begin. The FTM program combines high-repetition grasp and release with task-specific arm training drills to progress the client toward a functional goal. A body of research supports the FTM Arm Training Program; however, this program does not require the wrist or finger extension typically needed for participation in a constraint-induced program. Clinically observed improvements with use of the SaeboFlex (hand and wrist splint only) for 1 hour per day, 5 days per week, were improved scores on the Fugl-Meyer Assessment and the Box and Blocks test.[108] Another study of the SaeboFlex involving eight clients found that 7 of the 8 showed improved test scores on the upper limb Motricity Index after using the SaeboFlex for 12 weeks.[98]

Surgical Methods

Surgery to control hypertonicity is an option. Dynamic EMG can help orthopedic surgeons plan surgery. Orthopedic surgical intervention can improve function or release contractures. Examples of UE functional surgery include lengthening of the biceps tendon to reduce elbow flexion and to gain elbow extension; thumb-in-palm release; and transfer of the flexor carpi ulnaris tendon to the extensor carpi radialis longus or brevis tendon to reduce the deforming force of wrist flexion while simultaneously augmenting wrist extension. An example of a contracture release procedure is the flexor digitorum superficialis–to–profundus transfer to gain length in the extrinsic finger flexors.[63]

Therapists will encounter clients with severe spasticity who have undergone a neurosurgical procedure called **intrathecal baclofen pump** (ITB) implantation. This procedure enables baclofen, a spasticity-reducing medication, to enter the body at the spinal level, preventing the centrally mediated side effects of oral baclofen. The ITB dispenses the baclofen directly into the intrathecal (subarachnoid) space via a catheter attached to a subcutaneous implantable pump in the abdomen. The client must undergo a lumbar puncture test dose of intrathecal baclofen to determine candidacy before pump implantation. A 2-point lower limb spasticity reduction on the Ashworth Scale or MAS is needed for spinal spasticity, and a 1-point reduction is required for cerebral spasticity.[72]

The ITB has been shown to be very effective in reducing severe spinal spasticity and spasticity associated with multiple sclerosis, and it is also effective for cerebral spasticity. For additional details on medical and surgical treatments and their relation to occupational therapy, see Preston and Hecht's *Spasticity Management: Rehabilitation Strategies.*[87]

Pharmacological Agents

Pharmacological agents prescribed and administered by physicians include oral medications, short-term nerve blocks, and long-term blocks.

Clients with severe hypertonicity accompanied by severe pain may need evaluation to determine the cause of the pain. Drug therapy and other pain management techniques may be part of the treatment approach. The four commonly used oral medications for spasticity of UMN origin are baclofen, dantrolene sodium, tizanidine, and diazepam. These medications are generally well tolerated, but a common side effect is drowsiness. Dantrolene sodium acts at the skeletal muscle. It is preferred in cerebral spasticity because it is less apt to cause sedation, but it can cause weakness and liver damage. Tizanidine HCl is labeled for spasticity reduction in multiple sclerosis and spinal cord injury. Its side effects may include hypotension, sedation, and visual hallucinations. Side effects of diazepam include drowsiness, fatigue, and possible dependency. Neither diazepam nor baclofen can be discontinued suddenly because doing so may cause seizures.

Three antiepileptic drugs have been used off label for spasticity: pregabalin (Lyrica), topiramate (Topamax) and gabapentin (Neurontin).[77]

No matter which drug is used, it is crucial for the OT practitioner to alert the medical staff to any side effects that may interfere with the client's overall function.[77,87]

Nerve blocks and motor point blocks consist of injections of a chemical agent to diminish or obliterate tone. Short- and long-term blocks may be used. Short-term blocks are injections of an anesthetic (eg, bupivacaine) to temporarily reduce pain and muscle tone. Short-term blocks help the physician differentiate between hypertonus and contracture. Short-term blocks last 1 to 7 hours, depending on which anesthetic is used.[86]

Long-term blocks, which usually consist of injections of phenol or botulinum toxin type A (Botox) or botulinum toxin type B (Myobloc), generally last several months. Botox lasts for 2 to 5 months with spastic hypertonia. Botulinum toxin type B has been shown to diminish the negative effects of cervical dystonia for 12 to 16 weeks. Phenol blocks last 2 to 8 months, depending on whether the motor points (2 to 3 months) or the motor branch (8 months) is injected.[22,42]

Phenol and the botulinum toxins type A and type B have different mechanisms of action. Botulinum toxins type A and type B exert their effects by means of chemical denervation, whereas phenol works by means of motor point or motor branch neurolysis. All three types of blocks can be used to diminish or obliterate hypertonicity in the agonist.

Long-term blocks help prevent contractures and render the hypertonic muscle weak or flaccid. The effect and time interval of the long-term block give therapists the opportunity to increase antagonistic strength and function. A combination of long-acting blocks and casting or splinting is often used to treat hypertonicity. Long-term blocks in the upper extremities are commonly used in the subscapularis, brachioradialis, and flexor digitorum profundus.[87]

Hsu et al.[57] studied a 52-year-old client who had spastic hypertonia after a CVA. Botulinum toxin type A was injected into the elbow, wrist, and finger flexors; this treatment was combined with a 4-week program of modified constraint-induced movement therapy (CIMT) and a 5-month home exercise program. (CIMT involves constraining the sound arm to encourage use of the affected arm.) The client made functional progress, as evidenced by improved scores on the Motor Activity Log, Wolf Motor Function Test, Action Research Arm Test, and Fugl-Meyer Assessment of Motor Recovery.

Treatment of Rigidity

Decerebrate and decorticate rigidity can wax and wane. When rigidity is waning, it is recommended that the client be transferred to a wheelchair or a reclining chair because rigidity decreases in sitting. Rigidity is worse during episodes of agitation.[64] Parkinson's rigidity responds temporarily to heat, massage, stretching, and ROM exercises. Rocking back and forth before standing can aid in the transition. The Lee Silverman Voice Training BIG (LSVT BIG) program (described later in the chapter) involves exercises geared toward ameliorating rigidity. (See Chapter 35 for further discussion of Parkinson's disease and additional treatment strategies.)

Treatment of Flaccidity

Flaccidity stemming from UMN dysfunction (eg, a client recovering from spinal or cerebral shock caused by acute CNS insult or injury) is treated with facilitation techniques such as weight bearing, high-frequency vibration, tapping, quick stretch, bed positioning with weight on the flaccid side most of the time, and functional neuromuscular electrical stimulation. Splinting of the hand and wrist may be indicated for support. Therapists should closely supervise splinting because contractures can result from excessive splint wear. PROM exercises also are indicated. The arm can be passively positioned as normally as possible during ADL tasks to provide sensory and proprioceptive feedback. For example, when the client is eating, have him or her place the affected arm on the dining room table, resting on top of a piece of Dycem.[29] Client and family education on proper positioning and joint protection is important to prevent overlengthening of soft tissues and trauma (eg, the arm falls off the client's lap and bumps the wheel of the wheelchair).

Treatment of Incoordination

Treatment of incoordination is challenging. Activities graded on the basis of motor learning and control may be helpful for attaining proximal stability and then mobility. Therapy directed toward the modulation of reflexes and abnormal synergy patterns and the enhancement of postural control mechanisms, such as the righting and equilibrium reactions, can help improve coordination. Weight bearing, joint approximation, placing and holding techniques, and fixed points of stability (having the client stabilize the elbow or wrist on the tabletop) can be helpful.

It is critical that the therapist encourage the client to use his or her vision to help direct UE movements. The therapist should begin with small ranges of movement and gradually increase them as the client progresses. Initially work is done in the plane and direction of movement that are easiest for the client; it then progresses toward more difficult areas. Some of the involuntary movements of cerebellar or extrapyramidal origin, particularly primary movement disorders, are difficult to manage or change. Therapists have greater influence over movement disorders associated with TBI, stroke, and the first three stages of Parkinson's disease.

LSVT BIG, mentioned earlier, is an intensive, evidence-based treatment protocol for clients with all stages of Parkinson's disease (PD). The LSVT BIG protocol consists of 16 visits (four times per week for 4 weeks). It is delivered by occupational and/or physical therapists who have completed the LSVT BIG Training and Certification Workshop. The focus of the program is to address both the motor and sensory impairments related to PD by training larger amplitude movements and translating these movements into everyday functional activities.

Three studies have shown the efficacy of LSVT BIG in improving function in clients with PD. Ebersbach et al.[31] studied 60 clients with PD and randomly assigned them to three groups: home exercise, Nordic walking, or LSVT BIG (individual 1-hour treatment sessions, 4 days per week, for 4 weeks). The main outcome measure rated before and after treatment was the motor score of the United Parkinson's Disease Rating Scale (UPDRS). The clients in the LSVT BIG group showed a significant 5-point improvement on the UPDRS motor score, whereas the other two groups experienced mild deterioration.[31] Another study revealed that clients with PD who underwent 16 sessions of LSVT BIG had generalized transference of higher amplitude during reach and also demonstrated improved gait speed.[37] In both studies the clients were evaluated by blinded raters after treatment. A case series reported positive improvements in gait, balance, and bed mobility in three clients with PD.[59] The review article, "LSVT LOUD and LSVT BIG: Behavioral Treatment Programs for Speech and Body Movement in Parkinson Disease," by Fox et al.,[41] provides the reader with an overview of the rationale for the LSVT protocols, in addition to a description, summary of efficacy data, and discussion of limitations and future research directions.

Methods and devices to compensate for incoordination may be necessary to make BADLs and IADLs safer, more achievable, and more satisfying. The OT practitioner must obtain a thorough occupational profile to make appropriate activity and equipment choices and to determine adaptive strategies the client can carry over to the home environment. The physician may decide to use pharmacological agents or surgical intervention to try to dampen tremor or other involuntary movement patterns.

Surgical Intervention for Movement Disorders

Neurosurgical interventions for movement disorders may include stereotactic thalamotomy to reduce ballistic movement, essential tremor (multiple sclerosis), resting tremor (Parkinson Disease), and athetosis. Surgical treatment for dystonia may include ramisectomy, stereotactic thalamotomy, or ITB implantation.[32] Deep brain stimulation has been effective in tremor reduction in essential tremor and Parkinson's disease.[35]

Because of the current managed care system, occupational therapists are receiving more referrals than ever before from primary care physicians. Occupational therapists who have a basic knowledge of medical and surgical options for ameliorating motor control problems can play a triage role in suggesting referral to physician specialists.

Rehabilitation Robotics

Rehabilitation robotics is an exciting interdisciplinary field in which OT practitioners can participate. Recent rehabilitation robotics conventions have organized this field into three tracts: gerotechnology (user group characteristic), biorobotics (source of design inspiration), and neurorobotics (harness neurorecovery or neuron connectivity).[66]

Researchers at the Massachusetts Institute of Technology (MIT) invented the MIT-Manus, a device that robotically assists arms with paresis for clients who have had a CVA. The MIT study involved 96 clients, who were an average of 2 weeks post-CVA. Shoulder and elbow function improved twice as much in the experimental group (the group that used the MIT-Manus) as in the control group (the group that received conventional therapy).[103]

More information on the role of robotics in rehabilitation is available in the article by Krebs et al.[66] listed in the references.

Threaded Case Study

Daniel, Part 2

1. What performance skills or standardized assessments would you select to evaluate Daniel's motor function?

Rating Daniel's muscle tone on a mild-moderate-severe scale is a low-tech, quick way to rate the hypertonia throughout his treatment and to observe the influence it has on his movement over time. Spasticity often peaks at 3 months post-CVA and then starts to decline. This varies from client to client, depending on the level of brain damage. Active and passive range of motion (AROM and PROM) are also indicated for his shoulder through his fingers. PROM is needed to make sure he does not have any contractures that inhibit his ability to reach the steering wheel. AROM is needed to see whether he has the active range to reach the steering wheel, grasp it, and release it. Sensibility testing (eg, kinesthesia and Semmes-Weinstein monofilaments) would be useful. It is important to know whether Daniel can feel his hand position on the steering wheel. The Wolf Motor Function Test[14] or the Graded Wolf Motor Function Test[75] could be used initially and then once a month thereafter to monitor his functional progress.

2. What activities or intervention would you plan for Daniel to reduce the hypertonia in his right arm?

Weight bearing on a mat table or a kitchen counter with his right fingers, wrist, and elbow extended would serve as a good method of stretching Daniel's extrinsic finger flexors, wrist flexors, and elbow flexors. He can participate in activity with his left hand, such as putting away dishes or folding laundry one-handed.

The OT practitioner should consider fabricating a custom resting hand splint/orthotic that stretches his extrinsic finger flexors and wrist flexors. Wearing the splint/orthosis 7 hours at night is preferable so that it doesn't inhibit use of the affected extremity during the day.

Modality-certified OT practitioners can use ultrasound with concurrent stretch to lengthen tendons and muscles that have become shortened due to hypertonia/spasticity. In-clinic functional electrical stimulation can be used to strengthen antagonists to the spastic muscles (ie, triceps, wrist extensors, extrinsic finger extensors, and extensor pollicis longus to obtain thumb extension). If Daniel has good results in the clinic, a home functional electrical stimulation unit can be ordered with a physician's prescription.

3. What home exercise or activity program would you prescribe for Daniel to help him reach his goals of starting the ignition of his car and driving with his right upper extremity?

Daniel should perform passive and active stretching in any plane of motion that is needed for him to reach the steering wheel and also to turn on the ignition. This would include scapular protraction, shoulder flexion, elbow extension, forearm supination, wrist extension, finger flexion and extension, and lateral pinch. Throwing a ball forward can help him work out of the flexion synergy and speed up the release of his fingers. The hammer and inverted hammer exercises will help him gain ROM, motor control, and strength in his supinator muscles (biceps and supinator) (Figs.19.17 and 19.18). He needs both supination and lateral pinch to turn the key in the ignition. He can use therapy putty to help him acquire the strength to hold on to the car key. Home functional electrical stimulation units can be used to strengthen the triceps and the extensors of the fingers, wrist, and thumb.

FIG 19.17 Starting position for the inverted hammer exercise to strengthen the supinator muscles.

FIG 19.18 Ending position for the inverted hammer exercise to strengthen the supinator muscles. The therapist can put a cuff weight on the hammer when the client can do the exercise easily to full range.

Daniel reached his goals of driving and returning to work full duty as a salesperson 4 months after his CVA (Fig. 19.19).

FIG 19.19 Daniel's last day of therapy, driving himself to work.

Summary

From reading Daniel's case study, we can see how abnormal elements of motor control affect the quality of movement and the ability to perform in areas of occupation. The occupational therapist assesses muscle tone, upper extremity recovery, and coordination, using standardized tests and observation of movement during occupational performance. The results of the motor control assessment can help the client and the therapist collaborate on appropriate intervention. Ameliorating motor control problems can be a rewarding experience for the client and the therapist.

Review Questions

1. What is neuroplasticity?
2. Describe the circumstances in which a physician would recommend a long-term nerve block or a motor point block for a person with spastic wrist and finger flexors.
3. Describe the characteristics of rigidity.
4. Explain the major difference between spasticity and hypertonia.
5. Demonstrate how to perform an upper extremity muscle tone evaluation.
6. What is the name of the certification program that focuses on helping clients with Parkinson's disease take bigger steps and reach higher in ADLs?
7. What are equilibrium reactions?
8. Compare chorea and athetosis.
9. What is ataxia?
10. What is the most common type of tremor?

Occupation-Based Functional Motion Assessment

Alison Hewitt George, Amy Phillips Killingsworth

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, the student or practitioner[a] will be able to do the following:

1. Define occupation-based functional motion assessment.
2. Explain why it is desirable to assess motor function through observation of engagement in occupation and activity performance.
3. State two circumstances under which assessment of performance skills is indicated.
4. Define individual activity analysis, or "dynamic performance analysis."
5. Explain why it is not possible to do an accurate objective activity analysis.
6. List at least three questions that can guide the clinical observation and clinical reasoning of the occupational therapy (OT) practitioner while conducting an occupation-based functional motion assessment.
7. List factors other than range of motion (ROM), strength, and motor control that can affect motor performance.
8. Discuss how information gained from the occupation-based functional motion assessment differs from that gained during assessment of specific client factors.
9. State the minimum level of strength required throughout the lower extremities for normal stance and positioning.
10. Compare levels of muscle strength and associated endurance in the upper extremities.
11. List occupations that can be used to access functional motion in the upper extremities and in the lower extremities.

KEY TERMS

Functional motion assessment
Individual activity analysis
Objective activity analysis
Occupation-based functional motion assessment

Threaded Case Study

Raymond, Part 1

Raymond is a 60-year-old foreman of several lineman crews of the telephone company. He has been with the company for more than 40 years; although he could have moved into a more administrative position over the years, he has always enjoyed working out in the field, being a mentor to the younger workers, and dealing with emergencies. He is known throughout his neighborhood as the person to call when help is needed with home repair tasks, whether it is carpentry, plumbing, or electrical work. He is a member of a championship senior softball team and plays most weekends during the season, sometimes traveling out of town to participate in tournaments. He does quite a bit of volunteering through the outreach program at his church, participating in such activities as collecting, preparing, and delivering food to home-bound elderly and driving new immigrants to various appointments. He shares household duties with his wife and enjoys cooking for her.

Raymond was first diagnosed with rheumatoid arthritis 10 years ago, when he began experiencing pain and stiffness in his shoulders, hips, and knees. His symptoms were managed with medication and, except for occasional exacerbations, he was able to fully engage in those occupations that were meaningful to him. In the last 6 months he has experienced an exacerbation of his symptoms. The pain in his shoulders, hips, and knees has increased, and he also has begun experiencing pain in his wrist and hands. His wife began to notice Raymond's change in mood as he became increasingly reluctant to engage in occupations in which he always took the lead, such as helping his neighbors with home projects, preparing food in his church outreach program, and participating in the softball games.

Because he could not do things the way he used to, he did not want to do them at all. He stated that he did not want people seeing him fumbling as he attempted to hold tools or cooking utensils because his grip was so weak, nor did he want to let his teammates down because of the decreased power in his batting swing and speed in running the bases. At work he found himself giving more verbal instructions to his crew rather than demonstrating techniques, as he had always done before, at times speaking in a gruff, impatient tone, which was surprising to his fellow workers. His frustration with the increased amount of time it was taking him to complete activities of daily living (ADLs), such as shaving, buttoning his shirt, and putting on the boots he was required to wear at work, was making him irritable. The fatigue he was experiencing at the end of the day "just from trying to move my body around" was also adding to the depression of this client. This previously outgoing person was withdrawing and becoming more and more socially isolated.

The occupational therapist to whom he was referred began anticipating the needs of this client based on the profile she developed. Evaluating this client as he engaged in occupations in specific contexts would provide the best information for determining intervention strategies that would be most helpful, such as adaptive equipment and joint protection techniques. Getting information underlying those client factors (muscle strength, range of motion [ROM]) contributing to his decrease in function was critical. Arrangements were made to assess the client in his home and to make a job site visit. By observing the client perform occupation-based tasks and motions at work and home, the OT could obtain important information concerning his ROM, strength, and endurance and could assess his motor control.

Critical Thinking Questions

1. What is the advantage of administering an occupation-based functional motion assessment versus more specific assessments, such as joint measurement and manual muscle testing?

2. What information about the client's muscle strength and joint ROM can be determined through the occupation-based functional motion assessment? What cannot be determined?

3. What is the value of administering the occupation-based functional motion assessment in different environmental contexts?

Many physical disabilities cause limitations in motor performance skills and client factors, including joint ROM, muscle strength, and endurance or control of voluntary movement (gross and fine motor control). These physical impairments in body functions and motor skills result in movement limitations that can cause slight to substantial deficits in performance of areas of occupation and prevent pursuit of self-care, work, leisure, and educational and social activities. The **occupation-based functional motion assessment** is a way of assessing the ROM, strength, and motor control available for task performance by observing the client during performance of everyday occupations (ADLs, instrumental activities of daily living [IADLs], education, work, social participation, leisure activities, and rest and sleep) in varied contexts and environments.[1]

Because the primary responsibility of the occupational therapist is to assess occupational performance, identify performance problems, and plan intervention strategies that will improve the client's ability to fully engage in occupations, sensorimotor limitations first should be assessed through observation of functional activities. When improvement of performance skills is a goal of the intervention program, assessment of performance skills, occupation demands, and client factors in a variety of environmental contexts (eg, home, workplace, or school) may be indicated to make an objective assessment of physical limitations and gains (see Chapters 19, 21, and 22 for additional information).

Mental functions, including cognitive and perceptual abilities, such as motivation or the ability to sequence complex movement patterns, interpret incoming stimuli, or coping and behavioral regulation, can also affect motor function. These client factors must be considered in any performance evaluation (see Chapters 25 and 26). However, this chapter is limited to consideration of motor function (ie, ROM, strength, and motor control) during the occupation-based functional motion assessment.

OT Practice Notes

Except for a few diagnoses, specific assessments of ROM, muscle strength,[7] and motor control are seldom necessary. For example, performing a full ROM assessment or manual muscle test is time-consuming, can be tiring to the client, and may duplicate other services, whereas assessing these factors while the client is engaging in occupation yields the most comprehensive picture of the client's actual abilities and limitations.

Clinical Observation

It is possible to administer a gross assessment of joint mobility and muscle strength by having the client perform those motions associated with functional tasks (ie, a **functional motion assessment**). The OT practitioner could observe as the client reaches overhead, as would happen when putting dishes away in an overhead cupboard, or taking a step to the side, as when stepping into a bathtub.[11] This will give the practitioner some basic, although nonspecific, information about those factors that affect function.

OT practitioners (the OT in collaboration with the OTA) analyze the occupations of a client to assess the quality of that client's effectiveness in valued occupations, to identify the impact of contextual factors on performance, and to "determine the impact of personal factors (including health condition) on current performance."[6] With occupational analysis, client factors such as muscle strength, ROM, and motor control can be observed during the performance of ordinary ADLs, IADLs, work, and leisure tasks.[3] For example, while assessing ADLs, the therapist can observe for performance difficulties and movement patterns that may signal limited ROM, muscle weakness, muscle imbalance, poor endurance, limited motor control, and compensatory motions used for function.

An occupation-based functional motion assessment has an advantage over the functional motion assessment because, although the client will perform motions as described previously, there is the added resistance to body structures that will occur as the result of using equipment such as a sliding door, manipulating objects such as cards, or resisting fatigue and having endurance during repetitive activities such as folding clothes or bouncing a ball. Also, because the client is performing these tasks in environments and contexts that are meaningful, the client's full participation and engagement in the task may be heightened.

Essentially, when observing a client perform selected tasks, the occupational therapist is doing an **individual activity analysis** or "dynamic performance analysis"[11] to diagnose the occupational performance problems of that client. Because people perform the same task in a variety of ways and because there are so many variables in task performance, it is not possible to do an **objective activity analysis**, one that can be applied universally, and describe the sensorimotor requirements of the myriad of ADLs. The purpose of observation is to understand the client's occupational performance problems in the context of the interaction between the person, the task, and the environment.[6] This type of screening will serve the occupational therapist well in deciding a course of intervention for Raymond, who because of the current exacerbation status of his disease, is not a candidate for more specific muscle strength assessment (see Chapter 22). While observing Raymond in his home as he performs the functional tasks described later in this chapter, the therapist will not only be able to assess available ROM, but also make some determination of the client's muscle strength, endurance, and coordination.

The therapist's scientific knowledge of the particular dysfunction and an analysis of the ways in which activities are generally performed (activity demands) influence the assessment of performance problems and aid in the development of plans to remediate those problems. Analyzing the client while engaged in a specific occupation parallels activity analysis but also allows the practitioner to gain additional knowledge of the client's unique way of performing that occupation.[6]

The following are questions to guide the clinical observation and clinical reasoning processes.

1. Does the client have adequate ROM to perform the task?

   a. Where are the joint limitations?

   b. What are some possible causes of the limitations?

   c. Are there true ROM limitations, or are apparent limitations actually caused by decreased muscle strength?

2. Does the client have enough strength to perform the task?

a. In which muscle groups is there apparent weakness?

b. If strength appears inadequate to perform a task because the client cannot complete the ROM, is there truly muscle weakness, or is there actually limited ROM?

3. Does the client have enough motor control to perform the task?

a. Is the movement smooth and rhythmic?

b. Is movement slow and difficult (eg, as seen in spasticity and rigidity)?

c. Are there extraneous movements when the client performs the task (eg, tremors, athetoid, or choreiform movements)?

The observing OT practitioner must also consider the client's understanding of the instructions and perception of task importance, in addition to the possibility of sensory, perceptual, and cognitive deficits. An analysis of the results of the occupation-based functional motion assessment may indicate that formal assessment of performance skills or body functions is needed. For example, such an assessment may be needed to differentiate muscle weakness from limited ROM or to quantify (with a muscle grade) muscle weakness in specific muscle groups.

Assessing ROM, strength, and motor control by observing the client perform functional activities can aid in selecting meaningful intervention goals relative to improving occupational performance. The therapist can ask the client about his or her ability to perform the tasks of daily living but should also observe the client performing such activities as dressing, walking, standing, and sitting to make an accurate assessment.[5] Having the client perform ADLs in addition to other tasks associated with his or her habits and routines while interacting in varied environmental contexts can also add to the depth of information concerning the client's ROM and muscle strength. The occupational therapist delivering OT services to Raymond has determined that doing both a home visit and job site visit will enhance her understanding of the demands on this client. Observation of Raymond interacting with materials, equipment, tools, and products in these environments will provide information about those critical motions and complex motor patterns required for him to fully engage in those occupations most meaningful to him. Completion of the tasks by Raymond in the timely manner required in these contexts will also give information about the client's endurance, thus giving more information about his muscle strength.

Joint ROM, manual muscle testing, and motor control assessments (see Chapters 19, 21, and 22) will give the therapist specific information about the function of the musculoskeletal, neurophysiological, and sensorimotor systems. Although the tests require minimum to maximum active output by the client, the therapist will not be able to determine the client's ability to integrate these systems to perform specific goal-directed tasks based on the results of these assessments. Rather, the therapist will have information about movements of a specific limb or a combination of limbs. Under carefully controlled conditions, the therapist will know about the flexibility of the components of the joint and the strength of muscles to create movements such as flexion, abduction, and external rotation. However, the client's motor performance capabilities are not measured by these assessments. For example, the manual muscle test cannot measure muscle endurance (number of times the muscle can contract at its maximum level and resist fatigue), motor control (smooth rhythmic interaction of muscle function), or the client's ability to use the muscles for functional activities.[5]

OT Practice Notes

While observing a client performing functional activities, it would be most helpful if a therapist could also estimate the client's existing ROM, muscle strength, and motor control.

At his job site Raymond had difficulty stepping up into his truck (the cab of which was somewhat elevated due to the oversize tires), not having enough hip and knee flexion ROM. The OT also observed that if the truck was parked near a curb or if Raymond could step first on a box and then onto the step of the truck, thus requiring less flexion ROM, he had less difficulty. However, in both instances he lacked sufficient strength in hip and knee extension to launch himself into the truck without compensating with his upper extremities.

Occupation-Based Functional Motion Assessment

The activities listed in the following sections for the occupation-based functional motion assessment are suggested as a general starting place for the student or beginning practitioner (within the guidelines of the roles and responsibilities of the OT or the OTA). Only upper and lower extremity activities are included. Movements of the face, mouth, neck, and spine are beyond the scope of this chapter. Many more motions and tasks could be suggested in each category. The reader is referred to *Joint Motion and Function Assessment: A Research-Based Practical Guide,* by Clarkson,[5] for a comprehensive and detailed discussion of musculoskeletal assessment and its functional application.

Lower Extremity

Because of the somewhat stereotypical movements of the lower extremity, the arrangement of the large muscle groups, and the nature of the overall functions of weight bearing and ambulation, assumptions can be made about muscle strength during functional activities. For example, to assume a normal stance pattern, ambulate without any compensatory gait patterns, or position the lower extremities (without the assistance of the upper extremities) during dressing, a minimum of fair plus (F+) muscle strength is required in the musculature of the hips, knees, ankles, and feet. If muscle strength in the lower extremities is only F throughout the lower extremity, ambulation without aids will not be possible.[7] Good to normal muscle strength is required for the endurance to perform the small postural adjustments needed for maintained standing, repetitive movement patterns inherent in walking, and the lifting, maneuvering, and balancing on the lower limbs that usually occur during dressing.[7]

Hip Complex

The hip joints support the body weight. Each joint acts as a fulcrum when a person is standing on one leg. Hip movement makes it possible to move the body closer to or farther from the ground, bring the foot closer to the trunk, and position the lower limb in space.[5]

During functional activities, lumbar-pelvic movements accompany hip movement, which extends the functional capabilities of the hip joint. The hip is capable of flexion, extension, adduction, abduction, and internal and external rotation.[5]

Flexion and extension.

Full flexion and extension are required for many ADLs and IADLs. Standing requires full hip extension. Squatting, bending to tie a shoelace with the foot on the ground, and toenail care done with the foot on the edge of a chair all require full or nearly full hip flexion. Other activities that require moderate to full flexion and extension are donning pantyhose or socks, bathing the feet in a bathtub, ascending and descending stairs or a step stool, sitting and rising in a standard chair, and riding a stationary bicycle.[5]

Abduction and adduction.

Most ordinary ADLs and IADLs do not require full ranges of abduction and adduction. The main function of the hip abductors is to keep the pelvis level when one foot is off the ground. For ADLs, hip abduction may be used when stepping sideways into a shower or bathtub, donning trousers when sitting, squatting to pick up an object, sitting with the foot across the opposite thigh, getting on a bicycle, or, as in the case of Raymond, shifting weight from one foot to the other as he steps out when swinging the bat.[5,8]

Hip adduction brings the foot across the front of the body. An individual uses this motion when kicking a ball, moving an object on the floor with the foot, or crossing one thigh over the other for donning or removing shoes and socks.[5]

Internal and external rotation.

Internal rotation occurs when a person is pivoting medially on one foot. When a person is sitting, there is internal rotation when the person reaches to the lateral side of the foot for washing or donning socks. Internal rotators are active in walking.[5]

External rotation with hip flexion and abduction brings the foot across the opposite thigh for donning shoes or socks or examining the sole of the foot.[5,8]

Knee

The knee joint supports the body weight. With the foot fixed on the ground, knee flexion lowers the body toward the ground and knee extension raises the body. If the foot is off the ground, as in sitting, the knee and hip are used to orient the foot in space.[5]

Daily living activities that require moderate to full ranges of knee flexion and extension are standing and walking, squatting to lift an object from the floor, crossing the ankle of one foot over the thigh of the opposite leg, sitting down and rising from a chair, and dressing the feet.

Ankle and Foot

The foot is a flexible base of support when a person is on rough terrain. It functions as a rigid lever during terminal stance in the walking pattern. It absorbs shock when transmitting forces between the ground and the leg. The foot and ankle function to elevate the body from the ground when the foot is fixed. Dorsiflexion and plantar flexion occur at the ankle joint. Foot inversion and eversion occur at the subtalar joint.[5]

Plantar flexion.

Full plantar flexion is used when a person is rising on the toes to reach upward to a high shelf. Some plantar flexion is used to depress the accelerator in an automobile or the control pedal on a sewing machine and when donning socks or shoes.

Dorsiflexion.

Full range of dorsiflexion is needed to descend stairs. Dorsiflexion is used in such activities as positioning the foot to cut the toenails or tying shoelaces.[5]

Inversion and eversion.

Inversion and eversion function to provide flexibility when an individual is walking on uneven ground. Inversion is used when the foot is crossed over the opposite thigh and the sole is inspected.[5]

Threaded Case Study

Raymond, Part 2

In administering an occupation-based functional motion assessment at Raymond's home, the occupational therapist was able to observe that in his attempt to don his shoes and socks, Raymond was unable to abduct and externally rotate his hip sufficiently, in combination with full flexion of the knee, to place the ankle of one foot over the opposite thigh.

Upper Extremity

By simply observing a client engaging in functional activities, the therapist cannot make general assumptions as easily about muscle strength in the upper extremities as in the lower extremities. There are three reasons why this is the case: (1) the variety of ways in which the upper extremity can be positioned to complete any given task (ie, there is not one right way to do the task), (2) the complexity of motor patterns possible requiring gross motor and fine motor skill, and (3) the dependency of the distal joints and musculature on the more proximal joints for positioning.

If several people are observed donning shirts, it will be apparent that different techniques are used by each. One person may lift the arm out to the side, increasing shoulder abduction as the shirt is drawn onto the arm. Another person might prefer to dress with the arm more in front of the body, thus positioning the humerus in flexion. A third person might hyperextend the humerus as the shirt is pulled on. The difficulty, of course, is determining exactly how much ROM and muscle strength are minimally required at all of the joints involved when so many options are available to perform one task.

In the first two examples of donning a shirt, the musculature of the shoulder complex would certainly have to create more tension than if the humerus were in the adducted position. It would be inappropriate for the therapist to instruct the client on how to don the shirt if the therapist's goal was to attain some information regarding the client's level of independence in dressing and secondarily to make assumptions about ROM and muscle strength.

When observing a client perform occupation-based tasks and motions with the upper extremities, it is important to remember that even when it is not obvious or readily apparent, the muscles of the shoulder complex are contracting with varying degrees of tension. They may have to contract with enough force to position the hand in space and maintain it there, such as when a person is combing his or her hair. At other times the humerus must be held close to the body to provide a stable base from which the forearm, wrist, and hand can maneuver, such as when hitting the keys on a keyboard, cutting food with a knife, or writing. It would be an inaccurate assumption that the extremity is just hanging passively at the side, when in fact, the static contractions around the proximal joints make it possible for the musculature of the distal extremity to work effectively. Conversely, the shoulder complex may have to be a moving unit, as opposed to a positioning one, such as when moving groceries from a countertop to shelves in a kitchen cabinet.

General guidelines exist for assessing strength for function in the upper extremities. With good to normal endurance, the client with good (G) to normal (N) muscle strength throughout the upper extremity will be able to perform all ordinary ADLs and IADLs, work, play, and enjoy leisure and social participation occupations without undue fatigue.[7] The client with fair plus (F+) muscle strength usually will have low endurance and will fatigue more easily than a client with G to N strength. The client will be able to perform many basic ADLs and IADLs independently, but may need frequent rest periods. Work, play, and some social participation occupations may prove to be too strenuous, as in the case of Raymond attempting to hit a ball with force.

The client with muscle grades of fair (F) will be able to move parts against gravity and perform light tasks that require little or no resistance.[7] Low endurance is a significant problem and will limit the amount of activity that can be done. The client with low endurance probably will be able to eat finger foods and perform light hygiene if given the time and rest periods needed to reach the goals.

Poor (P) strength is considered below functional range, but the client with poor strength will be able to perform some ADLs with mechanical assistance and can maintain ROM independently when the range of motion is completed in gravity-eliminated planes or movement (see Chapter 30, Section 2, Mobile Arm Supports).

Clients with muscle grades of trace (T) and zero (0) will be completely dependent and unable to perform ADLs without externally powered devices. Some activities will be possible with special controls on equipment. Examples include power wheelchairs and electronic communication devices, such as voice recognition computers or environmental control systems.

Individuals use a variety of motor patterns when performing a functional task, and no one way is the right way to perform the task. These facts make it impossible for the therapist to predetermine the level of muscle strength, amount of ROM, and degree of motor control needed in the upper extremity to perform any given task. Individual styles of moving, numerous possibilities for compensatory movements when faced with loss of joint flexibility, poor endurance, lack of motor control, impaired sensation, and pain are all factors that may affect the client's ability to generate tension in a muscle or muscle group and sustain muscle activity. The pain Raymond experiences in his hands may be the primary cause of his inability to manipulate objects such as the buttons on his shirt.

Shoulder Complex

The shoulder complex is the most mobile joint complex in the body. Its function is to move the arm in space and position the hand for function.[9] The shoulder complex is composed of the acromioclavicular, sternoclavicular, scapulothoracic, and glenohumeral joints and the muscles, ligaments, and other structures that move and support these joints.[9,10] In the performance of functional activities, scapular, clavicular, and trunk motions normally accompany glenohumeral motion. These associated movements increase the range of glenohumeral motion for function. The shoulder complex functions in a coordinated manner that is accomplished through scapulothoracic and glenohumeral movement. This coordinated function is called scapulohumeral rhythm.[9,10] Thus, movements at the shoulder are actually combinations of several joint motions and are dependent on scapulohumeral rhythm in the performance of any given activity.[5]

Shoulder flexion and abduction with scapula upward rotation (overhead movements).

Activities such as placing an object (eg, book, box, or cup) on an overhead shelf or reaching overhead to pull on a light cord require these movements.

Shoulder extension and adduction with scapula downward rotation.

Activities such as reaching back for toilet hygiene, Raymond swinging his arm backward when preparing to pitch the softball, reaching backward to put an arm through the sleeve of a coat, and pulling open a refrigerator door require these movements.[5]

Horizontal adduction and abduction.

These movements allow the arm to be moved around the body. Reaching the opposite axilla or opposite ear for hygiene activities, opening and closing a sliding door, combing the hair on the opposite side of the head, and reaching the upper back while bathing are some activities that use horizontal adduction and abduction.[5]

Internal and external rotation.

Some degree of either internal or external rotation accompanies every glenohumeral motion. The ROM varies in various positions of the arm. Full range of external rotation is required for reaching the back of the head for combing or washing the hair. External rotation is often associated with supination when the elbow is extended, as when rotating a doorknob in a clockwise direction.[5]

Internal rotation is used when buttoning a shirt, eating, and drinking from a cup. Full range of internal rotation with scapulothoracic motion is used to reach into a back pocket, fasten a bra, put a belt through the belt loops on trousers, or do toilet hygiene. Internal rotation is often associated with forearm pronation, as when putting a pillow behind the low back, turning a screwdriver to unfasten a screw, rotating a doorknob in a counterclockwise direction, and pouring water from a vessel.[5]

Extension and adduction.

Extension and adduction are used to return the arm to the side of the body from shoulder flexion and abduction, as after reaching overhead. These motions are also used when quick movement or force is required, as when an individual is closing a vertically oriented window, crutch walking, or pushing off to rise from an armchair, or when stabilizing the humerus to the lateral trunk, as when carrying a basket of laundry.[5]

Flexion and adduction.

Flexion and adduction are used in activities that require reaching the same side of the body, such as washing the cheek or ear and combing the hair on the same side. Slight shoulder flexion with adduction is used for hand-to-mouth activities and putting on an earring back.

Elbow and Forearm

Elbow and forearm movements serve to place the hand for function.[9] Elbow flexion moves the hand toward the body, and elbow extension moves the hand away from the body. Forearm pronation or supination usually accompanies elbow flexion and extension. Pronation and supination position the hand precisely for the requirements of the given activity. The elbow and forearm support skilled and forceful movements of the hand that are used during performance of ADLs and work activities.[5]

Full or nearly full range of elbow flexion, usually with some humeral flexion and forearm supination, is used to bring food to the mouth, shave the face or underarms, hold a telephone receiver, place an earring on the ear, and reach the neck level of a back zipper.

Full range of elbow extension, usually with forearm pronation, is used when an individual is reaching to the feet to tie shoes, throwing a ball overhand, and using the arms to push off from a chair. Many other ADLs and IADLs require less than full range of these movements.[5]

Wrist and Hand

The wrist controls the length-tension relations of the extrinsic muscles of the hand. It positions the hand relative to the forearm for touch, grasp, or manipulation of objects.[8] Wrist extension and ulnar deviation are most important in performance of ADLs.[5] It is possible to perform some ADLs when there is a loss of wrist ROM by using compensatory movements of the proximal joints.

The primary functions of the hand are to grasp and manipulate objects and to discriminate sensory information about objects in the environment. The arches of the hand make it possible to adapt the hand to the shape of the object being manipulated.[12]

Power grip and precision grip are the bases of all hand activities. Power grip is used when force is required for grasping, such as holding a hammer handle, a full glass, or the handle of a purse or suitcase. Precision grip is used when an object is pinched and when it is being manipulated between the thumb and one or more fingers. Precision grip is used for holding a pencil, moving checkers or chess pieces, turning a key, threading a needle, and opening the cap of a medicine bottle.[12]

The occupational therapist observed Raymond in his home as he was preparing to make homemade soup. She noted that Raymond easily accessed ingredients that were on the first two shelves of above-counter cabinets, but displayed quite a bit of facial grimacing and two attempts reaching overhead to the top shelf. He was observed being able to fully open his fingers but not able to make a tight fist. When chopping vegetables, he was able to manage the less resistive ones, such as tomatoes and celery, but could not exert enough force to cut through the carrots. Although he could carry an empty pot to the sink without difficulty, he was not able to stabilize his wrists to carry a full pot of water to the stove. At his job site the occupational therapist again noted Raymond having difficulty holding some of the heavier tools in position and exerting appropriate force, such as with the large wire cutters.

Threaded Case Study

Raymond, Part 3

Due to the difficulty Raymond experienced when donning his socks and shoes, getting in and out of his truck, reaching overhead, and manipulating and applying needed force to kitchen and work tools, the occupational therapist has determined that ROM and muscle testing assessments should be administered to some of this client's specific joints and muscles.

After the occupation-based functional motion assessment, the next step in the OT process would be for the OT to plan the intervention. See Chapter 38 (Arthritis) for some ideas for interventions that could be implemented to return Raymond to participation in his customary rounds of occupation. Also, refer back to the beginning of this chapter and reflect on the three probative questions posed at the end of Raymond's case study; be able to describe the advantages of using the occupation-based functional motion assessment, the amount and type of information that was gleaned regarding Raymond from this assessment, and the value to the OT of conducting this assessment in both the home and work contexts and environments.

Summary

Many physical disabilities cause deficits in ROM, strength, and motor control that limit occupational performance. The occupational therapy practitioner (ie, the OT or the OTA under the supervision of the OT) is primarily responsible for assessing occupational performance, identifying performance problems, and planning intervention that will improve the client's occupational performance.

Because people perform the same activity in a variety of ways, the level of ROM, strength, or motor control needed to do a task is variable. Assessment of physical limitations can be made through observation of a client's performance while engaged in a variety of occupations. Therefore, as in the case of Raymond, the therapist must observe the client performing selected tasks in the person-task-environment interaction.[6]

While assessing the client's ability to perform ADLs, IADLs, work, or leisure occupations, the therapist should observe for sensorimotor problems. An analysis of the results of observation may indicate that an assessment of specific body factors or performance skills is needed.

Questions to guide clinical observation and clinical reasoning and suggested activities to assess function of the upper and lower extremities were outlined in this chapter.

Review Questions

1. Compare and contrast functional motion assessment with occupation-based task and motion assessment.
2. In occupation-based practice, how are sensorimotor functions first assessed?
3. What is meant by individual activity analysis?
4. Why is it not possible to do an objective activity analysis?
5. List three major questions that can guide the clinical observation and clinical reasoning of the OT practitioner when doing a occupation-based functional motion assessment.
6. Which factors, other than strength, ROM, and motor control, can affect the functional task-motion assessment?
7. How is the information gained from assessment of specific body factors different from that gained in an occupation-based functional motion assessment?
8. What is the minimum level of strength required throughout the lower extremities for normal stance and positioning?
9. List some activities or occupations that can be used to assess general function in the lower extremities: hip, knee, ankle, and foot.
10. Compare levels of muscle strength with endurance in the upper extremities.
11. List some activities that can be used to assess general function in the upper extremities: shoulder complex, elbow and forearm, and wrist and hand.

[a]In this chapter, the term *occupational therapy practitioner* refers to occupational therapists (OTs) or occupational therapy assistants (OTAs) as defined in the current version (2014) of the OT Framework, the "Occupational Therapy Practice Framework: Domain and Process," third edition (OTPF-3).[1] Throughout the chapter distinctions will be made regarding which practitioner, when appropriate, depending on the job responsibilities of each in the evaluation process as defined in three important documents published by the American Occupational Therapy Association (AOTA): the Standards of Practice for Occupational Therapy,[3] the Guidelines for Supervision, Roles, and Responsibilities During the Delivery of Occupational Therapy Services,[2] and the Scope of Practice for Occupational Therapy.[4] In general, the OT is responsible for all aspects of the evaluation process, and the OTA contributes to the process under the supervision of the OT.

Joint Range of Motion*

Tim Shurtleff, Vicki Kaskutas

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, the student or practitioner will be able to do the following:

1. Define active, passive, and functional range of motion (ROM).
2. List the purposes of measuring ROM.
3. Name two methods used to screen for ROM limitations.
4. Name disabilities for which joint measurement is often an assessment tool.

5. Describe how ROM measurements are used to select intervention goals and methods.
6. Describe how to establish ROM norms for clients with unilateral involvement.
7. Describe what the therapist should do before actually measuring the joints with the goniometer.
8. Describe proper positioning of the therapist and methods to support limbs.
9. List precautions for and contraindications to joint measurement.
10. List and describe the steps in the joint measurement procedure in correct order.
11. Describe how to record results of the joint measurement.
12. Measure all the joints of a typical practice subject by using the 180-degree method and correct procedure.
13. Describe at least three intervention strategies that can be used to increase ROM.

KEY TERMS

Active range of motion

End-feel

Functional range of motion

Goniometer

Threaded Case Study

Evelyn, Part 1

Evelyn is an 83-year-old woman who sustained a Colles fracture when she fell on her outstretched, nondominant left hand in an attempt to break her fall after tripping on a doorstop as she exited a building. The fracture was reduced, and Evelyn was placed in a hand-to-below-elbow cast for 6 weeks. On removal of the cast, Evelyn's wrist and hand appeared swollen. She complained of pain and stiffness in the carpometacarpal and metacarpal joints of her thumb and the metacarpophalangeal and proximal interphalangeal joints of her fingers. She was unable to make a fist or oppose her thumb to her fingers.

Evelyn is a widow; her two grown children live nearby. Before her injury she was independent in all activities of daily living and the majority of instrumental activities of daily living. She used public transportation to move around her community, although her children and friends usually drove her to appointments. Evelyn volunteered at the local hospital weekly in its telecare program and called elderly, homebound persons. She is an accomplished seamstress, makes all of her own clothing, and attends a weekly sewing class, primarily for the camaraderie of the other students, although she states, “There is always something new to learn.” She also enjoys baking for her family, gardening, and generally engaging in tasks that contribute to the upkeep of her home. She attends church regularly and enjoys dining out with friends and family members.

Since her injury, her ability to participate in occupations that are meaningful to her has been curtailed. She requires moderate to maximal assistance to hold a utensil in her left hand while cutting food with her right, wash and groom her hair, put on jewelry, bathe the right side of her body, transfer out of the bathtub, and engage in home maintenance tasks (e.g., changing bed linen). At her volunteer work site, she is unable to hold the telephone with her left hand while writing with her right hand. When cooking, she has difficulty stabilizing bowls, pots, and pans with her left hand while manipulating a cooking utensil with her right. Evelyn is experiencing a great deal of frustration with her loss of independence and inability to fully engage in occupations that got her out in the community and facilitated interaction with others.

In reviewing Evelyn's occupational profile, the occupational therapist must focus on client factors that are interfering with function. Loss of range of motion (ROM) in her left upper extremity, especially the inability to flex the fingers to make a fist and oppose the thumb to the fingers, which is required for fine motor activities, is prohibiting the client from fully engaging in the physical, social, personal, cultural, and spiritual contexts that bring meaning to her life. Before determining intervention goals and strategies, the therapist must assess her ROM limitations to establish a baseline for treatment. While reading and studying this chapter, keep in mind Evelyn's ROM limitations and the restrictions they impose on her engagement in occupation.

Critical Thinking Questions

1. Why should the occupational therapist proceed with caution when assessing the ROM limitations of this client?

2. What is the appropriate sequencing of joint measurement assessment for this client? What methods should be applied first?

3. What is the advantage of joint measurement in evidence-based practice?

Joint **range of motion** (ROM) is the amount of movement that is possible at a joint.[3] It is the arc of motion at a joint within a specific plane. When the joint is moved by the muscles that act on the joint, it is called **active range of motion** (AROM). When the joint is moved by an outside force such as the therapist, it is called **passive range of motion** (PROM).[3] In normal individuals, PROM is slightly greater than AROM because of the slight elasticity of soft tissue.[3,10] The additional PROM available at the end of normal AROM helps protect joint structures because it allows the joint to give and absorb extrinsic forces. If PROM is significantly greater than AROM for the same joint motion, muscle weakness is likely to be present.[14]

Decreased ROM can cause limited function and interfere with performance in areas of occupation. Limitations in ROM may occur as a result of injury to or disease in the joint itself or the surrounding joint tissue structures, joint trauma, or joint immobilization. These limitations may restrict the client's ability to perform successfully in chosen day-to-day occupations. Inflexibility at a joint may adversely affect both speed and strength of movement. A client who constantly has to work to overcome the resistance of an inflexible joint will probably demonstrate decreased endurance and fatigue during activity. The functional motion test (see Chapter 20), screening tests, and measurement of joint ROM with a goniometer can all be used to assess ROM.

OT Practice Notes

The primary concern of the occupational therapist is whether ROM is adequate for the client to engage in meaningful occupations.

Methods used to screen limitations in ROM involve the observation of AROM and PROM. To screen for AROM, the therapist asks the client to perform all the active movements that occur at the joint.[3] To screen for PROM, the therapist moves the joint passively through all of its motions to estimate ROM, detect limitations, and observe the quality of movement, **end-feel**, and the presence of pain.[3] The therapist can then decide at which joints precise ROM measurement is indicated.

Joint Measurement

The joints of the body need to move fluidly to perform the activities and occupations that people find meaningful, such as driving, parenting, working, playing, studying, and social participation. Reaching overhead to shampoo hair, squatting to pick up a child, and operating the foot pedals in an automobile require joint movements. A wide array of personal factors will influence joint motion, such as aging, obesity, developmental conditions, injuries and illnesses, and chronic health conditions. Body structures that affect joint range of motion include the bones and joints, ligaments and cartilage, muscles and tendons, skin and fat, and nervous system. The ability to generate tension of the muscles that are performing the movement is important, as is the ability of the muscles on the opposite side of the joint to be stretched to allow movement. Restricted ROM may result from skin contracture caused by adhesions or scar tissue; arthritis, fractures, burns, and hand trauma; displacement of fibrocartilage or the presence of other foreign bodies in the joint; bony obstruction or destruction; or soft tissue contractures, such as tendon, muscle, or ligament shortening. Limited ROM may be secondary to spasticity, muscle weakness, pain, and edema.[8,14] For example, for full knee extension ROM to occur, the muscles that straighten the knee must have adequate contractibility and the muscles that flex the knee must be long enough to stretch across the backside of the knee. Lifestyle, environmental, and occupational factors can also have an effect on joint mobility. Goniometry is an evaluation tool used to assess range of motion of the joints of the body.

ROM measurements can help the therapist identify treatment goals, intervention methods, and preventive activities to restore, compensate, modify, and prevent limitations and enhance occupational performance. ROM measurement is useful to identify limitations that interfere with function or may produce deformity, additional motion needed to increase functional capacity or reduce deformity, the need for splints and assistive devices, and progression of treatment. The use of formal **joint measurement** will assist in determining the efficacy of intervention modalities and may also serve as evidence in assisting the client to see the outcome of the intervention through quantifiable data.

Tables documenting ranges for normal ROM measurements exist in the literature.[3] These may be useful guides; however, ROM varies from one person to another. It is important to avoid making assumptions about ROM limitations identified when comparing to normative values—the client may be able to function remarkably well with the ROM limitations, whereas he or she may need more ROM than is considered “normal” to perform an especially meaningful activity. The occupational history and client interview will help identify baseline ROM. If one extremity is impaired, the analogous uninvolved part can also be a useful guide.[3,4] The presence of joint and other structural limitations from previous health conditions as well as the immediate illness or injury should be considered. Joints should not be forced when resistance is met on PROM. Pain may limit ROM, and crepitus (a grinding, crackling sound or feeling) may be heard or felt with movement in some conditions. Therefore before beginning joint measurement procedures, the therapist must explain what will be done and ask the client if he or she is experiencing any joint pain and, if so, where it is located and how severe it is. To not cause undue pain, the occupational therapist further explains to the client the importance of indicating any changes in pain throughout the procedure.

Planes and Axes of Movement

It is important to understand the planes and axes of movement. Motion occurs in three cardinal planes, one that is horizontal (the transverse plane) and two of which are vertical (the frontal [coronal] and sagittal planes) (Fig. 21.1). The axes, which are perpendicular to the joint, are the pivot point for the joints. The frontal (coronal) plane divides the body into anterior (front) and posterior (back) portions. Motions that occur in the frontal plane include abduction, adduction, and spine lateral flexion to the right and left (side bending) (Fig. 21.2). The sagittal plane divides the body into right and left portions—whether it is through the center of the entire body (spine) or through an extremity (upper or lower extremity). Motions that occur in the sagittal plane are flexion and extension (Fig. 21.3). The transverse (horizontal) plane divides the body into upper and lower portions—motion occurs around a vertical axis in the transverse plane, whether it is rotation to the right and left (spine), internal and external rotation (shoulder and hip), or pronation and supination (forearm) (Fig. 21.4).

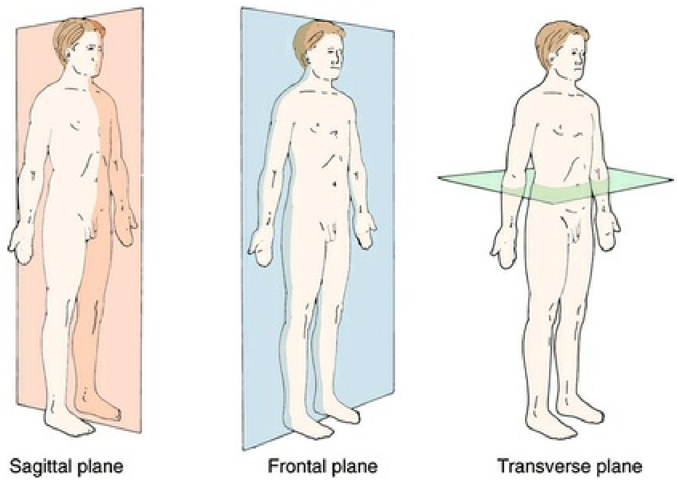

FIG 21.1 Sagittal, frontal, and transverse planes. (From Cameron MH, Monroe L: *Physical rehabilitation for the physical therapist assistant,* St. Louis, 2011, Saunders.)

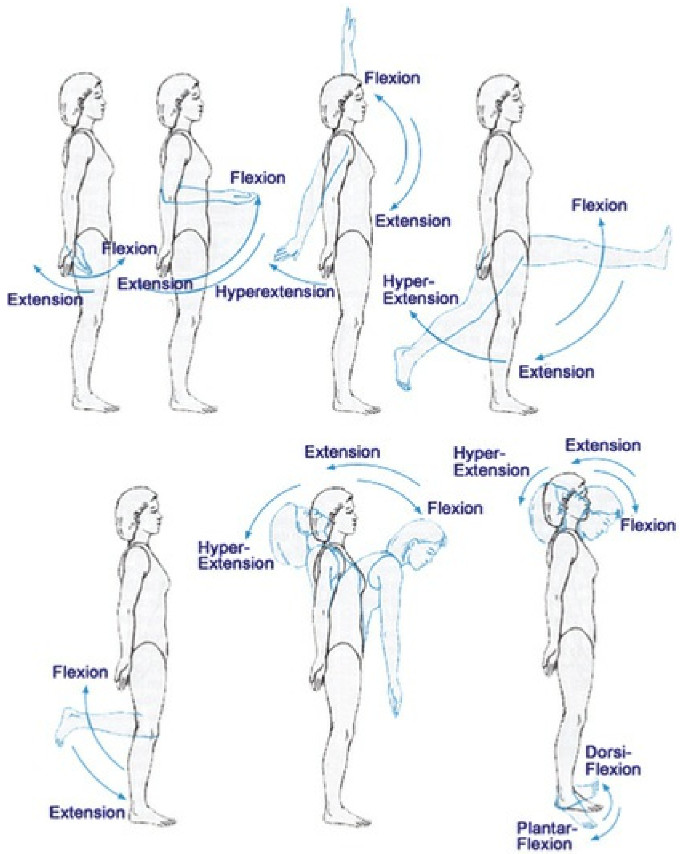

FIG 21.2 Motions that occur in the frontal plane include abduction, adduction, and spine lateral flexion to the right and left (side-bending). (Reprinted with permission from PM McGinnis: *Biomechanics of sport and exercise,* ed 3, pp. 184–185, Champaign, IL, Human Kinetics, 2013.)

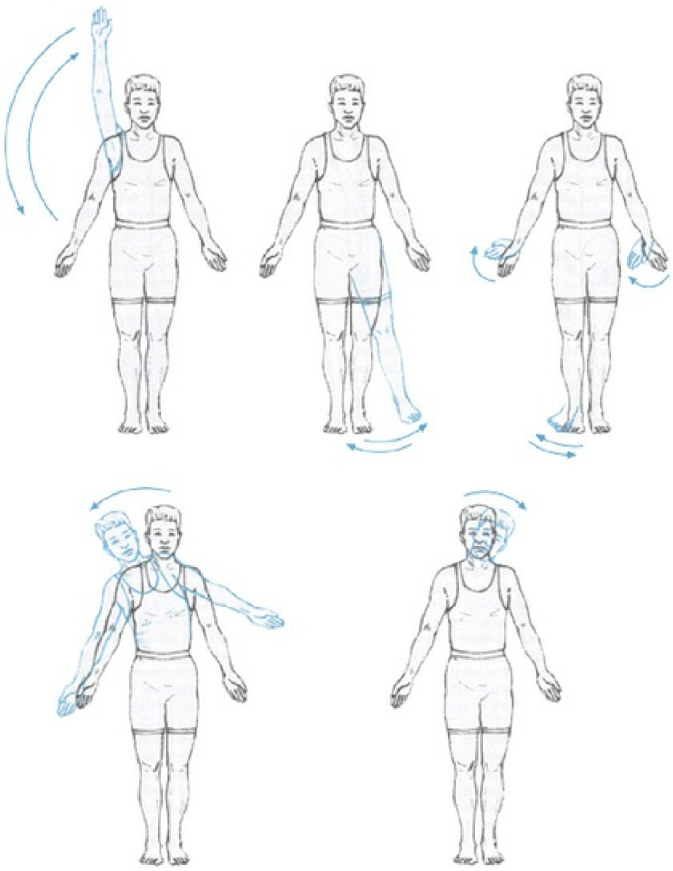

FIG 21.3 Motions that occur in the sagittal plane are flexion and extension. (Reprinted with permission from PM McGinnis: *Biomechanics of sport and exercise,* ed 3, p. 186, Champaign, IL, Human Kinetics, 2013.)

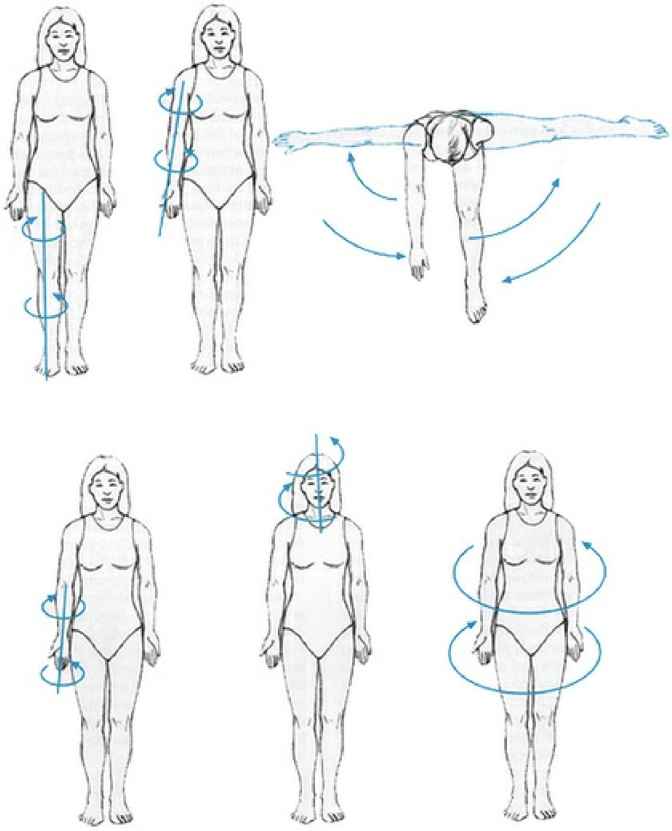

FIG 21.4 The transverse (horizontal) plane divides the body into upper and lower portions: motion occurs around a vertical axis in the transverse plane, whether it is rotation to the right and left (spine), internal and external rotation (shoulder and hip), or pronation and supination (forearm). (Reprinted with permission from PM McGinnis: *Biomechanics of sport and exercise,* ed 3, p. 188, Champaign, IL, Human Kinetics, 2013.)

Principles and Procedures in Joint Measurement

Before measuring ROM, the therapist should be familiar with average normal ROM ranges, joint structure and function, normal end-feel, safe handling methods, and bony landmarks related to each joint and joint axis.[3,4,10] The therapist should be skilled in correct positioning and stabilization for measurements, palpation, alignment and reading of the goniometer, and accurate recording of measurements.[10] For the most reliable measurements, it is best that the same therapist assesses and reassesses the client at the same time of day with the same instrument and the same measurement protocol.[3] Because that is not always feasible, when there are alternative measurement protocols and tools, the specific protocol used for measurement must be described with the measurement data to ensure test-retest and interrater reliability.

Visual Observation

The joint to be measured should be exposed, and the therapist should observe the joint and adjacent areas.[3] The therapist asks the client to move the part through the available ROM actively and independently, if muscle strength is adequate, and observes the movement.[4] The therapist should look for compensatory motions, posture, muscle contours, skin color and condition, and skin creases and compare the joint with the noninjured part, if possible.[3] The therapist should then move the part through its range to the tolerance of the client to see and feel how the joint moves and to estimate ROM.

Palpation

Feeling the bony landmarks and soft tissue around the joint is an essential skill gained with practice and experience. The pads of the index and middle fingers are used for **palpation**. The thumb is sometimes used. The therapist's fingernails should not make contact with the client's skin. Pressure is applied gently but firmly enough to detect underlying muscle, tendons, or bony structures. For joint measurement, the therapist must palpate to locate bony landmarks for placement of the goniometer.[3]

Positioning of Therapist and Support of Limbs

The therapist's position varies, depending on the joints being measured. When measuring finger or wrist joints, the therapist may sit next to or opposite the client. If sitting next to the client, the therapist should measure the wrist and finger joints on that side and then move to the other side to measure the joints on the client's opposite side. This procedure makes the client more comfortable (eliminating the need to stretch across the midline) and ensures more accurate placement of the goniometer. When measuring the larger joints of the upper or lower extremity, the therapist may stand next to the client on the side being measured. The client may be seated or lying down. The therapist needs to use good body mechanics when reaching, lifting, and moving heavy limbs. The therapist should use a broad base of support and stand with the head upright while keeping the back straight. The feet should be shoulde-width apart, with the knees slightly flexed. The therapist's stance should be in line with the direction of movement. The therapist should be positioned close to the client when lifting the limb. The limb should be supported at its center of gravity, approximately where the upper and middle thirds of the segment meet. To ensure patient comfort, the therapist's hands should be in a relaxed broad grasp that conforms to the contours of the part without pinching or allowing fingers to dig into the body part. The therapist can provide additional support by resting the part on his or her forearm.[3]

Precautions and Contraindications

In some instances, measuring joint ROM is contraindicated or should be undertaken with extreme caution. It is contraindicated if there is a joint dislocation or unhealed fracture, immediately after surgery on any soft tissue structures surrounding joints, in the presence of myositis ossificans, or when ectopic ossification is a possibility.[3]

Joint measurement must always be done carefully. The following situations call for extreme caution:

1. The client has joint inflammation or an infection.

2. The client is taking either medication for pain or muscle relaxants.

3. The client has osteoporosis, osteoarthritis or rheumatoid arthritis, hypermobility, or subluxation of a joint.

4. The client has hemophilia.

5. The client has a hematoma.

6. The client has just sustained an injury to soft tissue.

7. The client has a newly united fracture.

8. The client has undergone prolonged immobilization.

9. Bony ankyloses or excessive osteophyte formation around joint surfaces is suspected.

10. The client has carcinoma of the bone or any fragile bone condition (e.g., osteogenesis imperfecta [brittle bone disease]).[3,9]

End-Feel

PROM is normally limited by the structure and health of the joint and surrounding soft tissues. Thus ligaments, the joint capsule, muscle and tendon tension, contact of joint surfaces, and soft tissue approximation may limit the end of a particular ROM. Each of these structures has a different end-feel as the therapist moves the joint passively through its ROM. End-feel is the normal resistance to further joint motion because of stretching of soft tissue, ligamentous and joint capsule limitations, approximation of soft tissue, and contact of bone on bone. End-feel is normal when full ROM is achieved and the motion is limited by normal anatomical structures. Abnormal end-feel occurs when ROM is increased or decreased or when ROM is normal but structures other than normal anatomy stop the ROM.[3]

End-feel is normally classified as hard, soft, or firm. An example of hard end-feel is bone contacting bone when the elbow is passively extended and the olecranon process comes into contact with the olecranon fossa. Soft end-feel can be detected on elbow flexion when there is soft tissue apposition of the forearm with the elbow flexor muscles of the upper arm. A firm end-feel has a firm or springy sensation that has some give, as when the ankle is dorsiflexed with the knee in extension and ROM is limited by tension in the gastrocnemius muscle.[3]

In pathological states, end-feel is abnormal when PROM is increased or decreased significantly from the standards listed below or when PROM is normal but movement is stopped by structures other than normal anatomy.[3] For example, elbow flexion may have a hard end-feel due to a bony osteophyte or surgically implanted plate, or the end-feel may be firmer than normal due to excessively large muscle bulk. Practice and sensitivity are required for the therapist to detect different end-feels and to distinguish normal from abnormal.[3,10] The normal end-feel for each joint and directions for joint measurement are described in the following sections.

Two-Joint Muscles

Many of the deep muscles that move a joint cross only one joint; however, the more superficial muscles usually cross two or more joints. When a one-joint muscle contracts, it moves the one joint that it acts at; subsequently this muscle is stretched when the one joint that the muscle crosses is moved in the opposite direction. Because two-joint muscles act at two joints, they oppose the motion of two joints. A muscle that crosses two or more joints is not long enough to allow for full stretch when the joints that it crosses are simultaneously moved in the opposite direction. A two-joint muscle feels taut when it is at its full length over both joints that it crosses and before it reaches the limits of the normal ROM of both joints.[7] Positioning is of utmost importance as ROM at one joint may be affected by the position of the other joint due to passive insufficiency.[3] For example, the extrinsic finger flexor muscles cross anterior to the wrist and finger joints, so they have insufficient length to allow for simultaneous extension of the wrist and fingers. When joints crossed by two-joint muscles are being measured, it is necessary to place the other joint (the one not being measured) in a neutral or relaxed position to place the two-joint muscle on slack. In the finger flexor example, the wrist should be placed in a neutral position when measuring finger extension ROM to prevent passive insufficiency of the extrinsic finger flexor from restricting finger extension ROM. Similarly, when hip flexion is being measured, the knee should be flexed to place the hamstrings in the slackened position[3], and when knee flexion is measured, the hip should be flexed to relax the rectus femoris which crosses both the hip and knee joints. Avoiding passive insufficiency ensures that the measurement of a joint actually measures only the limits of the joint, and not unintended limits of the muscles.

Methods of Joint Measurement

There are two systems for measuring joint ROM: the 180-degree and the 360-degree systems. Both systems use a **goniometer**, a protractor with two arms (movable and static), to measure ROM. The goniometer is superimposed on the body in the plane in which the motion is to occur. The axis of the goniometer is placed on the moving joint, and the two arms are placed on the body parts that form the joint. When measuring the elbow joint, the axis is at the elbow, the static arm is on the proximal upper extremity, and the movable arm is on the forearm. In the 360-degree system the protractor is a full circle, whereas the protractor is a half circle in the 180-degree system. Either system can be used to measure the moving elbow joint with results easily transposed between systems. This chapter focuses on the 180-degree system; however, the 360-degree system is also briefly discussed.

180-Degree System

In the 180-degree system of joint measurement, the 0-degree position is the starting point for all joint motions. For most motions, the anatomical position (Fig. 21.5) is the starting or 0-degree position. All joint motions begin at the 0-degree position and increase toward 180 degrees.[3,5,10] Some motions cannot be related to the full circle. In these instances, a 0-degree starting position is designated (as anatomical or neutral position), and the movements are measured as increases from the 0-degree position. These motions occur in a horizontal plane around a vertical axis. They are forearm pronation and supination, hip and shoulder internal and external rotation, wrist radial and ulnar deviation, and thumb palmar and radial abduction (carpometacarpal flexion and extension).[5]

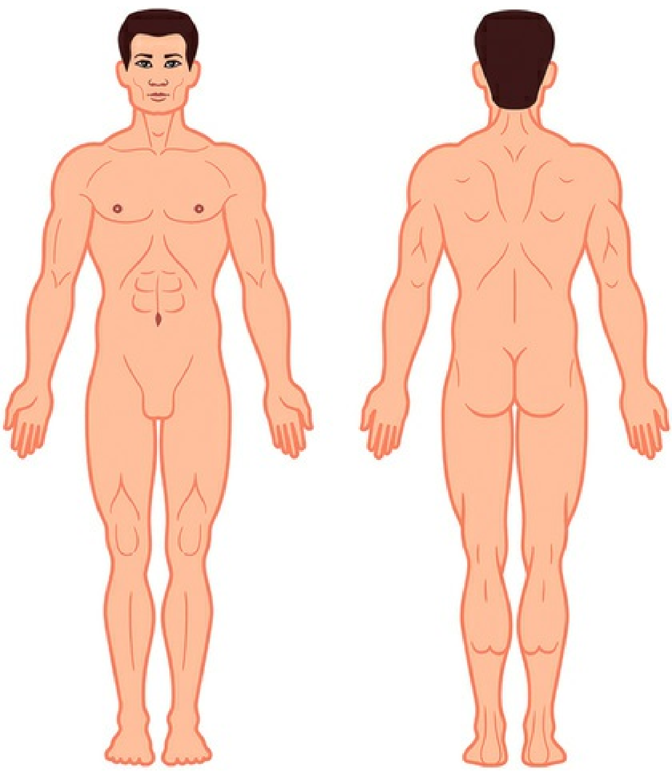

FIG 21.5 For most motions, the anatomical position is the starting or 0-degree position. (From GettyImages.com.)

360-Degree System

In this system, movements occurring in the coronal and sagittal planes are related to the full circle.

When the body is in the anatomical position, the circle is superimposed on it in the same plane in which the motion is to occur, with the goniometer axis placed on the joint center in line with the axis of movement. "The 0-degree (360-degree) position will be overhead and the 180-degree position will be toward the feet."[5] Thus, for example, shoulder flexion and abduction are movements that proceed toward the 0-degree position, and shoulder adduction and extension proceed toward the 360-degree position. The average normal ROM for shoulder flexion is 170 degrees. Therefore in the 360-degree system, the movement would start at 180 degrees and progress toward 0 to 10 degrees. The ROM recorded would be 10 degrees. On the other hand, shoulder extension that has a normal ROM of 60 degrees would begin at 180 degrees and progress toward 360 to 240 degrees, and 240 degrees would be the ROM recorded.[5] The total ROM of extension to flexion would be 240 to 10 degrees—that is, 230 degrees.[5,6]

Goniometers

Usually made of metal or plastic, goniometers come in several sizes and types and are available from medical and rehabilitation equipment companies.[5,10,11] The word *goniometer* is derived from the Greek *gonia,* which means "angle," and *metron,* which means "measure."[9,15] Thus goniometer literally means "to measure angles." The universal goniometer consists of a body attached to a stationary (proximal) bar, and a movable (distal) bar.[3,10] The stationary bar is attached to the body of the goniometer. The body is a half-circle or a full-circle protractor printed with a scale of degrees from 0 to 180 for the half-circle and 0 to 360 for the full-circle goniometer.[3,4] The movable bar is attached at the center, or axis, of the protractor and has a line or pointer on the protractor. As the movable bar rotates around the axis, the dial points to the number of degrees on the protractor scale.

Two scales of figures are printed on the half circle. Each starts at the 0-degree point and progresses toward 180 degrees, but in opposite directions, often printed in black and red. Because the starting position in the 180-degree system is always at the 0-degree point and increases toward 180 degrees, the outer row of figures is read if the bony segments being measured are end to end, as in elbow flexion. The inner row of figures is read if the bony segments being measured are alongside one another in anatomical position, as in shoulder flexion. The scale to read is the one that reads zero in the anatomically neutral position.

To ensure accuracy, it is best to use a goniometer that is long enough to allow for the stationary and movable arms to align over the majority of the length of the body parts that articulate at the joint. The grommet or rivet of the goniometer, which acts as the axis, must move freely yet be tight enough to remain where it was set when the goniometer is removed to be read after alignment with the joint.[4] For easy, accurate readings, some goniometers have a locking nut that can be tightened just before the goniometer is removed.[5] Plastic goniometers wear with age, can become loose, and are sometimes even loose when new. This makes them difficult to use because they do not stay in a final position to be read. Plastic goniometers may be tightened by gently tapping with a hammer on the rivet or grommet or squeezing it with pliers to approximate the plastic in a tightened position. The arms of the goniometer should be able to be moved with a gentle force applied with one hand, and the arms should stay in the position placed in during joint measurement.

Fig. 21.6 shows several types and styles of goniometers. The first five (labeled A-E in Fig. 21.6) are full-circle goniometers that have calibrations for both the 360-degree and the 180-degree systems printed on their face. B, C, and D have longer arms and are usually best for use on the large joints of the body. B and C are the same size, but note that one is shaded plastic and one is clear. They function the same and shading or clear may be more visible in some situations (as will become obvious with some of the pictures later in the chapter). F and H have half-circle protractors used for the 180-degree system. F is simply an inexpensive 6″ goniometer, like H, that has been cut to more easily measure the small joints of the hand and digits. The movable arms on F and H have an extension that crosses the axis and allows one to read either scale regardless of whether the convexity of the half circle is directed toward or away from the direction of motion. Thus the evaluator does not have to reverse the goniometer and thereby obscure the scale to read it. G, I, and J are special finger and hand goniometers (see Fig. 21.6). G and J have arms that are short and flattened. They are designed to lie flat over the finger joints and adjacent dorsal surfaces rather than on their lateral aspects, as is done for most of the larger joint motions. This style is also designed to be used on the hand and digits, but the protractor itself rotates and the flat side follows the dorsal surface of the joints of the hand rather than the arm rotating on the stationary protractor. Small plastic goniometers E and H are for finger measurement—these are inexpensive and easy to carry.

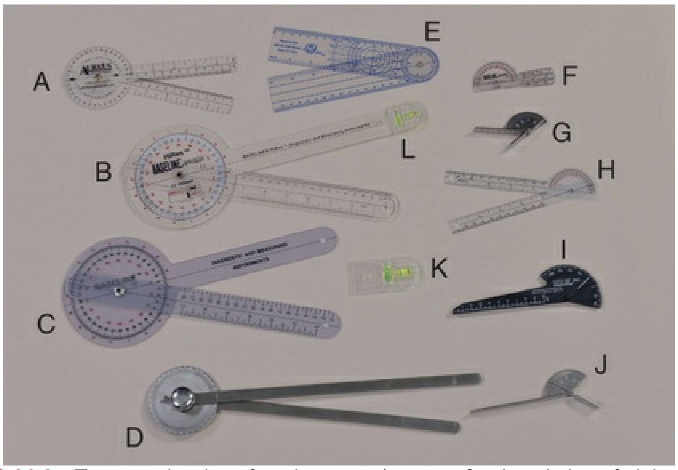

FIG 21.6 Types and styles of goniometers (see text for description of alphas).

Note that one of the larger goniometers (L) has a set of spirit levels on the end of the stationary bar. These enable correct vertical and horizontal orientation of the stationary bar and protractor for movements that are compared to the level line of the world when a patient is in anatomical or neutral position, (e.g., forearm pronation and supination, internal and external rotation of the shoulder when measured in abduction). K is a spirit level that can be slipped over the end of a large (12″) goniometer like C and removed when not needed.

Other types of goniometers are available. Some are inclinometers which have a fluid indicator that responds to gravity and provides the reading after the motion is completed but they must be read while they are on the body part.[5] Others can be attached to two body segments and have dials that register ROM electronically with digital output, but are usually only used in research settings. There are special goniometers for cervical and spine ROM measurements and for forearm rotation.[11] A tape measure or metric scale may also be used on some joints by measuring the distance between two segments; for example, the distance between the chin and chest when measuring cervical flexion, extension, and rotation (see the table dealing with the Motion Screen sequence) the distance between the center of the tips of two fingers for finger flexion or abduction (see Fig. 21.36, presented later in the chapter) and the distance between the tip of the thumb and the tip of the little finger for opposition (see Fig. 21.42, presented later in the chapter).[3]

Recording Measurements

180-Degree System

When using the 180-degree system, the evaluator should record the number of degrees at the starting position and the number of degrees at the final position after the joint has passed through the maximum arc of motion possible.[10] Normal ROM always starts at the 0-degree point in anatomical or neutral positions and increases toward 180 degrees. When it is not possible to start the motion at the 0-degree position because of limitation of motion, ROM is recorded by writing the number of degrees at the starting position followed by the number of degrees at the final position.[3] For example, elbow ROM limitations can be noted as follows:

- Normal: 0 to 140 degrees
- Extension limitation: 15 to 140 degrees
- Flexion limitation: 0 to 110 degrees
- Flexion and extension limitation: 15 to 110 degrees

Abnormal hyperextension of the elbow may be recorded by indicating the number of degrees of hyperextension below the 0-degree starting position with a minus sign, followed by the 0-degree position and then the number of degrees at the final position.[10] This may be noted as follows:

- Normal: 0 to 140 degrees
- Abnormal hyperextension: −20 to 0 to 140 degrees. A potential problem with this numbering system is that it works for an elbow but does not work well for joints like shoulders, hips, and metacarpals that naturally move past zero without indicating a potentially pathological excess ROM, which was written with the negative number previously.

An alternative that avoids this problem is the three number system. The three number system is used in joints that can move in either direction past their neutral position with zero being the typical anatomical position. No negative numbers are ever used to avoid the confusion cited earlier. For example, a shoulder may flex to 160 degrees, go through zero when hanging down in neutral (anatomical) position, and then continue in the sagittal plane to extend to 60 degrees of extension. This is written as 160/0/60. As in the preceding example, an elbow may flex to 140 degrees, straighten to zero, and go no farther with no hyperextension (140/0/0). But it may also hyperextend to 15 degrees, and the numbers would be written as 140/0/15. However, some people cannot completely extend their elbows to zero. Maybe they can only get to 12 degrees, slightly flexed. In this case their own unique neutral is 12 degrees and not the theoretical zero. This would be written as 140/12/0, indicating that they cannot go past 12 degrees of flexion (their joint's limit). The zero indicates that there is no extension or hyperextension beyond their unique neutral. Shoulder internal and external rotation is recorded similarly. Examples include pronation/0/supination of the forearm, flexion/0/extension, radial/0/ulnar deviation of the wrist and some smaller joints of the hand and analogous movements of the lower extremities. In each of these joints, it may be simpler and more efficient to write their movement with the zero (anatomical position) at a theoretical midpoint between the two extremes.

However, because there are alternative methods of recording ROM, the evaluator is advised to learn and adopt the particular method commonly and consistently used by the healthcare facility and professional peers with whom he or she works to limit any misunderstanding of AROM or PROM notation.

A sample form for recording ROM measurements is shown in Fig. 21.7. Average normal ROM for each joint motion is listed on the form and in Table 21.1. When recording ROM, there are rare instances when it is clinically important to measure every joint on the form. Every space on the form should be filled in with numbers for those joints tested. If the joint was not tested, "NT" should be entered in the space or some sections lined through to avoid confusion in the future.[3]

JOINT RANGE MEASUREMENTS

Client's name ______________________ Chart no. __________

TABLE 21.1
Average Normal Range of Motion (180-Degree Method)

Joint	Range of Motion	Associated Girdle Motion
Cervical Spine		
Flexion	0 to 45 degrees	
Extension	0 to 45 degrees	
Lateral flexion	0 to 45 degrees	
Rotation	0 to 60 degrees	
Thoracic and Lumbar Spine		
Flexion	0 to 80 degrees	
Extension	0 to 30 degrees	

Lateral flexion	0 to 40 degrees	
Rotation	0 to 45 degrees	
Shoulder		
Flexion	0 to 170 degrees	Abduction, lateral tilt, slight elevation, slight upward rotation
Extension	0 to 60 degrees	Depression, adduction, upward tilt
Abduction	0 to 170 degrees	Upward rotation, elevation
Adduction	0 degrees	Depression, adduction, downward rotation
Horizontal abduction	0 to 40 degrees	Adduction, reduction of lateral tilt
Horizontal adduction	0 to 180 degrees	Abduction, lateral tilt
Internal rotation		Abduction, lateral tilt
Arm in abduction	0 to 70 degrees	
Arm in adduction	0 to 40 degrees	
External rotation		Adduction, reduction of lateral tilt
Arm in abduction	0 to 90 degrees	

When joint measurements are performed in more than one position (e.g., as in alternative shoulder internal and external rotation positions noted later), the evaluating occupational therapist should note on the record the position in which the measurement was taken. The therapist should also note the position of the joint when the client experiences any pain or discomfort, the appearance of protective muscle spasm, and whether AROM or PROM was being measured. Record the points (degrees of ROM) where tightness started, progressed to discomfort, and then were felt as pain, and any deviations from recommended testing procedures or positions.[10] This becomes important information to document recovery from injury over time or as a result of therapist intervention.

Results of Assessment as the Basis for Planning Intervention

After joint measurement, the therapist should analyze the results in relation to the client's life role requirements. The therapist's first concern should be to correct ROM that is below functional limits. Many ordinary activities of daily living (ADLs) do not require the maximum ROM listed in the table. **Functional ROM** refers to the amount of joint range necessary to perform essential ADLs and instrumental activities of daily living (IADLs) without the use of special equipment. The first concern of intervention is to attempt to increase to functional levels any ROM that is limiting performance of self-care and home maintenance tasks.[8] For example, severe limitation of elbow flexion affects eating and oral hygiene. Therefore it is important to increase elbow flexion to nearly full ROM for function. Likewise, severe limitation of forearm pronation affects eating, washing the body, telephoning, caring for children, and dressing. Because sitting comfortably requires hip ROM of at least 0 to 100 degrees, a first goal might be to increase flexion to 100 degrees if it is limited. Of course, if additional ROM can be gained, the therapist should plan the progression of intervention to increase ROM to the normal range.

Some limitations in ROM may be permanent. The role of the therapist in such cases is to work out methods to compensate for the loss of ROM. Possibilities include assistive devices—such as a long-handled comb, brush, shoehorn, and a device to apply stockings—or adapted methods of performing a particular skill. (See Chapter 10 for further suggestions for ADL techniques in those with limited ROM.)

In many conditions, such as burns and arthritis, loss of ROM can be anticipated. The goal of intervention is to prevent joint limitation with splints, positioning, exercise, activity, and application of the principles of joint protection.

Limited ROM, its causes, and the prognosis for increasing ROM will suggest intervention approaches. Some of the specific methods used to increase ROM are discussed elsewhere in this text (see Chapters 29 and 39). These methods include stretching exercises, resistive activity and exercise, strengthening of antagonistic muscle groups, activities that require active motion of the affected joints through the full available ROM, splints, and positioning. To increase ROM, the physician may perform surgery or manipulate the part while the client is under anesthesia. The occupational therapist (OT), physical therapist (PT), or certified hand therapist may use joint mobilization techniques such as manual stretching with heat and massage.[8] Some surgeries (e.g., rotator cuff repair) require long periods of restriction of AROM while the surgery site (ligament grafts to bone) heals. During these periods (often 6–8 weeks), a shoulder can develop adhesive capsulitis (frozen shoulder) if it is not moved. During this precautionary period, it is often the role of the therapist (OT or PT) to passively move the shoulder on a regular treatment schedule specified by the surgeon to maintain joint mobility while observing surgical precautions of no AROM in physician-specified planes that would pull on the grafts and repairs. Monitoring PROM during these treatments provides data about progress or maintenance of joint ROM or will indicate problems to refer back to the surgeon.

Procedure for Measuring Passive Range of Motion

Average normal ROM for each joint motion is listed in Table 21.1, in Fig. 21.7, and before each of the following procedures used for measurement. The reader should keep in mind that ROM may vary considerably among individuals and these tables contain averages of maximum ROM. Normal ROM is affected by age, gender, injury, and other factors, such as lifestyle and occupation.[10] Therefore the client (C) in the illustrations may not always demonstrate the average maximum ROM listed for the particular motion.

In the following figures, the goniometer is shown in such a way that the reader can most easily see its positioning. Therefore the occupational therapist in the pictures may not always be in the optimum position for her own body mechanics during the measurement. For the purposes of clear illustration, the therapist is necessarily shown off to one side and may have only one hand, rather than two, on the instrument and the joint. For many of the motions the OT would typically be in front of the client, or the therapist's hands may obscure the goniometer. For this reason, do not assume that the pictures indicate the *correct* position for the therapist during measurement or feel that you must follow the picture precisely. How the therapist holds the goniometer and supports the part being measured clinically is determined by factors such as the position of the client, amount of muscle weakness, presence or absence of joint pain, and whether AROM or PROM is being measured. Both the therapist and the client should be positioned for the greatest comfort, correct placement of the instrument, and adequate stabilization of the part being tested to ensure the desired motion in the correct plane.

General Procedure: 180-Degree Method of Measurement[3,10]

1. The client should be comfortable and relaxed in the appropriate position (described later) for the joint measurement.

2. Uncover the joint to be measured.

3. Explain and demonstrate to the client what you are going to do, why, and how you expect him or her to cooperate.

4. If there is unilateral involvement, assess PROM on the analogous limb to establish normal ROM for the client.

5. Establish and palpate bony landmarks, which will be used to align the axis and arms of the goniometer.

6. Stabilize joints proximal to the joint being measured.

7. Ensure that when measuring joints that are operated by two-joint muscles (e.g., finger flexors, extensors, and rectus femoris), the other joint is positioned to put those muscles in a relaxed and lengthened state avoiding passive insufficiency, which will limit ROM of the joint you are measuring.

8. Move the part passively through ROM to assess joint mobility and end-feel.

9. Return the part to the starting position.

10. To measure the starting position, place the goniometer just over the surface of the joint and in the plane of movement. Place the axis of the goniometer over the axis of the joint by using the designated bony prominence or anatomical landmark. With some joints that are embedded in soft tissue (such as the glenohumeral joint), the therapist must visualize the correct joint center based on knowledge of skeletal anatomy and adjacent surface landmarks (e.g., two fingers inferior to the acromion is a good approximation of the placement of the glenoid fossa and humeral head, which are the true joint center). Place the stationary bar on or parallel to the longitudinal axis of the proximal part (e.g., the trunk) or along the stationary/proximal bone and place the movable bar on

or parallel to the longitudinal axis of the distal or moving bone. Keep the plane of the goniometer aligned with the correct plane of movement of the joint.

11. Record the number of degrees at the starting position and follow the movement or remove (or back off) the goniometer until maximum ROM is achieved. It is acceptable but not necessary to hold the goniometer in place and follow the joint through the arc of ROM. Measurements at each end of ROM are sufficient.

12. To measure PROM, hold the part securely above and below the joint being measured and gently move the joint through ROM. Do not force the joint. Watch for signs of pain and discomfort. (Note: PROM may also be measured by asking the client to move actively through ROM. Note the degree of AROM. From the final AROM position the therapist then moves the joint passively through the final few degrees to a normal stop or to the point where the client indicates movement becomes painful and measures PROM. There is no need to force a joint past a normal maximum ROM even if it is not painful (remember that there may also be sensory damage and pain may not be felt), even if it will go farther or joint or soft tissue damage may result.

13. Reposition the goniometer and record the number of degrees at the final position. It is often necessary to stabilize the joint in its maximum PROM position with one hand, with furniture or with an assistant in difficult cases. Learning to operate the goniometer with the other hand alone becomes a very useful skill in PROM measurement.

14. Remove the goniometer and gently place the part in the resting position.

15. Record the reading at the final position and make any notes on the evaluation form about which of the alternative measurement methods you might have used or variations from standard procedure that were necessary due to client condition or position.

Motion Screen/Motion Screening Test

It is almost never necessary to measure the range of motion of all of the joints of the body. Most injuries, disabilities, and health conditions only affect part of the body. The first step to measuring range of motion is to conduct a quick screen of the motions of the major joints of the body. This gives the therapist a first look at movement ability and limitations. It also gives the therapist early information about which motions to measure and document in detail, which to estimate as within normal limits (WNL) or within functional limits (WFL), and which to ignore because they are not limited enough to impair the client's ADLs, IADLs, or other important occupations. There are many varieties and sequences of motion screens with different levels of completeness. A new therapist in a treatment facility would be advised to confer with colleagues to see what they use as a screen so they can be consistent in the way their screens are documented and to ensure test-retest reliability for monitoring a patient's progress in treatment notes. The following motion screen provides an illustrated example of one way to do a screening.

1. The therapist stands in front of the client to model each movement and performs each movement as he or she asks the client in layperson's language to perform it. Because they are facing each other, the therapist should perform his or her movements on the opposite side (mirror image) from what he or she is asking the client to do so that clients are not confused by the left-right instructions compared to what they see as the therapist models each movement.

2. The screen is ideally performed standing, but if a client cannot stand unaided, it can be modified to be done from a sitting position.

3. Because some movements are mirror images, some are only illustrated with a left or right movement when both are requested in the screen.

4. Motion screen sequence:

A. Starting Position "Stand straight looking forward; look at me."	B. Cervical Flexion "Look down, bend your neck so your chin is close to your chest."	C. Cervical Extension "Look up, bend your head back as far as you can."	
D. Cervical Horizontal Rotation "Turn your head to the right as far as you can. Now turn your head to the left."	E. Thoracic Lateral Flexion "Bend your body as far as you can to the left. Now bend to the right."	F. Thoracic Horizontal Rotation "Twist your body to the right as far as you can. Now twist to the left."	G. Thoracic Flexion "Bend over and touch your toes or the floor."	H. Shoulder Flexion With Elbow Extension "Raise both arms as high and straight as you can."	I. Shoulder External/Lateral Rotation "Touch the back of your head with both hands."	

	J. Shoulder Internal/Medial Rotation "Touch your back with both hands."	K. Elbow Flexion "Bend your elbows up and touch your chin or shoulders."	L. Elbow Extension "Straighten your elbows down with palms forward."	M. Hip and Knee Flexion While Balancing and Weight Bearing "Squat down like this." (Therapist should stand near client to assist with balance.)	N. Alternative Methods for Hip and Knee Flexion *Top:* "While standing, lift your right knee as high as you can. Now your left knee. You can hold onto a chair if you need to." (Therapist should stand near client to assist with balance.) Or *Bottom:* "Sit down and pick up each knee as high as you can."	

	 O. Dorsiflexion "While sitting, point your foot up."	
P. Plantar Flexion "Now point your foot down." *The following movements can be done in either a sitting or standing position.*	
Q. Wrist Extension "Bend your elbows so both hands are out in front of you. Lift your hands at the wrist, like this."	
R. Wrist Flexion "Now bend your wrists down."	

	
S. Composite Digit Flexion "Make a fist with both hands, thumbs on top."	
T. Composite Digit Extension "Open both hands and spread your fingers."	
U. Forearm Supination "Turn your palms up."	
V. Forearm Pronation "Now turn your palms down."	
W. Thumb-Finger Opposition "Touch your thumbs to each of your fingers."	"Thank you. Are there any other movements that you are having problems with? If there are, please show me."	

Specific Directions for Joint Measurement Using the 180-Degree System

Spine

Cervical Spine

Measurements of neck movements are the least accurate because the neck has few bony landmarks and much soft tissue overlying the bony segments. It is also composed of a series of joints and therefore does not have only one axis.[4] Radiographic examination is the best means to make an accurate measurement of the specific joints.[12] However, general measurements may be taken with a tape measure to record the distance between the chin and chest for flexion and extension, between the chin and shoulder for neck rotation, and between the mastoid process and shoulder for lateral flexion.[3]

Approximate estimates of cervical flexion, extension, rotation, and lateral flexion may be made with the goniometer or by estimating the number of degrees of motion by using a fixed landmark and axis (e.g., midline on posterior aspect of head compared to the horizontal line from C7 to acromion or vertically down spine as proximal base of movement), and then measuring the arc of motion between those two lines [1,4]

Cervical Flexion

0 to 45 degrees

Neutral Position of the Client

Sitting or standing erect with the head vertical

Measurement

The client is asked to flex the neck so that the chin moves toward the chest. If a goniometer is used, the axis is placed over the angle of the jaw. The stationary bar is held in a horizontal position to align with the starting motion of the mandible. The movable bar follows the mandible toward the point of the chin (Fig. 21.8, A).

Alternative Method

The movable arm of the goniometer can be aligned with a tongue depressor, which the client is holding between the teeth. As the client performs neck flexion, the movable bar of the goniometer is adjusted downward to align with the new position of the tongue depressor.[4,10]

Alternative Method

The number of degrees of motion may be estimated, or the therapist may measure the number of inches or centimeters from the bone at the tip of the chin to the sternal notch.[1,3,10] Recognize that when the head is flexed forward, soft tissue may bunch up around the chin. The bony tip of the chin must be found by palpation to measure this distance (Fig. 21.8, B).

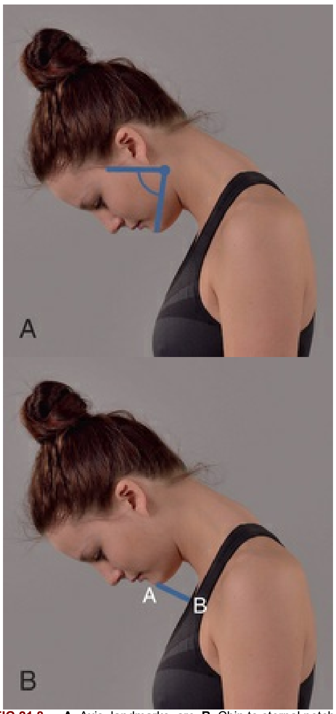

FIG 21.8 **A,** Axis, landmarks, arc. **B,** Chin to sternal notch.

Cervical Extension

0 to 45 degrees

Neutral Position of the Client

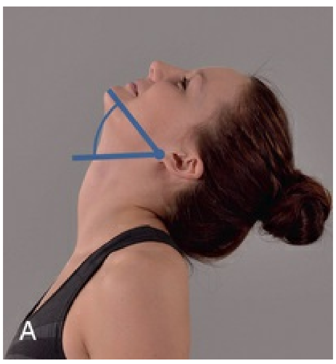
Sitting or standing erect with the head vertical

Measurement

The client is asked to extend the neck as though looking at the ceiling so that the back of the head approaches the thoracic spine. The number of degrees of motion may be estimated, or the number of inches or centimeters from the chin to the sternal notch may be measured.[3] If a goniometer is used, the axis is placed over the angle of the jaw and the stationary bar is held in a horizontal position corresponding with a theoretically level mandible. The therapist grasps the corner of the protractor and steadies his or her arm against the client's shoulder to stabilize and avoid substitution by extending the thoracic spine. The client can hold a tongue depressor in the teeth. The movable bar of the goniometer is moved upward to align with the mandible or the tongue depressor as the client extends the neck. It is important to document which method is used to ensure reliable measurements over time or between therapists (Fig. 21.9, A and B).[4,10]

Substitution

If cervical extension is inadequate, a client may attempt to achieve additional extension by extending the thoracic spine. Although this may enable the client to look upward, it does not increase cervical extension by changing the angle of the head to the trunk (see Fig. 21.9, C).



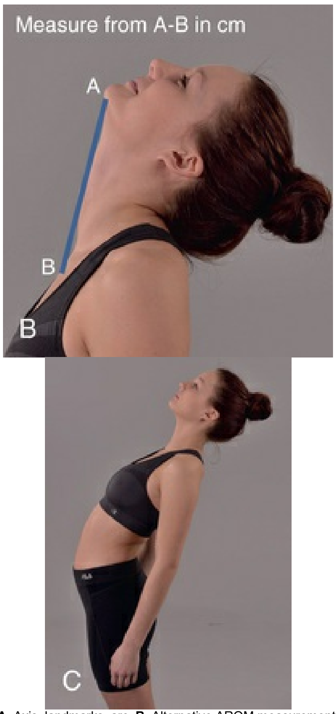


FIG 21.9 **A,** Axis, landmarks, arc. **B,** Alternative AROM measurement methods. **C,** Substitution.

Cervical Lateral Flexion

0 to 45 degrees

Neutral Position of the Client

Sitting or standing erect with the head vertical

Measurement

The client is asked to flex the neck laterally without rotation by moving the ear toward the shoulder. The number of degrees of motion may be estimated. If a goniometer is used, the axis is typically placed over the spinous process of C7 (the seventh cervical vertebra) if measured on the posterior neck, or with the axis pointed toward the larynx, if measured from the anterior side. The stationary bar may be over the shoulder toward the acromion if that yields a starting position of 0 degrees (Fig. 21.10, label 1) or parallel to the floor if the trunk is vertical so that the motion begins at 90 degrees. Or it may be aligned with the thoracic vertebra or sternum (Fig. 21.10, label 2), if the client is not positioned in a vertical position. On the posterior side, the movable bar is aligned with the midline of the external occipital protuberance or the midline of the forehead between the eyes if measured anteriorly. As an alternative method (Fig. 21.10, label 3) the therapist may measure the number of inches or centimeters between the mastoid process and the acromion process of the shoulder. Given these alternatives, and because there is no single standard method of measuring this movement, it is critical that the measurement method and landmarks be described in the notes to ensure reliability in repeat measurement.

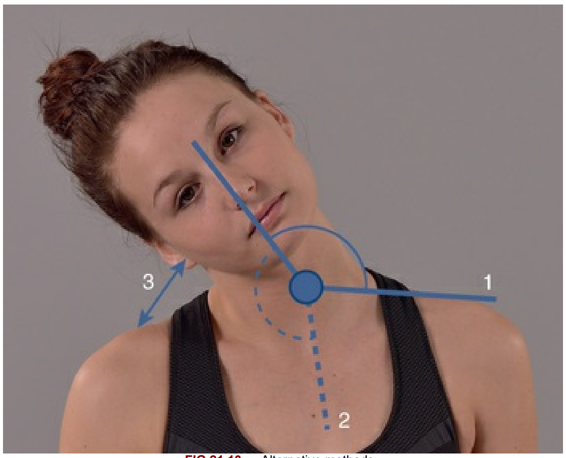

FIG 21.10 Alternative methods.

Cervical Horizontal Rotation

0 to 60 degrees

Neutral Position of the Client

Sitting or standing erect, with the head vertical, facing forward

Measurement

Sitting/Standing

The client is asked to rotate the head right or left without rotating the trunk. The therapist can provide stabilization to reduce shoulder movement due to trunk rotation. The amount of rotation may be estimated in degrees from the neutral position,[1] or a tape measure may be used to determine the distance from the tip of the chin to the acromion process of the shoulder. The measurement is taken first in the anatomical position and then again after the neck has been rotated. The difference in measurement between the two positions is the amount of rotation (Fig. 21.11).[3]

Supine

In the supine position or from a therapist position above the head with client in a seated position, a goniometer can be used. The goniometer will be set at 90 degrees with the axis placed over the vertex of the head. The stationary bar can be held in one of three positions. It can be held steady on the frontal plane relative to the trunk or aligned with the acromion process on the side being tested if sitting, or parallel to the floor in supine. The movable bar is aligned with the tip of the nose to follow the sagittal plane of the head.[4,10]

FIG 21.11 Measurement of the distance from the tip of the chin to the acromion process with neck rotated.

Thoracic and Lumbar Spine

Thoracic Flexion

0 to 80 degrees and 4 inches

Neutral Position of the Client

Standing erect, facing forward

Measurement

Four methods of estimating the range of spinal flexion are as follows:

1. Measure trunk forward flexion in relation to the longitudinal axis of the body (the therapist must hold the pelvis stable with the hands and observe any change in the client's normal lordosis), recording the level of the fingertips along the front of the client's leg.
2. Measure the number of inches or centimeters between the client's fingertips and the floor.
3. Measure the length of the spine from the seventh cervical vertebra to the first sacral vertebra when the client is erect and again after the client has flexed the spine (Fig. 21.12).[3,10]
4. The fourth is probably the most accurate of these clinical methods.[1] In a normal adult, the average increase in length in forward flexion of the spine is 4 inches (10 cm).[3] If the client bends forward at the hips with the back straight, no difference in length will occur.

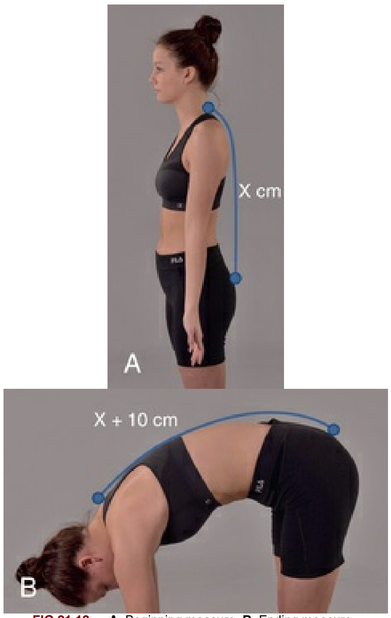

FIG 21.12 **A,** Beginning measure. **B,** Ending measure.

Thoracic Lateral Flexion

0 to 40 degrees

Neutral Position of the Client

Standing erect, facing forward

Measurement

Several methods may be used to estimate the range of lateral flexion of the trunk. A steel tape measure may be held in place during the motion and be used to estimate the number of degrees of lateral inclination of the trunk with respect to the vertical position. Other methods include estimating the position of the spinous process of C7 in relation to the pelvis; measuring the distance of the fingertips from the knee joint in lateral flexion (Fig. 21.13); measuring the distance between the tip of the third finger and the floor[3]; and with a long-arm goniometer (Fig. 21.13), placing the axis on S1 (or the mid pubic bone), the stationary bar perpendicular to the floor, and the movable bar aligned with C7 (or larynx).[1,10] Because there are several measurement method options, it is important to describe the method used in any treatment notes to ensure test-retest reliability if this movement is measured again.

FIG 21.13 Thoracic lateral flexion, ending measure. There is no beginning measurement shown.

Thoracic Extension

0 to 30 degrees (Fig. 21.14)

Neutral Position of the Client

Standing erect, facing forward

Measurement

The client is asked to bend backward while maintaining stability of the pelvis. If necessary, the therapist stabilizes the pelvis from the anterior when the measurement is taken in the standing position. The range of extension is estimated in degrees from the vertical by using the superior iliac crest as the pivotal point in relation to the spinous process of C7. With the client in the prone position, a pillow is placed under the abdomen and the client's hands are placed at shoulder level on the treatment table. The pelvis is stabilized with a strap or by an assistant, and the client extends the elbows to raise the trunk from the table. A perpendicular measurement is taken of the distance between the suprasternal notch and the supporting surface at the end of the ROM.[3]

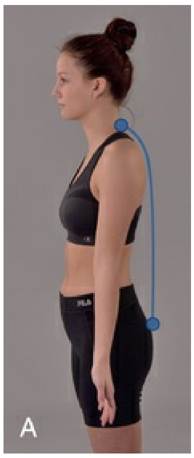

FIG 21.14 **A,** Beginning measure for thoracic extension. **B,** Ending measure for thoracic extension.

Thoracic Rotation	
0 to 45 degrees	
Neutral Position of the Client	
Standing erect, facing forward, or supine	
Measurement	
The client is asked to rotate the upper part of the trunk while maintaining a neutral position of the pelvis. It is, however, very difficult for a client to isolate trunk rotation from pelvic rotation (Fig. 21.15). The therapist may fix the pelvis firmly to maintain the neutral position and align the stationary bar on a perpendicular from a line between the left and right anterior superior iliac spine so that line projects into the sagittal plane with no rotation of the pelvis. This stabilization is especially important to isolate trunk rotation from hip and lower extremity rotation when the client is in the standing position. This motion is recorded in degrees by using the center of the crown of the head as a pivotal point and aligning the movable bar with the arc of motion made by the shoulder as it moves forward (or upward if measured in supine).	
Alternative Method	
Using the same goniometer placement, trunk rotation can also be measured in the sitting position. The seated position will stabilize the pelvis from moving with trunk rotation.	 FIG 21.15 Trunk and pelvic rotation without stabilization.

Upper Extremity[1-3,5,10,12]

Shoulder

Glenohumeral (GH) joint movement versus total shoulder movement.

It should be noted that scapula movement accompanies total shoulder movement. The range of shoulder motion is highly dependent on scapula mobility, which adds flexibility and wide ranges of motion to the shoulder. Although it is difficult to measure scapula movement directly with the goniometer, the evaluator should assess scapula mobility by observation of active motion or passive movement before proceeding with additional shoulder joint measurements. Scapular ROM can be noted as full or restricted.[3] If scapular motion is restricted, as when the musculature is in a state of spasticity or contracture, and the shoulder joint is moved into extreme ranges of motion (for example, above 90 degrees of flexion or abduction), pain at the end of ROM stops AROM or indicates to the therapist to stop PROM measurement or glenohumeral joint damage can result.

Isolating glenohumeral joint movement.

Approximately one-third of shoulder flexion, extension, and abduction comes from movement of the humerus in the glenohumeral joint, and one-third of total shoulder movement comes from scapular movement. This is referred to as “scapular rhythm.” All of the measurement methods presented next and the ranges of ROM shown are for total shoulder movement. However, in some cases (e.g., when treating a patient after a shoulder replacement or rotator cuff repair) it may be desirable to measure glenohumeral joint movement without scapular movement because the ROM of the humerus relative to the scapula is what is important and targeted in treatment. In that situation, the hand of the therapist can be laid on the scapula with the distal palm (the metacarpophalangeal joints of digits 2–4) on the spine of the scapula and the fingers over the acromion. In that position, the therapist can feel when the angle of the scapula begins to move (rotate for abduction, protract for extension, or retract for flexion) and can stop the client at that point to measure isolated GH joint movement using the same axis and goniometer arm positions (see movements: shoulder flexion, shoulder extension, and shoulder abduction). This method is also applicable to isolate and measure internal and external rotation of the humerus relative to the scapula when measured in a position of abduction of the shoulder (see movements: shoulder internal rotation [abducted], shoulder external rotation [abducted]).

Shoulder Flexion	0 to 170 degrees	
Position of the Client	
Seated or supine with the humerus adducted in neutral rotation	
Axis, Landmarks Arc, Position of the Goniometer	
The goniometer axis is placed over the center of the humeral head, just distal to the acromion process on the lateral aspect of the humerus. The stationary bar is parallel to the trunk, and the movable bar is parallel to the humerus aligned with the sagittal plane. If the landmarks are found before the movement into flexion, note that when the shoulder is flexed, the shape of the muscle mass changes as the shoulder flexes. The point on the skin where the initial axis is found in the neutral position moves upward and backward to the posterior surface of the shoulder and is no longer the axis of movement of the skeleton. Thus to take a measurement of the final position, the therapist should place the goniometer on the lateral surface of the shoulder by visualizing the axis through the center of the humeral head, which is just slightly superior to the crease formed by the distal end of the deltoid mass and approximately two fingers below the acromion, which can be palpated as the hollow between the proximal deltoid attachments when the shoulder is in flexion or abduction. Fig. 21.16, A, shows the landmarks for ideal placement of the axis and arms of the goniometer. Fig. 21.16, B (AROM), shows the client holding the limb herself in her maximum flexed position and the therapist's hand lightly holding the goniometer in place, with the axis aligned with the joint center and on the stationary and movable arms on the proximal and distal parts. Fig. 21.16, C (PROM), shows the therapist grasping the movable limb firmly, holding the goniometer while stabilizing the trunk with the right hand to offset her pressure on the limb toward maximum flexion and pushing the humerus to the shoulder's firm end-feel with the left hand while maintaining correct goniometer alignment.	

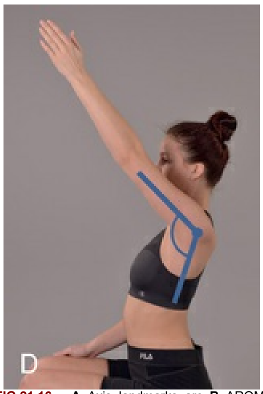

FIG 21.16 **A,** Axis, landmarks, arc. **B,** AROM. **C,** PROM. **D,** Substitution.

End-Feel

Firm[3]

Common Substitution

Sometimes a client has limitations of shoulder movement. Most clients want to please their therapist or have learned to use compensatory movements to “get the job done” so they can perform their ADLs, IADLs, or other occupations, even with limited ROM. As Fig. 21.16, D, shows, the individual may be able to reach a top shelf, but she has substituted thoracic extension for limited shoulder flexion to be able to elevate her arm and hand to reach her target. However, her shoulder AROM has not actually increased. In this illustration the arc of the model's shoulder flexion AROM is identical to that in the axis and landmark picture above (Fig. 21.16, A) where her thoracic spine is held in a neutral anatomical position and the stationary bar follows a vertical line. The evaluator must be careful to watch for substitutions and align the goniometer with the correct landmarks—that is, follow the thoracic spine, regardless of the angle of the spine, and not be tempted to follow a vertical line and incorrectly add ROM when there is no more than before.

Shoulder Extension

0 to 60 degrees (Fig. 21.17)

Neutral Position of the Client

Seated or prone, with no obstruction behind the humerus and the humerus in neutral rotation

Position of the Goniometer

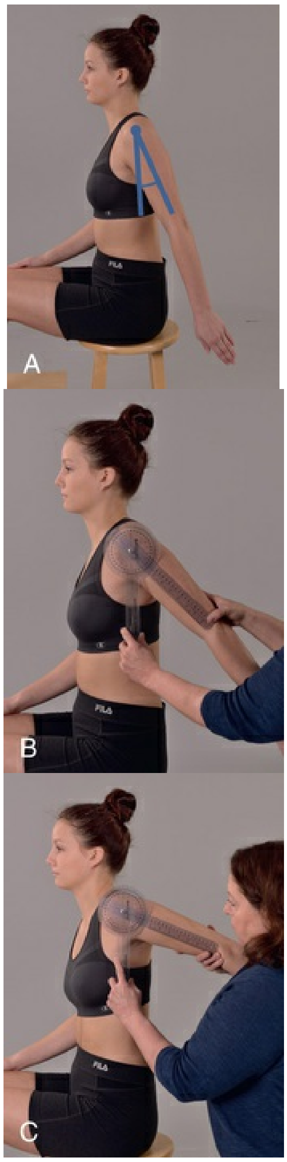
The axis for measuring shoulder extension is the same as for shoulder flexion, but the axis point appears to remain the same for the starting and final positions. Movement should be accompanied by only a slight upward tilt of the scapula. Excessive scapular motion should be avoided so only GH joint ROM is measured. Angular changes of the scapula can be seen if the shoulder is exposed, but they can also be palpated if a hand is laid on the scapula from behind with the palm over the spine of the scapula and the fingers over the acromion. During PROM the therapist must hold the goniometer while maximizing PROM, illustrated by the therapist pulling upward at the elbow in Fig. 21.17, C.

End-Feel

Firm[3]

Substitution

Just as with flexion, a substitution for limited extension may be accomplished by a client via excess anterior flexion of the trunk with no difference in actual extension of the glenohumeral joint or total shoulder ROM. If the client substitutes as in Fig. 21.17, D, the therapist can either stabilize the trunk with a firm hand on the anterior shoulder or compensate for the substitution by aligning the stationary bar with the upper trunk/thoracic spine and the movable bar still aligning with the humerus, yielding the same shoulder extension measurement as in Fig. 21.17, A.



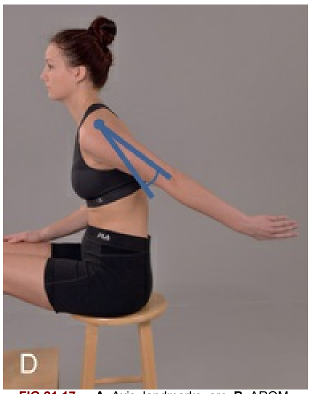


FIG 21.17 **A,** Axis, landmarks, arc. **B,** AROM. **C,** PROM. **D,** Substitution.

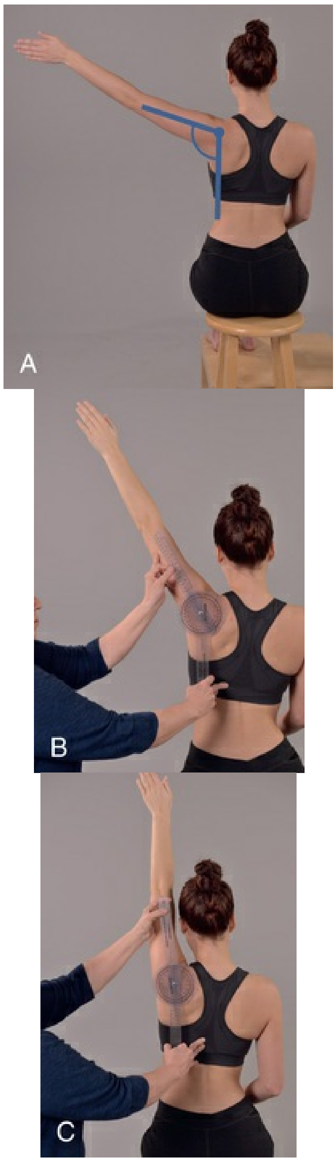
Shoulder Abduction
0 to 170 degrees (Fig. 21.18)
Neutral Position of the Client
Seated or lying prone, with the humerus in adduction and external rotation
Position of the Goniometer (Measure on the Posterior Surface)
The axis is below the acromion process on the posterior surface of the shoulder in line with the joint center at the head of the humerus. The therapist can visualize the joint center based on knowledge of skeletal anatomy (or approximate its position two fingers width directly below the acromion process). The stationary bar is parallel to the trunk, and the movable bar is parallel to the humerus, pointing at the lateral epicondyle. For PROM measurement those positions do not change but the therapist must find a way to hold the goniometer in position while also pushing the limb to maximum PROM. In Fig. 21.18, C, note that the therapist holds the goniometer in position with the thumb and index finger while using the palm and digits 3–5 to push the humerus to maximum PROM abduction.
End-Feel
Firm[3]
Substitution
Clients who cannot abduct to an ideal or desired level will likely substitute by leaning the trunk away from the limb thinking they are changing the angle of the joint itself when they are only raising the hand to accomplish the task at hand. This does not change the maximum AROM angle of the shoulder. When measuring ROM, the therapist follows the same landmarks and should still produce the same measurement as in Fig. 21.18, A, which shows landmarks and axis.



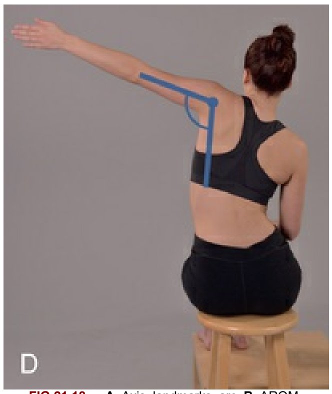


FIG 21.18 **A,** Axis, landmarks, arc. **B,** AROM. **C,** PROM. **D,** Substitution.

Shoulder Internal Rotation (Abducted)

0 to 60 degrees (Fig. 21.19)

Neutral Position of the Client

In seated or standing position, with the humerus abducted to 90 degrees, the elbow is flexed to 90 degrees, with the forearm in pronation, parallel to the floor. This position is used if there is no danger of posterior dislocation and if abduction is possible and not painful for the client.

Position of the Goniometer

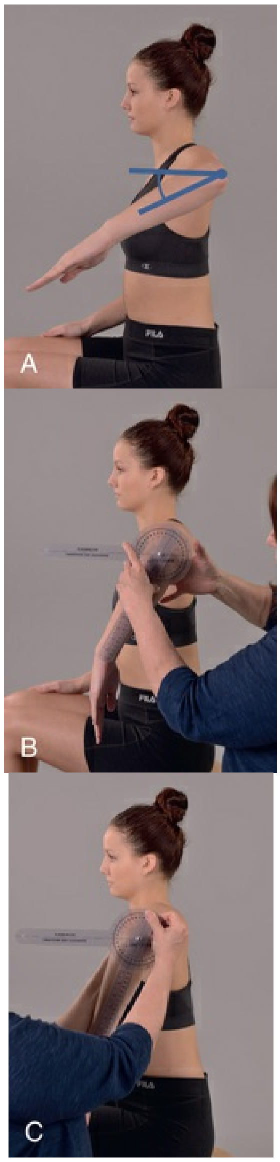
The axis is on the olecranon process of the elbow. The stationary bar is held in a horizontal position and the movable bar is parallel to the forearm, aligned with the ulna. For maximum precision, this is a measurement where the goniometer illustrated previously with the spirit level could be useful. The therapist could also sight along the stationary bar to a horizontal line in the room (e.g., a table, a line on the wall, or the joint between the wall and floor).

End-Feel

Firm[3]

Substitution

The client is substituting for inadequate internal rotation of the GH joint with excessive elevation of the scapula, which gives the illusion of increased internal rotation of the humerus and does cause the forearm to point more downward. Although the scapula is not visible in the photo (see Fig. 21.19, D), the stationary bar is still positioned perpendicular to the scapula just as it is while held horizontal in Fig. 21.19, A, relative to a neutral scapula, and should yield the same AROM measurement.



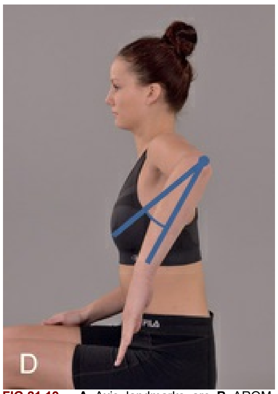


FIG 21.19 **A,** Axis, landmarks, arc. **B,** AROM. **C,** PROM. **D,** Substitution.

Shoulder Internal Rotation (Adducted–Alternative Position)

0 to 70 degrees

Neutral Position of the Client

The following position is used if abduction cannot be achieved: neutral (zero) rotation is when seated with the humerus adducted against the trunk, the elbow at 90 degrees, and the forearm at the midposition and perpendicular to the body (projected forward into the sagittal plane).[3]

Position of the Goniometer

The axis is on the olecranon process of the elbow, and the stationary bar is horizontal and pointed forward into the sagittal plane. The movable bar is parallel to the forearm and follows the arc of movement and moves in a horizontal plane. This position has a limitation in that maximum internal rotation ROM may not be achieved because the forearm's maximum arc in internal rotation stops at the abdomen.

Shoulder External Rotation (Abducted)

0 to 80 degrees (Fig. 21.20)

Neutral Position of the Client

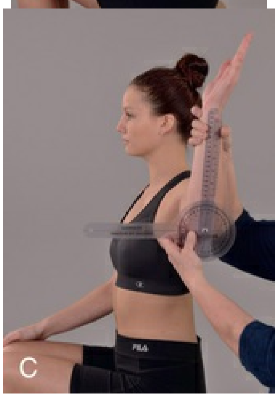
Starting in the same position as in Fig. 21.19, client seated or supine with the humerus abducted, the elbow is flexed to 90 degrees and the forearm pronated. This position is used when measuring internal rotation, if there is no danger of anterior dislocation of the humerus.[3]

Position of the Goniometer

The axis is on the olecranon process of the elbow, and the stationary bar is horizontal in neutral, parallel to the forearm (which points forward in the sagittal plane) at the beginning of the movement. The movable bar follows the forearm in a vertical arc in the sagittal plane to the end of ROM.

Substitution

When external rotation is limited, a client will often substitute thoracic extension to enable the hand to go higher. Actual external rotation of the shoulder does not change as indicated by the dotted line parallel to the upper thoracic vertebrae and the right angle symbol in Fig. 21.20, C, showing that the stationary bar is still perpendicular to the trunk. The client may develop this substitution to reach higher or might lean back to throw a ball higher and farther with some elevation rather than only be able to throw close and to the ground because of limited external rotation of the shoulder.



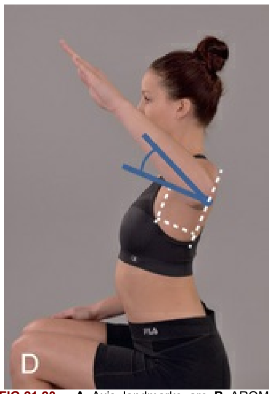


FIG 21.20 **A,** Axis, landmarks, arc. **B,** AROM. **C,** PROM. **D,** Substitution.

Shoulder External Rotation (Adducted–Alternative Position)
0 to 90 degrees
Neutral Position of the Client
This position is the same as the alternate position to measure internal rotation. The following position is used if abduction cannot be achieved: in seated or standing position the humerus is adducted, with the elbow held at the midlateral trunk with the elbow flexed to 90 degrees, the elbow is in midposition, perpendicular to the trunk, and the forearm is in neutral rotation.
Position of the Goniometer
The axis is aligned with and below the olecranon process of the elbow. In neutral, the stationary bar and movable bar are parallel to the forearm (which points forward in the sagittal plane) in zero rotation/starting position. The movable bar follows the forearm in a lateral arc in the horizontal plane to the end of AROM or PROM.
End-Feel
Firm[3]

Shoulder Horizontal Adduction
0 to 130 degrees.
Neutral Position of the Client
Seated erect with the shoulder to be tested abducted to 90 degrees, the elbow extended, and the palm facing down. The therapist may support the arm in abduction.[3]
Position of the Goniometer
The axis is over the acromion process. The stationary bar is parallel to the line between the left and right acromion, over the shoulder toward the neck, and the movable bar is parallel to the humerus on the superior aspect. The arm is rotated forward toward the opposite shoulder, past the anterior midline as far as possible in a horizontal plane.
End-Feel
Firm or soft[3]

Elbow

Flexion/Extension
0 to 135-150 degrees (Fig. 21.21, A-H)
Neutral Position of the Client
Standing, sitting, or supine with the humerus adducted, in neutral rotation (forearm pointed into sagittal plane) and the forearm supinated
Position of the Goniometer
The axis is placed over the lateral epicondyle of the humerus at the end of the elbow crease. The stationary bar is parallel to the midline of the humerus or aimed at the head of the humerus, and the movable bar is parallel to the radius. After the movement has been completed, the position of the elbow crease changes in relation to the lateral epicondyle because of the rise of the muscle bulk during the motion. The axis of the goniometer should be repositioned so that it is aligned with the lateral epicondyle.
End-Feel
Flexion: soft, hard, or firm. *Extension and hyperextension*: hard or firm.[3] End-feel for flexion of some joints, (elbow and knee) may depend on relaxed flexor muscle mass compared to the bulk of those muscles in flexion. Parts D and E of Fig. 21.21 illustrate the effect of muscle mass on AROM and PROM. In Fig. 21.21, D, during active flexion the muscle mass of the elbow flexors bulk up to flex the elbow and limit flexion with a firm end-feel. In Fig. 21.21, E, the elbow flexors are relaxed, allowing additional PROM flexion with a soft end-feel. Elbow extension typically starts at zero for neutral extension (Fig. 21.21, F). The elbow extends to a hard stop when the olecranon impacts the olecranon fossa. However, everybody is not typical; some cannot quite get their elbow to neutral (Fig. 21.21, G), whereas some may hyperextend a few degrees (Fig. 21.21, H). In such cases the measurement of ROM of elbow extension will use the same landmarks as noted earlier. The three-number notation system described earlier is useful to avoid confusion about the meaning of negative numbers when measuring elbow flexion/extension, especially when hyperextension or limited extension occurs.

Forearm

Forearm Supination	
0 to 80 or 90 degrees (Fig. 21.22)	Neutral Position of the Client	
Seated or standing with the humerus fully adducted, with the elbow flexed to 90 degrees, and the forearm in midposition (thumb up)	
Position of the Goniometer	
The arc to be measured is indicated in Fig. 21.22, A. The axis is at the ulnar border of the volar aspect of the wrist, just proximal to the ulnar styloid. The movable bar is resting against the volar aspect of the wrist, and the stationary bar is vertical, perpendicular to the floor (see Fig. 21.22, B). After the forearm is supinated, the goniometer should be repositioned so that the movable bar rests on a tangent across the middle of the curved center of the distal forearm, across the flexor tendons at the midpoint of the wrist between radial and ulnar styloids.	
Substitution	
The most common substitution for this movement is to slightly flex and adduct the shoulder allowing the forearm to only appear more supinated relative to the vertical line, but this does not actually change the ROM angle of forearm rotation measured at the wrist relative to the humerus (Fig. 21.22, C).	

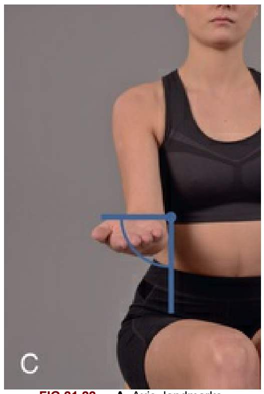

FIG 21.22 **A,** Axis, landmarks, arc. **B,** Partial AROM. **C,** Substitution.

Forearm Supination (Alternative Method)

0 to 80 or 90 degrees (Fig. 21.23)

Neutral Position of the Client

Seated or standing with the humerus adducted, the elbow at 90 degrees, and the forearm in midposition. In neutral position, place a pen or pencil in the client's hand. The client will rotate the forearm and pencil toward horizontal or beyond.

Position of the Goniometer

The axis is over the head of the third metacarpal. The stationary bar is perpendicular to the floor. The movable bar is held parallel to the pencil.

End-Feel

Firm.[3]

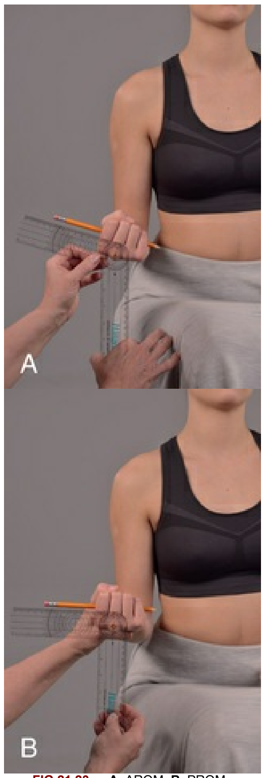

FIG 21.23 **A,** AROM. **B,** PROM.

Forearm Pronation

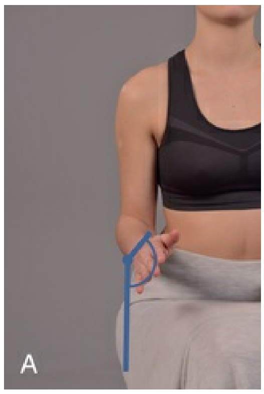
0 to 80 or 90 degrees (Fig. 21.24, A)

Position of the Client

Seated or standing with the humerus adducted, the elbow at 90 degrees, and the forearm in midposition (thumb up)

Position of the Goniometer

The axis is at the ulnar border of the dorsal aspect of the wrist, just proximal to the ulnar styloid. Place the goniometer so that the movable bar rests squarely across the center of the dorsum of the distal end of the forearm between the styloids. The stationary bar is held perpendicular to the floor with the forearm fully pronated for AROM (Fig. 21.24, A) and PROM (Fig. 21.24, B).



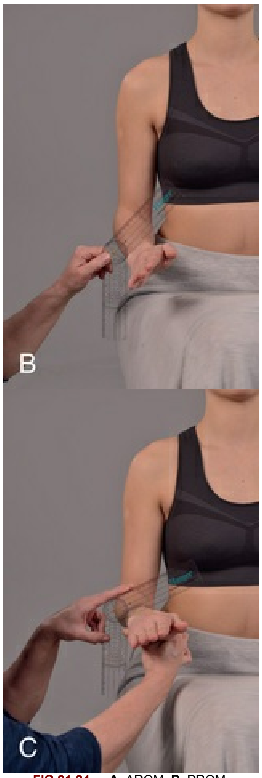


FIG 21.24 **A,** AROM. **B,** PROM. **C,** Substitution.

Forearm Pronation (Alternative Method)	
0 to 80 or 90 degrees (Fig. 21.25)	
Position of the Client	
Same as alternative method to measure supination. A pencil can be used to measure pronation. The client is seated or standing with the humerus adducted to neutral, elbow at 90 degrees, and the forearm in midposition. A pencil is placed in the hand. In neutral position (0 degrees) the pencil will be vertical, perpendicular to the floor.	
Position of the Goniometer	
When the forearm is rotated into pronation, the axis of the goniometer is over the head of the third metacarpal, the stationary bar is perpendicular to the floor, and the movable bar is parallel to the pencil.	
End-Feel	
Hard to firm[3]	
Substitution	
The most common substitution when ROM of forearm pronation is limited is to achieve the desired position of the forearm/hand using shoulder abduction (Fig. 21.25, C). This turns the wrist/hand flatter relative to the horizontal surfaces, but does not change the rotation angle of the forearm relative to the humerus. To avoid this substitution during measurement, instruct the client verbally (or stabilize) so the humerus remains in adduction (i.e., vertical or aligned with the trunk, with the elbow held close to the lateral trunk).	

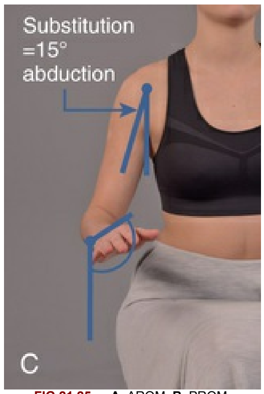

FIG 21.25 **A,** AROM. **B,** PROM. **C,** Substitution.

Wrist

Wrist Flexion

0 to 80 degrees (Fig. 21.26)

Neutral Position of the Client

Seated with the forearm in midposition and the hand and forearm resting on a table on the ulnar border with the wrist aligned with the forearm. The fingers are relaxed or extended to avoid passive insufficiency from tight extensors, which would limit wrist ROM in flexion.

Position of the Goniometer

The wrist is typically measured with the forearm in midposition, with the axis on the lateral aspect of the wrist just distal to the radial styloid in the anatomical snuffbox. The stationary bar is parallel to the radius, and the movable bar is parallel to the metacarpal of the index finger. This measurement could also be taken with the elbow partially flexed and the forearm resting on something (e.g., pillow, rolled towel, or bolster) that elevates the hand enough to clear the table and enables full ROM of the wrist while avoiding interference with the fingers on the table.[3]

End-Feel

Firm[3]

FIG 21.26 **A,** Axis, landmarks, arc. **B,** Partial AROM. **C,** PROM.

Wrist Extension

0 to 70 degrees (Fig. 21.27)

Neutral Position of the Client and Goniometer

The positions for the client and goniometer are the same as for wrist flexion, except that the wrist is extended and fingers should be relaxed in flexion instead of extended, to avoid passive insufficiency from tight flexors, which would limit wrist ROM in extension.

End-Feel

Firm or hard[3]

Measurement Error

Fig. 21.27, D, demonstrates a measurement error. Measuring passive wrist extension ROM with the fingers extended *may* result in inaccurate measurement of wrist extension PROM as the finger flexors *may* become passively insufficient, limiting the amount of wrist extension.

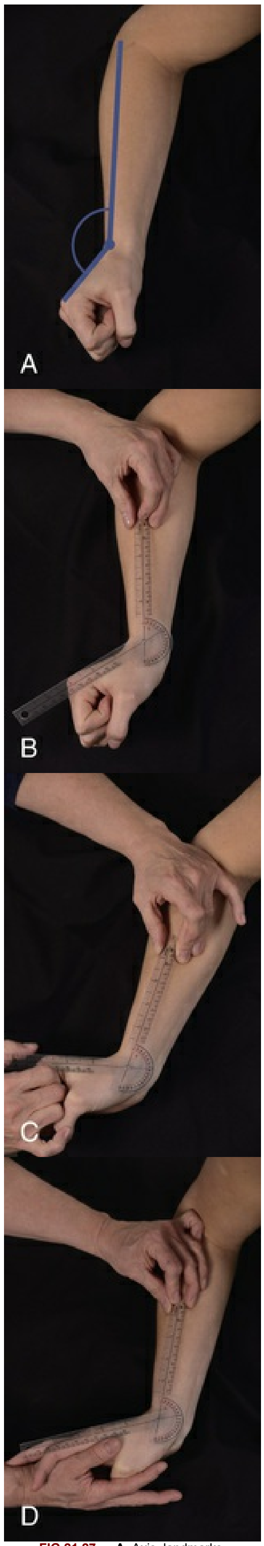

FIG 21.27 **A,** Axis, landmarks, arc. **B,** Partial AROM. **C,** PROM. **D,** Measurement error.

Wrist Radial Deviation

0 to 20 degrees (Fig. 21.28)

Neutral Position of the Client

Seated with the forearm pronated, the wrist at neutral (straight), the fingers relaxed in extension, and the palm of the hand resting flat on the table surface

Position of the Goniometer

Neutral (0 degrees) is a straight wrist and goniometer. The axis is on the dorsum of the wrist at the base of the third metacarpal, in a hollow that can be palpated over the capitate bone. The movable bar is parallel to the third metacarpal aligned with the third MCP joint and the stationary bar follows the midline of the dorsal aspect of the forearm.

End-Feel

Firm[3]

Substitution

A common substitution for limited radial deviation is to abduct the shoulder, and pronate the forearm and flex the wrist slightly, which turns the wrist/hand relative to the trunk but does not change wrist radial deviation AROM measurement relative to the forearm.

FIG 21.28 **A,** Axis, landmarks, arc. **B,** Partial AROM. **C,** PROM.

Wrist Ulnar Deviation

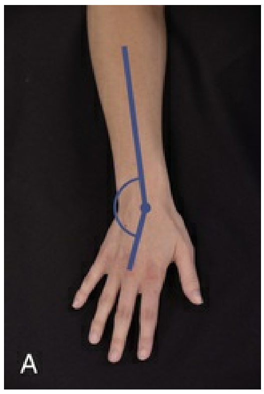
0 to 30 degrees (Fig. 21.29)

Position of the Client and Goniometer

Same client position and goniometer placement as for radial deviation. Wrist deviates toward the ulnar side.

End-Feel

Firm or hard[3]



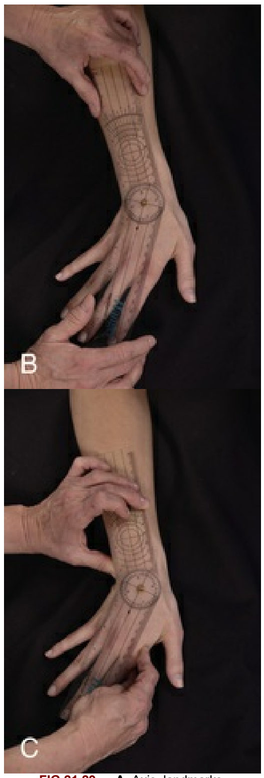


FIG 21.29 **A,** Axis, landmarks, arc. **B,** Partial AROM. **C,** PROM.

Fingers

Metacarpophalangeal (MP or MCP) Flexion
0 to 90 degrees The joint center viewed from the side is as indicated in Fig. 21.30, A. The actual axis is on the lateral side of the MP joint, but only the second digit (index finger) and the fifth digit (small finger) can be measured as in Fig. 21.30, B, on the side of the joint. So the most common method of measuring MP joints is to place the goniometer on the dorsal surface of the MP joint as in Fig. 21.30, C, on the dorsum of both the hand and proximal phalanx. The specialized goniometers illustrated are available to simplify dorsal ROM measurement. PROM is illustrated with Fig. 21.30, D-E. The MPs of digits 2–5 can all be measured in this manner.
Neutral Position of the Client
Seated with the elbow flexed. The forearm is in midposition, the wrist at 0-degree neutral position, the proximal and distal IP joints relaxed to avoid passive insufficiency, and the forearm and hand supported on a firm surface on the ulnar border.
Position of the Goniometer
Method 1
The axis is centered on the dorsal aspect of the metacarpophalangeal (MP) joint. The stationary bar lies on the dorsal surface of the hand, following the metacarpal for the MP joint being measured, and the movable bar lies on the dorsal surface of the proximal phalanx (see Fig. 21.30, B).
Method 2
The goniometer lies on the dorsal surface of the hand and digit (see Fig. 21.30, C). Or use specialized finger goniometers on the dorsal surfaces (Fig. 21.30, D-E)
End-Feel
Hard or firm[3]

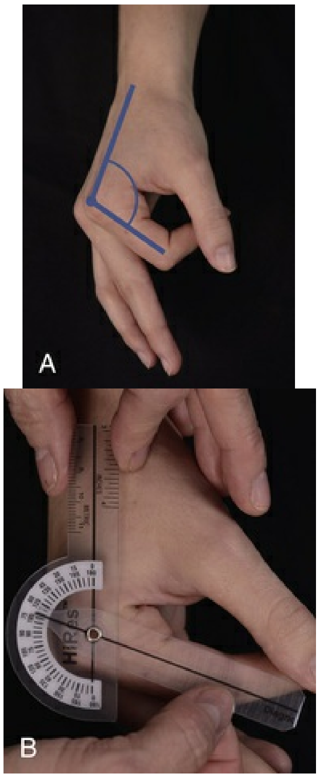

FIG 21.30 **A,** Axis, landmarks, arc. **B,** Lateral AROM. **C,** Dorsal AROM. **D-E,** Dorsal PROM with specialized goniometers.

Metacarpophalangeal Joint Extension/Hyperextension

0 to 45 degrees

Neutral Position of the Client

Seated with the forearm in midposition, the wrist at 0-degree neutral position, the interphalangeal joints relaxed or in flexion, and the forearm and hand supported on a firm surface on the ulnar border. Regardless of which way the protractor is turned on the goniometer, the extension angle being measured is illustrated in Fig. 21.31, A.

Position of the Goniometer

The axis is over the lateral aspect of the MP joint of the index finger. The stationary bar is parallel to the metacarpal, and the movable bar is parallel to the proximal phalanx. The small finger's MP joint may be measured similarly. ROM of the long and ring fingers can be estimated by comparison or specialized finger goniometers can be used on the dorsal surface of the hand and fingers.

An alternative is to place the goniometer on the volar aspect of the hand. With use of the edge of a shortened goniometer (a 6-inch goniometer can be cut to more easily measure the small joints of the hand), the axis is aligned over the MP joint being measured, the stationary bar is parallel to the metacarpal, and the movable bar is parallel to the proximal phalanx. As another alternative, these joints can be measured using specialized goniometers in the same way as illustrated under MP joint flexion (Fig. 21.31, C; see also Fig. 21.30, D-E).

End-Feel

Firm[3]

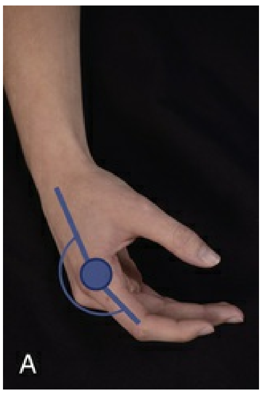

FIG 21.31 **A,** Axis, landmarks, arc. **B-C,** AROM. **D,** PROM.

Metacarpophalangeal Abduction

0 to 25 degrees (Fig. 21.32)

Neutral Position of the Client

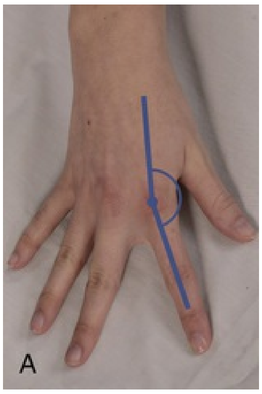
Seated with the forearm pronated, the wrist at 0-degree neutral deviation, the fingers straight, and the hand resting on a firm surface

Position of the Goniometer

The axis is centered over the MP joint being measured. The stationary bar is over the corresponding metacarpal, and the movable bar is over the proximal phalanx. The arc of the abduction angle is measured as the deviation from zero (0 = straight MP) for the MP/finger being measured. Measurements can be taken in both radial and ulnar directions for each finger.

End-Feel

Firm[3]



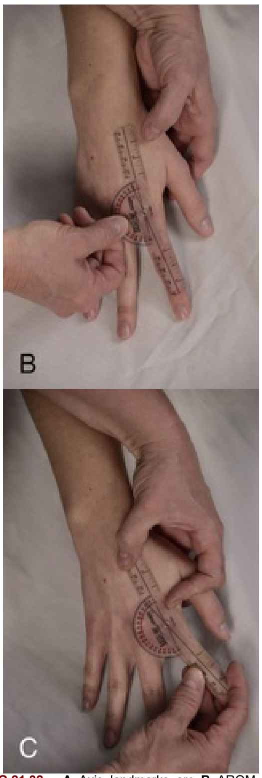


FIG 21.32 **A,** Axis, landmarks, arc. **B,** AROM. **C,** PROM.

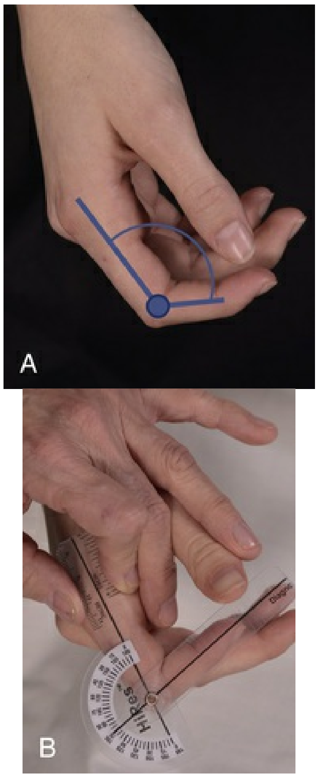
Proximal Interphalangeal (PIP) Flexion
0 to 110 degrees
Neutral Position of the Client
Seated with the forearm in midposition, the wrist at 0-degree neutral position or relaxed and slightly extended, with the forearm and hand supported on a firm surface on the ulnar border.
Position of the Goniometer
Method 1
The axis is centered on the lateral surface of the proximal interphalangeal (PIP) joint being measured. The stationary bar is placed along the lateral side of the proximal phalanx, and the movable bar follows the middle phalanx (Fig. 21.33, A-C).
Method 2
Using a shortened goniometer or a specialized goniometer (Fig. 21.33, D), place the stationary bar on the dorsum of the proximal phalanx and the movable bar on the dorsum of the middle phalanx. When the stationary and movable bars of the goniometer are so aligned, the axis will already be aligned with the joint center.



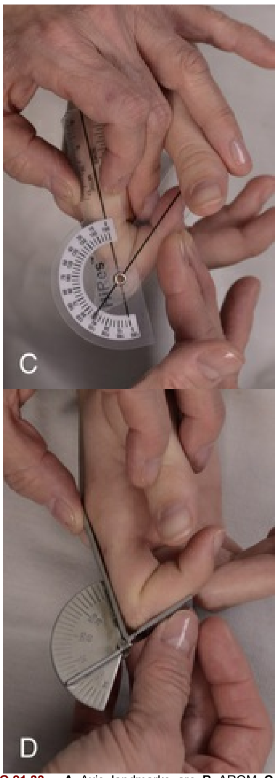


FIG 21.33 **A,** Axis, landmarks, arc. **B,** AROM. **C-D,** PROM.

Proximal Interphalangeal Flexion (Alternative Method)

This joint can also be measured with a ruler. The interphalangeal and MP joints of the fingers are flexed toward the palm. A ruler is used to measure from the midpoint of the middle phalanx of each finger to the proximal palmar crease (Fig. 21.34).[3]

End-Feel

Usually hard; may be soft or firm depending on the health of the surrounding tissues[3]

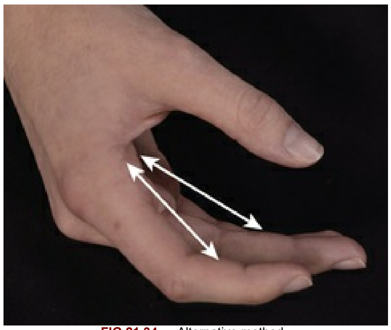

FIG 21.34 Alternative method.

Distal Interphalangeal (DIP) Flexion

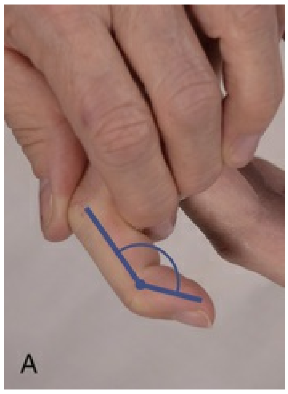
0 to 80 degrees (Fig. 21.35, A)

Neutral Position of the Client

Seated with the forearm in midposition, the wrist at 0-degree neutral deviation or relaxed with the wrist in slight extension, and the forearm and hand supported on the ulnar border on a firm surface

Position of the Goniometer

A shortened goniometer is best to measure the distal interphalangeal (DIP) flexion as a longer goniometer impacts the palm at maximum DIP flexion or interferes between the fingers. The axis is on the dorsal surface of the DIP joint. The stationary bar is over the middle phalanx, and the movable bar lies over the distal phalanx (Fig. 21.35, B). Alternative methods are to use a specialized goniometer on the dorsum of the DIP (Fig. 21.35, C). A standard long goniometer can be used (Fig. 21.35, D) on the sides of the index and small fingers, but this becomes difficult with the second and third fingers.



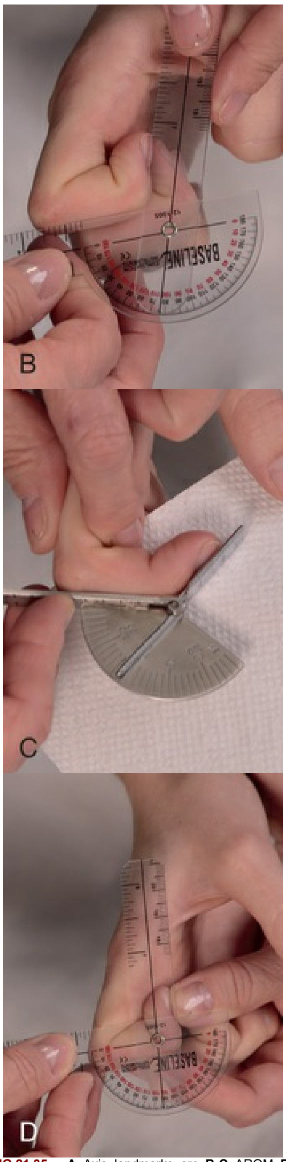


FIG 21.35 **A,** Axis, landmarks, arc. **B-C,** AROM. **D,** PROM.

PIP and DIP Composite Flexion (Alternative Method)

Some clients will have limited flexion of the fingers. In this case, isolating flexion of each digit and each joint can have limited value. Composite finger flexion can be measured if the client flexes all three finger joints (MP, PIP, and DIP) toward the palm. A measurement is then taken with a ruler from the tip of the middle finger to the proximal palmar crease. If digits 2–5 have similar flexion, this will yield a general composite measurement of finger flexion. Individual digit composite flexion can also be measured independently for each finger if the situation warrants it. Specific description of the measurement method is needed in notes to ensure the reliability of repeat measurement (Fig. 21.36).

End-Feel

Firm[3]

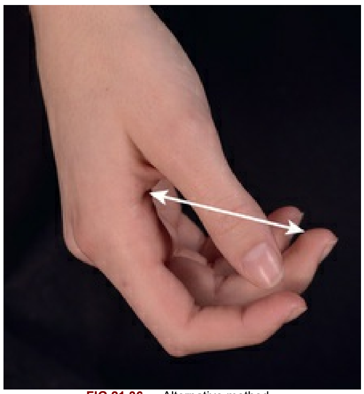

FIG 21.36 Alternative method.

Thumb

Thumb Carpometacarpal (CMC) Extension/Radial Abduction

0 to 50 degrees (Fig. 21.37)

Note: This joint may be called the trapeziometacarpal (TMC) joint by hand surgeons or hand therapists because it is the joint between the trapezium (one of the carpal bones) and the first metacarpal. It is the first of five CMC joints between the wrist and the hand and operates differently from the other CMC joints. It is a unique and mobile joint allowing more thumb flexibility than the other CMC joints provide to the metacarpals of the fingers. This joint enables the opposable thumb.

Neutral Position of the Client

Seated with the forearm pronated, wrist neutral, and the hand facing palm down, resting flat on a firm surface

Position of the Goniometer

The axis is over the dorsal surface of the thumb carpometacarpal (CMC or TMC) joint at the base of the thumb metacarpal in the anatomical snuffbox. The stationary bar is parallel to the radius, and the movable bar is aligned with the thumb metacarpal.

FIG 21.37 **A,** Axis, landmarks, arc. **B,** AROM. **C,** PROM.

Thumb CMC Extension/Radial Abduction (Alternative Method)

0 to 50 degrees

Position of the Client and Goniometer

The client is positioned the same as described in the first method. The axis is over the CMC joint at the base of the thumb metacarpal. The stationary bar is parallel to the second (index finger) metacarpal, and the movable bar is parallel to the first metacarpal and the thumb (see dotted line on Fig. 21.37, A) The axis will not be directly over the joint center but if both bars are parallel to the bones described, the axis will be correctly positioned automatically and the measurement will be correct.

End-Feel

Firm[3]

CMC Abduction/Palmar Abduction

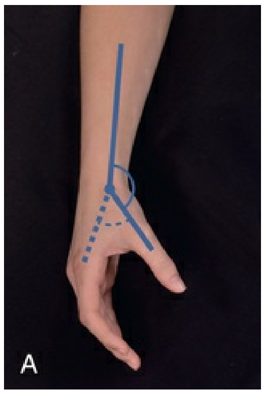
0 to 50 degrees (Fig. 21.38)

Position of the Client

Seated with the forearm in neutral, at 0-degree pronation/supination, the wrist flexion/extension at 0 degrees, and the forearm and hand resting on the ulnar border. The thumb is rotated in a plane toward a right angle from the palm of the hand.

Position of the Goniometer

The axis is at the junction of the thumb and index finger metacarpals (in the anatomical snuffbox). The stationary bar is over the radius, and the movable bar is parallel to the thumb and index finger metacarpals as illustrated in Fig. 21.38, A.



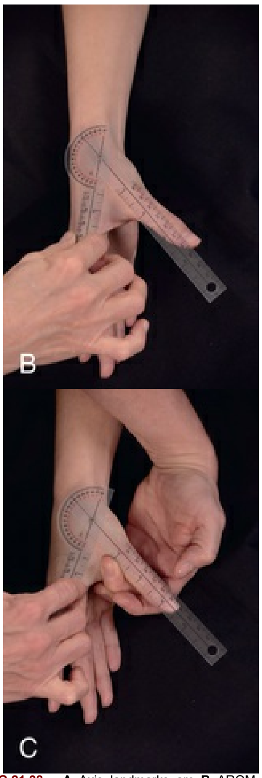


FIG 21.38 **A,** Axis, landmarks, arc. **B,** AROM. **C,** PROM.

CMC Palmar Abduction (Alternative Method)

0 to 50 degrees

Neutral Position of the Client

The client is positioned in the same way described in the first method.

Placement of the Goniometer

The axis is at the junction of the thumb and index finger metacarpals in the anatomical snuffbox. The stationary bar is parallel to the metacarpal of the index finger, and the movable bar follows the thumb metacarpal as illustrated in Fig. 21.38.

End-Feel

Firm[3]

Thumb Metacarpophalangeal (MP or MCP) Flexion

0 to 50 degrees (Fig. 21.39)

Neutral Position of the Client

Seated with the elbow flexed. The forearm is in 45 degrees of supination, the wrist at neutral deviation, the MP and interphalangeal joints relaxed in extension, and the hand and forearm supported on a firm surface.

Position of the Goniometer

The axis is on the dorsal surface of the MP joint. The stationary bar is over the thumb metacarpal, and the movable bar is over the proximal phalanx.

End-Feel

Hard or firm[3]

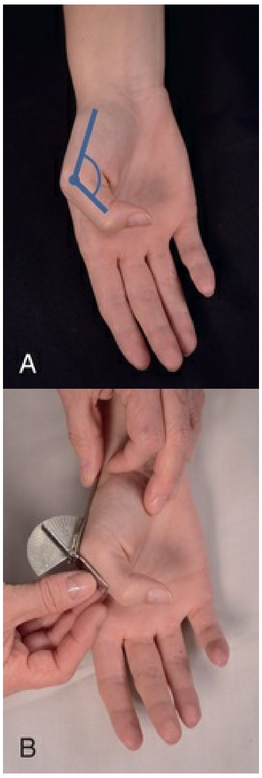

FIG 21.39 **A,** Axis, landmarks, arc. **B,** AROM. **C,** PROM.

Thumb Interphalangeal (IP) Flexion

0 to 90 degrees (Fig. 21.40)

Position of the Client

Same as described for thumb MP flexion

Position of the Goniometer

The axis is on the dorsal surface of the interphalangeal joint. The stationary bar is over the proximal phalanx, and the movable bar is over the distal phalanx. This joint can also be measured with a specialized or standard goniometer on the dorsal surface of the IP joint. Describe measurement method in clinical notes to ensure the reliability of repeat measurements.

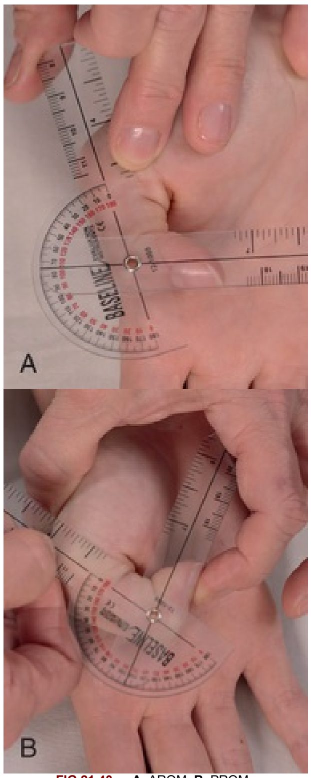

FIG 21.40 **A,** AROM. **B,** PROM.

Opposition

Deficits in opposition may be recorded by measuring the distance between the centers of the pads of the thumb and the fifth finger with a ruler (Fig. 21.41). Most goniometers have such a ruler printed on one of their long arms.

End-Feel

Soft or firm[3]

FIG 21.41 Opposition.

Lower Extremity[3,5,6,10,13]

Principles for measuring the upper extremity can easily be applied to the lower extremity (LE). We present one hip and one knee measurement in this chapter and refer readers to Reese and Bandy's

Joint Range of Motion and Muscle Length Testing for additional measurements.[13]

Hip

Hip Flexion
0 to 120 degrees (Fig. 21.42)
Neutral Position of the Client
Supine, lying with the hip and knee in 0-degree extension and rotation
Position of the Goniometer
The axis is found by palpating the lateral aspect of the hip for the greater trochanter of the femur. The stationary bar is centered over the middle of the lateral aspect of the pelvis, parallel to the trunk and to the horizontal surface upon which the client is lying. The movable bar is parallel to the long axis of the femur on the midline of the lateral aspect of the thigh, aiming at the lateral epicondyle of the knee joint. The knee is bent during the motion to relax the knee flexors and avoid passive insufficiency of the knee hamstrings at the hip.
End-Feel
Soft[3]

FIG 21.42 Hip flexion. AROM, end measure.

Knee

Knee Extension-Flexion
0 to 135 degrees (Fig. 21.43)
Position of the Client
The client should be supine, lying with the knees and hips flexed and the hip in 0-degree neutral rotation. In supine, the hip can be flexed, which relaxes the rectus femoris across the hip avoiding passive insufficiency of the hip flexor/knee extensor enabling maximal ROM in knee flexion. Knee flexion measured in prone may show less ROM due to the rectus femoris being on stretch from lying on a flat surface in prone.
Position of the Goniometer
With the client in the supine position, the axis is centered on the lateral aspect of the knee joint at the lateral epicondyle of the femur. The stationary bar is on the lateral aspect of the thigh, parallel to the longitudinal axis of the femur. The movable bar is parallel to the longitudinal axis of the fibula, aligned with the lateral malleolus, on the lateral aspect of the leg.
End-Feel
Soft[3]

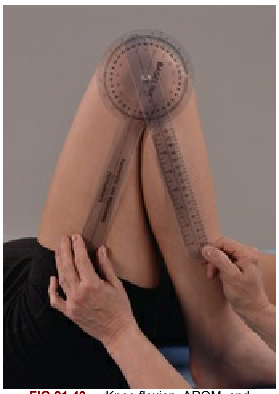

FIG 21.43 Knee flexion. AROM, end measure.

Threaded Case Study

Evelyn, Part 2

At the beginning of the chapter, Evelyn's case study was introduced. She is an active 83-year-old woman with a rich occupational life who sustained a Colles fracture in her left nondominant upper extremity, recently had her cast removed, and was experiencing residual problems (including joint ROM deficits). Readers were asked to consider three questions while studying the chapter:

Why should the therapist proceed with caution when assessing the ROM limitations of this client?

The therapist should proceed with caution with all clients; in Evelyn's case, heightened caution is necessary during joint measurement because of the edema, pain, and stiffness she is experiencing in the thumb and fingers of her recently injured left wrist. Failure to proceed with caution during measurement of ROM could exacerbate each of these symptoms.

What is the appropriate sequencing of joint measurement assessment for this client? What methods should be applied first?

It is important for the therapist to first have Evelyn actively move her joints through all available pain-free (or with tolerable pain) ROM throughout both her left affected upper extremity and her unaffected right upper extremity (for comparison purposes). Next, the therapist should passively move Evelyn's affected joints through the available pain-free (tolerable) ROM, note the end-feel, and estimate the ROM in those joints. Finally, the therapist measures the affected joints with a goniometer by following the specific sequential directions for measuring each of the joints.

What is the advantage of joint measurement in evidence-based practice?

An advantage of joint measurement in evidence-based practice is that the client's ROM baselines are recorded and the effectiveness of interventions can be determined or substantiated on the basis of the results of follow-up joint measurements. Once the therapist has collected these outcome data (along with similar data from other clients), a body of evidence regarding the effectiveness of intervention is compiled, which in turn can be used to select effective treatment of future clients with similar problems.

Summary

Joint measurement is used to evaluate ROM in persons whose physical dysfunction affects joint mobility. Measurements of ROM are used in setting intervention goals, selecting intervention methods, and making objective assessments of progress that allow the therapist to select the intervention methods most likely to target the affected joints.

Before measuring ROM, the therapist should know any precautions or contraindications concerning the client's condition that may determine how extensive the joint measurement procedure can be. The therapist should also know the principles of joint measurement. The procedure for measuring joint ROM involves correct positioning of the client and therapist, exposure of the joints to be measured, palpation, appropriate stabilization and handling of parts, and correct placement of the goniometer at the beginning and end of the ROM. To support the efficacy of intervention strategies and modalities, the therapist must also consider which method of reporting will best serve as evidence of effective intervention.

Directions and illustrations for measuring all of the major joint motions in the neck, trunk, and upper extremities are included in this chapter, as well as several major motions of the lower extremities. The content is designed for development of the fundamental techniques of joint measurement. The reader is referred to the references for more comprehensive treatment of the topic.[3,9,10,13]

Review Questions

1. Describe general rules for positioning the goniometer when measuring joint ROM.
2. With which conditions is joint measurement likely to be used?
3. List and discuss four purposes of joint measurement.
4. Is formal joint measurement necessary for every client? If not, how may ROM be assessed?
5. What is the benefit of conducting precise joint measurement with a goniometer?
6. What is meant by palpation? How is palpation done?
7. What should the therapist look for when observing joints and joint motions?
8. List at least five precautions during or contraindications to joint measurement.
9. What is meant by end-feel?
10. When measuring a joint crossed by a two-joint muscle, how should the occupational therapy practitioner position the joint not being measured?
11. List the steps in the procedure for joint measurement.
12. How is joint ROM measurement recorded on the evaluation form?
13. List the average normal ROM for elbow flexion, shoulder flexion, finger MP flexion, hip flexion, knee flexion, and ankle dorsiflexion.
14. Describe how to read the goniometer when using the 180-degree system of joint measurement.
15. What is functional ROM?
16. List three intervention methods that could be used to increase ROM.

Exercises

1. Measure all of the upper extremity joint motions of a normal client. Record the findings on the form in Fig. 21.7.
2. Repeat the first exercise, but the client should play the role of someone with several joint limitations.
3. Observe the joint motions used in ordinary ADLs/IADLs (e.g., self-care and home management). Estimate the functional ranges of motion for the following joint motions: shoulder flexion, external rotation, internal rotation, and abduction; elbow flexion; wrist extension; hip flexion and extension; knee flexion; and ankle plantar flexion.

Evaluation of Muscle Strength*

Vicki Kaskutas

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, the student or practitioner will be able to do the following:

1. Describe screening tests for muscle strength assessment.
2. Identify what is measured by the manual muscle test (MMT).
3. List diagnoses for which the MMT is appropriate and those for which it is not appropriate, with the rationale for each.
4. List the steps of the MMT procedure in correct order.
5. Describe the limitations of the MMT.
6. Define muscle grades by name, letter, and number.
7. Administer a MMT, using the directions in this chapter, on a normal practice subject.
8. Describe how results of the muscle strength assessment are used in intervention planning.

Case Study

Sharon

After a week of experiencing increasing numbness and weakness in her extremities and shortness of breath, Sharon, a 32-year-old woman, was admitted to an intensive care unit at a local hospital with acute respiratory distress, generalized musculoskeletal weakness, decreased sensory processing, and difficulty swallowing. Sharon complained of pain and tenderness in her muscles and was agitated and fearful. She was diagnosed as being in the acute phase of Guillain-Barré syndrome and was placed on a ventilator.[11] The occupational therapy (OT) practitioner fitted her with resting splints to support her weakened hands and minimize her muscle belly tenderness. When Sharon was moved from intensive care as the progression of the syndrome began to plateau, the therapist greatly reduced her fear by adapting a system that gave Sharon more control of her environmental context, allowing her to operate her call button, room lights, bed, and television.[20]

Sharon is a senior editor for a monthly food magazine. She has two children, ages 2 and 6. She has been married for 8 years; her husband is a sales representative for a computer company. They live in a two-story townhouse in an urban community. Sharon primarily works at home, going into the magazine's office once or twice a week. However, once a month, during the week the magazine is being published, her life “becomes a bit crazy,” and she may go into the office 5 days. She feels fortunate that she is able to employ a housekeeper/childcare person. In addition to caring for her home and family, Sharon is an avid photographer, exercises at a gym three times per week, and enjoys hiking and camping. She is a regular volunteer at her eldest child's school. She and her husband enjoy an active social life.

Six months after onset, Sharon is now being seen as an outpatient by an occupational therapist. Her disorder is in the recovery phase, with remyelination and axonal regeneration resulting in a generalized increase in muscle strength.[11] Sharon continues to be unable to fully engage in occupations that are meaningful to her, primarily because of residual weakness in her distal extremities and a moderate limitation in endurance. She is usually in a wheelchair but uses a walker in her home. She has an aide that comes in the morning to assist her with bathing and personal grooming and to drive her to her outpatient appointments. She states that "Although I can do things for myself, it takes so long that I end up being tired before my day even begins. I need help to safely shave my underarms and legs. Curling and blow-drying my hair can be exhausting." Sharon has also indicated that she cannot complete home maintenance tasks such as meal preparation (chopping foodstuff, managing pots and pans) and grocery shopping without assistance. She is unable to fully provide for the care and supervision of her children, especially the 2-year-old, nor can she access the second story of her home on a regular basis. She is limited in her ability to participate in outdoor and community occupations, which formerly brought her a great deal of satisfaction. She has been able to resume some of her job responsibilities at home on a limited basis with a voice-activated computer and is "grateful my employer still wants me and has been willing to make accommodations." She indicated that with all the progress she has made, she and her husband are trying to be realistic but are feeling more hopeful that she will make a full recovery.

In reviewing the above occupational profile, the therapist must focus on the client factors that are interfering with body function, namely, decreased muscle strength and endurance. Maintaining her arms at and above shoulder level without taking several rest breaks when vigorously brushing her back teeth, for example, remains a problem for Sharon. Another problem is applying enough force to open jars or perform fine motor activities, such as manipulating coins. These deficits are prohibiting the client from fully engaging in occupations for participation in the physical, social, personal, cultural, and spiritual contexts that bring meaning to her life.

Critical Thinking Questions

1. At what stage in this client's recovery should the occupational therapist first administer a muscle strength assessment?

2. Several methods are available for assessing muscle strength; what are they? What information regarding the client's status could be gained from each of these methods?

3. What is the relationship between the manual muscle test and graded activity with this client?

Many physical disabilities cause muscle weakness. Slight to substantial limitations of performance in areas of occupation—such as bringing food to one's mouth, lifting a child, removing items from a grocery store shelf, and getting into and out of bed—can result from loss of strength, depending on the degree of weakness and whether the weakness is permanent or temporary. If improvement is expected, the occupational therapist must assess the muscle weakness and plan an intervention that will enable occupational performance and increase strength.

Muscle Strength

Muscle strength is defined as "the amount of force generated by muscle contraction," and muscle contraction is the "process of development of tension in muscle tissue" (www.online-medical-dictionary.org). Muscular strength depends on a wide array of anatomical, physiological, neurological, sensory, motivational, cognitive, environmental, occupational, and habitual factors. Muscle weakness can restrict or prevent performance of occupations, including activities of daily living (ADLs), instrumental activities of daily living (IADLs), rest and sleep, education, work, play, leisure, and social participation. Muscle strength can be assessed by observing the client perform daily activities (see Chapter 20), screening tests, and manual muscle testing (MMT), when indicated.

OT practitioners must understand the components and function of the muscular system and its interaction with other systems of the body prior to performing MMT. To ensure that it is safe to evaluate muscle strength, any health conditions, injuries, or illnesses that the client may have should be known, and the OT practitioner must understand the effect that these condition(s) may have on the muscular system and contraindications to strength testing. Several factors should be screened or understood prior to assessing muscle strength, and the therapist must weigh the risks of strength testing with the benefits. Factors that may preclude a reliable and accurate assessment of strength should be considered, and muscle strength grades should never be reported unless the therapist can attest that the strength assessment is a true measure of strength and not a measure of other interfering factors such as pain, fatigue, motivation, cognition, or environmental conditions. This chapter assumes that the reader has this level of knowledge and clinical reasoning prior to participating in a strength assessment.

Causes of Muscle Weakness

Muscle strength varies greatly among individuals based on their stature, size, muscle fiber composition, occupations (work, leisure, play, and instrumental activities of daily living), age, sex, routines, roles, motivation, health, injuries, and illnesses. Obese individuals will likely sustain greater pressure during muscle testing of the limbs as they routinely lift heavy limbs to perform daily activities. Athletes will likely demonstrate better strength than sedentary workers who do not pursue occupations involving physical effort. As a result, there is wide variation in what is considered to be “normal” muscle strength.

There are many health-related causes for decreased muscle strength.

1. Health conditions affecting the muscle tissue can result in decreased strength, including injuries (muscle strain, tear, laceration, tendonitis and myositis), muscle length disorders (excessive tightness, length, or spasms), and a wide range of muscular dystrophies.

2. Because the muscular system requires messages from the nervous system to contract, strength can be affected due to conditions affecting the nervous system (brain, spinal cord, peripheral nervous system), whether due to disease, illness, or injury. This includes conditions such as stroke, traumatic brain injury, anoxia, amyotrophic lateral sclerosis, multiple sclerosis, tumor, cancer, spinal cord injury, peripheral nerve laceration or impingement, peripheral neuropathy, and nerve disease, to name a few. The nerve supply to muscle(s) can be damaged from bone fracture, osteoarthritis, or herniation of an intervertebral disk, which can result in decreased strength.

3. Autoimmune disorders and infectious disease often affect the muscular system, resulting in decreased strength. This includes syndromes such as myasthenia gravis, Guillain-Barré syndrome, rheumatoid arthritis, and systemic lupus erythematosus.

4. Endocrine and metabolic disorders can impact muscular function, such as Cushing syndrome, hyperthyroidism, and diabetes mellitus.

5. Inflammatory conditions, toxins, nutrition, and vitamin deficiencies may affect muscle strength.

6. Medical interventions can impact muscle strength due to surgery, immobilization, and medications. Clients who have been hospitalized for an extended period of time can lose a significant amount of strength. Fatigue and disuse can impact strength.

Various other factors can impact the amount of strength that a muscle demonstrates during MMT. These factors may or may not represent an actual muscle strength deficit, but they need to be considered during testing and when interpreting the results. This includes factors within the client (e.g., pain, cognition, motivation, and affect), physical environmental factors (e.g., temperature, noise, privacy, and distractions), and OT practitioner–related factors (e.g., therapeutic relationship, instructions provided, and handling techniques).

Methods to Evaluate Muscle Strength

Information regarding a client's muscle strength can be ascertained by several different methods. For many clients seen in occupational therapy, it is important to evaluate strength prior to implementing other evaluations or interventions. Depending on the specific needs, the OT practitioner should choose the most appropriate method of those listed here to evaluate strength. The OT practitioner should not assume a level of occupational performance based on strength. For example, a client with normal strength may be unable to perform his or her job, whereas a client with strength deficits may perform meaningful daily activities independently.

Screening tests are useful for observing areas of strength and weakness and for determining which areas require specific MMT.[6,10,12,19] Screening tests can help the therapist avoid unnecessary testing or duplication of services.[12] These tests are not as precise as MMT, and their purpose is to make a general evaluation of muscle strength and to determine areas of weakness, performance limitations, and the need for more precise testing. Screening may be accomplished by the following means:

1. Examining the medical record for results of previous muscle testing or daily activity performance.

2. Observing the client's movements while entering the clinic, moving about the hospital room, or getting in or out of a chair.

3. Observing the client perform functional activities, such as removing an article of clothing and shaking hands with the therapist.[6,12,13]

4. Performing an occupation-based functional motion assessment as described in Chapter 20.

5. Performing a gross check of bilateral muscle groups.[13] The client is comfortably seated in a sturdy chair or wheelchair and the OT practitioner asks the client to move both upper extremities through active range of motion. The OT practitioner applies pressure to both extremities at midrange of selected motions to obtain a gross estimation of strength.

In the case of Sharon, who during the acute stage of her illness had limited muscle strength, the OT practitioner would be able to detect changes by observing this client as she moved around her bed in an attempt to position herself. Initially Sharon might require maximal assistance for bed repositioning or for food intake. The therapist will notice a gradual increase in automatic movements of the limbs as Sharon raises her arms to her forehead to brush back her hair with her forearm, cups her hands around the water glass being held by her husband as she sips through a straw, bends and straightens her legs in an attempt to get comfortable, or momentarily lifts her trunk away from the surface of the bed. Observation of these spontaneous movements as Sharon begins to engage within the context of her environment can serve as preliminary and informal screening of this client's muscle strength.

Manual muscle testing measures the maximal contraction of a specific muscle or muscle group.[6,7] MMT is used to determine the amount of muscle power and to record gains and losses in strength. Criteria used to measure strength include evidence of muscle contraction, amount of range of motion (ROM) through which the joint passes when the muscle contracts, and amount of external pressure the muscle or muscle group can resist during contraction. Gravity is considered a form of resistance.[6,7,13] This chapter presents MMT of muscle groups, as this level of testing yields the type of data needed for most OT clinical settings. A muscle can be tested individually if a more precise measure is needed. This chapter also presents several common tests of the strength of individual muscles to help the reader envision the differences in testing procedures and discrete actions when testing individual muscles versus groups of muscles that perform a specific action. Readers requiring further details on group MMT are referred to Daniels and Worthingham,[10] Hislop and Montgomery,[12,13] and the Rancho Muscle Testing Guide.[21] Details about specific forms of MMT are available in Kendall and McCreary[14] and Cole, Furness, and Twomey.[8]

Purposes of Manual Muscle Testing

The purposes of MMT are to determine the amount of muscle power available, to discern how muscle weakness is limiting performance in meaningful occupations, to prevent deformities that can result from imbalances of strength, to determine the need for assistive devices as compensatory measures, to aid in the selection of occupations within the client's capabilities, to establish a baseline and guide intervention, and to evaluate the effectiveness of intervention strategies and modalities.[15] MMT of individual muscles can be essential for diagnosing some neuromuscular conditions, such as peripheral nerve lesions and spinal cord injury. In peripheral nerve or nerve root lesions, the pattern of muscle weakness may help determine which nerve or nerve roots are involved, whether the involvement is partial or complete, and progression over time. Careful evaluation can help determine the level(s) of spinal cord involvement and can indicate whether the cord damage is complete or incomplete.[14] Along with sensory evaluation, MMT can therefore be an important diagnostic aid in neuromuscular conditions.

Individual Differences in Manual Muscle Testing

The age, gender, body type, and lifestyle of the client; the muscle size and type and speed of contraction; the effect of previous training for the testing situation; joint position during the muscle contraction; previous training effects; and time of day, temperature, and fatigue all can affect muscle strength.[6,7] Occupations also influence the amount of pressure that a particular client can withstand during strength testing.[9,10,12-14] Strength tends to decline with age, and full resistance to the same muscle group will vary considerably from an 80-year-old man to a 25-year-old man.[7,14] One way to establish “normal” levels for individuals with one side affected is to test the unaffected extremity first. Learning about the activities, occupations, and tasks regularly performed in daily life can give the therapist a general idea; however, assumptions should be avoided. For example, a man who plays football for leisure or works as a construction worker is likely to have strength that is in the higher range of “normal.” Conversely, the strength of a female office worker should not be assumed based on her small stature, as she may bowl, play tennis, and make wood crafts in her leisure time.

Limitations of the Manual Muscle Test

When done correctly, MMT measures the strength of a muscle or group of muscles. Although information about quality of movements (speed, smoothness, rhythm, and abnormal movements such as tremors),[19] muscle tone (resistance to passive movement), and motor performance (the use of muscles for functional activities)[8] may be gathered while assessing active and passive ROM, these are not directly measured during MMT. Assessment of **muscle endurance** involves assessment of ability to repetitively contract and resist fatigue,[6] which are not measured during MMT. In fact, the therapist should limit the number of times that the muscle is maximally contracted during MMT to ensure that strength (and not muscle endurance or fatigue resistance) is being measured.

Contraindications and Precautions

MMT is contraindicated when the client has inflammation or pain in the region to be tested; a dislocation or unhealed fracture; recent surgery, particularly of musculoskeletal structures; myositis ossificans; or bone carcinoma or any fragile bone condition.[7,15] Because weak muscles fatigue easily, MMT should not be performed when the client is tired or especially fatigued for two reasons: (1) the results will not accurately reflect strength, and (2) negative ramifications can result when excessive force is applied to muscles that are compromised. Special precautions must be taken when resisted movement could aggravate the client's condition, as might occur with osteoporosis, subluxation or hypermobility of a joint, hemophilia or any type of cardiovascular risk or disease, abdominal surgery or an abdominal hernia, and fatigue that exacerbates the client's condition.[6,7] Until recently, MMT was not performed on clients with muscle spasticity, otherwise known as hypertonicity; however, recent literature notes that MMT can result in accurate results in clients with mild to moderate spasticity. Critics of MMT in clients with hypertonicity suggest that primitive reflexes and gross synergistic movement patterns make it impossible for the client to isolate joint motions, which is demanded in MMT procedures.[2,3,6,7,16] Refer to Chapters 19, 31 (Section 2), and 32 for detailed information about hypertonicity and MMT in clients with upper motor neuron disorders.

Unlike the passive range of motion (PROM) assessment discussed in Chapter 21, MMT requires the client's complete involvement in the testing procedure. MMT should not be compromised as a result of cognitive and language barriers, or the client's inability to perform the motor skills required for the test.[13] Screening of clients' ability to understand and follow directions and their willingness and ability to expend maximal effort should be ascertained prior to MMT. If the OT practitioner suspects that the results of an MMT may be compromised, MMT should not be performed. Likewise, if the therapist has any reason to believe that results of an MMT that was administered do not accurately measure muscle strength, the results should not be recorded in the client's record.

Role of Joint Range of Motion When Performing Manual Muscle Testing

The amount of motion through which a muscle group can move the body part is the first criterion used to evaluate MMT. As a result, it is common to perform MMT after evaluating ROM (see Chapters 20 and 21). The amount of ROM actively performed when the client contracts the muscle group (active range of motion [AROM]), is compared to the amount of ROM through which the OT practitioner can passively move the client's body part (PROM). It is important to note that PROM deficits do not affect the assignment of muscle strength grades. Despite a PROM limitation, muscle strength within the available AROM may be normal. ROM and the actions being muscle tested should be screened prior to assessing strength; if AROM is within functional limits, further ROM evaluation is not necessary as PROM will also be within functional limits. However, if AROM is limited, the therapist must take the joint through PROM to identify the available amount of joint mobility prior to assigning a muscle grade.

Let's consider a client who has elbow flexion ROM limitations of 120 degrees both passively and actively due to joint changes from an old fracture. Strength is not the factor limiting AROM, so the OT practitioner proceeds with the next step of MMT, placing the joint in midrange and applying pressure. It is important to record the PROM limitation along with the muscle grade noted during pressure application.[10] Conversely, if the client's PROM for elbow flexion is 160 degrees and AROM is only 120 degrees, pressure would not be applied, as the muscle group is only capable of moving the joint through partial ROM **against gravity**. Using a client's “actual” ROM rather than published ROM norms is preferred, as it is more specific and accurate. When assessing Sharon's muscle strength during the recovery phase of her illness, the OT practitioner most likely will find less active ROM than passive ROM due to muscle strength deficits. The discrepancy will decrease and strength will begin to recover as remyelination and axonal regeneration occur.

Role of Gravity When Performing Manual Muscle Testing

Gravity is a resistance force that the muscular system must overcome in order to move the body through ROM. Movement against gravity is one criterion used to assess muscle strength.[14] Movement of a body part against gravity in a vertical plane (i.e., away from the floor or toward the ceiling) through the joint's full available PROM signifies a certain level of muscle strength. If a client is not able to perform a movement against gravity (plane that is vertical), the effect of gravity on the body part is minimized to determine the amount of movement possible. This involves placing the body part in a position that allows motion to occur in a horizontal plane (i.e., parallel to the floor). This position has been referred to as the gravity-eliminated, gravity-minimized, or gravity-lessened test position.[10,14,16,19] Because the effect of gravity cannot be eliminated, *gravity minimized* or *gravity lessened* are more accurate terms. The term **gravity minimized**[10,14] is used in this chapter.

When the body part being moved has a substantial mass (and hence weight), the effect of gravity on muscle power must be considered when muscle testing. Such is the case when moving the trunk or head, lifting an entire extremity at the hip or shoulder, and performing knee, elbow, ankle, and wrist movements. In these cases, motion must occur in the vertical plane to account for gravity's effect, and when strength is inadequate to move the body part in the vertical plane, the body must be repositioned to measure movement in the horizontal or gravity-minimized plane. It is of lesser importance to position the body part with the motion occurring against gravity (in the vertical plane) when the moving body part is lightweight, such as the fingers and toes, and when rotating the forearm.[10,14] Therefore when assessing strength of the muscle group that moves the forearm, fingers, or toes, testing can occur in either the horizontal or vertical plane. For some actions, positioning in the against-gravity or gravity-minimized position is not feasible. For example, when testing scapula depression, the against-gravity position would require the client to assume an inverted position. In individual cases, positioning for movement in the correct plane may not be possible because of confinement to bed, generalized weakness, trunk instability, immobilization devices, medical devices, and precautions. In these instances, the OT practitioner must adapt the positioning to the client's needs and use clinical judgment in modifying the grading. The therapist should note modifications in positioning and grading when recording the results of the muscle test.

For consistency in procedure and grading, gravity-minimized positions and against-gravity positions are used in the manual muscle tests for all motions described later, except in cases in which the positioning is not feasible or would be awkward or uncomfortable for the client. Modifications in positioning and grading have been cited with the individual tests.

Application of Pressure During Manual Muscle Testing

Application of pressure (previously referred to as resistance in prior editions of this chapter) by the therapist is an additional external force used when assessing muscle strength. The amount of pressure a group of muscles performing an action can tolerate depends on a wide range of factors. Larger muscles have greater strength,[7,10] which relates to the diameter or cross section of the fibers that make up a muscle. The number of muscles responsible for an action (the agonists) also affects the strength of an action. For example, the three muscles primarily responsible for wrist flexion are larger, have more power, and can withstand more resistance than the one muscle that adducts each finger. As a result, the OT practitioner must consider the size and relative power of the muscles and modify the amount of pressure applied accordingly. The amount of pressure that can be applied to grade a particular muscle group varies among individual clients.[9,10,12-14]

Many other principles must be followed during the application of pressure. Pressure is applied opposite to the direction of the action being tested, and it should be applied directly opposite to the line of pull of the muscle or muscle group being tested. This means that the pressure is applied completely perpendicular to the long axis of the bony structure that is moving (Figure 22.1). Application of pressure in this manner allows for all of the therapist's force to be applied to “un-rotate” the joint and not to compress or distract the joint. Pressure is normally applied as distal as possible on the body part that is moving (avoiding crossing the next joint), which gives the therapist a longer moment arm. Application of pressure in a perpendicular manner to the moving body part and ensuring that pressure is applied as far distal as possible without crossing the next joint increase the therapist's biomechanical advantage, resulting in the need to use less force when applying pressure. The therapist should tell the client when the pressure is going to be applied, which allows the client to “set” the muscle. Pressure should be applied gradually and be adjusted to the client's abilities.[12] The body part proximal to the joint being tested should be well stabilized to ensure that pressure is directed only to the moving body part. To prevent interference with muscle contraction, pressure should not be applied directly over the muscle belly or tendon of the muscles that are contracting. In some cases, all of these principles regarding pressure application cannot be observed at the same time; the therapist considers the ramifications of breaking a principle, erring on the side of safety.

FIG 22.1 Application of pressure during MMT. The red arrow denotes pressure application by OT; the blue dotted line is the longitudinal axis of the moving body part. Note that pressure is applied perpendicular to the moving body part.

The break test should not evoke pain, and pressure should be released immediately if pain or discomfort occurs.[10] After applying pressure, the therapist grades the muscle strength according to the preceding standard definitions of **muscle grades**. This procedure is used for tests of strength of grades Fair+ (3+) and above. Pressure is not applied for tests of muscles from Fair (3) to Zero (0). Slight resistance is sometimes applied to a muscle that has completed the full ROM in the gravity-minimized plane to determine whether the grade is Poor+. Figure 22.2 shows a sample form for recording muscle grades.

MUSCLE EXAMINATION

Client's name ______________________________ Chart no.

Date of birth ______________ Name of institution ______________________

Additional data:

FIG 22.2 Sample form for recording the muscle examination. (Adapted from March of Dimes Birth Defects Foundation.)

Because weak muscles fatigue easily, the results of MMT may not be accurate if the client is tired. There should be no more than three repetitions of the test movement because fatigue can result in grading errors if the muscle becomes tired as a result of low endurance.[7,8] Pain, swelling, or muscle spasm in the area being tested may also interfere with the testing procedure and accurate grading. Such problems should be recorded on the evaluation form.[19] Psychological factors must be considered in interpreting muscle strength grades. When interpreting strength, the therapist must assess motivation, cooperation, and the effort put forth by the client.[10]

Palpation of Muscle Contraction

If there is no visible action when a muscle group is tested on a horizontal plane, the therapist must ascertain if the muscles are able to generate any tension; this is done via palpation. The therapist places his or her fingers (typically the tips of the index and long fingers) over the muscle belly or tendon of the muscles that perform the action being tested and moves the body part into the target position several times while instructing the client to attempt to move the joint in this manner. Palpating over the exact position of each muscle belly/tendon that performs is preferred; however, placement over the general area of the muscle group performing the action is acceptable. Because shoulder abduction occurs in the frontal (coronal) plane, the muscles performing abduction are palpable lateral to the glenohumeral joint (Figure 22.3, A). Similarly, knee flexion occurs in the sagittal plane and the distal lower extremity rotated into neutral; the muscles performing knee flexion are palpable posterior to the knee joint, with their muscle bellies lying superior and others inferior to the knee (Figure 22.3, B).

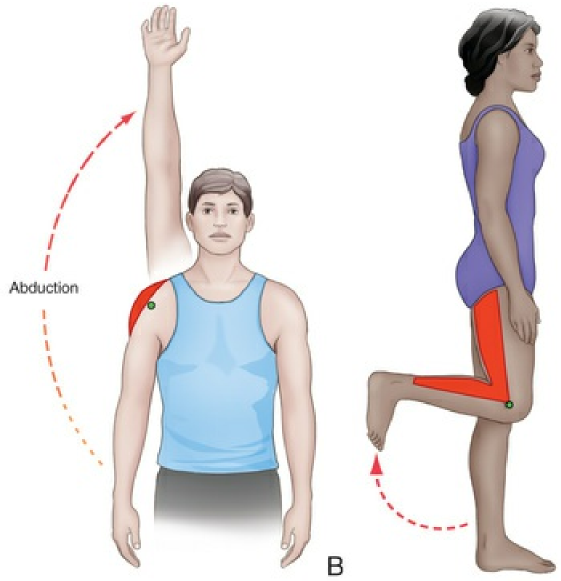

FIG 22.3 **A,** Muscles performing shoulder abduction. The green dot denotes general axis of motion and the red shape represents position of the shoulder abductor muscle group. **B,** Muscles performing knee flexion. The green dot denotes general axis of motion and the red shape represents position of the knee flexor muscle group.

When palpating for contraction, it is important to tell the client that although the muscles can be too weak to physically move the joint, there can still be muscular activity that the OT practitioner can feel when the client attempts to perform the motion. The client should be given several opportunities to generate tension. It is also important for the OT practitioner to know the location of the target muscles and their tendinous attachments to discern them from other muscles in the vicinity that may be attempting to substitute for the test action.

Substitutions

The OT practitioner must observe the client closely to ensure that the action that he or she performs is the exact motion that the muscle group that is being tested performs. The brain thinks in terms of movement and not in terms of contraction of individual muscles.[10] Thus a muscle or muscle group may attempt to compensate for the function of a weaker muscle to accomplish a movement. These movements are called **substitutions**.[6,7,14] The therapist must give careful instructions; provide correct positioning, stabilization, and palpation; and ensure that the test motion occurs without extraneous movements. To prevent substitutions, the correct position of the body should be maintained and movement of the part performed without shifting the body or turning the part.[6,7,14] Undetected trick movements can mask the client's problems, resulting in inaccurate treatment planning.[6] Palpation of the contractile tissue ensures that tension is being generated by the muscle under examination.[6,10] The technique for muscle testing described in this chapter does not use palpation when testing grades Normal, Good, and Fair. The muscles that work in concert to perform a joint action often originate in different locations, making palpation of the contractile tissue impossible. For example, the muscle bellies of the elbow flexors lie in the midarm, lateral forearm, and deep anterior elbow joint. In addition, one of the OT practitioner's hands is stabilizing the proximal body part and the other is applying pressure to the moving body part, leaving no hand free for palpation. This chapter describes body and joint positioning in detail, placement of the body part in a specific position, and subtle substitutions to help the OT practitioner identify substitutions. Palpation is utilized when the muscle grade is below Fair. Detecting substitutions is a skill that OT practitioners gain with time and experience.

Knowledge and Skill of the Occupational Therapist

The safety, reliability, and validity of MMT depends on the knowledge, abilities, and skills of the OT practitioner. This begins with detailed understanding of the muscular system (muscle anatomy, innervation, origin, and insertion), kinesiology (muscle action and function, direction of muscle fibers, the role of muscles in fixation and substitution), and skeletal system (joints, motions, end-feels, and normal range of motion). The therapist must be able to observe the contour of a muscle to determine if it is normal, atrophied, or hypertrophied. He or she must be able to detect abnormal movements, postures, and positions. The therapist must be able to position his or her body as well as the client's body and body part and apply stabilization and pressure adequately, or he or she must be able to instruct and closely supervise a proxy to help perform these physical skills. The ability to locate and feel contracting muscles is required. The OT practitioner must know and be competent using consistent methods in the application of test procedures. Careful observation of movement, careful and accurate palpation, correct positioning, consistency of procedure, and the experience of the therapist are critical factors in accurate testing.[10,12-14] Knowledge and experience are necessary to detect substitutions and interpret strength grades with accuracy.[12-14]

It is necessary for the OT practitioner to acquire skill and experience in testing and grading the muscles of a wide range of typical individuals of both genders and of all ages before determining how “normal” presents in the clinical setting. Although definitions of muscle grades are standardized, conducting a manual muscle test consists of both subjective and objective components. Subjective components relate to the OT practitioner's perception of how much pressure/resistance was applied, relative to expectations based on experience of what is typical strength for a person of that size, age, history, and so on. Objective factors primarily relate to the clients' range of motion in a specific plane. Collectively, the objective and subjective components inform the therapist's clinical reasoning to assign a specific muscle grade. Because many factors affect muscle strength, experience is required to help therapists differentiate among strength grades.[19]

Principles of Manual Muscle Testing

Preparation for Testing

After performing necessary screening tests, the client is positioned on a stable chair or table per directions outlined in specific testing procedures. If several tests are to be administered, they are sequenced to avoid frequent repositioning of the client.[12,13,21] Clothing is arranged or removed to avoid interference with motion, contraction, or application of pressure, and to allow for observation of muscle contour (symmetry between sides, hypertrophy, or atrophy). The OT practitioner is positioned close to the client's body part being tested to minimize upward and outward reaching. This allows for support of a weakened extremity on the OT practitioner's body, decreases the amount of force that must be generated when applying pressure, protects the OT practitioner's joint structures, and prevents overall fatigue.

Specific Procedure for Testing

To ensure accuracy and consistency, MMT must always be performed according to standardized procedures. If modifications are performed, they must be described and documented. The procedure for MMT of the extremities is described in Table 22.1. Procedures for testing the face, neck, and trunk are document elsewhere.[6,8,10,12-14]

TABLE 22.1

Manual Muscle Test Procedure

1. *Body position:* The client is placed in a stable position that allows the muscle group to perform the action against gravity (vertical plane).
2. *Action:* After being shown the motion to be tested, the client actively performs the action against gravity through the maximal available range of motion.*
3. *Test position.* The joint is positioned midway through the available range of motion.
4. *Stabilize.* The OT practitioner stabilizes the body part just proximal to the joint that is moving while simultaneously observing the motion.
5. *Pressure.* The OT practitioner applies pressure opposite to the direction of muscle contraction and movement.

*Depending on the results in step 2, the following procedures are followed:

(a) If the client demonstrates active ROM through the available PROM, the OT practitioner positions the joint in midrange (approximately 50% of full available PROM), stabilizes the body part proximal to the joint being tested (to isolate the muscle group, ensure the correct test motion, and prevent substitutions), and applies pressure perpendicular to the moving body part in a direction that is opposite to the motion being tested. Pressure is applied as distal as possible on the moving body part without crossing the next joint. For example, when elbow flexion is tested, the therapist applies pressure in the direction of extension. The client should be prepared to establish a maximal contraction when the OT practitioner applies pressure.[10,15]

(b) If AROM is less than the available PROM, the OT practitioner positions the client's body part in a manner that limits the effect of gravity (body part supported by the OT practitioner in a horizontal plane that is parallel to the ground) and the client is asked to perform the action in the gravity-minimized (horizontal) plane.

(i) If the client performs the motion through full available PROM on the gravity-lessened plane, the body part is placed at midrange and the therapist attempts to move the body part out of the position using slight pressure.

(ii) If the client is unable to perform the motion through full available PROM, no pressure is applied.

(iii) If no motion is noted in the horizontal plane, the therapist palpates over the muscle belly or tendon of the muscles being tested and asks the client to attempt the motion while palpating for muscle contraction.

Grading of Muscle Strength

The criteria for grading of muscle strength are listed in Table 22.2.[6,10,12,13,21]. The highest grade that can be assigned is grade 5, or Normal. For a client to be assigned this muscle grade, the client must demonstrate full AROM against gravity and tolerate maximal pressure. If a muscle group is able to complete full range against gravity but is unable to withstand the maximal pressure, it is assigned a grade 4, Good. The therapist will assign a grade 4 when the muscle “yields” or “gives” when it is no longer able to withstand maximal pressure. A muscle or muscle group is deemed a grade 3, Fair, if it can move through the full ROM against gravity but cannot tolerate additional pressure from the OT practitioner. The muscle group will easily yield if the therapist provides only slight pressure. If a muscle group is assigned a muscle grade of 2, Poor, the muscle group is able to complete full ROM in a gravity-minimized plane. If the muscle group is unable to move the body through any ROM of motion in a gravity-minimized plane but the therapist can feel tension or contraction in the muscle group upon palpation, the muscle is a grade 1, Trace. The client does not need to be placed in a gravity-minimized plane to palpate the muscle contraction. When the therapist is unable to feel the contraction, the muscle is assigned a grade 0, Zero. The decision tree in Figure 22.4 is a useful guide.

TABLE 22.2

Muscle Grades

Grade (Number)	Grade (Name)		Gravity	AROM	Pressure
5	Normal	N	Against	Full	Maximal
4	Good	G	Against	Full	Moderate
3+	Fair plus	F+	Against	Full	Slight
3	Fair	F	Against	Full	None
3–	Fair minus	F–	Against	More than 50%	None
			Against	Less than 50%	None
2+	Poor plus	P+	Gravity minimized	Full	Slight
2	Poor	P	Gravity minimized	Full	None
2–	Poor minus	P–	Gravity minimized	Partial	None
1	Trace	T	Against or gravity minimized	No motion	Contraction observed/felt
0	Zero	0	Against or gravity minimized	No motion	No movement

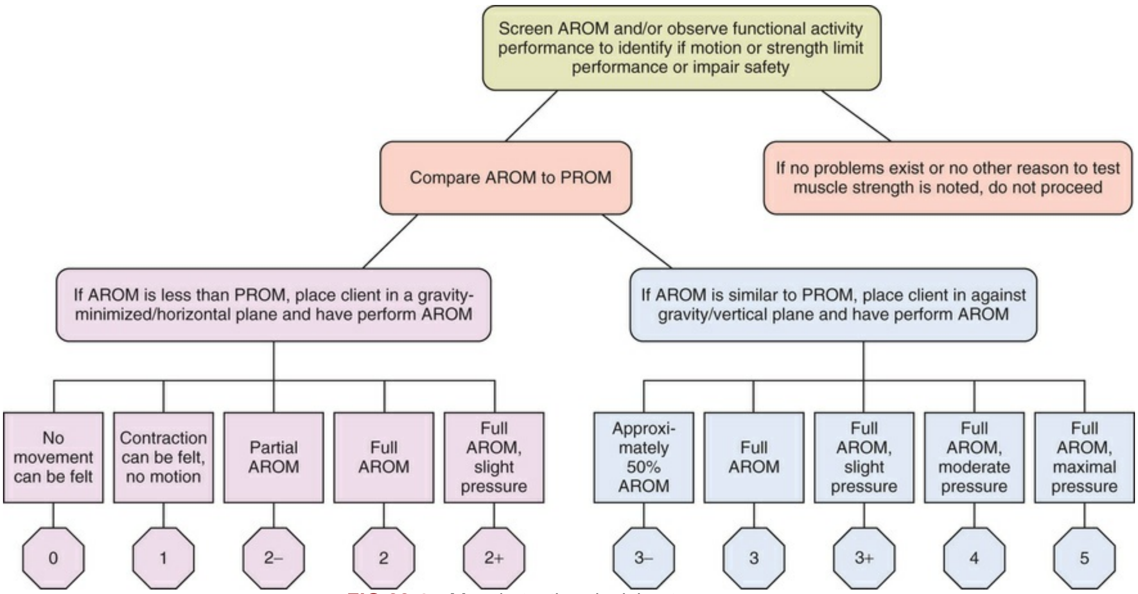

FIG 22.4 Muscle testing decision tree.

The purpose of using "plus" or "minus" designations with muscle grades is to "fine grade" muscle strength. These designations are likely to be used by the experienced OT practitioner. The results of two OT practitioners testing the same individual may vary up to a half grade, but there should not be a whole grade difference.[19] Practice among a work group of OT practitioners can standardize techniques and calibrate muscle grading to improve interrater reliability.

If tests of the forearm, fingers, and toes are performed against gravity rather than in the gravity-minimized plane, the standard definitions of muscle grades can be modified when muscle grades are recorded. Partial ROM against gravity is graded Poor (2), and full ROM against gravity is graded Fair (3).[10]

If the client cannot be placed in the correct position for the test, the OT practitioner must adapt the test and use clinical judgment in approximating strength grades.[19] In addition to correct positioning, test reliability and validity depend on careful stabilization, palpation of the muscles, and observation of movement.[10]

Manual Muscle Testing of the Upper Extremity

The muscles performing each action, their innervation, and the specific procedures for testing are described in the following sections. The practitioner is positioned to allow for optimal viewing of client positioning, which may not be the most mechanically advantageous position for the OT practitioner. The evaluator should stand as close as possible to the body part that is being tested. Pressure should always be applied perpendicular to the distal body part, which may not always be demonstrated in order to maintain optimal viewing of the client's positioning.

Shoulder Flexion (Fig. 22.5)

Muscles[10,18,22]	Innervation[6,10,18,22]
Anterior deltoid	Axillary nerve, C5, C6
Coracobrachialis	Musculocutaneous nerve, C5–7
Bicep brachii (short head)	Musculocutaneous, C5, C6
Pectoralis major (clavicular head)	Lateral and medial pectoral nerves, C5, C6

Procedure for Testing Grades Normal (5), Good (4), and Fair (3)

1. Body position	The client is seated on a supportive chair or mat—if trunk stability or balance is impaired, the trunk is externally supported. The therapist stands on the side being tested.	
2. Action	While demonstrating movement from neutral to full shoulder flexion, the therapist says, "Move your arm like I did." Observe the client actively performing the movement. Allow client's scapula and clavicle to move along with the humerus.	 FIG 22.5 **A,** Shoulder flexion: action—muscle grades 3 and above.
3. Test position	If client performs through available PROM, place shoulder at 90 degrees of flexion and proceed. If not, follow procedure for testing grades Poor, Trace, and Zero.	
4. Stabilize	Therapist stabilizes the scapula and clavicle by placing hand over superior shoulder girdle just proximal to glenohumeral joint. Client is stabilized in chair if needed.	
5. Pressure	Tell the client, "Don't let me move you." Apply pressure perpendicular to the distal humerus in downward fashion (toward shoulder extension), adjusting pressure to client's abilities. (a) Maximal pressure = Normal (b) Moderate pressure = Good (c) Minimal pressure = Good− (d) Slight pressure = Fair+ (e) No pressure = Fair	 FIG 22.5 **B,** Shoulder flexion: application of pressure.

Procedure for Testing Grades Poor (2), Trace (1), and Zero (0)

1. Body position	The client is side-lying on the side that is not being tested. If the client cannot maintain the weight of the upper extremity (UE) against gravity, the therapist supports it.[6,12] If the side-lying position is not feasible, the client may remain seated, and the test procedure is performed with grading modified.[10]	

		 FIG 22.5 **C,** Shoulder flexion: palpation—for muscle grades 2 and below.
2. Action	Beginning in midposition, move client's shoulder through partial flexion ROM twice while stating, "Move your arm like I did." (a) If client performs full ROM, place in 90 degrees of shoulder flexion and apply slight pressure perpendicular to the distal humerus toward shoulder extension. (i) If tolerates pressure = Poor+ (ii) No pressure = Poor (b) If client performs through partial ROM, do not apply pressure = Poor− (c) If client is unable to perform motion, place in 90 degrees of shoulder flexion and state, "Try to move your arm like I did." Palpate over anterior glenohumeral joint to feel for contraction in shoulder flexor muscle(s). (i) If muscle contraction palpable = Trace. (ii) If no contraction palpable = Zero.	

Substitution(s): Observe for flexion accompanied by horizontal adduction, external rotation, or scapula elevation.[10,15,21] Also look for hyperextension of the trunk.

FIG 22.5 **D,** Shoulder flexion: substitutions.

Note: Arm elevation in the plane of the scapula, about halfway between shoulder flexion and abduction, is called scaption. This movement is used for function more commonly than shoulder flexion or abduction. Scaption is performed by the deltoid and supraspinatus muscles. It is tested in a way similar to that used for shoulder flexion, except the arm is in a position 30 to 45 degrees anterior to the frontal plane.[6,12]

Shoulder Extension (Figs. 22.6 to 22.11)

Muscles[4,10,14,18,22]	**Innervation**[6,10,18,22]
Latissimus dorsi	Thoracodorsal nerve, C6–8
Teres major	Lower subscapular nerve, C5–7
Posterior deltoid	Axillary nerve, C5, C6
Infraspinatus	Suprascapular, C4–6
Teres minor	Axillary nerve, C5, C6
Triceps brachii (long head)	Radial nerve, C6–8
Pectoralis major (sternal head)	Lateral and medial pectoral nerves, C7, C8, T1

Procedure for Testing Grades Normal (5), Good (4), and Fair (3)

1. Body position	The client is sitting on chair without back or lying prone on mat. If trunk stability or balance is impaired, the trunk is externally supported. Shoulder is at side in neutral position.[6,7,12] The therapist stands behind the side being tested.	
2. Action	While passively moving the client's shoulder from neutral to shoulder extension, the therapist says, "Move your arm like I did." Observe the client actively performing the movement.	
3. Test position	If client performs through available PROM, place shoulder at 30 degrees extension and proceed. If not, follow procedure for testing grades Poor, Trace, and Zero.	

		 FIG 22.6 Shoulder extension: action—muscle grades 3 and above.  FIG 22.7 Shoulder extension: alternate test position—muscle grades 3 and above.
4. Stabilize	Therapist stabilizes scapula and clavicle by placing hand over superior shoulder girdle just proximal to glenohumeral joint. If sitting, client is stabilized in chair if needed.	
5. Pressure	Tell the client, "Don't let me move you." Apply pressure perpendicular to the distal humerus in downward fashion, adjusting pressure to client's abilities. (a) Maximal pressure = Normal (b) Moderate pressure = Good (c) Minimal pressure = Good− (d) Slight pressure = Fair+ (e) No pressure = Fair	 FIG 22.8 Shoulder extension: application of pressure.  FIG 22.9 Shoulder extension: application of pressure.

Procedure for Testing Grades Poor (2), Trace (1), and Zero (0)

1. Body position	The client is placed side-lying on side that is not being tested. If the client cannot maintain the weight of the UE against gravity, the therapist supports it.[6,12] If the side-lying position is not feasible, the client may remain seated or in prone, and the test procedure is performed with the grading modified.[10]	 FIG 22.10 Shoulder extension: positioning—for testing muscle grades 2 and below.
2. Action	Beginning in midposition, move the client's shoulder through partial extension ROM twice while stating, "Move your arm like I did" (see FIG 22.10). (a) If client performs full ROM, place in 30 degrees of shoulder extension and apply slight pressure perpendicular to the distal humerus. (i) If tolerates pressure = Poor+ (ii) No pressure = Poor (b) If client performs through partial ROM, do not apply pressure. (i) = Poor− (c) If client is unable to perform motion, place in 90 degrees of shoulder flexion and state, "Try to move your arm like I did." Palpate over posterior glenohumeral joint to feel for contraction in shoulder extensor muscle(s). (i) If muscle contraction palpable = Trace (ii) If no contraction palpable = Zero	
Substitution(s): If sitting, trunk flexion or scapular anterior tilting.  FIG 22.11 Shoulder extension: substitution.		

Shoulder Abduction (Figs. 22.12 to 22.14)

Muscles[10,14]	**Innervation**[10]
Middle deltoid	Axillary nerve, C5,6
Supraspinatus	Suprascapular nerve, C4, C5, C6

Procedure for Testing Grades Normal (5), Good (4), and Fair (3)

1. Body position	The client is seated on a supportive chair or mat. If trunk stability or balance is impaired, the trunk is externally supported. The therapist stands behind the client.[6,7,12]	
2. Action	While demonstrating movement from neutral to full shoulder abduction, the therapist says, "Move your arm like I did." Observe the client actively performing the movement. Allow client's scapula and clavicle to move along with the humerus.	

		 FIG 22.12 Shoulder abduction: action—muscle grades 3 and above.
3. Test position	If client performs through available PROM, place shoulder at 90 degrees of abduction and proceed. If not, follow procedure for testing grades Poor, Trace, and Zero.	
4. Stabilize	Therapist stabilizes scapula and clavicle by placing hand over superior shoulder girdle proximal to glenohumeral joint. Client is stabilized in chair if needed.	
5. Pressure	Tell the client, "Don't let me move you." Apply pressure perpendicular to the distal humerus in downward fashion toward adduction, adjusting pressure to client's abilities. If pressure is maximal = Normal, moderate = Good, minimal = Good−, slight = Fair+, and no pressure = Fair.	 FIG 22.13 Shoulder abduction: application of pressure.

Procedure for Testing Grades Poor (2), Trace (1), and Zero (0)

1. Body position	The client is in the supine position, lying with the arm to be tested resting at the side of the body. The therapist stands on the side to be tested,[10,12] providing UE support if needed.	
2. Action	(a) Beginning in midposition, move client's shoulder through partial abduction ROM twice while stating, "Move your arm like I did." a. If client performs full ROM, place in 90 degrees of shoulder abduction and apply slight pressure perpendicular to the distal humerus. (i) If tolerates pressure = Poor+. (ii) No pressure = Poor. (b) If client performs through partial ROM, do not apply pressure = Poor−. If client is unable to perform motion, place in 90 degrees of shoulder abduction and state, "Try to move your arm like I did." Palpate superior to glenohumeral joint to feel for contraction in shoulder abductor muscle(s). (i) If muscle contraction palpable = Trace. (ii) If no contraction palpable = Zero.	 FIG 22.14 Shoulder abduction: position and palpation—muscle grades 2 and below.
Substitutions: The long head of the biceps may attempt to substitute. Observe for elbow flexion and external rotation accompanying the movement.[12] The anterior and posterior deltoids can act together to effect abduction. The upper trapezius may attempt to assist. Observe for scapula elevation preceding movement.[7,15,21]		

Shoulder External Rotation (Figs. 22.15 to 22.19)

Muscles[4,10,14]	Innervation[4,10,14]
Infraspinatus	Suprascapular nerve, C5, C6
Teres minor	Axillary nerve, C5, C6
Posterior deltoid	Axillary nerve, C5, C6

Procedure for Testing Grades Normal (5), Good (4), and Fair (3)

1. Body position	The client is prone (or sitting), with the shoulder abducted to 90 degrees and the humerus in neutral rotation, elbow flexed to 90 degrees. The forearm is in neutral rotation, hanging over the edge of the table, perpendicular to the floor.[6-8,12] A rolled towel under distal humerus will elevate the humerus to full abduction and may increase comfort. The therapist stands in front of the supporting surface, toward the side to be tested.[10,14]	
2. Action	The therapist demonstrates the movement from neutral to full shoulder external rotation. The therapist then says, "Move your arm like I did."	 FIG 22.15 Shoulder external rotation: test position—muscle grades 3 and above.  FIG 22.16 Shoulder external rotation: alternate test position—muscle grades 3 and above.
3. Test position	If client performs through available PROM, place shoulder in midexternal rotation ROM (approximately 40 degrees) and proceed. If not, follow the procedure for testing grades Poor, Trace, and Zero.	
4. Stabilize	The therapist provides stabilization at the distal end of the humerus by placing a hand under the distal humerus on supporting table.[7,14]	
5. Pressure	The therapist tells the client, "Don't let me move you." Apply pressure perpendicular to the distal end of the forearm toward the direction of internal rotation, adjusting pressure to the client's abilities. If pressure is maximal = Normal, moderate = Good, minimal = Good−, slight = Fair+, and no pressure = Fair.	 FIG 22.17 Shoulder external rotation: application of pressure.

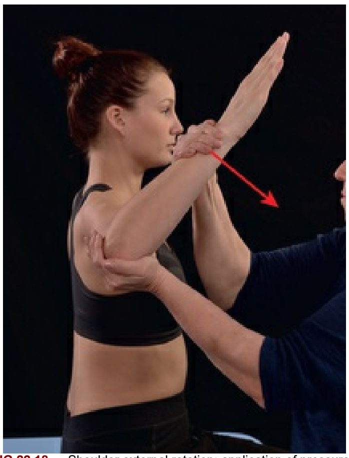

FIG 22.18 Shoulder external rotation: application of pressure.

Procedure for Testing Grades Poor (2), Trace (1), and Zero (0)

1. Body position	The client is seated, with arm adducted and in neutral rotation at the shoulder. The elbow is flexed to 90 degrees, with the forearm in neutral rotation. The therapist stands in front of the client toward the side to be tested.[6,7]	
2. Action	Move client's shoulder through partial external rotation ROM twice while stating, "Move your arm like I did." (a) If client performs full ROM, place in 40 degrees of external rotation and apply slight pressure to the distal forearm toward internal rotation. (i) If tolerates pressure = Poor+. (ii) No pressure = Poor. (b) If client performs through partial ROM do not apply pressure = Poor−. (c) If client is unable to perform motion, place in 40 degrees of external rotation and state, "Try to move your arm like I did." Palpate over posterior shoulder and scapula to feel for contraction in external rotators (see FIG 22.19). (i) If muscle contraction palpable = Trace. (ii) If no contraction palpable = Zero.	 FIG 22.19 Shoulder external rotation: position and palpation—muscle grades 2 and below.
Substitutions: If the elbow is extended and the client supinates the forearm, the momentum could aid external rotation of the humerus. Scapular adduction can pull the humerus backward and into some external rotation. The therapist should observe for scapula adduction and initiation of movement with forearm supination.[15,21]		

Shoulder Internal Rotation (Figs. 22.20 to 22.22)

Muscles[10,14,15]	Innervation[4,5,10]
Subscapularis	Subscapular nerve, C5–7
Pectoralis major	Medial and lateral pectoral nerves, C5–T1
Latissimus dorsi	Thoracodorsal nerve, C6–8
Teres major	Lower subscapular nerve, C5–6
Anterior deltoid	Axillary nerve, C5–6

Procedure for Testing Grades Normal (5), Good (4), and Fair (3)

1. Body position	The client is prone, with the shoulder abducted to 90 degrees, the humerus in neutral rotation, and the elbow flexed to 90 degrees. A rolled towel may be placed under the distal humerus (FIG 22.20). The forearm is perpendicular to the floor. The therapist stands on the side to be tested, just in front of the client's arm.[6-8,12]	

		 FIG 22.20 Shoulder internal rotation: test position—muscle grades 3 and above.
2. Action	While demonstrating movement from neutral to full internal rotation, the therapist says, “Move your arm like I did.” Observe the client actively performing the movement (FIG 22.21).	 FIG 22.21 Shoulder internal rotation: application of pressure.
3. Test position	If client performs through available PROM, place shoulder into midrange of internal rotation (approximately 40 degrees) and proceed.	
4. Stabilize	The therapist provides stabilization at the distal end of the humerus by placing a hand under the arm and on the supporting surface, as for external rotation.[6,7,10,14]	
5. Pressure	The therapist tells the client, “Don't let me move you,” then applies pressure at the distal end of the volar surface of the forearm anteriorly toward external rotation, adjusting pressure to the client's abilities (see FIG 22.21).	

Procedure for Testing Grades Poor (2), Trace (1), and Zero (0)

1. Body position	The client is seated, with the shoulder adducted and in neutral rotation, elbow flexed to 90 degrees with the forearm in neutral rotation. The therapist stands on the side to be tested[6,21] and supports forearm (FIG 22.22).	 FIG 22.22 Shoulder internal rotation: position and palpation—muscle grades 2 and below.
2. Action	Beginning in midposition, move client's shoulder through partial internal rotation ROM twice while stating, “Move your arm like I did.” (a) If client performs full ROM, place in midshoulder internal rotation (approximately 40 degrees) and apply slight pressure to distal forearm into internal rotation. (i) If tolerates pressure = Poor+. (ii) No pressure = Poor. (b) If client performs through partial ROM, do not apply pressure = Poor−. (c) If client is unable to perform motion, place in midrange of internal rotation (approximately 40 degrees) and state, “Try to move your arm like I did.” Palpate over anterior glenohumeral joint to feel for contraction in internal rotators (see FIG 22.22). (i) If muscle contraction palpable = Trace. (ii) If no contraction palpable = Zero.	
Substitutions: If the trunk is rotated, gravity will act on the humerus, rotating it internally.[6] The therapist should observe for trunk rotation. When the elbow is in extension, pronation of the forearm can substitute.[10,15,21]		

Shoulder Horizontal Abduction (Figs. 22.23 to 22.26)

Muscles[4,10,15]	Innervation[10,13]
Posterior deltoid	Axillary nerve, C5,6
Infraspinatus	Suprascapular nerve, C5,6

Procedure for Testing Grades Normal (5), Good (4), and Fair (3)

1. Body position	The client is prone, with the UE hanging over the edge of the mat, shoulder in about 90 degrees of scaption and neutral rotation, and elbow extended. The therapist stands on the side being tested[14,15] (FIG 22.23).	 FIG 22.23 Shoulder horizontal abduction: test position—muscle grades 3 and above.
2. Action	The therapist moves the client's UE from a position above into full horizontal abduction and says, "Move your arm like I did." Observe the client actively performing the movement (FIG 22.24).	 FIG 22.24 Shoulder horizontal abduction: application of pressure.
3. Test position	If client performs through available PROM, place shoulder into 90 degrees horizontal abduction (UE will be parallel to the floor) and proceed. If not, follow procedure for testing grades Poor, Trace, and Zero.	
4. Stabilize	The therapist provides stabilization over the scapula.[6,10] If needed, stabilization can move to the opposite scapula to stabilize the client's trunk (see FIG 22.24).	
5. Pressure	Tell the client, "Don't let me move you," then apply pressure over the distal humerus downward toward horizontal adduction. Be sure the table does not restrict motion (see FIG 22.24).	

Procedure for Testing Grades Poor (2), Trace (1), and Zero (0)

1. Body position	The client is seated, with the arm in 90-degree abduction and the palm down, supported on a high table or by the therapist.[6,12] (FIG 22.25). If a table is used to support the weight of the upper extremity, powder may be sprinkled on the surface or the limb can be placed on a rolling support (similar to a small skateboard) to reduce friction.	 FIG 22.25 Shoulder horizontal abduction: position and palpation for muscle grades 2 and below.
2. Action	Beginning in midposition, move client's shoulder through partial horizontal abduction ROM twice while stating, "Move your arm like I did."	

	(a) If client performs full ROM, place in 90 degrees of horizontal abduction and apply slight pressure to distal humerus toward horizontal adduction. (i) If tolerates pressure = Poor+. (ii) No pressure = Poor. (b) If client performs through partial ROM, do not apply pressure = Poor−. (c) If client is unable to perform motion, place in 90 degrees of horizontal abduction and state, “Try to move your arm like I did.” Palpate over posterior glenohumeral joint to feel for contraction in horizontal abductors. (i) If muscle contraction palpable = Trace. (ii) If no contraction palpable = Zero.	

Specific Muscle Testing: The posterior deltoid can be isolated by positioning the client in the sitting position, with the shoulder in 90 degrees abduction and approximately 35 degrees of internal rotation. The trunk is stabilized and pressure is applied over the distal humerus toward horizontal adduction and extension (FIG 22.26).[14]

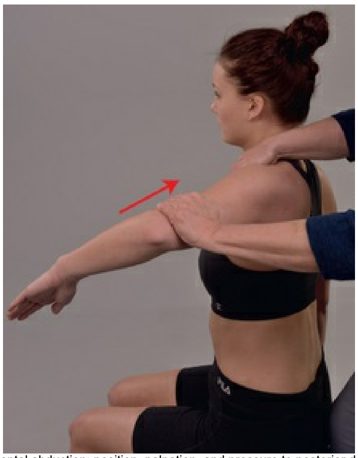

FIG 22.26 Shoulder horizontal abduction: position, palpation, and pressure to posterior deltoid for muscle grades 2+.

Substitutions: Latissimus dorsi and teres major may assist movement if the posterior deltoid is very weak. Movement will occur with more shoulder extension rather than at the horizontal level. Scapula adduction may produce slight horizontal abduction of the humerus, but trunk rotation and shoulder retraction would occur.[6,15,21] The long head of the triceps may substitute. Maintain some flexion at the elbow to prevent this.[12]

Shoulder Horizontal Adduction (Figs. 22.27 to 22.29B)

Muscles[4,12-14]	Innervation[4,10,12,13]
Pectoralis major	Medial and lateral pectoral nerves, C5-T1
Anterior deltoid	Axillary nerve, C5, C6
Coracobrachialis	Musculocutaneous nerve, C6, C7
Biceps brachii (short head)	Musculocutaneous nerve, C5, C6

Procedure for Testing Grades Normal (5), Good (4), and Fair (3)

1. Body position	The client is supine, with the shoulder abducted to 90 degrees, elbow flexed or extended. The therapist stands next to the client on the side being tested or behind the client's head.[4,6,7,10,12]	
2. Action	The therapist moves the client into horizontal adduction and says, “Move your arm like I did.” Observe the client actively performing the movement (FIG 22.27).	 FIG 22.27 Shoulder horizontal adduction: test position and action—muscle grades 3 and above.
3. Test position	If client performs through available PROM, place shoulder into midhorizontal adduction (approximately 80 degrees) (see FIG 22.27) and proceed. If not, follow procedure for testing grades Poor, Trace, and Zero.	
4. Stabilize	The therapist stabilizes the trunk by placing one hand over the anterior shoulder on the side opposite to that being tested to stabilize the trunk (FIG 22.28).	

		 FIG 22.28 Shoulder horizontal adduction: stabilizing and application of pressure.
5. Pressure	Tell the client, "Don't let me move you," then apply pressure over the distal humerus in outward direction toward horizontal abduction (see FIG 22.28).	

Procedure for Testing Grades Poor (2), Trace (1), and Zero (0)

1. Body position	The client is seated with shoulder in 90 degrees of shoulder abduction with arm supported on high table[4,12,21] or by therapist (FIG 22.29, A). If a table is used to support the weight of the upper extremity, powder may be sprinkled on the surface or the limb can be placed on a rolling support (similar to a small skateboard) to reduce friction.	 FIG 22.29 A, Shoulder horizontal adduction: position and palpation for muscle testing the clavicular portion grades 2 and below.
2. Action	Move client's shoulder into horizontal adduction twice while stating, "Move your arm like I did." (a) If client performs full ROM, place in slight horizontal adduction and apply slight pressure toward horizontal abduction. (i) If tolerates pressure = Poor+. (ii) No pressure = Poor. (b) If client performs through partial ROM, do not apply pressure = Poor−. (c) If client is unable to perform motion, place shoulder in slight horizontal abduction and state, "Try to move your arm like I did." Palpate over anterior shoulder girdle for muscle contraction. (i) If muscle contraction palpable = Trace. (ii) If no contraction palpable = Zero.	
Specific muscle testing: The sternal and clavicular heads of the pectoralis major can be tested individually. The above-described procedure tests the clavicular head (however, the thumb must point toward the opposite shoulder), whereas bringing the hand from the position demonstrated in FIG 22.29, B, toward the opposite hip (with the thumb pointing toward opposite hip) isolates the sternal head. Stabilization of the opposite hip is provided, and pressure is toward horizontal abduction and abduction.[14]  FIG 22.29 B, Shoulder horizontal adduction: position, palpation, and pressure to the sternal head of the pectoralis major—muscle grades 2+.		
Substitutions: If the pectoralis major is not functioning, strength will decline significantly.[15] Contralateral trunk rotation can substitute if trunk is not adequately stabilized.[6]		

Elbow Flexion (Figs. 22.30 to 22.32)

Muscles[10,12-14]	Innervation[12-14]
Biceps brachii	Musculocutaneous nerve C5, C6
Brachialis	Musculocutaneous nerve C5, C6
Brachioradialis	Radial nerve C5–7
Pronator teres	Median nerve C5, C6

Procedure for Testing Grades Normal (5), Good (4), and Fair (3)

1. Body position	Client is seated on a supportive chair or mat—if trunk stability or balance is impaired the trunk is externally supported. Shoulder and elbow in neutral. Therapist stands on side being tested.	

2. Action	While demonstrating movement from neutral to full elbow flexion with forearm supinated, the therapist says, "Move your arm like I did." Observe the client actively performing the movement (FIG 22.30).	 FIG 22.30 Elbow flexion: action.
3. Test position	If client performs through available PROM, place elbow at 90 degrees of flexion with forearm supinated and proceed. If not, follow procedure for testing grades Poor, Trace, and Zero.	
4. Stabilize	The therapist provides stabilization under the elbow joint.	
5. Pressure	Tell the client, "Don't let me move you." Apply pressure over the distal volar forearm in a downward fashion toward elbow extension, adjusting pressure to client's abilities (FIG 22.31). If pressure is maximal = Normal, moderate = Good, minimal = Good−, slight = Fair+, and no pressure = Fair.	 FIG 22.31 Elbow flexion: application of pressure.

Procedure for Testing Grades Poor (2), Trace (1), and Zero (0)

1. Body position	The client is sitting or supine with shoulder abducted to 90 degrees. UE can be supported on a high table with powder sprinkled on top to prevent friction. Therapist stands on side being tested and supports arm and forearm as needed (FIG 22.32).	 FIG 22.32 Elbow flexion: body position, action, and palpation—muscle grades 2 and below.
2. Action	Beginning in midposition, move client's elbow through partial extension ROM twice while stating, "Move your arm like I did." (a) If client performs full ROM, place in 90 degrees of elbow flexion and apply slight pressure over distal volar wrist perpendicular to forearm. (i) If tolerates pressure = Poor+. (ii) No pressure = Poor. (b) If client performs through partial ROM, do not apply pressure = Poor−. (c) If client is unable to perform motion, place in 90 degrees of elbow flexion and state, "Try to move your arm like I did." Palpate over anterior arm and forearm to feel for contraction in elbow flexor muscle(s). (i) If muscle contraction palpable = Trace. (ii) If no contraction palpable = Zero.	

Specific muscle testing: A supinated forearm position tests primarily the biceps brachii, whereas pronated position tests brachialis and pronator teres[15]; neutral forearm position tests brachioradialis.[10,12,13]
Substitution: Wrist and extrinsic finger flexors may assist elbow flexion, which will be preceded by finger and wrist flexion.[10,12,13,15]

Elbow Extension (Figs. 22.33 to 22.38)

Muscles[6,10,12]	Innervation[10,12-14]
Triceps	Radial nerve, C6–8
Anconeus	Radial nerve, C7, C8, T1

Procedure for Testing Grades Normal (5), Good (4), and Fair (3)

1. Body position	The client is supine with shoulder in 90 degrees flexion, sitting with shoulder in full flexion, or prone with humerus abducted to 90 degrees. The elbow is flexed. The therapist stands next to the client, just behind the extremity to be tested.[7,14,21]	
2. Action	While demonstrating movement from elbow flexion to full extension, the therapist says, “Move your arm like I did.” Observe the client actively performing the movement (FIGS 22.33 and 22.34).	 FIG 22.33 Elbow extension: action.  FIG 22.34 Elbow extension: action—alternate action method.
3. Test position	If client performs through available PROM, place elbow in 45 degrees of flexion and proceed. If not, follow procedure for testing grades Poor, Trace, and Zero.	
4. Stabilize	The therapist provides stabilization at the humerus, avoiding the contracting fibers on posterior humerus.	
5. Pressure	The therapist tells the client, “Don't let me move you,” then applies pressure at the distal end of the forearm into elbow flexion, adjusting pressure to the client's abilities[3] (FIG 22.35) The elbow should not be locked in full extension, as this can cause joint injury.[6,10]	

		 FIG 22.35 Elbow extension: application of pressure.

Procedure for Testing Grades Poor (2), Trace (1), and Zero (0)

1. Body position	The client is sitting with shoulder in 90 degrees flexion, scaption, or abduction.[7,10,12] Shoulder and forearm are in neutral rotation. The therapist supports the weight of the arm while standing next to the client's arm being tested[10] (FIG 22.36).	 FIG 22.36 Elbow extension: application of pressure.
2. Action	Beginning in midposition, move client's elbow through partial extension ROM twice while stating, "Move your arm like I did" (FIG 22.37). (a) If client performs full ROM, place in 90 degrees of elbow flexion and apply slight pressure perpendicular to the forearm. (i) If tolerates pressure = Poor+. (ii) No pressure = Poor. (b) If client performs through partial ROM, do not apply pressure = Poor−. (c) If client is unable to perform motion, place in 90 degrees of shoulder flexion and state, "Try to move your arm like I did." Palpate just superior to the dorsal elbow over the tendon (FIG 22.38), or over the middorsal humerus over the muscle belly to feel for contraction in elbow extensor muscle(s). (i) If muscle contraction palpable = Trace. (ii) If no contraction palpable = Zero.	 FIG 22.37 Elbow extension: body position, action, and palpation—muscle grades 2 and below.

		 FIG 22.38 Elbow extension: alternate body position, action, and palpation—muscle grades 2 and below.
Substitutions: Extrinsic finger and wrist extensors may substitute for weak elbow extensors, as their proximal attachment crosses the elbow joint in a posterior manner. Observe for the presence of finger and wrist extension preceding elbow extension. When the client is upright, gravity and eccentric contraction of the biceps will effect elbow extension from the flexed position.[15] Scapula depression with shoulder external rotation aided by gravity may result in elbow extension.[6] The elbow will assume an extended position when a client who is sitting with the hand fixed on the bed or mat (closed chair) performs scapular protraction and contracts the shoulder flexors to move the proximal attachment. Once the elbow is "locked" in hyperextension, the client's body weight maintains elbow extension.		

Forearm Supination (Figs. 22.39 to 22.42)

Muscles[4,10,13]	Innervation[6,10,13]
Biceps brachii	Musculocutaneous nerve, C5, C6
Supinator	Radial nerve, C7–C8

Procedure for Testing Grades Normal (5), Good (4), and Fair (3)

1. Body position	The client is seated, with the humerus adducted, the elbow flexed to 90 degrees, and the forearm pronated. The therapist stands in front of the client or next to the client on the side to be tested.[6,7,10,12,13]	
2. Action	While demonstrating movement from neutral to full forearm supination, the therapist says, "Move your arm like I did." Observe the client actively performing the movement (FIG 22.39).	 FIG 22.39 Forearm supination: action.
3. Test position	If client performs through available PROM, place forearm in neutral position and proceed. If not, follow procedure for testing grades Poor, Trace, and Zero.	
4. Stabilize	If client is able to stabilize humerus next to side, therapist can use both hands to comfortably apply pressure to client. If not, therapist stabilizes humerus just proximal to elbow.[6,10]	
5. Pressure	Tell the client, "Don't let me move you." Therapist can "sandwich" the forearm between both hands on midforearm, applying pressure into pronation (FIG 22.40). Therapist can also grasp around the dorsal aspect of the distal forearm with the fingers and heel of the hand, while turning the arm toward pronation. Adjust pressure to client's abilities (FIG 22.41).	 FIG 22.40 Forearm supination: application of pressure.

		 FIG 22.41 Forearm supination: application of pressure—alternate method.

Procedure for Testing Grades Poor (2), Trace (1), and Zero (0)

1. Body position	The client is seated with shoulder and elbow flexed to 90 degrees and the upper arm resting on table or supported by the therapist (FIG 22.42). Can test lying supine with shoulder in neutral and elbow flexed to 90 degrees, or prone with shoulder in 90 degrees abduction and forearm lying over edge of table in a position perpendicular to the floor.[6,7,21] The therapist stands next to client on the side to be tested.	 FIG 22.42 Forearm supination: body position, action, and palpation—muscle grades 2 and below.
2. Action	Beginning in midposition, move client's forearm into supination twice while stating, "Move your forearm like I did." (a) If client performs full ROM, place in midposition and apply slight pressure toward pronation. (i) If tolerates pressure = Poor+. (ii) No pressure = Poor. (b) If client performs through partial ROM, do not apply pressure = Poor−. (c) If client is unable to perform motion, place forearm in midposition and state, "Try to move your forearm like I did." Palpate over anterior dorsal forearm just distal to lateral epicondyle to feel supinator contraction or over volar elbow for biceps brachii. (i) If muscle contraction palpable = Trace. (ii) If no contraction palpable = Zero.	
Specific muscle testing: To test only the supinator muscle, the elbow and shoulder are fully flexed to make the biceps actively insufficient. In this position it is hard to tell if the forearm is pronated or supinated, resulting in pressure applied into pronation. The therapist should orient to forearm position when the elbow is flexed. **Substitutions**: With the elbow flexed, external rotation and horizontal adduction of the humerus will effect forearm supination. With the elbow extended, shoulder external rotation will place the forearm in supination. The brachioradialis can bring the forearm from full pronation to midposition. Wrist and thumb extensors, assisted by gravity, can initiate supination. The therapist should note any external rotation of the humerus, supination to midline only, and initiation of motion by wrist and thumb extension.[10,13,15,21]		

Forearm Pronation (Figs. 22.43 to 22.46)

Muscles[4,12,13,15]	**Innervation**[12,14]
Pronator teres	Median nerve, C6,7
Pronator quadratus	Median nerve, C8, T1

Procedure for Testing Grades Normal (5), Good (4), and Fair (3)

1. Body position	The client is seated, with the shoulder and elbow flexed to 90 degrees, and the forearm supinated (FIG 22.43). The therapist stands beside client on the side to be tested.[6,7,10,13]	

		 FIG 22.43 Forearm pronation: action.
2. Action	While demonstrating movement from neutral to full forearm pronation, the therapist says, “Move your forearm like I did.” Observe the client actively performing the movement.	
3. Test position	If client performs through available PROM, place forearm in neutral position and proceed. If not, follow procedure for testing grades Poor, Trace, and Zero.	
4. Stabilize	If client is able to stabilize humerus next to side, therapist can use both hands to comfortably apply pressure to client. If not, therapist stabilizes humerus just proximal to elbow to prevent shoulder abduction.[6,7,10,14]	
5. Pressure	Tell the client, “Don't let me move you.” Therapist can “sandwich” the forearm between both hands on midforearm, applying pressure into supination (FIG 22.44). Therapist can also grasp around the dorsal aspect of the distal forearm with the fingers and heel of the hand, while turning the arm toward supination (FIG 22.45). Adjust pressure to client's abilities.	 FIG 22.44 Forearm pronation: application of pressure.  FIG 22.45 Forearm pronation: application of pressure—alternate method.

Procedure for Testing Grades Poor (2), Trace (1), and Zero (0)

1. Body position	The client is seated with shoulder and elbow flexed to 90 degrees and upper arm resting on table or supported by therapist. Can test with client in side-lying or supine with shoulder in neutral and elbow flexed to 90 degrees, or prone with shoulder in 90 degrees abduction and forearm lying over edge of table in a position perpendicular to the floor.[21] The therapist stands next to client on the side to be tested.	
2. Action	Beginning in midposition, move client's forearm into supination twice while stating, “Move your forearm like I did.” (a) If client performs full ROM, place in midposition and apply slight pressure toward supination. (i) If tolerates pressure = Poor+. (ii) No pressure = Poor. (b) If client performs through partial ROM do not apply pressure = Poor−. (c) If client is unable to perform motion, place forearm in midposition and state, “Try to move your forearm like I did.” Palpate over anterior volar forearm just distal to elbow and the volar distal forearm for muscle contraction (FIG 22.46). (i) If muscle contraction palpable = Trace. (ii) If no contraction palpable = Zero.	

		 FIG 22.46 Forearm pronation: body position, action, and palpation—muscle grades 2 and below.
Specific Muscle Testing: To isolate the pronator quadratus only, the elbow is fully flexed to render the pronator teres actively insufficient.[14] **Substitutions**: With the elbow flexed, internal rotation and abduction of the humerus will produce apparent forearm pronation. With the elbow extended, internal rotation can place the forearm in a pronated position. Brachioradialis can bring the fully supinated forearm to midposition. Wrist flexion, aided by gravity, can effect pronation.[6,7,10,12,13,15,21]		

Wrist Extension (Figs. 22.47 to 22.49)

Muscles[10,12,14]	Innervation[6,12]
Extensor carpi radialis longus	Radial nerve, C6, C7
Extensor carpi radialis brevis	Deep branch of radial nerve, C7, C8
Extensor carpi ulnaris	Posterior interosseous nerve off radial nerve, C7, C8

Procedure for Testing Grades Normal (5), Good (4), and Fair (3)

1. Body position	The client is seated or supine with the forearm resting on the supporting surface in pronation, and the fingers and thumb relaxed. The therapist sits opposite to or next to the client on the side to be tested.[10,14]	
2. Action	While demonstrating movement from neutral to full wrist extension, the therapist says, “Move your wrist like I did” (FIG 22.47). Observe the client actively performing the movement.	 FIG 22.47 Wrist extension: action.
3. Test position	If client performs through available PROM, place the wrist in slight extension and proceed. If not, follow procedure for testing grades Poor, Trace, and Zero.	
4. Stabilize	The therapist stabilizes over the volar or dorsal aspect of the distal forearm.[6,10,14]	
5. Pressure	Tell the client, “Don't let me move you.” Apply pressure dorsally over distal metacarpals in perpendicular fashion toward flexion, adjusting pressure to client's abilities (FIG 22.48). If pressure is maximal = Normal, moderate = Good, minimal = Good−, slight = Fair+, and no pressure = Fair.	 FIG 22.48 Wrist extension: application of pressure.

Procedure for Testing Grades Poor (2), Trace (1), and Zero (0)

1. Body position	Client is seated or supine with forearm resting in midposition on its ulnar border,[10,21] and fingers and thumb relaxed.	
2. Action	Move client's wrist into extension twice while stating, “Move your wrist like I did.” (a) If client performs full ROM, place in slight wrist extension and apply slight pressure toward wrist flexion. (i) If tolerates pressure = Poor+. (ii) No pressure = Poor. (b) If client performs through partial ROM do not apply pressure = Poor−. (c) If client is unable to perform motion, place forearm in midposition and state, “Try to move your wrist like I did.” Palpate over posterior dorsal forearm and dorsal wrist for muscle contraction (FIG 22.49). (i) If muscle contraction palpable = Trace. (ii) If no contraction palpable = Zero.	 FIG 22.49 Wrist extension: body position, action, and palpation—muscle grades 2 and below.

Specific muscle testing: Each wrist extensor muscle can be tested individually by combining wrist extension with radial deviation (extensor carpi radialis longus and brevis) or wrist extension with ulnar deviation (extensor carpi ulnaris). Pressure is performed opposite to the action.

Substitution: The extensor digitorum and extensor pollicis longus can initiate wrist extension, but finger or thumb extension will precede wrist extension.[6,7,12,13,15,21]

Wrist Flexion (Figs. 22.50 to 22.52)

Muscles[10,13]	**Innervation**[5,10,13]
Flexor carpi ulnaris	Ulnar nerve, C7–T1
Palmaris longus	Median nerve, C7–T1
Flexor carpi radialis	Median nerve, C6–8

Procedure for Testing Grades Normal (5), Good (4), and Fair (3)

1. Body position	The client is seated or supine with the forearm resting in nearly full supination on the supporting surface, fingers and thumb relaxed. The therapist is seated opposite or next to the client on the side to be tested.[10,14]	
2. Action	While demonstrating movement from neutral to full wrist flexion, the therapist says, “Move your wrist like I did” (FIG 22.50). Observe the client actively performing the movement.	 FIG 22.50 Wrist flexion: action.
3. Test position	If client performs through available PROM, the therapist places the wrist in slight wrist flexion and proceeds. If not, follow procedure for testing grades Poor, Trace, and Zero.	
4. Stabilize	The therapist stabilizes the forearm,[10,14] therapist's hand under dorsal forearm increases client comfort.	
5. Pressure	Tell the client, “Don't let me move you.” Apply pressure dorsally over distal volar palm toward extension, adjusting pressure to client's abilities (FIG 22.51). If pressure is maximal = Normal, moderate = Good, minimal = Good−, slight = Fair+, and no pressure = Fair.	 FIG 22.51 Wrist flexion: application of pressure.

Procedure for Testing Grades Poor (2), Trace (1), and Zero (0)

1. Body position	Client is seated or supine with forearm resting in midposition on its ulnar border[10,21] and fingers and thumb relaxed.[10] The therapist sits opposite or next to the client on the side being tested.	
2. Action	Move client's wrist into flexion twice while stating, “Move your wrist like I did.”	

	(a) If client performs full ROM, place in slight wrist flexion and apply slight pressure toward wrist flexion. (i) If tolerates pressure = Poor+. (ii) No pressure = Poor. (b) If client performs through partial ROM do not apply pressure = Poor−. (c) If client is unable to perform motion, place forearm in midposition and state, “Try to move your wrist like I did.” Palpate over volar forearm and wrist for muscle contraction (FIG 22.52). (i) If muscle contraction palpable = Trace. (ii) If no contraction palpable = Zero.	 FIG 22.52 Wrist flexion: body position, action, and palpation—muscle grades 2 and below.
Specific muscle testing: Each wrist flexor muscle can be tested individually by combining wrist flexion with radial deviation (flexor carpi radialis) or wrist flexion with ulnar deviation (flexor carpi ulnaris). The palmaris longus is tested by having the client oppose the thumb and small finger while flexing the wrist.[14] Pressure is applied to un-oppose (reposition) the thumb and extend the wrist. **Substitution**: The extrinsic finger flexors can also assist wrist flexion, but the motion will be preceded by flexion of the fingers.[6,15,21]		

Wrist Radial Deviation (Figs. 22.53 to 22.55)

Muscles[10,13]	Innervation[5,10,13]
Flexor carpi radialis	Median nerve, C6–8
Extensor carpi radialis longus	Radial nerve, C6, 7
Extensor carpi radialis brevis	Deep branch of radial nerve, C7, C8

Procedure for Testing Grades Normal (5), Good (4), and Fair (3)

1. Body position	The client is seated or supine with forearm in neutral rotation and wrist in slight extension and neutral deviation. Thumb will be pointing up. The therapist is seated or standing next to the client on the side to be tested.	
2. Action	While demonstrating movement from neutral to full wrist radial deviation, the therapist says, “Move your wrist like I did” (FIG 22.53). Observe the client actively performing the movement.	 FIG 22.53 Wrist radial deviation: action.
3. Test position	If client performs through available PROM, place the wrist in midradial deviation and proceed. If not, follow procedure for testing grades Poor, Trace, and Zero.	
4. Stabilize	The therapist stabilizes the forearm; therapist's hand under dorsal ulnar forearm increases client comfort.	
5. Pressure	Tell the client, “Don't let me move you.” Apply pressure radially over the distal second metacarpal or through the entire hand (not fingers) toward ulnar deviation, adjusting pressure to client's abilities (FIG 22.54). If pressure is maximal = Normal, moderate = Good, minimal = Good−, slight = Fair+, and no pressure = Fair.	 FIG 22.54 Wrist radial deviation: application of pressure.

Procedure for Testing Grades Poor (2), Trace (1), and Zero (0)

1. Body position	Client is seated or supine with volar surface of forearm resting on table, bed, or supported by therapist. The therapist sits opposite or next to the client on the side being tested.	
2. Action	Move client's wrist into radial deviation twice while stating, “Move your wrist	

	like I did." (a) If client performs full ROM, place in midradial deviation and apply slight pressure through distal second metacarpal or entire hand toward ulnar deviation. (i) If tolerates pressure = Poor+. (ii) No pressure = Poor. (b) If client performs through partial ROM, do not apply pressure = Poor−. (c) If client is unable to perform motion, place forearm in midposition and state, "Try to move your wrist like I did." Palpate over distal radial wrist for muscle contraction (FIG 22.55). (i) If muscle contraction palpable = Trace. (ii) If no contraction palpable = Zero.	 FIG 22.55 Wrist radial deviation: body position, action, and palpation—muscle grades 2 and below.
Substitution: The thumb extrinsic muscles (abductor and extensor pollicis longus) can radially deviate the wrist, but wrist motion will be preceded by thumb movement.		

Wrist Ulnar Deviation (Figs. 22.56A to 22.57)

Muscles[10,12,14]	**Innervation**[6,12]
Extensor carpi ulnaris	Posterior interosseous nerve off radial nerve, C7, C8
Flexor carpi ulnaris	Ulnar nerve, C7–T1

Procedure for Testing Grades Normal (5), Good (4), and Fair (3)

1. Body position	The client is seated or supine with forearm in neutral rotation and wrist in slight extension and neutral deviation. To get the action against gravity, the client's elbow and shoulder must be flexed. The therapist is seated or standing next to the client on the side to be tested.	
2. Action	While demonstrating movement from neutral to full ulnar deviation, the therapist says, "Move your wrist like I did." Observe as the client actively performs the movement (FIG 22.56, A).	 FIG 22.56 **A,** Wrist ulnar deviation: action.
3. Test position	If client performs through available PROM, place the wrist in midulnar deviation and proceed. If not, follow procedure for testing grades Poor, Trace, and Zero.	
4. Stabilize	The therapist stabilizes the distal forearm; therapist's hand under the distal radial forearm.	
5. Pressure	Tell the client, "Don't let me move you." Apply pressure radially over distal fifth metacarpal or through the entire hand (not fingers) toward radial deviation, adjusting pressure to the client's abilities (FIG 22.56, B). If pressure is maximal = Normal, moderate = Good, minimal = Good−, slight = Fair+, and no pressure = Fair.	 FIG 22.56 **B,** Wrist ulnar deviation: application of pressure.

Procedure for Testing Grades Poor (2), Trace (1), and Zero (0)

1. Body position	Client is seated or supine with volar surface of forearm resting on table, bed, or supported by therapist. The therapist sits opposite or next to the client on the side being tested.	
2. Action	Move client's wrist into ulnar deviation twice while stating, “Move your wrist like I did.” (a) If client performs full ROM, place in midulnar deviation and apply slight pressure on ulnar border of hand (not fingers) toward radial deviation. (i) If tolerates pressure = Poor+. (ii) No pressure = Poor. (b) If client performs through partial ROM, do not apply pressure = Poor−. (c) If client is unable to perform motion, place wrist in midposition and move toward ulnar deviation while stating, “Try to move your wrist like I did.” Palpate over the ulnar wrist and distal forearm for muscle contraction (FIG 22.57). (i) If muscle contraction palpable = Trace. (ii) If no contraction palpable = Zero.	 FIG 22.57 Wrist ulnar deviation: body position, action, and palpation—muscle grades 2 and below.

Metacarpophalangeal Flexion (Figs. 22.58 to 22.63)

Muscles[1,4,18,22]	Innervation[10,12,18,22]
Lumbricals 1 and 2 (index and long)	Median nerve, C8, T1
Lumbricals 3 and 4 (ring and small)	Ulnar nerve, C8, T1
Dorsal interossei (index, long, and ring)	Deep branch of ulnar nerve, C8, T1
Palmar interossei (index, ring, and small)	Deep branch of ulnar nerve, C8, T1
Flexor digitorum superficialis	
Flexor digitorum profundus	
Flexor digiti minimi (small)	

Procedure for Testing Grades Normal (5), Good (4), and Fair (3)

1. Body position	The client is seated or supine with forearm fully supinated and wrist stabilized in neutral resting on a supporting surface.[8] The therapist sits next to the client on the side being tested.	
2. Action	While demonstrating movement from neutral to full metacarpophalangeal (MP) flexion, the therapist says, “Move your finger(s) like I did” (FIG 22.58). Observe the client actively performing the movement.	 FIG 22.58 Metacarpophalangeal flexion: action.
3. Test position	If client performs through available PROM, place the MP joint(s) in midflexion and proceed (see FIG 22.58). If not, follow procedure for testing grades Poor, Trace, and Zero.	
4. Stabilize	The therapist stabilizes the metacarpal of digit being tested. If digits 2–5 are tested simultaneously, metacarpals 2–5 are stabilized.	
5. Pressure	Tell the client, “Don't let me move you.” Apply pressure over the volar proximal phalange(s) toward MP extension, adjusting pressure to client's abilities. If pressure is maximal = Normal, moderate = Good, minimal = Good−, slight = Fair+, and no pressure = Fair. FIG 22.59 depicts simultaneous testing of digits 2–5, with the intrinsic muscles that flex the MP joints targeted (as the interphalangeal [IP] joints are in extension), whereas FIG 22.60 depicts index finger testing only, allowing the extrinsic finger flexors to assist as the PIP joint is flexed.	 FIG 22.59 Metacarpophalangeal flexion: application of pressure to all digits.

FIG 22.60 Metacarpophalangeal flexion: application of pressure to index finger.

Procedure for Testing Grades Poor (2), Trace (1), and Zero (0)

1. Body position	Client's hand is resting on table or bed on the ulnar side of forearm and hand. The therapist is opposite or next to the client on the side being tested.	
2. Action	Move client's MP joint(s) into flexion twice while stating, "Move your finger(s) like I did." Digits can be tested simultaneously or individually depending on the need. (a) If client performs full ROM, place in mid-MP flexion and apply slight pressure toward MP extension. (i) If tolerates pressure = Poor+. (ii) No pressure = Poor. (b) If client performs through partial ROM, do not apply pressure = Poor−. (c) If client is unable to perform motion, place MP joints in midposition and state, "Try to move your finger(s) like I did." Palpate over the volar palm for muscle contraction (FIG 22.61); however, the intrinsics are very deep and contraction may not be palpable.[15,21] The first dorsal interossei is palpable over the distal web space. Contraction of the extrinsic finger flexors is palpable over the volar wrist (FIG 22.62). (i) If muscle contraction palpable = Trace. (ii) If no contraction palpable = Zero.	 FIG 22.61 Metacarpophalangeal flexion: body position, action, and palpation—muscle grades 2 and below. Palpation over volar surface of the palm.  FIG 22.62 Metacarpophalangeal flexion: body position, action, and palpation—muscle grades 2 and below. Alternate palpation method over volar surface of the wrist.

Specific muscle testing: To isolate the intrinsic muscles that flex the MP joints, MP flexion must be performed with the IP joints in full extension as the intrinsics perform IP extension concomitantly with MP flexion. When testing the extrinsic finger flexor muscles, the IP joints are flexed along with the MP joints; however, the extrinsic flexors are best isolated by testing their actions at the proximal interphalangeal (PIP) joints (flexor digitorum superficialis) or distal interphalangeal (DIP) joints (flexor digitorum profundus).[15,21] These tests are described in PIP and DIP sections.

Substitution: The joints of the fingers will move into a flexed position when the wrist is moved into extension; however, the motion is not due to active contraction of any muscles that flex the fingers. Because the extrinsic finger flexors pass volar to the wrist joint, they are of insufficient length to allow the fingers to stay extended when the wrist is actively or passively moved into extension; this is known as tenodesis, as insufficient tendon excursion pulls the fingers into flexion (FIG 22.63). To prevent tenodesis action, the wrist should be stabilized while testing the muscles that flex the fingers so the client cannot actively extend the wrist.

FIG 22.63 Metacarpophalangeal flexion: substitution—tenodesis action.

Metacarpophalangeal Extension (Figs. 22.64 to 22.67)

Muscles[10,13]	Innervation[10,13,18]
Extensor digitorum (ED)	Radial nerve, C7, C8
Extensor indicis	Posterior interosseous nerve, C7, C8
Extensor digiti minimi (EDM)	Posterior interosseous nerve, C7, C8
Lumbricals 1 and 2 (index and long)	Median nerve, C8, T1
Lumbricals 3 and 4 (ring and small)	Ulnar nerve, C8, T1
Dorsal interossei (index, long, and ring)	Deep branch of ulnar nerve, C8, T1
Palmar interossei (index, ring, and small)	Deep branch of ulnar nerve, C8, T1

Procedure for Testing Grades Normal (5), Good (4), and Fair (3)

1. Body position	The client is seated, with the forearm pronated and the wrist in neutral to slight extension, MP and IP joints relaxed in partial flexion.[7,10,12] The therapist sits opposite or next to the client on the side to be tested.	
2. Action	While demonstrating movement from neutral to full MP extension, the therapist says, “Move your finger(s) like I did” (FIG 22.64). Observe the client actively performing the movement.	 FIG 22.64 Metacarpophalangeal extension: action.
3. Test position	If client performs through available PROM, place the MP joint in midextension and proceed. If not, follow procedure for testing grades Poor, Trace, and Zero.	
4. Stabilize	The therapist stabilizes the wrist and metacarpals slightly above the supporting surface.[10,12-14] If testing fingers individually, the metacarpal corresponding to the finger being tested is stabilized.	
5. Pressure	Tell the client, “Don't let me move you.” Provide pressure to each finger individually on the dorsum of the proximal phalanx toward MP flexion (FIG 22.65).[6,10,14] Digits 2–5 can be tested simultaneously. If pressure is maximal = Normal, moderate = Good, minimal = Good−, slight = Fair+, and no pressure = Fair.	 FIG 22.65 Metacarpophalangeal extension: application of pressure.

Procedure for Testing Grades Poor (2), Trace (1), and Zero (0)

1. Body position	Client's hand is resting on table or bed on the ulnar side of forearm and hand.[10,12] The therapist is opposite or next to the client on the side being tested.	
2. Action	Move client's fingers into MP extension twice while stating, “Move your fingers like I did.” Digits can be tested simultaneously or individually depending on the need. (a) If client performs full ROM, place in mid-MP extension and apply slight pressure over distal proximal phalange(s) toward MP flexion. (i) If tolerates pressure = Poor+. (ii) No pressure = Poor. (b) If client performs through partial ROM do not apply pressure = Poor−. (c) If client is unable to perform motion, place MP joint in midposition and state, “Try to move your finger(s) like I did.” Palpate the ED tendons where they course over the dorsum of the hand[6,7,10] (FIGS 22.66 and 22.67). In some	

	individuals, the EDM tendon can be palpated or visualized just lateral to the ED tendon to the fifth finger. The extensor indicis tendon can be palpated or visualized just medial to the ED tendon to the first finger.[6] The intrinsic MP extensors are small and deep, making palpation difficult for anything besides the first dorsal interossei. (i) If muscle contraction palpable = Trace. (ii) If no contraction palpable = Zero.	 FIG 22.66 Metacarpophalangeal extension: body position, action, and palpation—muscle grades 2 and below. Palpation of the individual tendons of the ED.  FIG 22.67 Metacarpophalangeal extension: body position, action, and palpation—muscle grades 2 and below. Simultaneous palpation of all of the tendons of the ED.

Specific muscle testing: To isolate the extrinsic MP extensors, the IP joints should remain in some flexion,[6,12] as the ED becomes actively insufficient if the IP joints are concurrently in IP extension.
Substitutions: With the wrist stabilized, no substitutions are possible. When the wrist is not stabilized, passive insufficiency of the ED can produce MP extension through tenodesis action.[6,7,10,13,15,21]

Proximal Interphalangeal Flexion, Second Through Fifth Fingers (Figs. 22.68 to 22.70)

Muscles[10,14]	Innervation[6,10,12]
Flexor digitorum superficialis (FDS)	Median nerve, C7, C8, T1
Flexor digitorum profundus (FDP)	Median and ulnar nerves, C8, T1

Procedure for Testing Grades Normal (5), Good (4), and Fair (3)

1. Body position	The client is seated, with the forearm supinated, wrist at neutral, fingers extended, and hand and forearm resting on the dorsal surface.[6,10,12] The therapist sits opposite or next to the client on the side being tested.	
2. Action	While demonstrating movement from neutral to full PIP flexion, the therapist says, "Move your finger like I did" (FIG 22.68). Observe the client actively performing the movement.	 FIG 22.68 Proximal interphalangeal flexion: action.
3. Test position	If client performs through available PROM, place the PIP joint in midflexion and proceed. If not, follow procedure for testing grades Poor, Trace, and Zero (0).	
4. Stabilize	The therapist stabilizes the MP joint and proximal phalanx of the finger being tested in extension. [6,7,10,14]	
5. Pressure	Tell the client, "Don't let me move you." Apply pressure over volar middle phalanx toward PIP extension,[6,10,14] adjusting pressure to client's abilities (FIG 22.69). If pressure is maximal = Normal, moderate = Good, minimal = Good−, slight = Fair+, and no pressure = Fair.	

		 FIG 22.69 Proximal interphalangeal flexion: application of pressure.

Procedure for Testing Grades Poor (2), Trace (1), and Zero (0)

1. Body position	The client is seated, with the forearm in neutral rotation and the wrist at neutral, resting on the ulnar border.[12,21] The therapist sits opposite or next to the client on the side to be tested.	
2. Action	Move client's PIP joint into PIP flexion twice while stating, "Move your finger like I did." (a) If client performs full ROM, place in mid-PIP flexion and apply slight pressure toward PIP extension. (i) If tolerates pressure = Poor+. (ii) No pressure = Poor. (iii) If the test for grades Poor and below is done with the forearm in full supination, partial ROM against gravity may be graded Poor.[10] (b) If client performs through partial ROM, do not apply pressure = Poor−. (c) If client is unable to perform motion, place PIP joint in midposition and state, "Try to move your finger like I did." Palpate over the volar proximal phalanx and palm for muscle contraction (FIG 22.70). (i) If muscle contraction palpable = Trace. (ii) If no contraction palpable = Zero.	 FIG 22.70 Proximal interphalangeal flexion: body position, action, and palpation—muscle grades 2 and below. Simultaneous palpation of all of the tendons of the FDS.
Specific muscle testing: It is often important to isolate the flexor digitorum superficialis to ensure that it is intact and functioning. If DIP flexion precedes PIP flexion, the FDP is assisting with PIP flexion.[7,12,13,15,17,21] Stabilizing all of the fingers not being tested in MP and IP extension prevents the FDP from flexing the PIP joint. Many individuals cannot isolate flexion of the small finger PIP joint, even with MP stabilization. To ensure that the FDP is inactive, the therapist may wiggle the DIP joint while applying pressure to the middle phalanx.[4,6,12,15,21] **Substitution**: Active insufficiency of the extrinsic finger flexors can result in apparent finger flexion through partial ROM when the wrist is actively or passively extended due to tenodesis,[10,13,21] so the therapist should ensure this is not the mistaken for active finger flexion.		

Distal Interphalangeal Flexion, Second Through Fifth Fingers (Figs. 22.71 to 22.74)

Muscle[10,13]	**Innervation**[10,13]
Flexor digitorum profundus (FDP)	Median and ulnar nerves, C8, T1

Procedure for Testing Grades Normal (5), Good (4), and Fair (3)

1. Body position	The client is seated, with the forearm supinated, wrist at neutral, and fingers extended.[10] The therapist sits opposite or next to the client on the side being tested.[12]	
2. Action	While demonstrating movement from neutral to full PIP flexion, the therapist says, "Move your finger like I did" (FIG 22.71). Observe the client actively performing the movement.	

		 FIG 22.71 Distal interphalangeal flexion: action.
3. Test position	If client performs through available PROM, place the DIP joint in midflexion and proceed. If not, follow procedure for testing grades Poor, Trace, and Zero.	
4. Stabilize	The therapist stabilizes the PIP joint and middle phalanx in extension on the finger being tested.[6,21]	
5. Pressure	Tell the client, “Don't let me move you.” Apply pressure over volar distal phalanx toward DIP extension,[6,7,10,14] adjusting pressure to client's abilities (FIG 22.72). If pressure is maximal = Normal, moderate = Good, minimal = Good−, slight = Fair+, and no pressure = Fair.	 FIG 22.72 Distal interphalangeal flexion: application of pressure.

Procedure for Testing Grades Poor (2), Trace (1), and Zero (0)

1. Body position	The client is seated, with the forearm in midposition and the wrist at neutral, resting on the ulnar border.[12,21] The therapist sits opposite or next to the client on the side to be tested.	
2. Action	Move client's DIP joint into flexion twice while stating, “Move your finger like I did.” (a) If client performs full ROM, place in mid-DIP flexion and apply slight pressure toward PIP extension. (i) If tolerates pressure = Poor+. (ii) No pressure = Poor. (iii) If the test for grades Poor and below is done with the forearm in full supination, partial ROM against gravity may be graded Poor.[10] (b) If client performs through partial ROM, do not apply pressure = Poor−. (c) If client is unable to perform motion, place DIP joint in midposition and state, “Try to move your finger like I did.” Palpate over the volar proximal surface of the middle phalanx[6,10,15] (FIG 22.73) and palm for muscle contraction (FIG 22.74). (i) If muscle contraction palpable = Trace. (ii) If no contraction palpable = Zero.	 FIG 22.73 Distal interphalangeal flexion: body position, action, and palpation—muscle grades 2 and below. Palpation of the FDP tendon of the index finger.

		 FIG 22.74 Distal interphalangeal flexion: body position, action, and palpation—muscle grades 2 and below. Palpation of the FDP tendons.
Substitutions: None possible during the testing procedure if the wrist is well stabilized because the FDP is the only muscle that can flex the DIP joint when it is isolated. During normal hand function, however, wrist extension with tendon action of the finger flexors can produce partial flexion of the DIP joints.[10,15,21]		

Finger Abduction (Figs. 22.75 to 22.77)

Muscles[10,12]	Innervation[10,12]
Dorsal interossei of the second, third, and fourth fingers	Ulnar nerve, C8, T1
Abductor digiti minimi (fifth finger)	Deep branch of ulnar nerve, C8, T1

Procedure for Testing Grades Normal (5), Good (4), and Fair (3)

1. Body position	The client is seated or supine with forearm pronated (neutral position can be used for index and long radial abductors), wrist in neutral, and fingers extended and adducted. The therapist is seated opposite or next to the client on the side to be tested.[10,13]	
2. Action	While demonstrating movement from neutral to full finger abduction, the therapist says, "Move your fingers like I did." Observe client actively perform the movement of spreading the fingers apart (FIGS 22.75 and 22.76).	 FIG 22.75 Finger abduction: action—all fingers.  FIG 22.76 Finger abduction: action—individual fingers (index finger).
3. Test position	If client performs through available PROM, place the finger in midabduction and proceed. If not, follow procedure for testing grades Poor, Trace, and Zero.	
4. Stabilize	The therapist stabilizes the wrist and metacarpals on the supporting surface.	
5. Pressure	Tell the client, "Don't let me move you." Apply pressure over lateral proximal phalanx (index and long fingers) and medial proximal phalanx (long, ring, and	

	small fingers)[6,14] toward adduction, adjusting pressure to client's abilities (FIG 22.77). An alternative mode of resistance is to flick each finger toward adduction. If the finger rebounds, the grade is N (5).[12] Note that the long finger is the axis for the hand so it abducts both radially and ulnarly. If pressure is maximal = Normal, moderate = Good, minimal = Good−, slight = Fair+, and no pressure = Fair. If not tested against gravity, use professional judgment when grading. For example, partial ROM in the gravity-minimized position may be graded Poor and full ROM graded Fair.[10,13]	 FIG 22.77 Finger abduction: application of pressure.

Procedure for Testing Grades Poor (2), Trace (1), and Zero (0)

1. Body position	The client is seated or supine with forearm pronated, wrist in neutral, and fingers extended and adducted. The therapist is seated opposite or next to the client on the side to be tested.[10,13]
2. Action	Move client's finger into abduction twice while stating, "Move your finger like I did." (a) If client performs full ROM, place in mid-MP abduction and apply slight pressure toward adduction. (i) If tolerates pressure = Poor+. (ii) No pressure = Poor. (b) If client performs through partial ROM, do not apply pressure = Poor−. (c) If client is unable to perform motion, place MP joint in midabduction and state, "Try to move your finger like I did." Palpate over lateral metacarpal for index and long fingers, and medial metacarpal for muscle contraction. Because the muscles for long and ring fingers are very small and deep, contraction may not be palpable. (i) If muscle contraction palpable = Trace. (ii) If no contraction palpable = Zero.
Substitutions: Extensor digitorum can assist weak or absent finger abduction, but abduction will be accompanied by MP extension.[6,15,21]	

Finger Adduction (Figs. 22.78 to 22.81)

Muscles[10-14]	**Innervation**[10,13]
Palmar interossei, second, fourth, and fifth fingers	Ulnar nerve, C8, T1

Procedure for Testing Grades Normal (5), Good (4), and Fair (3)

1. Body position	The client is seated or supine. Forearm is pronated (shoulder in 90 degrees abduction) to test index finger (FIG 22.78), and forearm is in midposition to test ring and small fingers (FIG 22.79). Wrist is in neutral position and fingers extended and abducted.[10,13] The therapist is seated opposite or next to the client on the side to be tested.	 FIG 22.78 Finger adduction: position and action—to test the index finger.  FIG 22.79 Finger adduction: position and action—to test ring and little finger.
2. Action	While demonstrating movement from neutral to full finger adduction, the therapist says, "Move your finger like I did." Observe the client adducting the index, ring, and small fingers toward the middle finger (see FIGS 22.78 and 22.79).	
3. Test position	If client performs through available PROM, place the finger in adduction and proceed. If not, follow procedure for testing grades Poor, Trace, and Zero.	
4. Stabilize	The therapist stabilizes the wrist and metacarpals.[6]	
5. Pressure	Tell the client, "Don't let me move you." Apply pressure over medial proximal phalanx (index finger) (FIG 22.80) and lateral proximal phalanx (ring and small fingers) (FIG 22.81) toward abduction, adjusting pressure to client's abilities.[6,14] These muscles are very small, and resistance must be modified to accommodate their comparatively limited power. Fingers can be grasped at the distal phalanx and flicked in the direction of abduction. If the finger snaps back to the adducted position, the grade is Normal.[12] If pressure is maximal = Normal, moderate = Good, minimal = Good−, slight = Fair+, and no pressure = Fair. If not tested	

against gravity, use professional judgment when grading. The therapist's judgment must be used in determining the degree of weakness. Achievement of full ROM may be graded Fair and partial ROM graded Poor.[10,12]

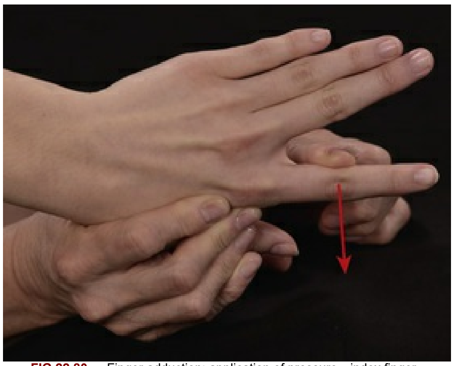

FIG 22.80 Finger adduction: application of pressure—index finger.

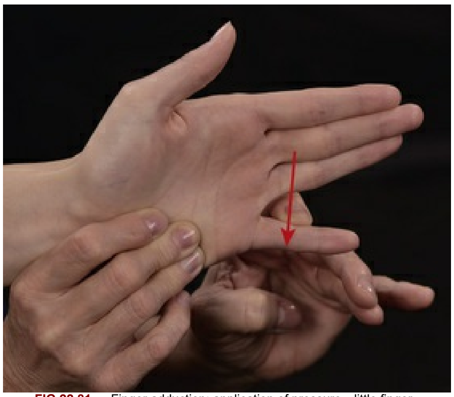

FIG 22.81 Finger adduction: application of pressure—little finger.

Procedure for Testing Grades Poor (2), Trace (1), and Zero (0)

1. Body position	The client is seated or supine with forearm pronated, wrist in neutral, and fingers extended and abducted. The therapist is seated opposite or next to the client on the side to be tested.[10,13]
2. Action	Move client's finger into adduction twice while stating, "Move your finger like I did." (a) If client performs full ROM, place in adduction and apply slight pressure toward abduction. (i) If tolerates pressure = Poor+. (ii) No pressure = Poor. (b) If client performs through partial ROM, do not apply pressure = Poor−. (c) If client is unable to perform motion, place MP joint in midabduction and state, "Try to move your finger like I did." Because these muscles are very small and deep, contraction is not usually palpable.[6] (i) If muscle contraction palpable = Trace. (ii) If no contraction palpable = Zero.
Substitutions: Flexor digitorum profundus and superficialis can substitute for weak adductors, but IP flexion will occur with finger adduction.[13,15,21]	

Interphalangeal Extension (Figs. 22.82 to 22.85)

Muscles[10,13]	**Innervation**[10,13,18]
Lumbricals 1 and 2 (index and long)	Median nerve, C8, T1
Lumbricals 3 and 4 (ring and small)	Ulnar nerve, C8, T1
Dorsal interossei (index, long, and ring)	Deep branch of ulnar nerve, C8, T1
Palmar interossei (index, ring, and small)	Deep branch of ulnar nerve, C8, T1

Procedure for Testing Grades Normal (5), Good (4), and Fair (3)

1. Body position	The client is seated or supine with forearm supinated and wrist in midextension and neutral deviation. The therapist is seated or standing next to the client on the side to be tested.	
2. Action	While demonstrating movement from neutral to full PIP and DIP extension, the therapist says, "Move your finger like I did." Observe the client actively straightening both IP joints (FIG 22.82).	 FIG 22.82 Interphalangeal extension: action—to test the index

		finger.
3. Test position	If client performs through available PROM, place the IP joints in midextension and proceed. If not, follow procedure for testing grades Poor, Trace, and Zero.	
4. Stabilize	The therapist stabilizes the proximal phalanx.	
5. Pressure	Tell the client, “Don't let me move you.” Apply pressure over the dorsal middle (FIG 22.83) and distal phalanx (FIG 22.84) toward flexion, adjusting pressure to client's abilities. If pressure is maximal = Normal, moderate = Good, minimal = Good−, slight = Fair+, and no pressure = Fair.	 FIG 22.83 Interphalangeal extension: application of pressure—middle phalanx.  FIG 22.84 Interphalangeal extension: application of pressure—distal phalanx.

Procedure for Testing Grades Poor (2), Trace (1), and Zero (0)

1. Body position	The client is seated or supine with forearm in midforearm rotation and wrist in midextension and neutral deviation. The therapist is seated or standing next to the client on the side to be tested (FIG 22.85).	 FIG 22.85 Interphalangeal extension: body position, action, and palpation—muscle grades 2 and below.
2. Action	Move client's PIP and DIP joints into extension twice while stating, “Move your finger like I did.” (a) If client performs full ROM, place in midextension and apply slight pressure toward flexion. (i) If tolerates pressure = Poor+. (ii) No pressure = Poor. (b) If client performs through partial ROM do not apply pressure = Poor−. (c) If client is unable to perform motion, place extension in midposition and state, “Try to move your	

	finger like I did." Because the intrinsic hand muscles that perform IP extension are very small and deep, it may be difficult to palpate for muscle contraction. (i) If muscle contraction palpable = Trace. (ii) If no contraction palpable = Zero.	
Substitution: Because the extensor digitorum inserts into the dorsal hood, if the wrist and MP joints are positioned in flexion (to prevent the ED from becoming actively insufficient), the ED can extend the IP joints. Passive tension in the ED can also result in finger extension at the MP and IP joints via tenodesis action. Positioning the wrist in extension when testing IP extension prevents this substitution from occurring.		

Thumb Metacarpophalangeal Extension (Figs. 22.86 to 22.88)

Muscles[10,12-14]	**Innervation**[10,12-14]
Extensor pollicis brevis (EPB)	Radial nerve, C7, C8
Extensor pollicis longus (EPL)	Radial nerve, C7, C8

Procedure for Testing Grades Normal (5), Good (4), and Fair (3)

1. Body position	The client is seated or supine with forearm in midposition, wrist in neutral, and hand and forearm resting on the ulnar border.[6,10,13] Because thumb extension occurs in the sagittal plane (plane parallel to the hand), the thumbnail should face the ceiling to test against gravity. The therapist is seated or standing next to the client on the side to be tested. The thumb is flexed into the palm at the MP joint, and the IP joint is extended but relaxed.	
2. Action	While demonstrating movement from neutral to full extension, the therapist says, "Move your thumb like I did." Observe the client actively extending the thumb MP joint (FIG 22.86). It is difficult for many people to extend the MP joint without extending the IP joint simultaneously.	 FIG 22.86 Thumb metacarpophalangeal extension: action.
3. Test position	If client performs through available PROM, place the thumb in midextension and proceed. If not, follow procedure for testing grades Poor, Trace, and Zero.	
4. Stabilize	The therapist stabilizes the first metacarpal and wrist in neutral.[6]	
5. Pressure	Tell the client, "Don't let me move you." Apply pressure over the dorsal surface of the proximal phalanx toward MP flexion,[6,10,12-14] adjusting pressure to client's abilities (FIG 22.87). If pressure is maximal = Normal, moderate = Good, minimal = Good−, slight = Fair+, and no pressure = Fair.	 FIG 22.87 Thumb metacarpophalangeal extension: application of pressure.

Procedure for Testing Grades Poor (2), Trace (1), and Zero (0)

1. Body position	Forearm is fully pronated and resting on the volar surface,[21] or forearm is supinated to about 70 degrees resting on dorsal surface. The therapist sits opposite or next to the client on the side being tested, except that the therapist may stabilize the first metacarpal, holding the hand slightly above the supporting surface. The test may also be performed in the same manner as for grades Normal to Fair, with modified grading.[10]	
2. Action	Move client's thumb MP into extension twice while stating, "Move your thumb like I did." (a) If client performs full ROM, place in mid-MP extension and apply slight pressure toward MP flexion. (i) If tolerates pressure = Poor+. (ii) No pressure = Poor. (iii) If midposition of the forearm was used, partial ROM is graded Poor and full ROM is graded Fair.[10,12] (b) If client performs through partial ROM do not apply pressure = Poor−. (c) If client is unable to perform motion, place MP in midposition and state, "Try to move your thumb like I did." Palpate the extensor pollicis brevis tendon on the dorsoradial aspect of the base of the first metacarpal (FIG 22.88). It lies just medial to the abductor pollicis longus tendon on the radial side of the anatomical snuffbox, which is the hollow space created between the EPL and EPB tendons when the thumb is fully extended and radially abducted.[4,6,7] (i) If muscle contraction palpable = Trace. (ii) If no contraction palpable = Zero.	

			 FIG 22.88 Thumb metacarpophalangeal extension: body position, action, and palpation—muscle grades 2 and below.

Specific muscle testing: To isolate the extensor pollicis brevis, the thumb IP joint should be flexed or relaxed to prevent extensor pollicis longus from acting.[6,7,13,15,21] It is difficult for many individuals to isolate this motion.

Thumb Interphalangeal Extension (Figs. 22.89 to 22.92)

Muscles[10,12-14]	**Innervation**[10,12-14]
Extensor pollicis longus (EPL)	Radial nerve, C7, C8

Procedure for Testing Grades Normal (5), Good (4), and Fair (3)

1. Body position	The client is seated or supine, forearm in midposition, wrist at neutral, and hand and forearm resting on the ulnar border.[6,10,13] The thumb is adducted, the MP joint is extended or slightly flexed, and the IP is flexed.[6] The therapist sits opposite or next to the client on the side being tested. Because IP extension occurs in a plane parallel to the palm, the thumbnail should be facing the side.	
2. Action	While demonstrating movement from neutral to full IP extension, the therapist says, "Move your thumb like I did" (FIG 22.89). Observe the client actively performing the movement.	 FIG 22.89 Thumb interphalangeal extension: action.
3. Test position	If client performs through available PROM, place the thumb in midextension and proceed. If not, follow procedure for testing grades Poor, Trace, and Zero.	
4. Stabilize	The therapist stabilizes the wrist in neutral position, the first metacarpal, and the proximal phalanx of the thumb.[6]	
5. Pressure	Tell the client, "Don't let me move you." Apply pressure over dorsal distal phalanx toward flexion,[6,10,14] adjusting pressure to client's abilities (FIG 22.90). If pressure is maximal = Normal, moderate = Good, minimal = Good−, slight = Fair+, and no pressure = Fair.	 FIG 22.90 Thumb interphalangeal extension: application of pressure.

Procedure for Testing Grades Poor (2), Trace (1), and Zero (0)

1. Body position	Forearm is fully pronated and resting on the volar surface,[21] or forearm is supinated to about 70 degrees resting on dorsal surface. The therapist may stabilize so that the client's hand is held slightly above the supporting surface. The thumb is adducted and IP joint is flexed. The therapist sits opposite or next to the client on the side being tested.	
2. Action	Move client's thumb IP into extension twice while stating, “Move your thumb like I did.” (a) If client performs full ROM, place in extension and apply slight pressure toward flexion. (i) If tolerates pressure = Poor+. (ii) No pressure = Poor. (iii) If tested against gravity, partial ROM is graded Poor.[10] (b) If client performs through partial ROM do not apply pressure = Poor−. (c) If client is unable to perform motion, place IP joint in midposition and state, “Try to move your thumb like I did.” Palpate the EPL tendon on the dorsal surface of the hand medial to the EPB tendon, between the head of the first metacarpal and the base of the second on the ulnar side of the anatomical snuffbox[4,6,10] (FIG 22.91). The EPL tendon may also be palpated over the dorsal proximal phalanx (FIG 22.92). (i) If muscle contraction palpable = Trace. (ii) If no contraction palpable = Zero.	 **FIG 22.91** Thumb interphalangeal extension: body position, action, and palpation of the EPL—muscle grades 2 and below.  **FIG 22.92** Thumb interphalangeal extension: body position, action and alternate palpation of the EPL—muscle grades 2 and below.
Substitution: A quick contraction of the flexor pollicis longus followed by rapid release will cause the IP joint to rebound into extension.[6] IP flexion will precede IP extension.[7,15] The abductor pollicis brevis, the flexor pollicis brevis, the oblique fibers of the adductor pollicis, and the first palmar interosseous can extend the IP joint because of their insertions into the extensor expansion of the thumb.[14,20] Stabilization of the wrist in slight extension prevents thumb extension occurring from passive tension in the EPL with wrist flexion.		

Thumb Metacarpophalangeal Flexion (Figs. 22.93 to 22.95)

Muscles[10,12-14]	**Innervation**[10,12-14]
Flexor pollicis brevis (FPB)	Median, C8, T1
Flexor pollicis longus (FPL)	Median nerve, C8, T1

Procedure for Testing Grades Normal (5), Good (4), and Fair (3)

1. Body position	The client is seated or supine. Thumb flexion occurs in the sagittal plane (the plane parallel to the hand), so to perform this movement against gravity the client's shoulder is internally rotated and flexed to approximately 90 degrees (upper extremity must be parallel to the floor). The forearm will be fully pronated with the thumbnail facing the floor. The therapist is seated next to or opposite the client.[7,10,14]	
2. Action	While demonstrating movement from neutral to full MP flexion, the therapist says, “Move your thumb like I did.” Observe the client actively performing the movement (FIG 22.93).	

		 FIG 22.93 Thumb metacarpophalangeal flexion: action.
3. Test position	If client performs through available PROM, place the finger in midflexion and proceed. If not, follow procedure for testing grades Poor, Trace, and Zero.	
4. Stabilize	The therapist stabilizes the wrist and first metacarpal.[12]	
5. Pressure	Tell the client, "Don't let me move you." Apply pressure over the volar surface of the proximal phalanx toward MP extension, adjusting pressure to client's abilities[6,7,10,14] (FIG 22.94). If pressure is maximal = Normal, moderate = Good, minimal = Good−, slight = Fair+, and no pressure = Fair.	 FIG 22.94 Thumb metacarpophalangeal flexion: application of pressure.

Procedure for Testing Grades Poor (2), Trace (1), and Zero (0)

1. Body position	Client is seated with supinated forearm resting on table or in therapist's hand. The therapist sits opposite or next to the client on the side being tested.	
2. Action	Move client's MP into flexion twice while stating, "Move your thumb like I did." (a) If client performs full ROM, place in midflexion and apply slight pressure toward extension. (i) If tolerates pressure = Poor+. (ii) No pressure = Poor. (b) If client performs through partial ROM do not apply pressure = Poor−. (c) If client is unable to perform motion, place MP in midposition and state, "Try to move your thumb like I did." Palpate the client over the middle of the palmar surface of the thenar eminence just medial to the abductor pollicis brevis muscle[6,10] (FIG 22.95). (i) If muscle contraction palpable = Trace. (ii) If no contraction palpable = Zero.	 FIG 22.95 Thumb metacarpophalangeal flexion: body position, action, and palpation—muscle grades 2 and below.
Specific muscle testing: To test the integrity of the flexor pollicis brevis, ensure that the IP joint remains extended during MP flexion.[6,7,12,13,15,21] It may not be possible for some individuals to isolate flexion to the MP joint. **Substitution**: Quick extension of the thumb is followed by a "rebound" to a flexed position if the first metacarpal and wrist are not stabilized.		

Thumb Interphalangeal Flexion (Figs. 22.96 to 22.98)

Muscles[6,10,12]	**Innervation**[10,13]
Flexor pollicis longus (FPL)	Median nerve, C8, T1

Procedure for Testing Grades Normal (5), Good (4), and Fair (3)

1. Body position	The client is seated or supine. Thumb flexion occurs in the sagittal plane (the plane parallel to the hand), so to perform this movement against gravity the client's shoulder is internally rotated and flexed to approximately 90 degrees (upper extremity must be parallel to the floor). The forearm will be fully pronated with the thumbnail facing the floor. The therapist is seated next to or opposite the client.[7,10,14]	
2. Action	While demonstrating movement from neutral to full IP flexion, the therapist says, "Move your thumb like I did" (FIG 22.96). Observe the client actively performing the movement.	

		 FIG 22.96 Thumb interphalangeal flexion: action.
3. Test position	If client performs through available PROM, place the thumb in midflexion and proceed. If not, follow procedure for testing grades Poor, Trace, and Zero.	
4. Stabilize	The therapist stabilizes the wrist and first metacarpal.[12]	
5. Pressure	Tell the client, “Don't let me move you.” Apply pressure over the volar surface of the distal phalanx toward MP extension adjusting pressure to client's abilities[6,10,12-14] (FIG 22.97). If pressure is maximal = Normal, moderate = Good, minimal = Good−, slight = Fair+, and no pressure = Fair.	 FIG 22.97 Thumb interphalangeal flexion: application of pressure.

Procedure for Testing Grades Poor (2), Trace (1), and Zero (0)

1. Body position	Forearm is fully pronated and resting on the volar surface,[21] or forearm is supinated to about 70 degrees resting on dorsal surface. The IP joint is flexed. The therapist sits opposite or next to the client on the side being tested.	
2. Action	Move client's thumb IP into extension twice while stating, “Move your thumb like I did.” (a) If client performs full ROM, place in extension and apply slight pressure toward flexion. (i) If tolerates pressure = Poor+. (ii) No pressure = Poor. (b) If client performs through partial ROM, do not apply pressure = Poor−. (c) If client is unable to perform motion, place IP in midposition and state, “Try to move your thumb like I did.” Palpate over the volar surface of the palmar surface of the proximal phalanx[6] (FIG 22.98). (i) If muscle contraction palpable = Trace. (ii) If no contraction palpable = Zero.	 FIG 22.98 Thumb interphalangeal flexion: body position, action, and palpation—muscle grades 2 and below.
Substitution: Quick extension of the thumb is followed by a “rebound” of the thumb IP joint into a flexed position if the proximal phalanx and metacarpal are not stabilized. The therapist should observe for IP extension preceding IP flexion.[6,7,12,13,15,21]		

Thumb Palmar Abduction (Also Referred to as Abduction of the Carpal-Metacarpal Joint) (Figs. 22.99 to 22.100B)

Muscles[13,14]	**Innervation**[13,14]
Abductor pollicis brevis (APB)	Median nerve, C8, T1
Abductor pollicis longus (APL)	Posterior interosseous nerve, C7, C8 continuation of deep branch of radial nerve

Procedure for Testing Grades Normal (5), Good (4), and Fair (3)

1. Body position	The client is seated or supine, forearm in supination, wrist at neutral, and thumb relaxed in adduction against the volar aspect of the index finger. The therapist	

	sits opposite or next to the client on the side to be tested.[6,7,10,12-14]	
2. Action	Thumb abduction, also known as palmar abduction, is movement of the first metacarpal in a plane perpendicular to the palm.[6,14] While demonstrating movement from neutral to full abduction, the therapist says, “Move your thumb like I did” (FIG 22.99). Observe the client actively performing the movement and note that movement is occurring at the carpal-metacarpal joint.	 FIG 22.99 Thumb palmar abduction: action.
3. Test position	If client performs through available PROM, place the thumb in abduction and proceed. If not, follow procedure for testing grades Poor, Trace, and Zero.	
4. Stabilize	The therapist stabilizes the wrist (and hand if needed).	
5. Pressure	Tell the client, “Don't let me move you.” Apply pressure distal first metacarpal toward adduction (the palm),[6,14] adjusting pressure to client's abilities (FIG 22.100, A). If pressure is maximal = Normal, moderate = Good, minimal = Good−, slight = Fair+, and no pressure = Fair.	 FIG 22.100 **A,** Thumb palmar abduction: application of pressure.

Procedure for Testing Grades Poor (2), Trace (1), and Zero (0)

1. Body position	Client is seated with the forearm and wrist in neutral, ulnar border of forearm and hand resting on table.[12,21] The therapist sits opposite or next to the client on the side being tested.	
2. Action	Move client's thumb into abduction twice while stating, “Move your thumb like I did.” (a) If client performs full ROM, place in abduction and apply slight pressure toward adduction. (i) If tolerates pressure = Poor+. (ii) No pressure = Poor. (b) If client performs through partial ROM, do not apply pressure = Poor−. (c) If client is unable to perform motion, place in abduction and state, “Try to move your thumb like I did.” Palpate over volar radial wrist (Figure 22.100, B) and superior surface of the thenar eminence for muscle contraction. (i) If muscle contraction palpable = Trace. (ii) If no contraction palpable = Zero.	 FIG 22.100 **B,** Thumb palmar abduction: body position, action, and palpation—muscle grades 2 and below.
Specific muscle testing: It is very difficult to test the abductor pollicis brevis and longus independently.		

Thumb Radial Abduction (Also Referred to as Extension of the Carpal-Metacarpal Joint) (Figs. 22.101 to 22.103)

Muscles[12,14]	Innervation[12,14]
Extensor pollicis brevis (EPB)	Radial nerve, C7, C8
Extensor pollicis longus (EPL)	Radial nerve, C7, C8
Abductor pollicis longus (APL)	Radial nerve, C6–8

Procedure for Testing Grades Normal (5), Good (4), and Fair (3)

1. Body position	The client is seated or supine, forearm in neutral rotation, wrist at neutral, thumb adducted and slightly flexed across the palm. Hand and forearm are resting on the ulnar border.[14] The therapist sits opposite or next to the client on the side being tested.	
2. Action	While demonstrating movement from neutral to full carpal-metacarpal extension, the therapist says, “Move your thumb like I did.” Observe the client performing the movement. The thumb should extend at the carpal-metacarpal joint as well as the MP and IP joints (FIG 22.101).	

		 FIG 22.101 Thumb radial abduction: action.
3. Test position	If client performs through available PROM, place the finger in midabduction and proceed. If not, follow procedure for testing grades Poor, Trace, and Zero.	
4. Stabilize	The therapist stabilizes the wrist and metacarpals of the fingers.[10,14]	
5. Pressure	Tell the client, "Don't let me move you." Apply pressure over distal, lateral surface of the first metacarpal toward flexion, adjusting pressure to client's abilities (FIG 22.102). If pressure is maximal = Normal, moderate = Good, minimal = Good−, slight = Fair+, and no pressure = Fair.	 FIG 22.102 Thumb radial abduction: application of pressure.

Procedure for Testing Grades Poor (2), Trace (1), and Zero (0)

1. Body position	Client is seated with forearm in supination; dorsal surface of forearm resting on table.[10] The therapist sits opposite or next to the client on the side being tested.	
2. Action	Move client's first carpal-metacarpal (CMC) joint into extension twice while stating, "Move your thumb like I did." (a) If client performs full ROM, place in extension and apply slight pressure toward flexion. (i) If tolerates pressure = Poor+. (ii) No pressure = Poor. (b) If client performs through partial ROM do not apply pressure = Poor−. (c) If client is unable to perform motion, place CMC in extension and state, "Try to move your thumb like I did." Palpate over dorsal lateral wrist for tension in the EPB, EPL, or APL (FIG 22.103). (i) If muscle contraction palpable = Trace. (ii) If no contraction palpable = Zero.	 FIG 22.103 Thumb radial abduction: body position, action, and palpation—muscle grades 2 and below.
Specific muscle testing: Action in the EPB, EPL, and APL can be isolated by palpation and often visualization of the tendons in the lateral wrist. **Substitution**: Stabilization of the wrist prevents radial deviation from CMC extension.		

Thumb Adduction (Figs. 22.104 to 22.106)

Muscles[10,12-14]	Innervation[10,12-14]
Adductor pollicis (AP)	Ulnar nerve, C8, T1

Procedure for Testing Grades Normal (5), Good (4), and Fair (3)

1. Body	The client is seated or supine, forearm pronated, wrist at neutral, and thumb	

position	relaxed and in palmar abduction.[10,13,21] The therapist is sitting opposite or next to the client on the side to be tested.	
2. Action	While demonstrating movement from neutral to full adduction, the therapist says, “Move your thumb like I did” (FIG 22.104). Observe the client adducting the thumb into the palm.[10,12]	 FIG 22.104 Thumb adduction: action.
3. Test position	If client performs through available PROM, place the finger in midadduction and proceed. Space must be allowed between the first and second metacarpals for the therapist's finger. If not, follow procedure for testing grades Poor, Trace, and Zero.	
4. Stabilize	The therapist stabilizes the wrist and metacarpals by grasping the hand around the ulnar side and supporting it slightly above the resting surface.[10,13]	
5. Pressure	Tell the client, “Don't let me move you.” Apply pressure downward toward palmar abduction by placing finger between first and second metacarpals or grasping the first metacarpal head[10] (FIG 22.105). Adjust pressure to client's abilities. If pressure is maximal = Normal, moderate = Good, minimal = Good−, slight = Fair+, and no pressure = Fair.	 FIG 22.105 Thumb adduction: application of pressure.

Procedure for Testing Grades Poor (2), Trace (1), and Zero (0)

1. Body position	Client is seated with the forearm and wrist in neutral, ulnar border of forearm and hand resting on table.[21] The therapist sits opposite or next to the client on the side being tested.	
2. Action	Move client's wrist into adduction twice while stating, “Move your thumb like I did.” (a) If client performs full ROM, place in adduction and apply slight pressure toward abduction. (i) If tolerates pressure = Poor+. (ii) No pressure = Poor. (b) If client performs through partial ROM do not apply pressure = Poor−. (c) If client is unable to perform motion, place first CMC in midposition and state, “Try to move your thumb like I did.” Palpate the AP on the palmar side of the thumb web space[6,15] (FIG 22.106). (i) If muscle contraction palpable = Trace. (ii) If no contraction palpable = Zero.	 FIG 22.106 Thumb adduction: body position, action, and palpation—muscle grades 2 and below.
Substitution: The FPL or EPL may substitute; however, adduction will be preceded by thumb flexion or extension.[13,15,21]		

Opposition of the Thumb to the Fifth Finger (Figs. 22.107 to 22.109)

Muscles[10,13]	**Innervation**[10,13]
Opponens pollicis	Median nerve, C8, T1
Opponens digiti minimi	Ulnar nerve, C8, T1

Procedure for Testing Grades Normal (5), Good (4), and Fair (3)

1. Body position	The client is seated or supine, with forearm supinated, wrist at neutral, thumb in palmar abduction, and fifth finger extended.[6,7,10,14] The therapist sits opposite or next to the client on the side to be tested.	
2. Action	While demonstrating movement from open hand with small finger abducted and thumb extended, the therapist says, “Touch your thumb to your small finger like I did.” Observe the client opposing the thumb to touch the thumb pad to the pad of the fifth finger, which flexes and rotates toward the thumb (FIG 22.107).[6,7]	

		 FIG 22.107 Thumb opposition: action.
3. Test position	If client performs through available PROM, proceed with stabilization. If not, follow procedure for testing grades Poor, Trace, and Zero.	
4. Stabilize	Rest forearm and wrist on table with padding to stabilize, as both of the therapist's hands must be free to apply pressure.	
5. Pressure	Tell the client, "Don't let me move you." Apply pressure at the distal ends of the first and fifth metacarpals toward reposition of these bones and flattening of the palm of the hand (FIG 22.108).[10,12] Adjust pressure to client's abilities. If pressure is maximal = Normal, moderate = Good, minimal = Good−, slight = Fair+, and no pressure = Fair.	 FIG 22.108 Thumb opposition: application of pressure.

Procedure for Testing Grades Poor (2), Trace (1), and Zero (0)

1. Body position	Client is seated with elbow flexed and resting on table, forearm and wrist in neutral and hand in open position. Therapist supports forearm and wrist if weak. The therapist sits opposite or next to the client on the side being tested.	
2. Action	Touch client's thumb tip to the small fingertip twice while stating, "Move your fingers like I did." (a) If client performs full ROM, leave in opposed position and apply slight pressure toward reposition. (i) If tolerates pressure = Poor+. (ii) No pressure = Poor. (b) If client performs through partial ROM, do not apply pressure = Poor−. (c) If client is unable to perform motion, touch client's thumb tip to small fingertip and state, "Try to move your fingers like I did." Palpate the thenar and hypothenar eminences of the palm[6,10,15] (FIG 22.109). (i) If muscle contraction palpable = Trace. (ii) If no contraction palpable = Zero.	 FIG 22.109 Thumb opposition: body position, action, and palpation—muscle grades 2 and below.
Substitution: APB will assist with opposition by flexing and medially rotating the CMC joint, but the IP joint will extend. The FPB will flex and medially rotate the CMC joint, but the thumb will not move away from the palm of the hand. The FPL will flex and slightly rotate the CMC joint, but the thumb will not move away from the palm, and the IP joint will flex strongly.[15,21] The DIP joints of the thumb and little finger may flex to meet, giving the appearance of full opposition.[7,12]		

Manual Muscle Testing of the Lower Extremity

Muscle testing of lower extremity (LE) motions follows the same principles as those used for the upper extremity. Because the distal LE rotates in utero to allow humans to ambulate in a bipedal fashion, the muscles that flex the knee, ankle, and toes lie posterior to the knee joint, and the extensors lie anterior. LE muscle strength is traditionally measured by OT professionals via screening and not manual muscle testing, therefore this chapter presents only some of the LE motions.

Hip Extension (Figs. 22.110 to 22.111)

Muscles[6,12,14]	Innervation[10,13]
Gluteus maximus	Inferior gluteal nerve, L5–S2
Semitendinosus	Sciatic nerve, L5–S2
Semimembranosus	Sciatic nerve, L5–S2
Biceps femoris (long head)	Sciatic nerve, L5–S2
Adductor magnus	Obturator, L2–4

Procedure for Testing Grades Normal (5), Good (4), and Fair (3)

1. Body position	The client is seated or supine with forearm in neutral rotation and wrist in slight extension and neutral deviation. The therapist is seated or standing next to the client on the side to be tested. The client is prone, with the hip at neutral and the knee flexed to about 90 degrees[6,12] or extended.[12] The therapist stands next to the client on the opposite side.[14] Two pillows may be placed under the pelvis to flex the hips.[6,7]	
2. Action	While demonstrating movement from neutral to full hip extension, the therapist says, "Move your leg like I did." Observe the client actively performing the movement (FIG 22.110).	 FIG 22.110 Hip extension: action.
3. Test position	If client performs through available PROM, place the hip in midextension and proceed. If not, follow procedure for testing grades Poor, Trace, and Zero.	
4. Stabilize	The therapist stabilizes over the iliac crest on the side being tested.[10,12]	
5. Pressure	Tell the client, "Don't let me move you." Apply pressure at the distal end of the posterior aspect of the thigh, downward, toward flexion,[10,12-14] adjusting pressure to client's abilities (FIG 22.111). If pressure is maximal = Normal, moderate = Good, minimal = Good−, slight = Fair+, and no pressure = Fair.	 FIG 22.111 Hip extension: application of pressure.

Procedure for Testing Grades Poor (2), Trace (1), and Zero (0)

1. Body position	Client is in a side-lying position. The therapist stands in front of the client, supporting the upper leg in extension and slight abduction.[10] The lower leg (to be tested) is flexed at the hip and knee.
2. Action	Move client's leg into hip extension twice while stating, "Move your leg like I did." (a) If client performs full ROM, place in midextension and apply slight pressure toward flexion. (i) If tolerates pressure = Poor+. (ii) No pressure = Poor. (b) If client performs through partial ROM, do not apply pressure = Poor−. (c) If client is unable to perform motion, place hip in midposition and state, "Try to move your hip like I did." Palpate over the middle posterior surface of the buttock[15] and the posterior thigh for muscle contraction. (i) If muscle contraction palpable = Trace. (ii) If no contraction palpable = Zero.
Specific muscle testing: The gluteus maximus can be isolated by keeping the knee flexed while extending the hip to minimize the action of the hamstring muscles on the hip. **Substitution**: Elevation of the pelvis and extension of the lumbar spine can produce some hip extension. In the supine position, gravity and eccentric contraction of the hip flexors can return the flexed hip to extension.[15] Hip external rotation, abduction, or adduction may be used to substitute.[7]	

Hip Abduction (Figs. 22.112 to 22.113)

Muscles[6,10,12]	Innervation[10,12-14]
Gluteus medius	Superior gluteal nerve, L4–S1
Gluteus minimus	Superior gluteal nerve, L4–S1
Tensor fasciae latae	Superior gluteal nerve, L4–S1
Sartorius	Femoral nerve, L2

Procedure for Testing Grades Normal (5), Good (4), and Fair (3)

1. Body position	The client assumes a side-lying position, with the upper leg (to be tested) with the knee extended and hip extended slightly beyond the neutral position and slight forward rotation of the pelvis[12]; the lower leg is flexed at the hip and knee to provide a wide base of support.[7] The therapist stands behind or in front of the client.[6,7,10,12-14]	
2. Action	The client abducts the upper leg, lifting the leg upward toward the ceiling (FIG 22.112).	 FIG 22.112 Hip abduction: action.
3. Test Position	If the client performs through available PROM, place the leg in mid hip abduction and proceed. If not, follow the procedure for testing grades Poor, Trace, and Zero.	
4. Stabilize	Provide stabilization at the pelvis over the iliac crest.[10,14]	
5. Pressure	Tell the client "Don't let me move you." Provide pressure at the point just proximal to the knee in a downward direction toward adduction (FIG 22.113).	 FIG 22.113 Hip abduction: application of pressure.

Procedures for Testing Grades Poor (2), Trace (1), and Zero (0)

1. Body Position	The client is supine, with both legs extended and in neutral rotation. The therapist stands next to the client on the opposite side.[10] The therapist may use one hand to support at the ankle and slightly lift the test leg off the surface, being careful to offer no resistance or assistance to the movement.[12]
2. Action	Move client's leg into hip abduction moving the free leg sideward twice while maintaining neutral rotation during this movement and stating "Move your leg like I did." (a) If patient performs full ROM, place leg in mid-abduction and apply slight pressure toward adduction. (i) If tolerates pressure = Poor+. (ii) No pressure = Poor. (b) If patient performs through partial ROM, do not apply pressure = Poor−. (c) If client is unable to perform motion, place hip in mid-abduction position and state "Try to move your hip like I did." Palpate the gluteus medius on the lateral aspect of the ilium above the greater trochanter of the femur. (i) If muscle contraction palpable = Trace. (ii) If no contraction palpable = Zero.
Substitution: Lateral muscles of the trunk may contract to bring the pelvis toward the thorax, effecting partial abduction at the hip.[10] If the hip is externally rotated, the hip flexors may assist in abduction.[6,7,10,15]	

Hip External Rotation (Figs. 22.114 to 22.115)

Muscles[10,12]	Innervation[10,12]
Quadratus femoris	Femoral nerve, L2–4
Piriformis	Sacral plexus, S1, S2
Obturator internus	Sacral plexus, L5–S1
Obturator externus	Obturator nerve, L3, L4
Gemellus superior	Obturator internus, L5, S1
Gemellus inferior	Obturator internus, L5, S1

Procedure for Testing Grades Normal (5), Good (4), and Fair (3)

1. Body position	The client is seated, with knees flexed over the edge of the table. A small pad or folded towel is placed under the knee on the side to be tested. The therapist stands in front of the client toward	

	the side to be tested.[6,10,12-14]	
2. Action	While demonstrating movement from neutral to full external rotation, the therapist says, “Move your leg like I did.” Observe the client actively rotating the thigh outwardly; the foot will move medially or toward the midline (FIG 22.114).	 FIG 22.114 Hip external rotation: action.
3. Test position	If client performs through available PROM, place the hip in midexternal rotation and proceed. If not, follow procedure for testing grades Poor, Trace, and Zero.	
4. Stabilize	The therapist stabilizes the lateral aspect of the knee on the side to be tested. The client may grasp the edge of the table to stabilize the trunk and pelvis.[6,10,14]	
5. Pressure	Tell the client, “Don't let me move you.” Apply pressure at the medial aspect of the lower leg, just proximal to the ankle, in a lateral direction toward internal rotation over the distal leg (just proximal to the ankle joint) medially,[6,7,10,12-14] adjusting pressure to client's abilities. Because the long lever arm multiplies the force significantly, it is extremely important to apply pressure carefully and gradually; joint injury can occur if pressure is sudden and forceful (FIG 22.115). Clients with knee instability should be tested in the supine position.[7,10] If pressure is maximal = Normal, moderate = Good, minimal = Good−, slight = Fair+, and no pressure = Fair.	 FIG 22.115 Hip external rotation: application of pressure.

Procedure for Testing Grades Poor (2), Trace (1), and Zero (0)

1. Body position	The client is supine, with hips and knees extended; the hip to be tested is internally rotated. The therapist is standing next to the client on the opposite side.[10,12]
2. Action	Move client's hip into external rotation twice while stating, “Move your leg like I did.” Observe the client actively rotating the thigh.[10] (a) If client performs full ROM, place in midexternal rotation and apply slight pressure toward internal rotation. (i) If tolerates pressure = Poor+. (ii) No pressure = Poor. (iii) Muscles are graded Poor if ROM in the gravity-minimized position can be achieved against slight resistance during the second half of the ROM. (b) If client performs through partial ROM, do not apply pressure = Poor−. (c) If client is unable to perform motion, place hip in midposition and state, “Try to move your leg like I did.” These deep muscles are difficult or impossible to palpate.[6] Action of the external rotators may be detected by palpating deeply posterior to the greater trochanter of the femur.[10] (i) If muscle contraction palpable = Trace. (ii) If no contraction palpable = Zero.
Substitution: The gluteus maximus may substitute for the deep external rotators when the hip is in extension. The sartorius may substitute, but external rotation will be accompanied by hip flexion, abduction, and knee flexion.[7,15]	

Knee Extension (Figs. 22.116 to 22.117)

Muscles[10]	Innervation[10]
Rectus femoris	Femoral nerve, L2–4
Vastus intermedius	Femoral nerve, L2–4
Vastus medialis	Femoral nerve, L2–l4
Vastus lateralis	Femoral nerve, L2–l4
Tensor fasciae latae	Superior gluteal nerve, L4–S1

Procedure for Testing Grades Normal (5), Good (4), and Fair (3)

1. Body	The client is seated, with knees flexed over the edge of the table and feet	

position	suspended off the floor. The client may lean backward slightly to release tension on the hamstrings and grasp the edge of the table for stability.[6,10,12] The therapist stands next to the client on the side to be tested.[6,12]	
2. Action	While demonstrating movement from neutral to full knee extension, the therapist says, “Move your knee like I did.” Observe the client actively performing the movement (FIG 22.116).	 FIG 22.116 Knee extension: action.
3. Test position	If client performs through available PROM, place the knee in midextension and proceed. If not, follow procedure for testing grades Poor, Trace, and Zero.	
4. Stabilize	The therapist stabilizes the thigh by placing one hand under the client's knee to cushion it from the edge of the table. The client may grasp the edge of the table.[7,10,12-14]	
5. Pressure	Tell the client, “Don't let me move you.” Apply pressure on the anterior surface of the leg, just above the ankle, with downward pressure toward knee flexion,[6,10,14] adjusting pressure to client's abilities. Because resistance to a locked knee can cause joint injury,[10] ensure that the knee is tested in midextension and not at the end ROM of knee extension[7,10] (FIG 22.117). If pressure is maximal = Normal, moderate = Good, minimal = Good−, slight = Fair+, and no pressure = Fair.	 FIG 22.117 Knee extension: application of pressure.

Procedure for Testing Grades Poor (2), Trace (1), and Zero (0)

1. Body position	The client assumes a side-lying position on the side to be tested. The lower leg is positioned with the hip extended and the knee flexed to 90 degrees. The therapist stands behind the client.
2. Action	Move client's knee into extension twice while stating, “Move your leg like I did.” (a) If client performs full ROM, place in midknee extension and apply slight pressure toward flexion. (i) If tolerates pressure = Poor+. (ii) No pressure = Poor. (b) If client performs through partial ROM, do not apply pressure = Poor−. (c) If client is unable to perform motion, place knee in midposition and state, “Try to move your leg like I did.” Palpate over the anterior aspect of the thigh. (i) If muscle contraction palpable = Trace. (ii) If no contraction palpable = Zero.
Substitutions:	Tensor fasciae latae may substitute for or assist weak quadriceps. In this case, hip internal rotation will accompany knee extension.[6,10,14] Observe for hip movement.

Ankle Dorsiflexion (Figs. 22.118 to 22.119)

Muscles[6,10,12]	**Innervation**[6,10,14]
Tibialis anterior	Peroneal nerve, L4–S1
Extensor digitorum longus	Deep fibular nerve, L5–S1
Peroneus (fibularis) tertius	Superficial fibular nerve, L5, S1, S2
Extensor hallucis longus	Deep fibular nerve, L5, S1

Procedure for Testing Grades Normal (5), Good (4), and Fair (3)

1. Body position	The client is seated, with the legs flexed at the knees, over the edge of the table. The therapist sits in front of the client, slightly to the side to be tested.[6,10,12-14]	
2. Action	While demonstrating movement from neutral to full dorsiflexion, the therapist says, “Move your foot like I did.” Observe the client actively performing the movement (FIG 22.118).	

		 FIG 22.118 Ankle dorsiflexion: action.
3. Test position	If client performs through available PROM, place the ankle in middorsiflexion and proceed. If not, follow procedure for testing grades Poor, Trace, and Zero.	
4. Stabilize	The therapist stabilizes the leg, just above the ankle. The client's heel can rest in the therapist's lap.[6,12]	
5. Pressure	Tell the client, "Don't let me move you." Apply pressure on the dorsal aspect of the foot (top of foot), toward plantar flexion[6,10,14] adjusting pressure to client's abilities (FIG 22.119). If pressure is maximal = Normal, moderate = Good, minimal = Good−, slight = Fair+, and no pressure = Fair.	 FIG 22.119 Ankle dorsiflexion: application of pressure.

Procedure for Testing Grades Poor (2), Trace (1), and Zero (0)

1. Body position	Client is positioned in a side-lying position.[7,10] The therapist stands or sits opposite or next to the client on the side being tested.
2. Action	Move client's ankle into dorsiflexion twice while stating, "Move your foot like I did." (a) If client performs full ROM, place in midankle dorsiflexion and apply slight pressure toward plantar flexion (toward the floor). (i) If tolerates pressure = Poor+. (ii) No pressure = Poor. (b) If client performs through partial ROM, do not apply pressure = Poor−. (c) If client is unable to perform motion, place ankle in middorsiflexion and state, "Try to move your foot like I did." Palpate over the anterior medial aspect of the ankle joint[6,7,10] and the anterior surface of the leg, just lateral to the tibia.[15] (i) If muscle contraction palpable = Trace. (ii) If no contraction palpable = Zero. (iii) If the against-gravity position is used, exercise clinical judgment to determine muscle grades. Partial ROM against gravity can be graded Poor.[12] If the test is performed in the supine position for these grades, standard definitions of muscle grades may be used.[10]
Specific muscle testing: To isolate the peroneus tertius, dorsiflexion should be combined with eversion, whereas the tibialis anterior is isolated with the foot in inversion and dorsiflexion. To prevent the extensor hallucis longus and extensor digitorum longus, do not allow the toes to extend.[7,10,12-15]	

Foot Eversion (Figs. 22.120 to 22.121)

Muscles[10,14]	**Innervation**[10,14]
Peroneus longus	Peroneal nerve, L4–S1
Peroneus brevis	Superficial fibular nerve L5–22
Peroneus tertius	Superficial fibular nerve L5–22

Procedure for Testing Grades Normal (5), Good (4), and Fair (3)

1. Body position	The client assumes a side-lying position, with the lower leg flexed at the knee to keep it out of the way. The upper test leg is in hip extension with neutral rotation, knee extension, and ankle plantar flexion with foot inversion.[6]	
2. Action	While demonstrating movement from neutral to full eversion, the therapist says, "Move your foot like I did." Observe the client actively performing the	

	movement. Eversion is normally accompanied by some degree of plantar flexion[14,15] (FIG 22.120).	 **FIG 22.120** Foot eversion: action.
3. Test position	If client performs through available PROM, place the foot in eversion and proceed. If not, follow procedure for testing grades Poor, Trace, and Zero.	
4. Stabilize	The therapist stabilizes the leg above the ankle in a medial or lateral manner.[6]	
5. Pressure	Tell the client, "Don't let me move you." Apply pressure against the lateral border and the plantar surface of the foot toward inversion and dorsiflexion (FIG 22.121),[6,14] adjusting pressure to client's abilities. If pressure is maximal = Normal, moderate = Good, minimal = Good−, slight = Fair+, and no pressure = Fair.	 **FIG 22.121** Foot eversion: application of pressure.

Procedure for Testing Grades Poor (2), Trace (1), and Zero (0)

1. Body position	The client is supine, hip extended and in neutral rotation.[10] The knee is extended, and the ankle is in midposition.
2. Action	Move client's foot into eversion twice while stating, "Move your foot like I did." (a) If client performs full ROM, place in mideversion and apply slight pressure toward inversion. (i) If tolerates pressure = Poor+. (ii) No pressure = Poor. (b) If client performs through partial ROM, do not apply pressure = Poor−. (c) If client is unable to perform motion, place foot in midposition and state, "Try to move your foot like I did." Palpate over the upper half of the lateral aspect of the calf, ankle, and lateral border of the foot and over the base of the fifth metatarsal.[6,10,15] (i) If muscle contraction palpable = Trace. (ii) If no contraction palpable = Zero.
Specific muscle testing: To isolate the peroneus tertius, allow dorsiflexion along with eversion. To prevent the extensor hallucis longus from acting, do not allow the toes to extend.[7,10,12-15]	

Results of Assessment as a Basis for Intervention Planning

When planning intervention for maintenance or improvement of strength, the OT practitioner considers several factors in the clinical reasoning process before determining intervention priorities, goals, and modalities. Results of the muscle strength assessment will suggest the progression of the intervention program. What is the degree of weakness? Is it generalized or specific to one or more muscle groups? Are the muscle grades generally the same throughout, or is there significant disparity in muscle grades? If there is disparity, is there an imbalance of strength between the agonist and antagonist muscles that necessitates protection of the weaker muscles during OT intervention or when ADLs and IADLs are performed? When substantial imbalance between an agonist muscle and an antagonist muscle is noted, intervention goals may be directed toward strengthening the weaker group while maintaining the strength of the stronger group. Muscle imbalance may also suggest the need for an orthosis to protect the weaker muscles from overstretching while recovery is in progress. Examples of such orthoses are devices such as the bed footboard, used to prevent overstretching of the weakened ankle dorsiflexors, and the wrist cock-up splint, which can prevent overstretching of weakened wrist extensors.

Muscle grades will suggest the level of therapeutic activity or exercise that can help to maintain or improve strength. Is the weakness mild (G range), moderate (F to F+), or severe (P to 0)?[15] Muscles graded F+, for example, could be strengthened by active assisted exercise or light activity against gravity. Likewise, muscles graded P will require activity or exercise in the gravity-minimized plane, with little or no resistance, to increase strength. (See Chapter 29 for further discussion of appropriate exercise and activity for specific muscle grades.)

Endurance of the muscles (i.e., how many repetitions of the muscle contraction are possible before fatigue sets in) is an important consideration in intervention planning. A frequent goal of the therapeutic activity program is to increase endurance as well as strength. Because MMT does not measure endurance, the therapist should assess endurance by engaging the client in periods of exercise or activity graded in length to determine the length of time that the muscle group can be used in sustained activity. A correlation between strength and endurance is usually noted. Weaker muscles tend to have less endurance than stronger ones. When selecting intervention modalities for increasing endurance, the therapist may elect not to tax the muscle to its maximal ability but rather to emphasize repetitive action at less than the maximal contraction to increase endurance and prevent fatigue.[15]

Sensory loss, which often accompanies muscle weakness, complicates the ability of the client to perform in an activity program. If little or no tactile or proprioceptive feedback is obtained from motion, the impulse to move is decreased or lost, depending on the severity of sensory loss. Thus the movement may appear weak and ineffective even when strength is adequate for performance of a specific activity. With some diagnoses, a sensory reeducation program (see Chapter 23) may be indicated to increase the client's sensory awareness and feedback received from the part. In other instances, the therapist may elect to teach compensation techniques to address the sensory loss. These techniques include the use of mirrors, video playback, and biofeedback, which can be used as adjuncts to the strengthening program.

Other important considerations in the therapist's clinical reasoning include the diagnosis and expected course of the disease. Is strength expected to increase, decrease, or remain about the same? If strength is expected to increase, what is the expected recovery period? What is the effect of exercise or activity on muscle function? Will too much activity delay the progress of recovery? If muscle power is expected to decrease, how rapid will the progression be? Are there factors to be avoided, such as vigorous activity or an exercise program that can accelerate the decrease in strength? If strength is declining, is special equipment practical and necessary? How much muscle power is needed to operate the equipment? How long will the client be able to operate a device before a decrease in muscle power makes it impracticable?[15] In Sharon's case, the therapist must be aware of the change in her muscle strength. It is expected that muscle strength will return in a proximal-to-distal pathway, and it is critical to protect the intrinsic muscles of the hand against overexertion to ensure the possibility of full recovery. Frequent muscle testing of select muscle groups will serve as a means to monitor progression of the disease and to assist in the introduction of appropriate intervention strategies.[11,20]

The therapist should assess the effect of muscle weakness on the ability to perform ADLs; this can be observed during assessment. Which tasks are most difficult to perform because of muscle weakness? How does the client compensate for the weakness? Which tasks are most important for the client to be able to perform? Is special equipment necessary or desirable for the performance of some ADLs, such as mobile arm support for independence in eating (see Chapter 30, Section 2).

If the client is involved in a total rehabilitation program and is receiving several other healthcare services, the activity and exercise programs must be synchronized and balanced to meet the client's needs rather than the needs of the professionals, their schedules, and possibly their competition. The occupational therapist must be aware of the nature and extent of programs in which the client is engaged in physical therapy, recreation therapy, and any other services. Ideally, all members of the healthcare team should plan the exercise and activity programs together to ensure that they complement one another.

OT Practice Notes

The therapist must consider the following questions: What is the client doing in each of the therapies? How long is each treatment session? Are the goals of all of the therapies similar and complementary, or are they divergent and conflicting? Is the client being overfatigued in the total program? Are the various treatment sessions provided in rapid succession, or are they well spaced to meet the client's need for rest periods?

On the basis of these considerations and others pertinent to the specific client, the occupational therapist can select enabling and purposeful activities designed to maintain or increase strength, improve the performance of ADLs, and enable the use of special equipment, while protecting weak muscles from overstretching and overfatigue.

Summary

Many diseases and injuries result in muscle weakness. Screening tests can be used to assess the general level of strength available for the client to engage in ADLs; IADLs; and sleep and rest, educational, work, and leisure occupations. These tests can also help determine which clients and muscle groups might require MMT.

MMT evaluates the level of strength in a muscle or muscle group. It is used with clients who have motor unit (lower motor neuron) disorders and orthopedic conditions. It does not measure muscle endurance or **muscle coordination**, and it cannot be used accurately in upper motor neuron disorders when spasticity and or patterned/synergistic motion is present or when selective motion is not present.[1]

Accurate assessment of muscle strength depends on the knowledge, skill, and experience of the occupational therapist. Although there are standard definitions of muscle grades, clinical judgment is important in accurate evaluation.

Muscle test results are used to plan intervention strategies to improve occupational performance, compensate for muscle weakness, and increase strength. In some cases, muscle test results can also be used to track the expected course and progression of the disease or disorder, which can assist the OT practitioner when choosing intervention modalities and strategies, and when setting goals, as in Sharon's case.

Review Questions

1. List three general classifications of physical dysfunction in which muscle weakness is a primary symptom.
2. List at least three purposes for assessing muscle strength.
3. Discuss five considerations and their implications in intervention planning that are based on the results of muscle strength assessment.
4. Define endurance.
5. How can muscle weakness be differentiated from joint limitation?
6. If there is joint limitation, can muscle strength be measured accurately? How is strength recorded when available ROM is less than normal?
7. What does MMT measure?
8. What are the limitations of MMT?
9. When is MMT contraindicated?
10. What are the criteria for determining muscle grades?
11. In relation to the floor as a horizontal plane, describe or demonstrate what is meant by the terms *with gravity assisting, with gravity minimized, against gravity*, and *against gravity and resistance.*
12. List five factors that can influence the amount of resistance against which a muscle group can hold.
13. Define the muscle grades: N (5), F− (3−), F (3), P (2), P− (2−), T (1), and zero (0).
14. Explain what is meant by substitution.
15. How are substitutions most likely to be ruled out in the muscle testing procedure?
16. List the steps in the muscle testing procedure.
17. Is it always necessary to perform MMT to determine level of strength? If not, what alternatives may be used to make a general assessment of strength?
18. List the purposes of screening tests.

Evaluation of Sensation and Intervention for Sensory Dysfunction*

Michelle R. Abrams, Cynthia C. Ivy

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, the student or practitioner will be able to do the following:

1. Describe how sensation is positioned within the current (2014) Occupational Therapy Practice Framework (OTPF-3).
2. Describe and compare the differences in sensory loss caused by a central nervous system dysfunction and that caused by a peripheral nerve repair.
3. Perform a sensory evaluation on a client with a peripheral nerve problem.
4. Instruct a client in an appropriate program for sensory reeducation, describe ways to upgrade the program, and name the criteria that reflect a client's readiness to have the program upgraded.
5. Explain why lack of protective sensation puts people at risk for serious injury and what types of injury are possible.
6. Identify whether a client is a candidate for compensatory strategies for sensory dysfunction, discriminative sensory reeducation, and/or cortical reorganization based on sensory evaluation findings.

KEY TERMS

Allodynia
Chemoreceptors
Dermatome
Desensitization

Dysesthesia
Graded motor imagery
Habituation
Hyperalgesia
Hypersensitivity
Kinesthesia
Mechanoreceptors
Neuropathy
Neuroplasticity
Nociceptors
Paresthesia
Proprioception
Stereognosis
Thermoreceptors
Tinel's sign

Threaded Case Study

Don, Part 1

Don is a 79-year-old, right hand–dominant gentleman who sustained a spinal cord injury 45 years ago, with resultant incomplete paraplegia at the level of T12. He has relied solely on his bilateral upper extremities for his occupations because he has functioned independently from a wheelchair level since the injury. In the course of his extensive arm use, he has developed severe bilateral carpal tunnel syndrome. The sensory loss and increased pain associated with carpal tunnel syndrome are leading to difficulties with wheelchair mobility and his ability to complete basic and higher level self-care tasks. During the occupational therapy (OT) initial evaluation, the client stated that the client factor that has had the greatest impact on his life is the sensory loss in his hands. This is leading to difficulty with occupational performance, including his wheelchair mobility, because he now needs to use his vision to see how his hands are placed around the rim of the wheels for fear of them getting caught and injured in the spokes of the wheel. He believes that his wheelchair mobility signifies his level of independence and also provides for bilateral upper extremity exercise. He states that he typically chooses not to park in a "handicap" spot in order to allow others "who really need it" to park there, and that he enjoys the extra exercise he feels he gains by parking farther away and using his arms to maneuver the wheelchair to get to his destination. Don believes that transitioning to a motorized wheelchair at this time would be a symbol of weakness and a loss of function. He has recently undergone a right endoscopic carpal tunnel decompression, and his hand surgeon anticipates excellent sensory recovery. However, Don will need to make modifications to try to reduce weight bearing on his hands during his recovery so as not to further irritate the median nerve as it passes through the carpal tunnel.

Critical Thinking Questions

1. What sensory tests would be most appropriate for Don?

2. Describe a sensory reeducation program that would be appropriate for Don.

3. What will you tell Don regarding typical sensory recovery after carpal tunnel release and the modifications that he will have to make to try to minimize weight bearing through his hands?

Threaded Case Study

Mario, Part 1

Mario is an 84-year-old, right hand–dominant male who sustained a circular saw injury, with resultant amputation of his right fourth (ring) finger and fifth (small) finger at the level of the fingertips, just distal to the distal interphalangeal (DIP) joints. He is an active senior who had been in the tile and granite profession and now enjoys woodworking, wine making, and dancing with his wife. He has osteoarthritis throughout many joints of his body, including his hands, hips, and knees, but is otherwise generally healthy. He has had prior hand surgeries, followed by hand occupational therapy for joint replacements in his fingers and also a thumb fracture. These surgical corrections and injuries grossly affected his function due to limitations in active range of motion (AROM) and functional strength, but they did not directly affect his sensation in his fingertips. Although Mario considered losing the tips of two fingers a relatively minor injury compared to the recovery required for joint replacements in his hand, he has come to realize the functional implications of sensory dysfunction. He not only has decreased sensation at the residual portion of his amputated digits, he also has hypersensitivity, along with phantom limb pain (PLP). Mario communicated that his leisure activities are the occupations that are the most affected by the amputation and resultant sensory dysfunction. He reports specific difficulty with tool use in both woodworking and wine making. He also notices negative effects in his social participation because he has become less comfortable with driving, which he needs to do in order to go dancing with his wife; the sensory changes make it difficult to adequately and confidently grip the steering wheel. In order to sufficiently cover the residual portion of his fingers with soft tissue, surgical amputation was performed distal to the DIP joint of both his ring and small fingers. His hand surgeon expects full recovery in terms of AROM at that joint, but Mario will have sensory dysfunction at the residual distal ends of his ring and small fingers.

Critical Thinking Questions

1. Why does sensation affect Mario's occupational roles?

2. How can an occupational therapist incorporate purposeful activity into Mario's treatment plan to enhance sensory perceptual skills?

3. What types of treatment methods may you incorporate to improve the remapping of his brain to connect him with his fingers once again?

People who have not experienced sensory problems probably take for granted all that sensation contributes to their daily occupational performance. By comparison, people with sensory dysfunction are likely to be acutely aware of the lost picture that normal sensation provides. This chapter discusses the functional impact of somatosensory system dysfunction on occupational performance.

Sensation is explored in terms of touch, temperature, pain, **proprioception** (sense of position; for example, with loss of proprioception, the person experiences a lack of coordination with everyday tasks, such as buttoning), and stereognosis (the ability to identify an item with the vision occluded). Techniques for sensory testing, desensitization, and sensory reeducation also are presented. This chapter offers cases illustrating sensory loss deficits and stimulates clinical reasoning that guides evaluation, intervention, and outcomes appropriate to various diagnoses.

Sensation (also called sensibility) is a body function, a component of the client factors that influence both the motor and processing aspects of performance skills.[1] Although there are several realms of sensibility or sensation in the body (e.g., the olfactory realm, the auditory realm, and even emotionality), this chapter is specific to cutaneous sensation and joint proprioceptive sensation. According to the OTPF-3, the area of occupation that Don is limited in is the activity of daily living (ADL) of functional mobility because the lack of sensation in his first three digits affects his ability to grasp and maneuver the rims of his wheelchair. Within the domain of occupation, this dysfunction will also affect his social participation. Client factors affected include body functions, including mental functions, sensory functions, and pain due to the sensory loss. Body structures include the structure of the nervous system affected by sensory dysfunction. For this reason, sensation and sensory dysfunction may affect clients' performance in nearly all areas of occupation, including ADLs, education, work, play, leisure, and social participation. For people with carpal tunnel syndrome, as in Don's case, the sensory loss typically involves the thumb, index finger, long finger, and radial half of the ring finger. This distribution of sensory loss makes it difficult to pinch with a tip pinch or three-point pinch and to grasp objects with a lateral key pinch. It often forces people to oppose their thumb to the pad of their small finger instead. This would lead to difficulties for Don in maintaining a functional grasp and lateral pinch on his wheelchair rims.

All clients with sensory dysfunction, regardless of etiology, should be evaluated to determine the occupational impact of the sensory loss. The specific sensory tests and interventions may vary. depending on the diagnosis and the prognosis for recovery. The battery of tests selected is contingent on whether the diagnosis defines the problem as either central nervous system (CNS) or peripheral nervous system (PNS) in origin, and if CNS, whether the brain or the spinal cord is involved.

A person with CNS injury with brain involvement, with or without spinal cord injury, is more likely to have deficits in proprioception and stereognosis. Persons with CNS injury may also have difficulty processing sensory feedback, which would become evident during the evaluation and may require further testing (see Chapters 25 and 26). If there is a CNS injury that only involves the spinal cord, there may be a loss of all sensation at the dermatome at the level of injury and below.

A person with PNS injury is more likely to have deficits in touch pressure awareness and two-point discrimination. A client with a history of a cerebrovascular accident (CVA), which would be considered a prior CNS insult, who then sustains a wrist fracture (a PNS injury), should be evaluated for proprioception and stereognosis, and also for pressure threshold and two-point discrimination because both the CNS and PNS systems are affected. Raynaud's phenomenon, brachial plexus injury, neuroma, severed nerve, and amputation are examples of other conditions that may lead to sensory dysfunction from the PNS. However, radiculopathy, traumatic brain injury, neurodegenerative diseases, and CNS cancers or cancer treatments may lead to sensory dysfunction in the CNS.

Furthermore, it is useful to have the sensory test follow the motor examination and functional interview with the client (refer to Chapters 19 and 20). These two preceding portions of the evaluation will allow for greater information to determine where to begin sensory testing and the battery of sensory tests on which to focus. In Don's case, the OT interview allowed the therapist to focus on the distribution of the median and ulnar nerves of the hand. In Mario's case, the motor evaluation, which was normal, revealed that his functional deficits were due entirely to the sensory loss.

Somatotopic Arrangement

Sensory information is received and organized somatotopically in the primary somatosensory cortex of the brain. The sensory homunculus (Fig. 23.1) is a diagram that shows the arrangement and proportions of cortical areas representing the surface of the body. Areas with large cortical representation indicate a high density of sensory receptors. As shown in Fig. 23.1, somatotopic arrangement is such that axons providing information from the index finger are situated closer to those from the thumb than to those from the foot. There is also a motor homunculus, or diagram, that follows roughly the same arrangements. Sound research studies have demonstrated the relevance of somatotopic arrangement to therapeutic strategies for normalizing impaired sensation. These strategies are effective because of the brain's plasticity, or ability to adapt to new needs.[28]

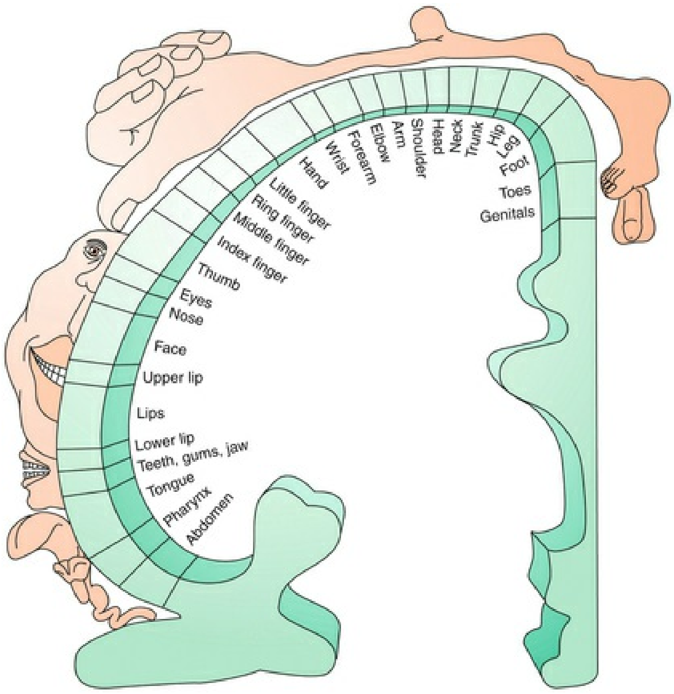

FIG 23.1 Sensory homunculus. (From Copstead LC, Banasik JL: *Pathophysiology*, ed 5, St Louis, 2013, Saunders.)

Within the somatosensory cortex there is an inherent capacity for plasticity involving the complex firing of neurons and neurotransmitters.[7] Topographical reorganization of the cerebral cortex occurs after injury and can be influenced by sensory input and through learning and experience. This has been described by the neurologist and author Frank R. Wilson as a dynamic interplay of sensorimotor and cognitive functions.[32] Referred sensations and phantom limb pain (pain felt in a part removed from its point of origin) in persons with amputations are examples of cortical reorganization. Newer techniques are being developed and used to address cortical reorganization at a clinical level.

Neuroplasticity

Our brain has the plasticity, called **neuroplasticity**, to mechanically induce neuronal reorganization. Instances in which this occurs include the processes of habituation, learning, memory, and cellular recovery after an injury. Along with changes in synaptic connections, there are also changes in nonneuronal cells. Some tenets of neuroplasticity are:

- Sensory perception is a dynamic process that is experienced by the CNS.[7,20]
- Receptor morphology is affected by hand use. The axiom “Use it or lose it” is particularly applicable here. Immobilization or disuse (e.g., a casted fracture or a highly guarded injured upper extremity) contributes to retrogressive modifications in receptors. Conversely, promoting normal use may stimulate new receptors.[28]
- Because there is overlap of the receptive fields of various nerve fibers, a single stimulus will excite different receptors.[6]

Neurons may die after CNS injuries such as spinal cord lesions and strokes. The nervous system accommodates for injuries with behavioral, physiologic, and anatomic changes. Over time, the CNS can adapt by altering the strength of neural transmission through modifications in the structure and function of neurons and synapses. It can be stimulating clinically to realize that occupational therapists facilitate recovery through functional activities and involvement in occupation resulting in somatosensory reeducation.[20]

Somatosensory System

The somatosensory system processes sensory input from superficial sources, such as the skin, and from deep sources, such as the musculoskeletal system. Sensation is stimulated by receptors in the periphery of the body (PNS), and the sensory information then travels through afferent neurons, carrying nerve impulses from the receptors to the brain (CNS).

Somatosensory receptors are individualized to respond to specific types of input. These receptors are categorized as mechanoreceptors, chemoreceptors, and thermoreceptors. **Mechanoreceptors** respond to touch, pressure, stretch, and vibration and are stimulated by mechanical deformation. **Chemoreceptors** respond to cell injury or damage and are stimulated by substances (neuropeptides) that the injured cells release. **Thermoreceptors** respond to the stimulation of heating or cooling. Each of these three types of receptors has a subset called **nociceptors**, which sense pain when stimulated.[18] Afferents, which are peripheral axons that carry information toward the brain, are categorized by the diameter of the axon. Axons with larger diameters transmit their information more quickly, in part because they are myelinated. In contrast to the axons with the larger diameter, pain is frequently carried on small-diameter, unmyelinated axons.

Disturbances in somatosensation may be manifested as paresthesia, hyperalgesia, hypersensitivity, dysesthesia, or allodynia. **Paresthesia** is a tingling, electrical, or prickling sensation. Tapping the volar aspect of the wrist may elicit paresthesias in the distribution of the median nerve in a person who has carpal tunnel syndrome due to the compressive nature of the disease. When such tapping elicits paresthesia, it is referred to as **Tinel's sign**. **Hyperalgesia** is increased pain and may occur during nerve regeneration. **Hypersensitivity** is increased sensory pain. Mario experienced hyperalgesia and hypersensitivity at his amputation sites after his surgery. **Desensitization** helps normalize the phenomenon of hypersensitivity. **Dysesthesia** is an unpleasant sensation that may be spontaneous or reactive to stimulation. **Allodynia** is pain caused by a stimulus that would not normally cause pain. An example of allodynia would be seen when a person with complex regional pain syndrome (CRPS), formerly referred to as reflex sympathetic dystrophy (RSD), experiences pain with the mere movement of air wafting over the involved arm (Table 23.1).

TABLE 23.1
Disturbances in Somatosensation

Sensory Disturbance	Description
Paresthesia	Tingling, electrical or prickling sensation
Hyperalgesia	Increased pain; often occurs during nerve regeneration
Hypersensitivity	Increased sensory pain
Dysesthesia	Unpleasant sensation that may be spontaneous or a reaction to stimulation
Allodynia	Pain caused by a stimulus that would not normally cause pain

A **dermatome** is the area of skin supplied by one spinal dorsal root and its spinal nerve. The affected dermatome correlates with the level of the spinal cord lesion. However, some peripheral nerves have innervation patterns that differ from dermatome patterns. This is due to regrouping of sensory axons in the brachial plexus and in the lumbosacral plexus (Fig. 23.2). The clinical significance of such regrouping is that sensory assessment along a dermatomal pattern is more appropriate in clients with CNS lesions, not PNS lesions. In addition, because of the central processing of deep sensory input, clients with some CNS lesions (e.g., CVA and multiple sclerosis) are more likely to have deficits in vibration, proprioception, stereognosis, and temperature. Clients with CNS dysfunction in the spinal cord and those with PNS lesions are more likely to experience deficits in pain, pressure threshold, and two-point discrimination. According to the American Spinal Injury Association (ASIA), persons with spinal cord injury are classified according to their “sensory level,” which is the most caudal intact dermatome for both pinprick and light touch.[2] **Neuropathy** is defined as impairment of the PNS. Large sensory nerve fibers carry signals of vibration, light touch, and proprioception, whereas the smaller fibers, which are also often not myelinated, transmit messages of temperature and pain. Testing for light touch, proprioception, temperature, and pain will help discern whether small or large sensory nerve fibers are affected.

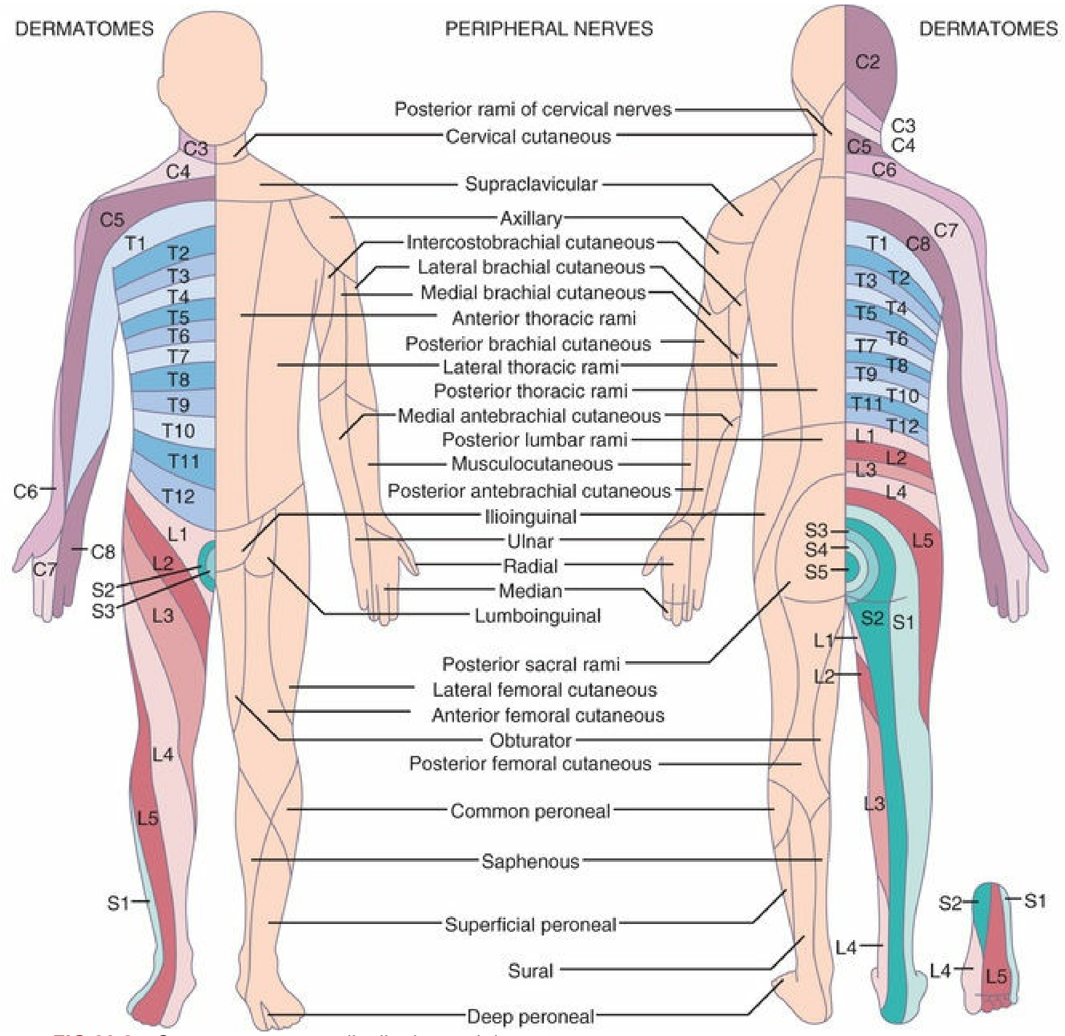

FIG 23.2 Cutaneous sensory distribution and dermatomes. (From Lundy-Ekman L: *Neuroscience: fundamentals for rehabilitation,* ed 3, St Louis, 2007, Saunders.)

Superficial Sensation

Pain, temperature, and touch are facets of superficial sensation, also called cutaneous sensation. Compared with the more proximal body parts, the distal parts have a higher density of receptors and smaller receptive fields.[16] This arrangement contributes to enhanced fingertip sensation, such as the ability to distinguish between one and two stimuli that are close together. The relevance of this in terms of daily occupations is that normal two-point discrimination enables a person to distinguish a dime from a penny without vision, as when one manipulates the coins in a pocket or wallet. Fig. 23.3 shows normal two-point discrimination values over various locations within the body.

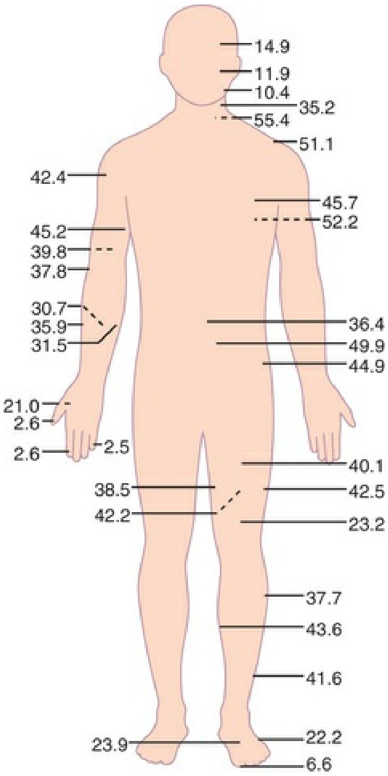

FIG 23.3 Normal two-point discrimination values over different locations of the body. (From Lundy-Ekman L: *Neuroscience: fundamentals for rehabilitation,* ed 4, St Louis, 2013, Saunders.)

Blisters, altered sweat patterns, calluses, shiny or dry skin, blanching of the skin, scars, and wounds are indicators of possible autonomic sensory problems and indicate the need to instruct the client in the use of compensatory techniques, such as vision, during daily occupations. In people with sensory problems, healing is slowed because of decreased vascularity because the blood vessels are also controlled by autonomic nerves. An absence of "wear" marks (e.g., calluses) or lack of dirt or grease stains on the hands of a mechanic, for example, may suggest that the hand is not being used. Nerve damage results in atrophy of soft tissue, which increases the tissue's susceptibility to injury because of the lack of protective padding.

Because upper extremity cutaneous sensory fibers and sympathetic nervous system fibers follow the same pathways, sympathetic phenomena may correlate with sensory function. In the upper extremity, the median nerve has more sympathetic fibers than the ulnar nerve, which may explain the increased risk for CPRS in clients with median nerve injury. Therefore, it is important to assess Don for vasomotor function (e.g., blotching of the skin), sudomotor function (e.g., abnormal sweating), pilomotor changes (e.g., absence of goose bumps), and trophic changes (e.g., atrophy of finger pulp or hair growth) because all of these signs are indicators of CRPS.

Prior to sensory testing, a history should be obtained through client interview and review of medical reports. The history should include information on name, age, hand dominance, gender, occupation, date of injury, nature of injury, client description of the sensory problem and how sensation affects functional hand use, screening of motor function, and grip and pinch tests, if appropriate. In addition, any medications the client takes that may interfere with sensation should be noted. Some examples are gabapentin, an antiseizure medication that is sometimes used to treat nerve pain, and chemotherapy medications, which may sometimes induce peripheral neuropathy.

The most accurate sensory evaluation requires an environment free of background noise, high-quality instruments, consistent testing techniques, cooperative clients, and competent testers. It is important to support the client's hand fully, positioning it with a foam wedge or towels to prevent it from moving because movement could provide sensory information that interferes with the test being administered (Fig. 23.4). For all sensory testing, the client's vision should be occluded. This is accomplished by asking the client to keep the eyes closed or by occluding the area by other means, such as with a manila folder (Fig. 23.5). A hand grid worksheet may be used to record the findings (Fig. 23.6).

FIG 23.4 The full forearm rests on a towel for sensory testing with a golf tee.

FIG 23.5 Vision occlusion during sensory testing behind a manila folder.

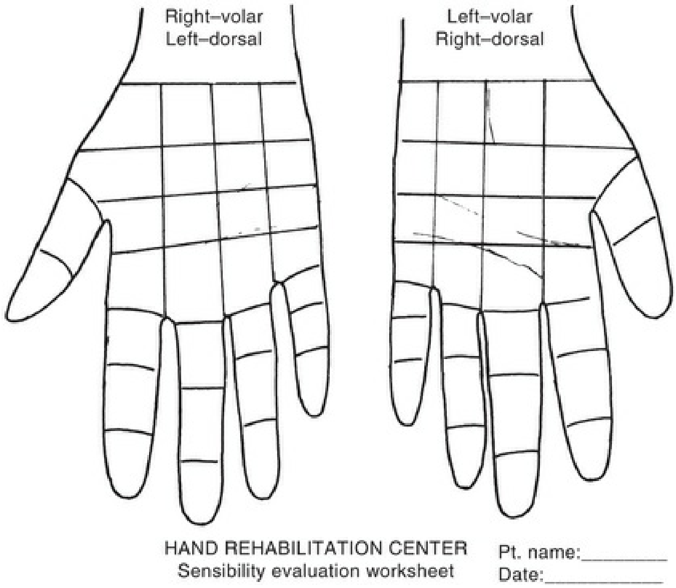

FIG 23.6 Hand grid worksheet. (From Mackin EJ, et al, editors: *Rehabilitation of the hand and upper extremity,* ed 5, St Louis, 2002, Mosby.)

Sensory screening is a time-saving method to determine some parameters of the sensory loss experienced. With hand screening, specific sites can be used to reflect larger portions of the hand innervated by the same peripheral nerve. For screening Don's median nerve function, test the thumb tip, index tip, and index proximal phalanx. For screening ulnar nerve function, test the distal and proximal ends of the small finger and the proximal ulnar aspect of the palm. For screening the radial nerve, test the dorsal part of the thumb web space (Fig. 23.7).[4] Screening may also be used for central nerves: for dermatome C5, test the anterior lateral elbow; test C6 on the dorsum of the thumb at the distal phalanx; test C7 at the dorsal middle phalanx of the long finger; test C8 at the dorsal middle phalanx of the small finger; and test T1 on the anterior medial elbow (Fig. 23.8).

Pain Sensation

Pain is an unpleasant sensory and perceptual experience that is associated with either actual or potential cellular damage. The experience of pain is subjective and multidimensional.[12] Pain can be tested by pinching the digit firmly or by using a sharp point, as with a golf tee or the end of a partially unwound paper clip. Recent practices caution that one should avoid traditional use of a safety pin in testing pain sensation so as not to draw blood and risk compromising tissue. Providers would need to follow Universal Precautions and use a new, sterilized safety pin with each patient to minimize the risk to the patient.

Intact pain sensation is indicative of available protective sensation. Sharp/dull testing, using both ends of a golf tee, would be an alternative method to rule out a digital nerve laceration. This could also be accomplished by use of a paper clip opened to expose one end (Fig. 23.9).

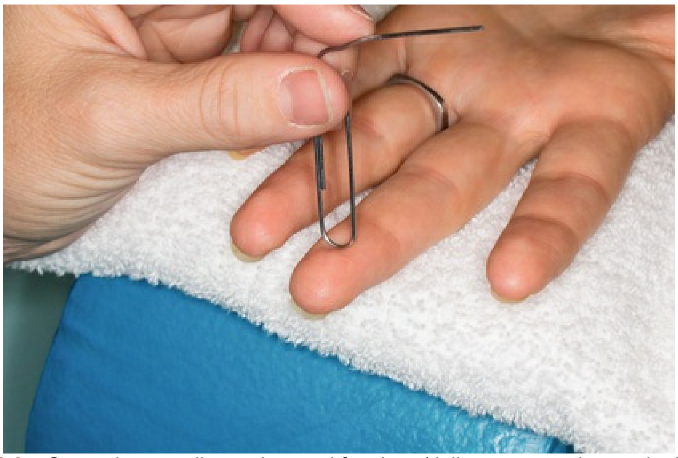

FIG 23.9 Opened paper clip can be used for sharp/dull sensory testing on the hand.

Test for pain (protective sensation)

Procedure

- Using a golf tee or an opened paper clip, assess the amount of pressure required to elicit a pain response on the uninvolved hand. This is the amount of pressure that the examiner will use on the involved side.

- Alternate randomly between the sharp and dull sides of the golf tee or paper clip and ensure that each spot has one sharp and one dull application (see Figures 23.4 and 23.9).

Response

- The client indicates "sharp" or "dull" after each application.

Scoring

- Intact protective sensation: Correct response to both sharp and dull
- Impaired protective sensation: Incorrect response to both sharp and dull
- Absent protective sensation: Inability to perceive being touched
- Hyperalgesic: Heightened pain reaction to the stimulus

Temperature Awareness

Temperature awareness is another test for protective sensation. Thermal receptors detect warmth and cold. In the clinic it is important to test temperature sensation before applying heat or cold modalities to avoid burn injuries. Thermal receptors are also critical for a person to be able to determine a safe water temperature for bathing. A client who lacks temperature awareness must learn compensatory strategies, such as testing the water temperature with an unaffected body part.

Test for temperature awareness (protective sensation)

Procedure

- Apply test tubes or metal cylinders filled with hot or cold fluid randomly to areas of the involved hand.

Response

- The client indicates "hot" or "cold" after each application.

Scoring

- A correct response to both cold and hot indicates intact temperature awareness.
- An incorrect response to either or both indicates impaired temperature awareness.

Testing for Touch Sensation

Two-point discrimination.

Two-point discrimination and touch pressure testing with monofilaments are two different tests examining various aspects of sensation. Two-point discrimination is a test for receptor density and is a good test to use for mapping improvement after nerve repair. Moving two-point discrimination returns before static two-point discrimination and is an indicator of recovery. One criticism concerns potential variability in the force of application during testing. Nonetheless, good interrater reliability has been reported with the Disk-Criminator tool.[24]

Test for static two-point discrimination

Procedure

- Use a device such as the Disk-Criminator or a Boley gauge with blunt testing ends (Fig. 23.10).

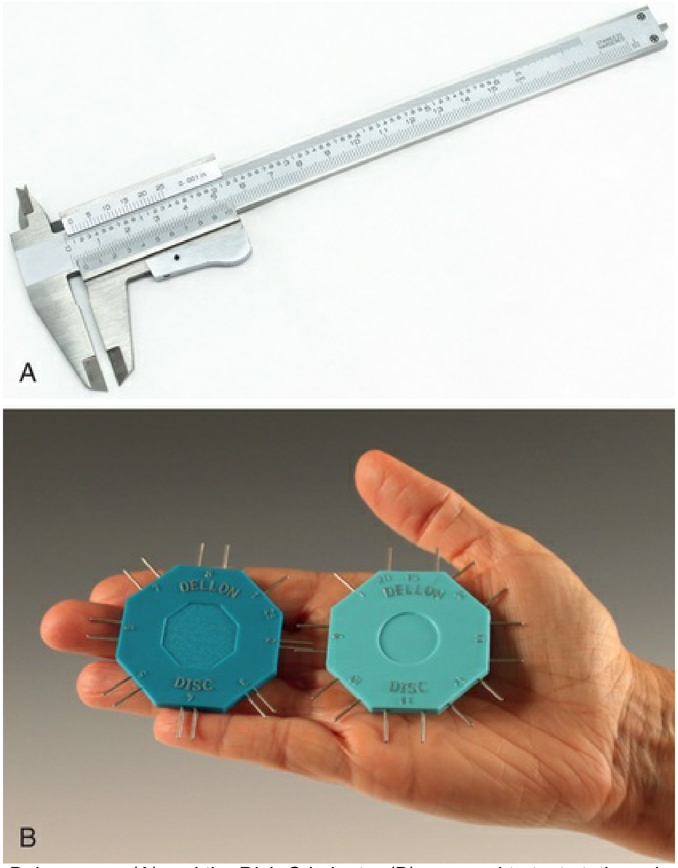

FIG 23.10 The Boley gauge (A) and the Disk-Criminator (B) are used to test static and moving two-point discrimination. (A, iStock.com; B, courtesy Danmic Global, San Jose, CA.)

- Test only the tip of each finger because the fingertip is the primary area of the hand used for exploration of objects.
- Begin with a distance of 5 mm between the testing points.
- Randomly test one or two points on the radial and ulnar aspects of each finger for 10 applications. Apply testing points parallel to the longitudinal axis of the finger so that the adjacent digital nerve is not stimulated (Fig. 23.11).

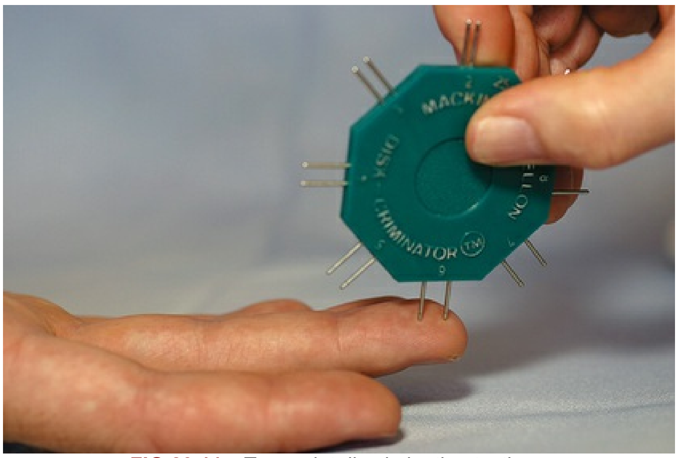

FIG 23.11 Two-point discrimination testing.

- Pressure is applied lightly; stop just when the skin begins to blanch.

Response

- The client will respond "One" or "Two" or "I don't know" after each application.

Scoring

- The client responds accurately to 7 of 10 applications at that number of millimeters of distance between the two points.
- Norms are as follows:

- 1 to 5 mm: Normal static two-point discrimination
- 6 to 10 mm: Fair static two-point discrimination
- 11 to 15 mm: Poor static two-point discrimination
- 1 point perceived: Protective sensation only
- No points perceived: Anesthetic area

Test for moving two-point discrimination

Procedure

- Begin with a distance of 8 mm between points.
- Randomly select one or two points. Move proximal to distal on the distal phalanx, parallel to the longitudinal axis of the finger, so that the adjacent digital nerve is not stimulated (see Fig. 23.11).
- The pressure applied is just enough for the client to appreciate the stimulus.
- If the client responds accurately, decrease the distance between the points and repeat the sequence until you find the smallest distance that the client can perceive accurately.

Response

- The client responds "One," "Two," or "I don't know."

Scoring

- The client responds accurately to 7 of 10 applications.
- Norms are as follows:

- 2 to 4 mm (ages 4 to 60): Normal moving two-point discrimination[17]
- 4 to 6 mm (ages 60 or older): Normal moving two-point discrimination[11]

Touch Pressure

Light touch is perceived by receptors in the superficial skin. Pressure (or deeper touch) is perceived by receptors in the subcutaneous and deeper tissues. Light touch is important for fine discriminatory hand use, whereas deep pressure is important as a form of protective sensation. Touch pressure testing examines the spectrum from light touch to deep pressure. Touch pressure testing is a good test to use for clients with nerve compression, such as carpal tunnel syndrome. Many practitioners test two-point discrimination and the touch pressure of their hand therapy patients in order to gain a more objective clinical picture and track progress. Having intact light touch pressure awareness is an indicator of better sensation than having only intact deep touch pressure awareness. Light touch pressure awareness has to be intact for two-point discrimination to be testable because the two-point discrimination test uses light touch.

Touch pressure is tested with a set of 20 monofilaments. The Semmes-Weinstein Monofilaments are often used in clinics, although there are various other brands of kits at this time. These monofilaments are of varying thickness and are marked with numbers that represent a mathematical formula of the force required to bow them when applied perpendicularly. They are color coded to correspond to five threshold categories. Practitioners will frequently use an abbreviated set of five monofilaments, one for each of these categories, often referred to as the mini-kit.

Test for touch pressure

Procedure (using full kit)

- Begin with monofilament 1.65.
- Apply the monofilament for 1 to 1.5 seconds at the pressure needed to bow the monofilament (applied perpendicularly) (Fig. 23.12).

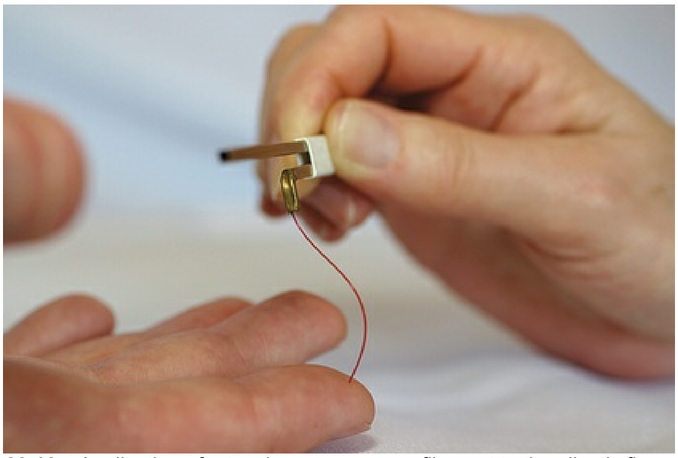

FIG 23.12 Application of a touch pressure monofilament to the client's fingertip.

- Hold the pressure for 1 to 1.5 seconds.
- Lift the monofilament in 1 to 1.5 seconds.
- The proper amount of pressure is achieved when the filament bends.
- Repeat this three times in the same spot for monofilaments 1.65 to 4.08; monofilaments higher than 4.08 are applied only once.
- Randomly select areas of the hand to test, and change the time interval between the application of monofilaments.
- If the client does not perceive the monofilament, proceed to the next (thicker) monofilament and repeat the sequence until you reach monofilament 6.65.
- If the client does perceive the monofilament, record this number on the hand grid and proceed to the next area of the hand.

Response

- The client says "Touch" when he or she feels the monofilament. The client does not need to localize or verbalize where the touch is felt on the hand.

Scoring

- The client responds to at least one of the three applications of the monofilament.
- Norms are as follows:

- Green (1.65 to 2.83): Normal light touch
- Blue (3.22 to 3.61): Diminished light touch

- Purple (3.84 to 4.31): Diminished protective sensation
- Red (4.56 to 6.65): Loss of protective sensation
- Untestable (6.65+): Inability to feel the largest monofilament

Alternate testing (using the mini-kit)

- When the mini-kit is used, the same procedure, response, and scoring as outlined above apply, but there is only one monofilament per threshold that corresponds to the five threshold categories.
- The five monofilaments used in the mini-kit are:

- Green (2.83), which indicates normal light touch
- Blue (3.61), which indicates diminished light touch
- Purple (4.31), which indicates diminished protective sensation
- Red (4.56 and 6.65), which indicates loss of protective sensation
- Untestable (6.65+), which indicates inability to feel the largest monofilament

Proprioception

Conscious proprioception derives from receptors found in muscles, tendons, and joints and is defined as awareness of joint position in space. It is through cerebral integration of information about touch and proprioception that objects can be identified by tactile cues and pressure. If proprioception is impaired, it may be difficult to gauge how much pressure to use when holding a paper cup.

Test for proprioception

Procedure

- Hold the lateral aspect of the elbow, wrist, or digit.
- Move the body part into flexion or extension (Fig. 23.13).

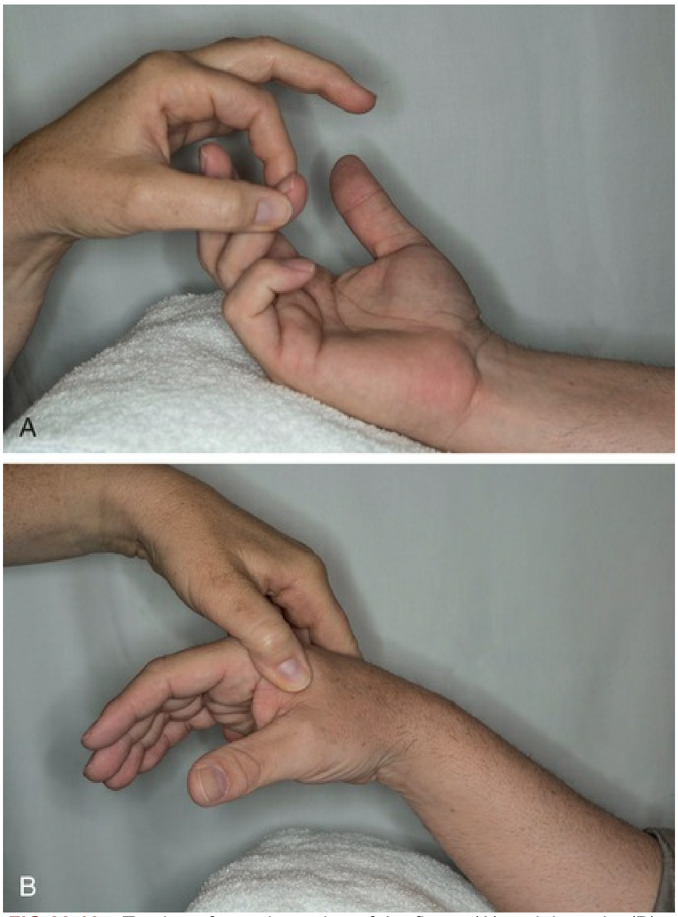

FIG 23.13 Testing of proprioception of the finger (A) and the wrist (B).

Response

- The client indicates whether the body part is being moved up or down, with "Up" and "Down" corresponding to the movement into either flexion or extension, depending on the joint. In the case of the wrist movements, "In" and "Out" may also be used for ulnar and radial deviation.

Scoring

- An accurate response indicates intact proprioception.

The term **kinesthesia** is sometimes used interchangeably with the term proprioception but can also be defined as awareness of joint movement. Some therapists make a distinction between these two terms and test for kinesthesia by moving the unaffected limb into a certain posture and having the client copy the movement with the affected side while the eyes are closed.

Stereognosis

Stereognosis is the use of both proprioceptive information and touch information to identify an item with the vision occluded. Without stereognosis, it is impossible to pick out a specific object such as a coin or a key from one's pocket, use a zipper that fastens behind you, or pick up a plate from a sink of sudsy water.

The Dellon modification[9,10] of the Moberg Pickup Test[22] is a good test for stereognosis for clients with injuries involving the median and/or ulnar nerves. This test requires the client to have the ability to participate motorically, so motor loss or weakness should be factored into the choice of this assessment. This test is based on the Moberg Pickup Test, which is a timed motor test that does not require identification of objects.[22]

Dellon modification of the Moberg Pickup Test

Procedure

- Begin with a group of 12 standardized items: wing nut, large nut, hex nut, small square nut, screw, key, nickel, dime, washer, safety pin, paper clip, and nail.
- If the ulnar nerve is not involved, tape the ulnar two fingers to the client's palm if possible.
- Test 1

- The client places the items one at a time into a box as quickly as possible (Fig. 23.14).

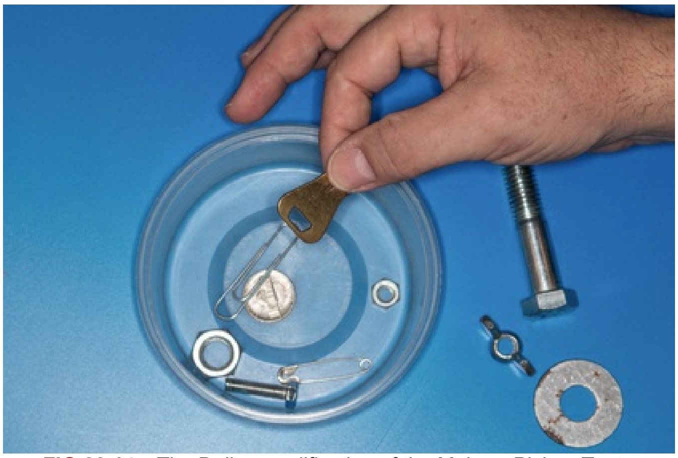

FIG 23.14 The Dellon modification of the Moberg Pickup Test.

- Record the time for two trials.

- Test 2 (initiate test 2 only if the client's deficits do not appear to be too severe during test 1).

- With the client's vision occluded, the examiner places the items into the client's radial three digits one at a time.

- The examiner records the time that it takes to identify each item, with a maximum of 30 seconds for each item.

- Each item is placed in the client's hand two times.

Response

- Test 1: The client places the items in a box as quickly as possible with the radial three digits.
- Test 2: The client manipulates the objects and attempts to identify them as quickly as possible.

Scoring

- Test 1: The time that it takes to place all the items in the box.
- Test 2: The time that it takes to identify all the items.

Localization of Touch

Localization of touch is considered to be a test of functional sensation because there is a high correlation between this test and the test for two-point discrimination. Localization of touch is an important test to perform after nerve repair because it helps determine the client's baseline and projected functional prognosis. This test can be done with a constant (static) touch or a moving touch. Localization of touch is higher order and processed in the cerebral cortex. Because it is considered to be a test of tactile discrimination that requires cortical processing, it is different from touch pressure testing.

Test for localization of touch

Procedure

- Apply the finest monofilament that the client can perceive to the center of a corresponding zone on the hand grid.
- Once the client feels a touch, have him or her open his or her eyes and use the index finger to point to the exact area where the stimulus was felt.
- Place a dot on the hand grid for a correct response.
- Place an arrow from the site of the actual stimulation to the identified site if the stimulus is identified incorrectly.

Response

- The client attempts to identify the exact location of a stimulus.

Scoring

- Correct identification of the area within 1 cm of actual placement indicates intact touch localization.[4]

Desensitization

The existence or persistence of hypersensitivity will often limit use of the affected body part and may prevent sensory reeducation from proceeding, so it is important to address this problem early, if possible, as in the case of Mario, who will need to adjust to his amputated fingertips prior to regaining full functional hand use. Desensitization for hypersensitivity is a form of treatment that aims to elicit habituation and thereby reduce the client's hypersensitivity and improve function. **Habituation** is a decrease in a response after repeated benign stimuli. There is a reduction in the excitatory neurotransmitters released, and if the stimulation continues over a prolonged period, a permanent alteration will occur, consisting of a reduction in the number of synaptic connections.[5]

Desensitization uses graded stimulation with procedures and modalities that can be slightly aversive but tolerable. The stimuli are upgraded to be slightly more noxious as the client's tolerance increases.[31] Lois Barber, an occupational therapist and pioneer in hand splinting and hand therapy, developed a desensitization approach that exposes the hypersensitive area to textures such as sandpaper, contact particles (e.g., rice), and vibration.[3] Treatment is performed for 10-minute intervals, three or four times a day. Clients can incorporate desensitization into their daily routine. For example, they may find that rubbing the hand on their textured shirt or denim pants is desensitizing and can be performed easily throughout the day.

Sensory Reeducation

Stimulation and use of a body part affect the cortical map.[21] The passage of time, use of the involved hand, and training all help promote improved functional sensibility.[13] Children have greater capacity for neural regeneration and neuroplasticity than older people do. Motivation and the ability to concentrate enhance the results of sensory reeducation. Sensory reeducation has been shown to improve the sensation of fingertip replantations even without repair of the nerves.[24] There are two types of clients who may benefit from sensory reeducation: those who require reeducation to compensate for the dangers associated with sensory loss and those who may need to effect change on nervous systems that are either hypersensitive or more dormant. These two groups are candidates for instruction in compensatory strategies for sensory loss and candidates for discriminative sensory reeducation.

Compensatory Strategies for Sensory Loss

People who lack protective sensation are at risk for serious injury because they cannot feel pinprick or hot or cold exposure. Blisters may develop after holding hot objects with people not realizing this until they visually examine the hand or notice the stench of burning flesh. After a CVA a person with left hemiparesis and left neglect may inadvertently move the left hand on top of a stove burner during a cooking task. If the client lacks protective sensation, he or she will be burned without feeling the painful sensory stimulus of the hot stove. A person such as Don is at risk for getting fingers caught in the spokes of his wheelchair due to the lack of protective sensation in his first three digits. The same frequently happens to individuals with C6 quadriplegia. Protective sensation in their thumb, index finger, and long finger may be intact, whereas sensation in their ring and little fingers is absent.

Callahan[8] identified the following instructions for compensatory strategies for sensory loss, which she refers to as protective sensory reeducation:

- Protect from exposure to sharp items or to cold or heat.
- Try to soften the amount of force used when gripping an object.
- Use built-up handles on objects whenever possible to distribute gripping pressure over a greater surface area.
- Do not persist in an activity for prolonged periods. Instead, change the tool used and rotate the work task often.
- Visually examine the skin for edema, redness, warmth, blisters, cuts, or other wounds. This is important because tissue heals more slowly when a nerve injury has occurred.
- If there is tissue injury or damage, be very careful in treating and try to avoid infection.
- Maintain skin suppleness as much as possible by applying moisturizing agents.

Discriminative Sensory Reeducation

Clients are candidates for discriminative sensory training if they have intact protective sensation with recognition of at least 4.31 on the touch pressure monofilament test. A client such as Don, who is not able to localize the stimulus but can feel it is still a candidate for discriminative sensory reeducation, as is a client with hypersensitivity, such as is the case with Mario. A client with a brain insult or nerve injury resulting in reduced discriminative sensation will be unable to fasten a bra in the back, manipulate a clasp on a necklace, or locate a wallet in a bag or pocket with the vision occluded. Discriminative sensory reeducation is graded by initially using grossly dissimilar objects, such as a spoon and a penny, and progressing over time to more similar objects, such as a dime and a penny.

When planning discriminative sensory reeducation intervention, it works best to identify short-term goals that are achievable and that will enhance function despite the sensory loss. If the client has motor involvement and cannot manually manipulate the stimulus, the stimulus can be moved over the hand instead. Discriminative sensory reeducation involves training in both localization and graded discrimination.

Localization

Localization of moving touch tends to return before localization of constant touch. Retraining is done for both. With the client's eyes closed, the eraser end of a pencil or the therapist's finger is used to touch the client's hand in the midline of one zone of the hand grid. This makes documentation easier and the intervention more accurate and consistent and minimizes afferent activity from adjacent areas of the skin. The stimulus is applied with either a moving or a constant touch. The client is told to open his or her eyes and point to the area that was touched. It has been shown that activity in the visual cortex is enhanced when touch of the hand is added to the visual stimulation, as long as the touch is provided on the same side as the visual stimulation.[30] If the answer was incorrect, the process is repeated. The steps are repeated again with the eyes closed. The full process is then repeated in a new area. As the client improves, the stimulus is changed to a lighter and smaller touch.

Graded Discrimination

Stimulation is graded from that requiring gross discrimination to that requiring fine discrimination. Levels of difficulty in discrimination are represented by sequencing of the following three categories: (1) same or different, (2) how they are the same or different, and (3) identification of the material or object.

The stimulus is applied to the skin in an area corresponding to the hand grid. Either the hand or the stimulus is moved to provide input. As earlier, the eyes are closed, then opened, and then closed for the retraining steps. Various textures can be used, such as different grades of sandpaper or fabric, or objects such as nuts and bolts or coins (Fig. 23.15). When using various textures as the stimulus, instruct the client to rub five different textures along the numb or hypersensitive areas for 2 minutes each, watching what he or she is doing for the first minute and then closing the eyes for the second minute.

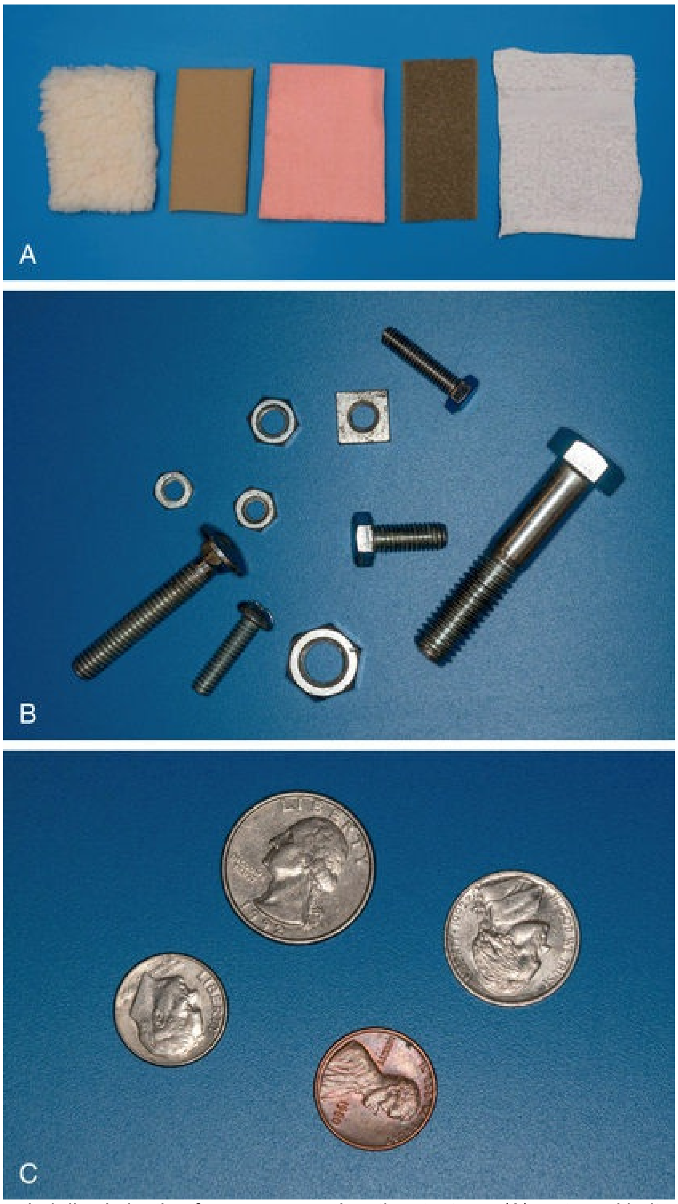

FIG 23.15 Graded discrimination for sensory reeducation: textures (A), nuts and bolts (B), and coins (C).

Another version of discriminative training involves tracing a geometrical shape or a letter or number on the fingertip or small area of the hand. This can be done with a fingertip, the end of an instrument such as a small dowel, or a pencil eraser. The client tries to identify the figure.

Difficulty is increased by adding the requirement of in-hand manipulation for motor stimulation if appropriate and by occluding the vision. Discriminative training can include identifying objects out of a box, retrieving objects from rice or sand, or performing ADLs with the eyes closed. Progress can be determined by improvement in the number of accurate responses, better mapping of areas of localization, increased speed of completing motor tasks, better status of two-point discrimination, and improved level of function involving ADLs overall.

Cortical Reorganization

Occupational therapists can use graded motor imagery to affect cortical reorganization. **Graded motor imagery** is a treatment regimen that includes interventions such as mirror visual feedback, imagined hand movements, and laterality training.[23]

In their studies, Ramachandran and Rogers-Ramachandran[26] speculated that PLP after amputation results from a disruption of the normal interaction between motor intention to move the limb and the absence of appropriate sensory or proprioceptive feedback to complete that motor task. The authors proposed that visual feedback may interrupt the pathologic cycle between the motor intention and sensibility. They developed a process by which a mirror could be used to superimpose an image of the normal limb on the location where the individual "felt" the phantom limb. Clinical observation and functional imaging studies were examined in subsequent research.[14] Based on these studies, Harris[15] hypothesized that disorganized cortical representations may lead to the experience of peripheral pain or sensory disturbances based on a disconnect between motor intention and proprioceptive or visual feedback.

Mirror therapy, one of the treatment techniques used by OTs, is based on this research. In mirror therapy the client positions the hands on either side of a mirror so that the affected hand is placed in back of the mirror and the nonaffected hand is placed in front of it; all of the client's attention is focused on the image in the mirror (Fig. 23.16).[19,29] Mirror therapy can be incorporated into treatment of sensory dysfunction by placing the same textures or simple items (e.g., coins, beans, or foam pieces) in front of and behind the mirror. The client (as in the case of Mario, who experiences PLP in his distal fingers) is then coached by the therapist to use both hands simultaneously to stimulate bilateral sensory receptors with attempts to affect cortical remapping. If pain in the affected hand precludes the client's ability to complete the task, then an imagined hand movement technique should be incorporated: the affected hand would not move beyond the limits of pain, but the unaffected hand would continue with the task. and the client's attention would continue to focus on the mirror.

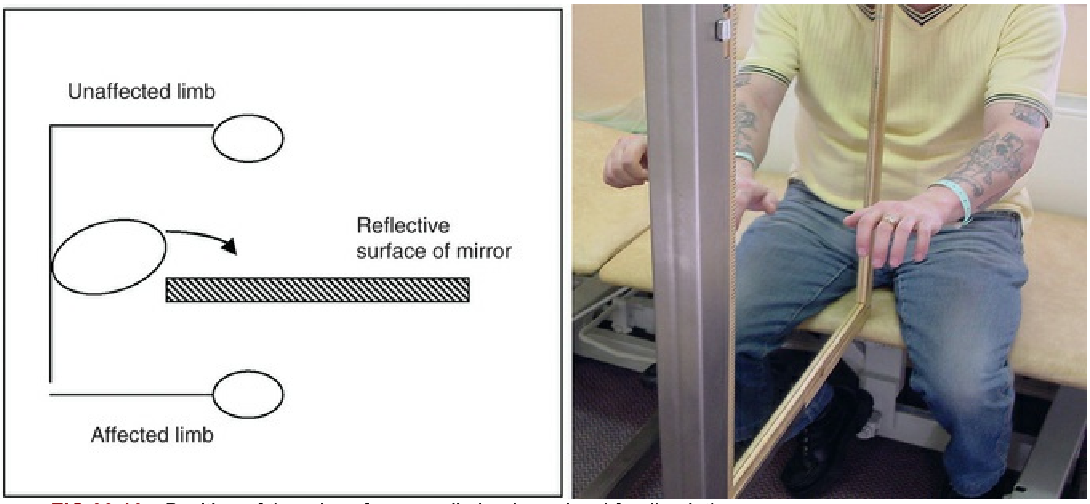

FIG 23.16 Position of the mirror for upper limb mirror visual feedback therapy. (From McCabe C: Mirror visual feedback therapy: a practical approach, *J Hand Ther* 24:171–178, 2011.)

Reinersmann et al.[27] studied limb laterality recognition tasks for their effect on the lateralization of the somatosensory system of the cerebral cortex.[27] The authors based their study of this use of the intervention on the assumption that cortical body representation becomes disrupted in disease states such as CRPS and PLP, resulting in a change in the client's body schema. They showed that there were delayed reaction times and higher error rates, compared to healthy subjects, when the client was presented with pictures of right and left hands and asked to identify the laterality of the limb (Fig. 23.17).[25] After a 4-day training course, both the healthy subjects and the clients with CRPS and PLP improved in their reaction time in the laterality recognition task. From studies such as these a connection can be drawn between the dysfunction in lateralization in the somatosensory cortex and various disease processes that affect sensation, such as CRPS and PLP. Because improvements in laterality recognition can be visualized through various treatments, as shown in these studies, this may indicate the possibility that laterality recognition training may lead to cortical reorganization.

FIG 23.17 The Recognise Hand Flash Cards (Noigroup Products; *https://www.noigroup.com*) are examples of laterality training cards. The pictures demonstrate different positions of the right and left hands. (From Priganc VW, Stralka SW: Graded motor imagery, *J Hand Ther* 24:164–169, 2011.)

Summary

Now, using the information provided in this chapter regarding the evaluation of sensation and the determination of appropriate OT intervention for sensory dysfunction, review the application of this knowledge to the two case studies presented.

Threaded Case Study

Don, Part 2

The most appropriate sensory tests for Don would be touch pressure, two-point discrimination, and the Dellon modification of the Moberg Pickup Test. Assess for touch pressure first because light touch must be intact for two-point discrimination to be tested. The Dellon modification of the Moberg Pickup Test is particularly appropriate for Don because it tests sensory function of the digits that carpal tunnel syndrome is affecting. Those digits, including the thumb, index, long, and radial aspect of the ring finger, are generally used for fine motor coordination in picking up small objects such as medications and pinching the rim of his wheelchair. Don is a good candidate for discriminative sensory reeducation to stimulate neural recovery. In order to simulate grasping the rims of his wheelchair with a lateral pinch without the need for his vision to assist, Don could practice identifying objects out of a bowl of rice with his eyes opened and then eyes closed. He could also work to find and pinch marbles or small pegs out of Theraputty with the use of his vision and with his vision occluded. Tell Don that typical recovery after successful carpal tunnel release includes decreased hypersensitivity as the desensitization program progresses. The common progression of recovery is improved pain, followed by reduced numbness, and then diminished tingling sensation. Sensory disturbances after a carpal tunnel release may take several months to fully recover. The OT should assess whether progress has been made since before surgery and would provide intervention if the progress is delayed or if there is an unintended negative outcome, such as hypersensitivity. Progress should be assessed on each visit, although threshold testing may not demonstrate significant gains at each testing, especially when the mini-kit is used.

Don should expect improving ability to feel and manipulate small objects as sensory recovery proceeds proximally to distally, with the fingertips being the last to recover. Deeper pressure will be felt before lighter pressure, and it will be easier to discern a nickel before he can discern a dime with his vision occluded; this will progress as two-point discrimination improves. Given Don's unique situation of using a wheelchair for all functional mobility, he must take special care to avoid weight bearing on his hands whenever possible so as not to further irritate the surgical site at the carpal tunnel. He may benefit from wearing a prefabricated wrist cock-up orthosis, which has a metal insert along the carpal tunnel and through the volar wrist to provide both support and a barrier during obligatory weight bearing for transfers and functional mobility.

Threaded Case Study

Mario, Part 2

In applying new knowledge of sensation to Mario's case, we note that several of his occupational leisure roles involve the use of significant tactile sensibility. This includes manipulating tools for woodworking to grade the pressure that he is applying with his grip, or the need to feel the texture of grapes in his fingertips during wine making. Sustaining a grasp on the steering wheel can be painful with the altered PLP in his residual digits, which causes Mario to choose not to drive to the dance hall and thereby eliminates one of his favorite occupations of dancing with his wife. An OT can incorporate purposeful activity into Mario's treatment plan to enhance sensory perceptual skills by having Mario bring some of his tools for woodworking or wine making to therapy. The therapist can work with Mario to determine whether there are activity modifications or compensatory strategies that can be implemented to allow him maximal functional independence in these tasks. Types of treatment methods that may be incorporated to improve the remapping of

Mario's brain to connect him with his partially amputated fingers once again include mirror therapy and laterality recognition cards.

Review Questions

1. Describe how the PNS and the CNS are connected and ways that sensory testing differs between the two.
2. Explain why the fingertips have enhanced sensation compared with more proximal body parts.
3. Name three signs that represent altered sympathetic nervous system status.
4. Explain how desensitization works.
5. What are the three categories of sensory reeducation and how do they differ?

Evaluation and Treatment of Visual Deficits After Brain Injury

Mary Warren

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, the student or practitioner will be able to do the following:

1. Describe the role vision plays in enabling a person to complete daily occupations.
2. Describe the components of the visual perceptual hierarchy as a framework for assessment and treatment of visual processing impairment.
3. Describe how to use evaluation results to establish an intervention plan.
4. Describe the changes that may occur in visual acuity, visual field, oculomotor control, visual attention, and visual scanning in adults after an acquired brain injury.
5. Select appropriate assessments to screen visual acuity, visual field, oculomotor control, visual attention, and visual scanning in adults with acquired brain injury.
6. Identify preparatory tasks and methods, activities, and occupation interventions to address visual processing deficits in adults with an acquired brain injury.
7. Describe the role of the occupational therapist on the rehabilitation team addressing visual impairment in an adult with an acquired brain injury.

KEY TERMS

Binocular vision
Convergence insufficiency
Diplopia
Hemiinattention
Oculomotor control
Paralytic strabismus
Pattern recognition
Sensory fusion
Visual acuity
Visual attention
Visual cognition
Visual field deficit (VFD)
Visual fields
Visual memory
Visual neglect
Visual perception
Visual perceptual hierarchy
Visual scanning or search

Threaded Case Study

Penny

Penny Periwinkle, age 70, sustained a right cerebrovascular accident (CVA) from a posterior cerebral artery occlusion. She also has a 5-year history of adult-onset type 2 diabetes mellitus. The stroke caused a left homonymous hemianopia and possible hemiinattention. Penny's ophthalmologist referred her to University Low Vision Rehabilitation Clinic because Penny stated that since her vision loss, she has been unable to read or drive. Penny is also a well-known local artist, famous for her detailed ink drawings of local architecture, and she is no longer able to engage in this occupation. Penny has been married for 45 years. She has one son who lives several states away and no other family in the area. Her husband, Pot, sustained a severe stroke 5 years ago. Pot has right hemiplegia and global aphasia and requires assistance for all daily activities. Penny is his primary caregiver. Penny describes herself as fiercely independent, and she has refused outside help in caring for Pot. She faces significant challenges continuing in her roles as caregiver and artist.

Critical Thinking Questions

1. How does a left homonymous hemianopia limit Penny's ability to perform reading, driving, and other daily occupations?
2. Does Penny actually have hemiinattention, or does she have an uncompensated left hemianopia?
3. What intervention approaches can be used to increase Penny's independence and participation in daily occupations?

Role of Vision in Daily Occupations

Vision is the primary way the brain engages and learns from the world.[90] We use vision to explore the environment for resources and threats and then use the information we acquire to make decisions about how to complete our daily occupations and respond to the events occurring around us. We rely on vision because the visual system provides an efficient conduit for bringing information into the brain, and it offers certain attributes that provide us with the capability to rapidly assess and make decisions about our environment.

- *Vision is our most far-reaching sensory system and takes us farther into the environment than any of our other senses.* We can see lightning before we hear thunder; see a car careening toward us before we hear the squeal of the tires or smell the exhaust. By warning us of changes in our environment, vision enables us to *anticipate* developing situations and formulate a plan to handle them and achieve a successful outcome. So when an object is unexpectedly flung in our direction, we duck, or when we see the banana peel on the floor, we walk around it.
- *Vision can rapidly convey large amounts of detailed information.* Vision is a truly integrative sense in that it provides us with all the information we need to identify the objects in our environment and size up situations. Using vision we can instantly recognize objects, but we require more time to identify them by touch or by hearing a verbal description. Because we can rapidly get a complete picture using our visual system, we prefer the visual medium when we need to size up situations quickly and completely. This explains the popularity of television as a medium for conveying information and why we rush to watch TV when we hear about the unfolding of a significant event, such as the attack on New York City on September 11, 2001.
- *Vision provides the processing speed we need to adapt to dynamic environments.* We operate in two types of environments: static and dynamic. In static environments we are the only object moving in the room. This removes the temporal (eg, timing) requirement for an activity; we can decide when to start and stop movement and how long to take to complete an activity. In contrast, dynamic environments contain objects moving independently of us. This added temporal requirement requires us to simultaneously monitor our own movement and that of other moving objects, and only vision provides the processing speed we need to either interact with moving objects or avoid them.

Because of these attributes, we use vision as our primary interface with the world to guide how we respond to our surroundings. We rely on vision to size up situations. We say to ourselves, “He looks harmless,” or “That looks delicious.” Our language is peppered with phrases that reflect the importance of vision in decision making, such as, “I'll believe it when I see it,” “I'll keep an eye out for it,” or “I can see what you mean.” We rely on vision for social communication, using it to detect and respond to the subtle gestures and facial expressions of our companions and to understand the emotional nuance in conversations. Vision also plays an important role in our ability to safely navigate environments by warning of upcoming obstacles, such as a curb or broken pavement, and our motor actions are often driven by what we see. For example, you may be dedicated to your diet until you see the plate of donuts sitting on the table and find yourself reaching for one.

The takeaway message is that “vision rules!” It is the primary way we acquire information; it dominates our daily occupations, including recreational activities (think of life without Facebook and YouTube, watching or playing sports, or completing crafts); and it provides us with the ability to participate in dynamic, unpredictable activities, such as driving. Research has shown that even mild vision impairment from brain injury can significantly disrupt a person's life, and significant visual impairment can be devastating.[28,113]

Brief Overview of Visual Processing in the Brain

For vision to be used for occupation, the raw material of vision (eg, the pattern of light that falls on the retina) must be transformed into images of the surrounding environment that can be compared with stored visual memories and used to make decisions and respond to unfolding events. The visual processing journey encompasses many areas of the brain. Along the way, visual input is sorted out, refined, and combined with other sensory input to provide a product that can be used for adaptation.[10,53,16-68,138] The process begins in the anterior visual system, where the structures of the eye focus light rays onto the photoreceptor cells of the retina. The photoreceptor cells record the patterns of light and convey this visual input over the optic nerve and tract to the lateral geniculate nucleus (LGN; also called the lateral geniculate body) of the thalamus[10,68] (Fig. 24.1).

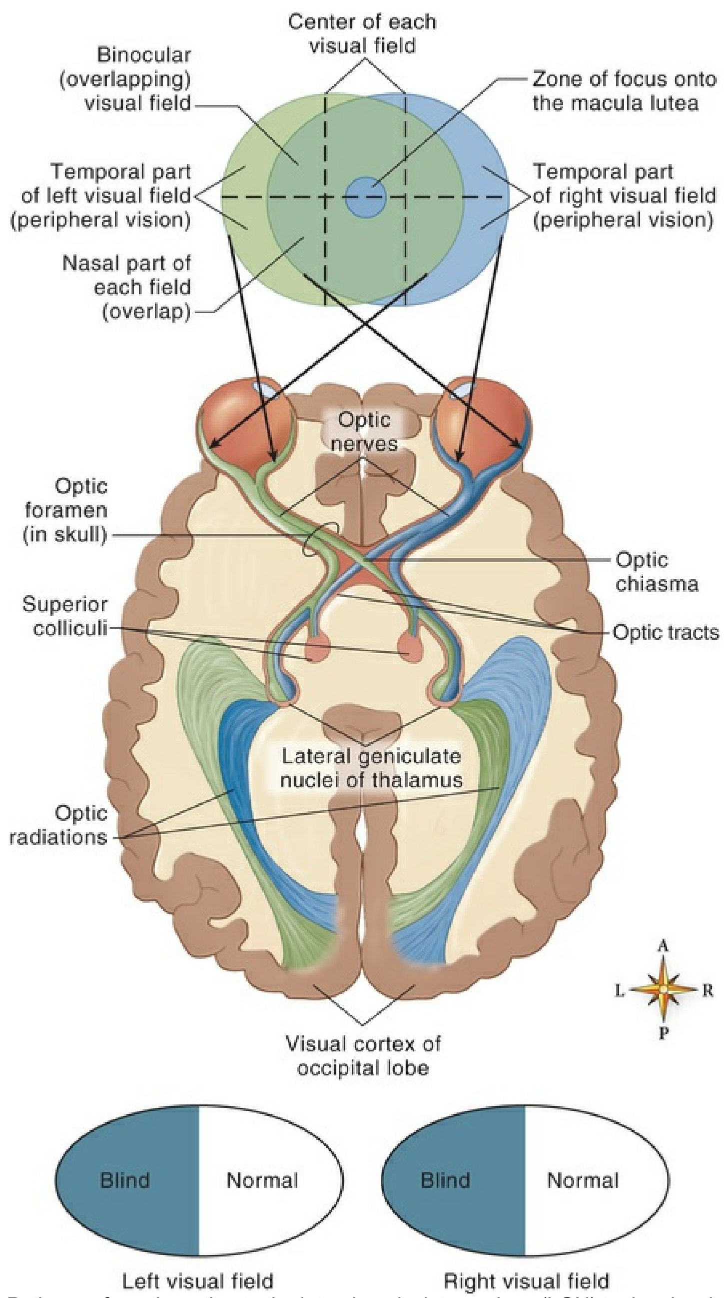

FIG 24.1 Pathways from the retina to the lateral geniculate nucleus (LGN) to the visual cortex. The reddish shaded areas show the pathway conveying visual field information—from the left half of the visual space surrounding the person—from the retina to the occipital lobe in the right hemisphere. The blue shaded areas show the pathway conveying visual field information—from the right half of the visual space

surrounding the person—to the occipital lobe in the left hemisphere. The top of the diagram shows how the visual fields of each eye overlap to provide a binocular field. The far ends of the field retain their individual color to show how the far peripheral field can be seen only by one eye because the nose occludes the other eye's view. (From Patton K, Thibodeau G: *Anatomy and physiology*, ed 9, St Louis, 2016, Elsevier.)

The optic nerve conveys visual input from just one eye. However, at the optic chiasm, the nasal fibers of the optic nerves cross over to the other side, and the temporal fibers continue on a straight pathway. This newly merged visual input from the two eyes continues on toward the LGN, traveling along the optic tracts. Because of this arrangement, when the optic tracts reach the LGN, they are providing visual input from the same hemifield in each eye. Thus, the right LGN receives images from the left half of the visual field in both eyes, and the left LGN receives images from the right half of the visual field in both eyes.[10,68] From the LGN, visual input representing one half of the visual field in each eye travels over the geniculocalcarine tracts (GCTs) to the primary visual area of the occipital lobe (the visual cortex).[68] Information from the left half of the visual field is conveyed over the GCT in the right hemisphere to the right occipital lobe, and information from the right half of the visual field is conveyed over the GCT in the left hemisphere to the left occipital lobe.

Penny's stroke occurred from an occlusion in the posterior cerebral artery feeding the right hemisphere of the brain. Consequently, the GCTs in the right hemisphere were damaged, and Penny developed a left *homonymous hemianopia.*

The visual input that enters the cortex through the calcarine fissure of the occipital lobe is used to build and maintain a library of images in the posterior cortical areas of the brain; the prefrontal areas of the cortex will draw on these posterior areas to make decisions, direct actions, and achieve goals.[51] As visual input enters the primary visual cortex, this area of the occipital lobes sorts through the incoming visual information, sharpening and fine-tuning visual detail, and then disperses this information to the posterior areas of the temporal and parietal lobes.[51,66,68,117] The posterior temporal lobe combines visual details with language and auditory input to visually identify objects.[55,66] The purpose of this processing is to answer the "what" question, as in "What am I looking at?" The posterior areas of the parietal lobe integrate vision with input from all the other senses to create internal sensory maps, which are used to orient the body in space.[11,55,66,67] Visual information processed in the posterior parietal lobe answers the "where" questions by tuning in the brain to the presence of objects surrounding the body and determining their spatial relationship to the body and to each other.[53] The sensory maps of the posterior parietal lobes are body centered and dynamic, changing in shape and content as the body moves through space.[11,21,92]

The prefrontal areas, which function as the chief executive officer of the brain, use the visual library created by the occipital lobes and posterior temporal and parietal lobes to make decisions and formulate plans.[53] The frontal eye fields, in the prefrontal lobes, direct voluntary visual search of the environment based on an expectation (memory) of where the key visual information will be found.[53,82] For example, if you were looking for a light switch in a room, your frontal eye fields would direct your visual search toward the walls because that is where you expect to find a light switch. You would not waste time searching the floor or the ceiling. Directing visual search based on the expected location of crucial visual information enables the prefrontal lobes to quickly process visual information, and it gives a person the ability to successfully engage in activities that require rapid response to visual input, such as driving or walking down a busy street. The prefrontal lobes are also responsible for directing working visual (spatial) memory.[53,140] Working memory is the ability to hold more than one piece of information "on deck" in memory and ready for immediate recall to assist in completing a task.[53] Working visual memory is the specific ability to hold a picture of an object and its location in mind while completing a task.[53] We use working memory to stay on task while completing activities. An example of working visual memory would be holding a picture of a specific brand of canned tomatoes and its location in the grocery aisle in the mind's eye while shopping for the ingredients to make chili. It is "working" memory in the sense that once you accomplish the task, you let go of the memory of the tomatoes and replace it with the next item on your list.

The brainstem and cerebellum also process visual information and contribute to the ability to use vision for daily activities.[82,147] The brainstem contains several important centers involved in visual processing. It works independently of the cortex to control basic visual functions, such as the light (pupillary) reflex, blink response, and accommodation reflex.[68,82] The superior colliculi, in the midbrain of the brainstem, are responsible for detecting moving visual stimuli that appear in the peripheral visual fields.[68,82] When motion is detected, the superior colliculi automatically initiate eye movement toward the direction of the detected motion. In performing this function, the superior colliculi serve as an early warning system to prevent the brain from being caught off guard by events occurring in the environment. The brainstem works in conjunction with the cortex and cerebellum to control other visual functions, most notably executing eye movements and focusing.[82,147]

The motor nuclei of cranial nerves (CN) III, IV, and VI, which control the extraocular muscles and move the eyes, are located in the brainstem. These cranial nerves are under the control of the brainstem, cortex, and cerebellum.[82,147] The cortex uses eye movements to shift attention to objects in the environment and fixate on critical details needed to complete a task. The cerebellum adds synergy to eye movements to ensure that the eye lands precisely on the target so it can be clearly seen. Finally the brainstem houses the vestibular nerve nuclei and many pathways that integrate the vestibular system with eye movements to provide gaze stability during movement.[82]

It is important to remember that the many brain areas that contribute to visual processing must work together for a person to make sense of what is seen and thus use visual information to adapt.[53,66,92,117] Millions of long and short neural fibers (eg, white matter pathways) tie the various cortical and subcortical structures together, forming a complex network that produces effective and efficient visual processing.[48] Just as in a car the fuel-injection system is as crucial to performance as the spark plugs, visual processing will not be completed efficiently unless all its components are working together. Brain injury disrupts communication within the system and creates gaps in the vision network. The specific type of visual deficit that occurs after brain injury depends on the area or areas of the brain affected by the injury and whether the injury caused structural damage to the brain or damaged the pathways that connect brain areas.[156] Moderate to severe brain injuries often cause structural damage to brain areas, which recover more slowly, whereas mild (concussive) injuries cause more shearing and disruption of the white matter pathways connecting the network, and these may recover more quickly.[28,156]

Process for Evaluation and Intervention

Hierarchical Model of Visual Processing

The ability to use vision to adapt to the environment requires the integration of vision within the brain to transform the raw data supplied by the retina into cognitive concepts (rules) that enable us to interpret and understand the visual world. Visual perceptual processing can be conceptualized as an organized hierarchy of visual processes and functions that interact with and subserve each other.[158,159] The **visual perceptual hierarchy** (Fig. 24.2) consists of visual cognition (visuocognition), visual memory, pattern recognition, visual scanning, and visual attention. These perceptual processes are supported by three basic visual functions that form the foundation of the hierarchy: oculomotor control, **visual fields**, and visual acuity. In the hierarchy, each process is supported by the one that precedes it and cannot properly function without integration of the lower level process. Thus, the ability to use **visual perception** to adapt is the result of the interaction of all of the processes in the hierarchy in a unified system. Although each perceptual process is discussed individually in this section, the reader should remember that the ability to use vision for daily activities requires that the processes work in synergy. Although discrete perceptual processes can be identified, they do not operate independently of one another.

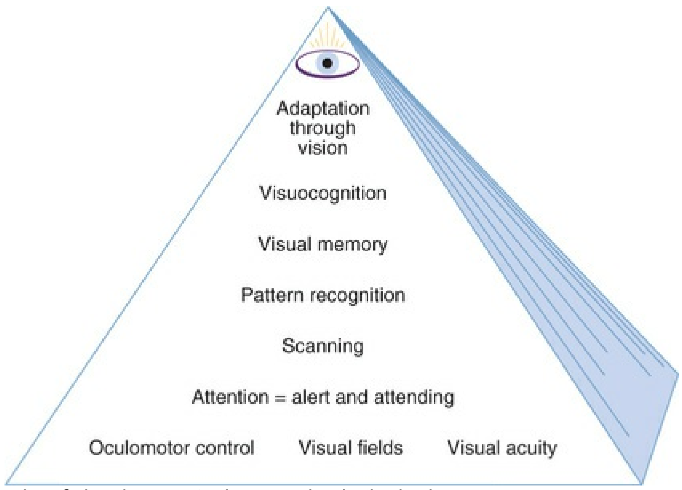

FIG 24.2 Hierarchy of visual perceptual processing in the brain. (From Warren M: A hierarchical model for evaluation and treatment of visual perceptual dysfunction in adult acquired brain injury. *Am J Occup Ther* 47:55–66, 1993.)

The highest order process in the hierarchy is visual cognition. **Visual cognition** can be defined as the ability to manipulate visual input and integrate vision with other sensory information to gain knowledge, solve problems, formulate plans, and make decisions. The development of visual cognition begins in childhood, when we combine vision with sensory input from the body to develop cognitive concepts (eg, rules) of how space and objects operate.[90] We then apply these rules to interpret what we see and make decisions. For example, if we see an adult human who is 12 inches tall, we assume that the adult must be several yards away because we know from experience that adults are not 12 inches high. Because visual cognition enables complex visual analysis, it serves as a foundation for all our academic endeavors and occupations.

Visual cognition cannot occur without the support of **visual memory**, the next process level in the hierarchy. Mental manipulation of visual input requires the ability to create, retain, and recall memories of images to use for comparison during visual analysis. For example, to interpret the illustration in Fig. 24.3, a person must be able to recall memories of the shapes of both a goose and a hawk. Adults and older children can easily resolve this illusion, but a typical toddler lacks the stored memories of the shapes of these birds to identify them. Emotion is an important component of visual memory. Emotion focuses attention and increases the likelihood that images will be stored in memory.[53,90,117,138] It is easy to recall an image of your favorite food or your childhood pet; much more difficult to remember the face of the person who rang up your groceries for you a week ago.

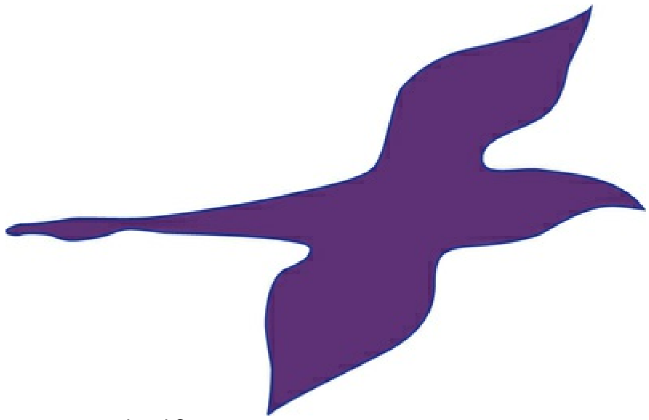

FIG 24.3 Is this a goose or a hawk? (From Warren M: A hierarchical model for evaluation and treatment of visual perceptual dysfunction in adult acquired brain injury. I, *Am J Occup Ther* 47:55–66, 1993.)

To store and access images in memory, the person must recognize the pattern making up the image. **Pattern recognition**, which subserves visual memory in the hierarchy, involves identifying the salient features of an object and using these features to distinguish the object from its surroundings.[53] A salient feature is one that distinguishes a particular object from another. For example, the salient feature that differentiates an E from an F is the lower horizontal line on the E. Pattern recognition is developed through repetition; the ability to recognize patterns improves from having seen them before in meaningful contexts. Children (and adults) spend hours viewing and deciphering patterns to develop a large library to assist with object recognition.[53] Generic memory, a subset of memory, consists of images that can be accessed by a broad range of sensory input. These images represent the common objects we use every day. An apple is an example of an everyday object that can be accessed through generic memory. To conjure up the image of an apple, I could show you an apple, but I could also have you close your eyes and then put an apple in your hand to feel, or I could release the scent of an apple, or place a slice of apple on your tongue. In each case you should easily be able to identify the object as an apple.

Pattern recognition cannot be accomplished without the next process in the hierarchy: organized *scanning* of the visual array. **Visual scanning** or **search** is accomplished through the use of saccadic eye movements. A saccade is a movement of the eye toward an object of interest in the environment. The purpose of a saccade is to focus on the object with the fovea, the area of the retina with the greatest ability to process detail. In scanning a visual scene, the eyes selectively focus on the elements critical for accurately interpreting the array.[53,82,171] The most important details are reexamined several times through a series of saccades to ensure that correct identification is made. Unessential elements in the scene are ignored.[82,171]

Visual scanning or search is actually an expression of **visual attention**. The saccadic eye movements observed in scanning reflect the engagement of visual attention as it is shifted from object to object.[53,82,117] Visual search occurs on two levels: an automatic or reflexive level, largely controlled by the brainstem (through the superior colliculi), and a voluntary level, driven by the cortex.[53,82] On a reflexive level, visual attention (and therefore visual search) is automatically engaged by any novel object moving or suddenly appearing in the peripheral visual field, such as a flash of light.[67,82] The eyes quickly move to focus on and identify the object to protect us from unexpected intrusions in the environment. Voluntary visual search, directed by the prefrontal areas of the cortex, is completed for the explicit purpose of gathering information needed to make a decision or formulate a plan.[53] Voluntary search is purposefully and consciously driven by a desire to locate certain objects in the environment, such as a misplaced set of keys, or to obtain certain information, such as where an exit is located. Voluntary visual search is completed in an organized, efficient, symmetric, and predictable pattern based on the qualities of the visual array and the goal.[79] For example, we execute a left-to-right and top-to-bottom scanning pattern when reading paragraphs of text written in English. The search pattern executed to locate a specific object in an environment is guided by the anticipated location of the object, but it is also driven by highly visible objects that “pop out” in the visual array.[95] A bright red stoplight at an intersection is an example of a feature that pops out and grabs a person's attention in an environment.

Visual attention, which subserves scanning in the hierarchy, is a critical prerequisite for visual cognitive processing. If and how a person attends to an object or information determines whether the brain will use the visual input in making decisions. People who do not attend to visual information will not initiate a search for visual information, and therefore will not complete pattern recognition or lay down a visual memory, and ultimately cannot use the visual input for making decisions. Similarly, people who attend to visual information in a random and incomplete way often lack sufficient or accurate information on which to base a decision.[117]

The level and type of visual attention the brain engages depends on the type of visual analysis needed. For example, the type of attention needed to be aware that a chair is in the room is different from the type needed to identify the style of the chair. The first instance requires a *global* awareness of the environment and the location of objects within it; the second requires *selective* visual attention to see the details of the chair and identify its features.[117] Also, a person needs to be able to use more than one type of visual attention at the same time. For example, when a woman crosses a crowded room to talk to a friend, she must be aware of the movement of other people and the placement of obstacles in the room to avoid collisions; at the same time, she must continue to focus on her friend (or target) to make contact. A large amount of neural processing is devoted to directing visual attention. Because of this, attention can be disrupted easily by brain injury, but it also has the potential for recovery with intervention.[47,53,117]

Engagement of visual attention and the other higher level processes in the hierarchy cannot occur without concise visual input from the environment.[159] As mentioned, three primary visual functions ensure that the brain receives high-quality visual input: oculomotor control, visual field, and visual acuity. **Oculomotor control** enables eye movements to be completed quickly and accurately and keeps the image focused on the fovea to ensure that it can be clearly seen. The visual fields register the visual scene and ensure that the brain receives complete visual information. Visual acuity ensures that details of the environment and tasks can be seen, including color. Thus, these visual functions supply the cortex with accurate, complete, and detailed information, which is needed to direct attention, complete pattern recognition to identify objects, lay down and access visual memory, and complete cognitive processing.[159]

Brain injury or disease can disrupt visual processing at any level in the hierarchy. Because of the unity of the hierarchy, if brain injury impairs a lower level process or function, the processes above it will also be compromised.[159] When this occurs, the client may appear to have a deficit in a higher level process, even though the deficit actually has occurred at a lower level in the hierarchy. Effective evaluation and intervention require an understanding of how brain injury affects the integration of vision at each process level and how the levels interact to enable visual perceptual processing.

Penny's left homonymous hemianopia prevents her from automatically seeing objects in the left half of her visual field. Because she does not see objects on the left, she may not attend to or search for objects on her left side. Her failure to search for objects on the left side limits her ability to locate items needed for daily activities. It also limits her ability to build an accurate spatial map of her environment; consequently, she collides with objects on the left as she tries to navigate environments. Members of the rehabilitation team working with Penny notice that she is inattentive to the left side, and their evaluation will reveal the cause of the inattention.

How Vision Impairment Affects Occupational Performance

Visual impairment can occur from disease, trauma, and aging.[82] Older adults especially may experience a combination of causes. In our case study, for example, Penny sustained a hemianopia from a stroke, which is a traumatic event, but she also has diabetes, a disease that causes many vision-related impairments.[76] Visual impairment can alter the quality and amount of visual input into the brain or alter how the brain processes and uses incoming visual input.[82] Either way, clients with brain injuries can experience a decrease in the ability to use vision to complete daily occupations. Changes are observed in vision-dependent activities (ie, activities that can be completed successfully only by using visual input).[91] Two of the most vision-dependent daily activities are reading and driving. However, good vision also is required for many instrumental activities of daily living (IADLs), such as meal preparation, financial management, and medication management, and some basic ADLs (BADLs), such as applying makeup. Clients with visual impairment may process visual information so slowly that they are unable to participate in dynamic activities such as driving or in group activities (eg, playing cards with friends).

People with vision impairment are also prone to making errors because of insufficient or poor-quality visual input. They may misread the amount due on a bill and write a check for the wrong amount, or step out in front of an oncoming car because they did not see it. Continuously making even small errors can erode an individual's self-efficacy and confidence. The person may stop engaging in even highly valued occupations because of fear and frustration.[91,157] In addition, because vision is needed most to engage successfully in dynamic environments, people with vision impairment often limit participation in community environments, which can lead to social isolation. The inability to complete valued occupations, combined with limited social participation, can lead to depression in individuals such as Penny, who acquire vision impairment after a lifetime of good vision.[64,113]

Clearly, visual impairment may limit the client's participation in many vision-dependent daily activities inside and outside the home.[163]

Recall, for example, that Penny was referred for therapy because she has difficulty reading, and she also is unable to drive.

Yet, despite its significance, the effect of visual impairment on occupational performance is often attributed to other causes, such as motor or cognitive impairment, especially when the visual impairment occurs in conjunction with a brain injury. The reason is that visual impairment is a hidden disability. Unlike hemiplegia, which can be easily observed after a stroke, significant visual impairment (eg, hemianopia) has few outward signs.

Despite the fact that she is missing 50% of her vision, Penny looks just like a normally sighted adult as she waits in the therapy gym for her intervention session with the occupational therapist.

Evaluation and Intervention Process in Occupational Therapy

Specific OT assessments and interventions for vision impairment are described later in the chapter. First, it is important to consider the process of OT evaluation and intervention. As stated in the "Occupational Therapy Practice Framework: Domain and Process," third edition,[4] (OTPF-3), the current version (2014) of the OT Framework, the profession of occupational therapy is grounded in the belief that "active engagement in occupation promotes, facilitates, supports and maintains health and participation" (OTPF-3, p. S4). Although it is important for clients to become independent in their daily occupations, the ultimate goal is participation. Participation is driven by effort and a belief that one is capable of successfully completing an activity, and it is strongly influenced by personal expectations, current abilities, context, and environment.

Penny told her ophthalmologist that she could no longer paint, even though the ophthalmologist found that her visual acuity, and thus her ability to see details and color, was normal. Is Penny really incapable of engaging in this valued occupation, or is the effort required to participate too great for her to derive any pleasure from painting? Or does she feel that she can no longer measure up to her previous high standard of performance?

To answer these questions and determine why Penny feels unable to paint, the occupational therapist must consider the interrelatedness of the client factors, performance skills, performance patterns, context, and environment that contribute and enable Penny to engage in this occupation.

Evaluation

The evaluation conducted by the occupational therapist has three purposes: (1) to identify limitations in occupation, (2) to link the occupational limitations to the presence of a visual impairment, and (3) to develop an appropriate intervention plan based on the results of the evaluation. In addressing evaluation and intervention, it is important to remember that a client's visual performance is significant not in terms of how it deviates from an established norm, but rather in how it interferes with occupational performance. A client is considered to have a visual impairment that requires intervention if the impairment interferes with performance of a necessary or desired daily occupation.

A team approach is required to provide effective intervention to a client with vision impairment. The OT must collaborate with the ophthalmologist and/or optometrist to understand how the client's vision has changed and address visual impairments. Both of these eye care specialists diagnose, manage, and treat visual impairment. As physicians, ophthalmologists are primarily responsible for diagnosing and treating the medical conditions that cause the visual impairment.[3] Board-certified neuroophthalmologists treat the largest number of people with visual impairment from brain injury. Consequently, they often work with occupational therapists and serve as referral sources and consultants to OT practice. *Optometrists* are independent healthcare providers who have a clinical doctorate of optometry from a postgraduate university program. Although they are not medical doctors, optometrists also diagnose and treat medical conditions causing vision loss and provide most of the primary eye care in the United States.[5] Some optometrists specialize in neurorehabilitation and provide services to individuals with brain injury.

Because Penny's stroke affected only her vision, she did not need inpatient rehabilitation and instead was seen by her ophthalmologist, who referred her to a low vision outpatient rehabilitation program.

However, many clients with brain injury experience significant deficits in multiple body functions and require more comprehensive inpatient and outpatient rehabilitation programs. In an ideal medical rehabilitation program, the ophthalmologist or optometrist would also be a member of the rehabilitation team and evaluate the client's vision at several intervals during the recovery period. The eye care physicians would provide information to the other team members on the client's overall eye health; diagnose deficits in visual acuity, visual field, and oculomotor control; and provide a prognosis and medical and optical management of the client. Currently however, eye care physicians are rarely integrated into rehabilitation teams, and the client must be referred to the physician's practice. Obtaining a referral can be a difficult and time-consuming process. To justify referral to the eye care specialist, the OT will be expected to provide evidence to the medical director or case manager overseeing the client's recovery that a visual impairment may be present and the impairment limits occupational performance. For this reason, the occupational therapist must be well versed in completing basic visual assessments to screen for visual impairment.

Several assessments are available to occupational therapists to screen visual performance. This chapter uses subtests from the Brain Injury Visual Assessment Battery for Adults (biVABA, *http://www.visabilities.com*), developed by the author, to illustrate evaluation.[158] The biVABA was designed specifically as a tool to help occupational therapists develop effective intervention plans for adults with visual impairment caused by brain injury. The battery consists of 17 subtests, including commonly used assessments to screen basic visual function, along with tests designed specifically for occupational therapists. The term *screen* is purposefully used to describe the level of assessment conducted by the occupational therapist. By definition, a screening assessment is a quick assessment that can suggest whether an impairment may exist. However, it is not conclusive; that is, it is not able to actually state the cause of the impairment or diagnose the condition. As licensed healthcare providers, occupational therapists do not have the professional qualifications to state the cause (eg, diagnose a visual condition)—that is the role of the ophthalmologist or optometrist. In Penny's case, the ophthalmologist diagnosed Penny's hemianopia and referred her to occupational therapy with that diagnosis.

If Penny had sustained a more severe stroke and been admitted to a rehabilitation floor without an ophthalmologist diagnosing the hemianopia, the occupational therapist, completing an initial assessment of Penny, might screen for a visual field deficit using one of the assessments described later in this chapter. The results of the screening assessment might suggest that Penny had a left hemianopia, but the OT would not be able to state that in the OT assessment. For the diagnosis of hemianopia to have been made, Penny would have had to have been referred to an ophthalmologist.

Intervention

Recovery from brain injury often spans months or years rather than days or weeks. Some vision impairment from brain injury (notably some forms of oculomotor impairment) have been shown to respond to restorative interventions and improve over time.[145,146] Other types of impairment (notably visual field deficits, such as Penny's hemianopia) usually are more permanent,[25,124] and still others (eg, visual attention deficits) may recover slowly over several months.[29,42,71] Currently there is little research evidence to support the efficacy of interventions that aim to restore visual function to normal levels.[29,124,146] In addition, most of the proposed restorative interventions require significant amounts of therapy time and cannot be implemented within the very brief time allotted to rehabilitation.[71,112,145,146,149] If there is no guarantee that intervention can restore visual processing to normal levels during the time the client is receiving occupational therapy services, and if the client's vision is limiting his or her ability to participate in needed and valued occupations, the focus of OT intervention is compensatory to enable the client to use current visual abilities to participate in valued activities and occupations. This focus aligns with the overarching goal of OT intervention, as stated in the OTPF-3, to promote the client's health and participation despite disability.[4] This focus also is consistent with current research showing that neuroplasticity in the brain is stimulated when a person attempts to engage in meaningful tasks.[47]

Although all types of OT intervention can be used, interventions that use activities and occupations to enable the client to engage in meaningful daily activities should be the primary focus of therapy. Education and training can be used in conjunction with occupation to increase the effectiveness of the intervention. Among the OT intervention approaches described in the practice Framework, modifying the context of the occupation and environment to enable compensation and adaptation is the key approach. Environmental modification is a significant, even critical, part of every intervention provided to the client, regardless of the type of vision impairment, because it facilitates visual processing at every level of the visual perceptual hierarchy. Because modification is used with all clients with vision impairment, its components are described here and then mentioned again in the sections on specific visual deficits.

We rely on vision to provide us with details about our world; the visual components of an environment, which include lighting, contrast, pattern, and size, can either facilitate or impede a person's ability to learn about and engage the environment. People with vision impairment, whether from brain injury, age-related eye disease, or simply aging, are especially influenced by the visibility of the task and the environment. To create an environment that enables the client to use his or her current visual processing as efficiently as possible, the therapist modifies the basic visual components of the task and environment to create a more visible context. This is accomplished by evaluating the activity and occupational demands of the desired occupation. The occupational therapist identifies the objects needed to complete the activity and assesses their properties to determine whether and how to modify them to make them as visible as possible to the client. At the same time, the OT considers the space demands of the environment where the occupation or activity will be completed and determines the modifications needed to increase its visibility.

Maximum visibility of a task and an environment can be achieved by considering and implementing the modifications presented in the next four sections.

Increase the Contrast of Key Components of the Task and Environment

Key components are the features of a task or an environment that guide completion of the desired occupation. Changing the background color to contrast with an object can help the client see the object more clearly. The application of this technique can be as simple as using a black cup for milk and a white cup for coffee. If the background color cannot be changed (eg, carpeted steps), color can be added to the object or feature to make it more visible. For example, on carpeted stairs, a line of bright orange duct tape can be applied to the edge of each step to distinguish between them; or, a person may purchase a bright pink cover for his or her cell phone to locate it more easily.[41,50]

Reduce or Eliminate Any Background Pattern

Patterned backgrounds have the effect of camouflaging the objects lying on them. Using solid colors on background surfaces such as bedspreads, place mats, dishes, countertops, rugs, towels, and furniture coverings can increase the visibility of objects placed on them. Clutter also creates significant and often distracting patterns in an environment, making it more difficult to locate objects. People with visual processing deficits perform best in simple environments that contain only the objects needed for daily occupations.[50]

Enlarge Critical Features of Objects and Environments

Increasing the size of a feature or object makes it more visible. Instructions can be reprinted in larger print, medications and other items relabeled, and calendars enlarged. The last line of print that is easily read on the reading acuity test card indicates the minimum size that print should be enlarged for the client. Contrast should be increased in addition to size; it does little good, for example, to enlarge print if the print is faint. Black on white or white on black print is usually more visible than any other color combination. Many commonly used items now are available in larger print, including calculators, clocks, watches, telephones, and check registers; health devices (eg, glucose monitors, blood pressure cuffs, and weight scales); and leisure items (eg, playing cards, games, and puzzles).

When vision-dependent steps in a task or task components cannot be made more visible, the occupational therapist should consider eliminating them from the occupation. For example, toothpaste can be applied directly to the tongue rather than the toothbrush; phone numbers can be voice dialed; and prechopped vegetables can be purchased.

Provide Adequate, Good-Quality Illumination

Increasing the intensity, amount, and quality of available light enables objects and environmental features to be seen more readily and reduces the need for high contrast between objects. For example, facial features can be identified more easily if a person's face is fully illuminated. Lighting should be strategically placed to provide full, even illumination without areas of surface shadow. The light should be positioned as close to the task surface as possible to obtain optimal brightness and illumination of the task.[41]

Many people with acquired brain injury experience photophobia, an abnormal sensitivity to light that is uncomfortable and often painful.[2,24,45] Light sensitivity is a complaint voiced by people with traumatic brain injury (TBI); neurologic diseases (eg, Parkinson's disease and multiple sclerosis), and age-related eye disease (eg, macular degeneration, diabetic retinopathy, and glaucoma).[45] For these individuals, light is often both friend and foe; they need more illumination to see the details in the environment, but at the same time, lighting often causes visual stress and uncomfortable side effects, including excessive blinking, tearing, eye pain, and headache. These side effects cause people to avoid or limit participation in occupations that occur in environments where lighting cannot be controlled (eg, virtually all community environments) or to take sometimes extreme measures to reduce light emission into the eye, such as by wearing dark sunglasses and wide-brimmed hats indoors, using thick drapes on windows, and turning off all lights in a room.

The challenge for the occupational therapist is to find lighting sources that provide adequate illumination without discomfort. Many occupational therapists use the Lux IQ Diagnostic System (*http://www.jasperridge.net*), a standardized light assessment, to determine the best color and type of light for a client with light sensitivity. Fluorescent lighting, so commonly used because of its energy efficiency, is actually the least tolerated light source. Fluorescent lighting emits a short wavelength flicker (50 to 60 Hz) that can be quite noxious to individuals with photophobia associated with TBI and migraine.[2,45] Halogen bulbs often provide a well-tolerated source of bright illumination, and LED is generally tolerated well. However, all types of lighting should be considered, including fluorescent, because there is a wide variation among clients. Tinted eyeglass lenses or fit-over shields and a wide-brimmed hat may reduce glare and ease discomfort in situations in which lighting cannot be controlled, such as community use environments.[45] Changing the background on computer screens and smart phones from white to a darker color may also alleviate some eyestrain. Using blinds to filter incoming light from windows and covering glare-prone surfaces (eg, countertops) with nonglare materials can create a more comfortable environment.[41]

A structured environment also reduces visual stress by creating an explicit and predictable environment that places less demand on visual attention. Cluttered environments with haphazardly placed objects create challenges even for people with normal visual processing. If possible, the number of objects in the environment should be reduced and those remaining arranged in an orderly fashion. Items used daily should be arranged on accessible shelves in single rows. Rarely used items should be stored on upper and lower shelves or removed. Commercially available organizing systems can be used to store items together to create workstations. For example, all items used for grooming can be placed together in a basket. Once closets and shelves have been rearranged and simplified, the family and the client should be educated on the importance of maintaining the structure. The practice of putting items back where they belong and maintaining organization reduces cognitive load and frustration and facilitates independence.

It also is important for the occupational therapist to help the client establish performance patterns to support occupational performance. Establishing routines, such as shopping at off hours to avoid a crowded grocery store, reduces both cognitive and visual stress. Establishing a habit of leaving the keys in a bowl by the door reduces the need for visual search; cleaning eyeglasses daily ensures a brighter image.

Evaluation and Intervention for Specific Visual Deficits

The visual perceptual hierarchy provides the framework for the discussion of evaluation and intervention for specific visual impairments from brain injury. Many of the changes in visual processing after brain injury occur because of impairment in lower levels of the hierarchy. When this lower level processing is disrupted, the visual input into the brain can be limited, inconsistent, or of poor quality, impairing the brain's ability to use vision for occupational performance. This section describes evaluation and intervention for impairments that occur in the first five levels of the hierarchy: visual acuity, oculomotor control, visual field, visual attention, and visual scanning.

Visual Acuity

Visual acuity is the ability to see visual details and color. In delivering these details, acuity contributes to the brain's ability to quickly identify objects. Good acuity, therefore, facilitates information processing and decision making. For this reason, occupational therapists must know whether the client's acuity has been diminished by the brain injury or another cause and collaborate with the eye physicians to make sure the client has the best possible acuity.

Acuity results from a multistep process that begins with the focusing of light onto the retina.[66,68,82] Light rays enter the eye through the pupil and are focused on the retina by the anterior structures of the eye: the cornea, lens, and optic media (Fig. 24.4). The photoreceptor cells in the retina, acting like film in a camera, process the light and record a “picture” that is relayed to the rest of the brain via the optic nerve and pathway.[66] Although the concept is simple, the process is complex and involves many components. These components include the ability to focus light precisely onto the retinal cells, maintain a sharp focus over various focal distances, obtain sufficient illumination of the retina to capture a quality image, and transmit the image to centers in the brain for perceptual processing.[66,68] Any compromise of the structures involved in this process will cause the image to blur and reduce acuity.[51,147]

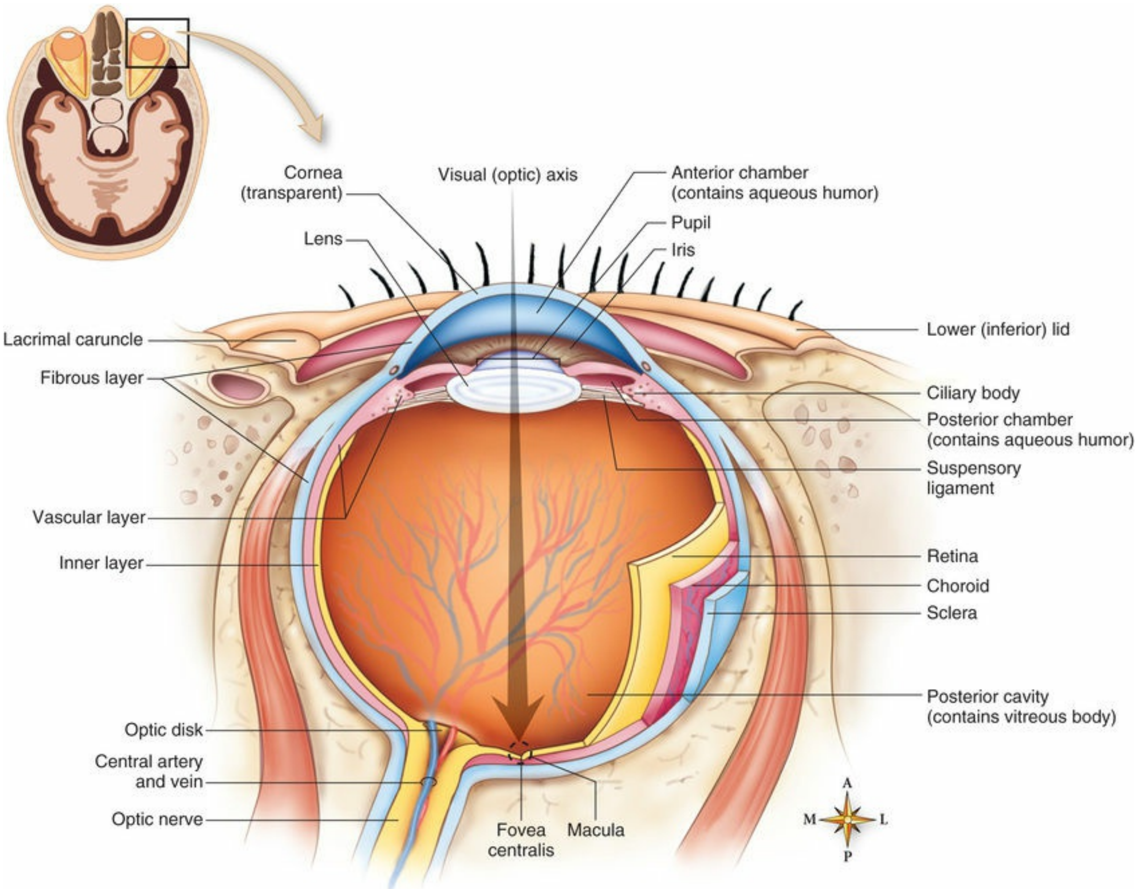

FIG 24.4 The structures of the eyeball. Images pass through the transparent cornea, lens, and vitreous to focus on the photoreceptor cells of the retina. (From Patton K, Thibodeau G: *Anatomy and physiology*, ed 9, St Louis, 2016, Elsevier.)

Visual acuity is measured by having the person identify progressively smaller optotypes on a chart placed at a specified distance. The optotypes may be letters, numbers, or symbols. Acuity level is commonly expressed in the United States as a Snellen equivalent fraction (eg, 20/20).[52] The Snellen chart is often used as a quick means of determining visual acuity. The fraction represents a ratio of the test distance to the size of the optotype. In everyday terms, a measurement of 20/20 means that standing at a distance of 20 feet, the viewer can see the letter (or optotype) that a person with normal vision can see at 20 feet; 20/200 would indicate that a person standing at a distance of 20 feet can see an optotype that a person with normal vision could identify at 200 feet.

Visual acuity is associated with the ability to see high-contrast, black-on-white optotypes on a test chart. However, visual acuity actually represents a continuum of visual function ranging from the ability to detect high-contrast features on one end of the continuum to the ability to detect low-contrast features (eg, beige on white) on the other end. Low-contrast acuity, also known as contrast sensitivity, is the ability to detect the borders of objects reliably as they decrease in contrast (rather than size) from their background.[101] Contrast sensitivity makes it possible to distinguish and identify faint features of objects, such as the curve of a concrete curb or the protrusion of the nose on the face. Because much of the environment is made up of low-contrast features, contrast sensitivity is a critical visual function for safely negotiating the environment. For example, curbs and steps are routinely the same color throughout, and without contrast sensitivity, it would not be possible to see the depth in the curb or step. Carpets, walls, doors, doorframes, and furniture also are often monochromatic; without the ability to distinguish low-contrast features, it might not be possible to locate a door or avoid a chair jutting out into the pathway. One of the most common low-contrast objects is the human face. Human faces contain very little color differentiation between the facial features: the nose is the same color as the forehead, cheeks, and chin. To see the unique features of a human face requires very good contrast sensitivity. Research has shown that people with brain injury may experience impaired low-contrast acuity even when their high-contrast acuity is within normal limits.[101] Therefore, both forms of acuity (high and low contrast) must be measured to obtain an accurate assessment of acuity function.

Two forms of high-contrast visual acuity are measured: distance acuity and reading (near) acuity. Distance acuity is the ability to see objects at a distance. Near acuity, the ability to see objects clearly as they come close to the eye. depends on the neural process of accommodation.[147] Accommodation enables the eye to maintain clear focus on objects as they come closer.[54,82] When an object approaches the eye, its point of focus on the retina is pushed farther back, eventually causing the image to go out of focus. The eye adjusts for this through the process of accommodation. There are three basic steps to the process. As the object comes closer, (1) the eyes converge (turn inward) to ensure that the light rays entering the eye stay parallel and in focus; (2) the crystalline lens of the eye thickens to refract the light rays more strongly and shorten the focal distance; and (3) the pupil constricts to reduce scattering of the light rays. These three steps keep objects in focus when the person is viewing them up close. Multiple neural structures are involved in coordinating accommodation, including the cone photoreceptor cells in the retina, the optic nerve, LGN, occipital lobe, posterior parietal lobe, frontal eye fields, cerebellum, and both nuclei of the CN III (ie, the oculomotor nerve).[147] Much of the coordination occurs through the midbrain area of the brainstem, which is vulnerable to closed TBI.[54,56,147]

Individuals with accommodative dysfunction may demonstrate normal distance acuity (which does not require accommodation) and impaired reading acuity (which requires accommodation). A normal byproduct of aging, called presbyopia, can also reduce accommodation. Until the fourth decade of life, the accommodation process works efficiently to ensure equal acuity when an individual views objects up close and at a distance. However, as a person approaches age 50, the lens of the eye gradually becomes less flexible, which reduces its ability to keep images in focus as they come closer; the result is presbyopia.[31] People with this condition frequently complain of difficulty reading small print. Presbyopia is corrected either by using reading glasses to magnify print or, if the person already wears eyeglasses, by adding a magnifying lens or “reading aid” to the base of the lenses to create a bifocal.

Deficits in Visual Acuity

Most deficiencies in visual acuity are caused by defects in the optical system (the cornea or lens or even the length of the eyeball) that cause images to be focused poorly on the retina.[52,65,66] The three most common optical defects affecting acuity are myopia (nearsightedness), hyperopia (farsightedness), and astigmatism (Fig. 24.5).[52] In myopia, the image of an object is focused at a point in front of the retina; therefore, it is blurred when it reaches the retina. Myopia is corrected by placing a concave lens in front of the eye. In hyperopia, the image comes into focus behind the retina; this causes the image to remain out of focus on the retina. Hyperopia is corrected by placing a convex lens in front of the eye. In astigmatism, light is focused differently by two meridians 90 degrees apart. This defect usually is the result of a cornea that is not perfectly spherical, but instead shaped more like a spoon, or when the cornea is dimpled rather than smooth. Astigmatism causes images to blur because the two meridians cannot be simultaneously focused on the retina. Astigmatism is corrected by placing a cylindrical lens in front of the eye.

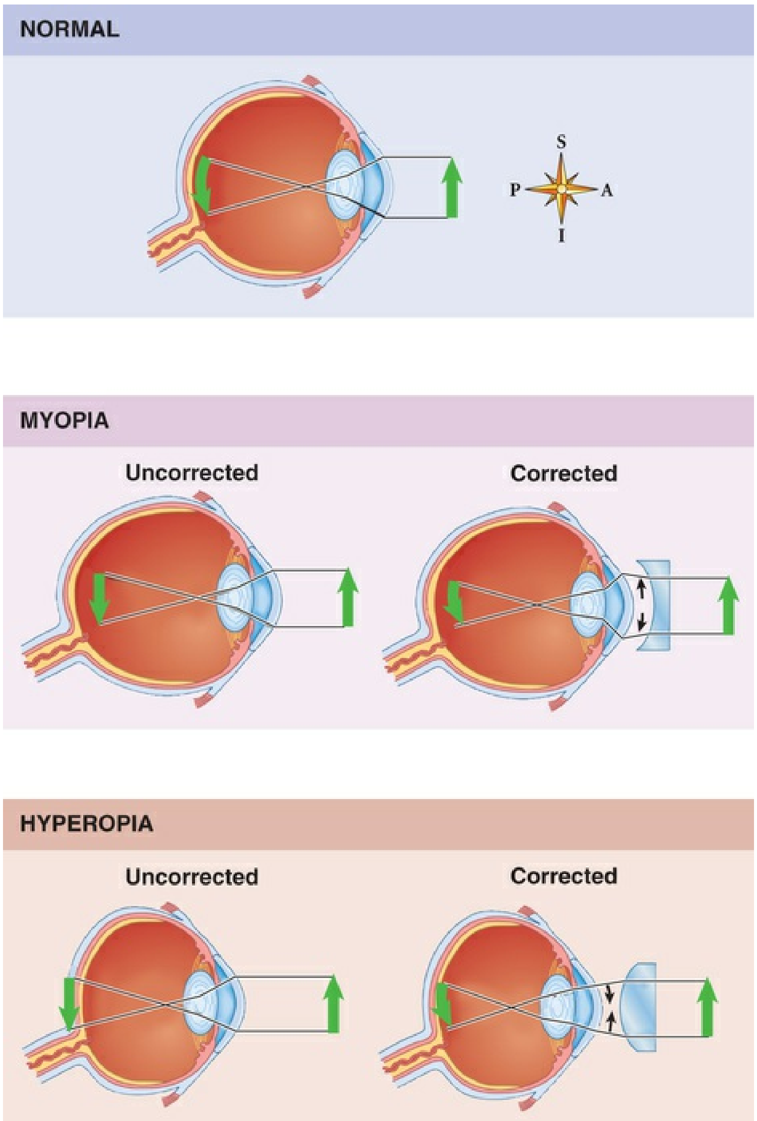

FIG 24.5 Normal, myopic, and hyperopic optical refraction of light coming into the eye and the types of lens used to correct myopic and hyperopic optical refractive errors. (From Patton K, Thibodeau G: *Anatomy and physiology*, ed 9, St Louis, 2016, Elsevier.)

Reduced visual acuity from acquired brain injury primarily occurs as a result of difficulty focusing, retinal damage, optic nerve damage, and/or damage to the occipital lobe and posterior cortical processing areas of the brain.[a] These areas may be damaged by trauma or a disease process.[20,32,83,126]

It is not possible to describe all the conditions that can cause reduced acuity after brain injury, but the following four sections discuss some of the more common ones.

Difficulty focusing.

Sharp focusing of an image on the retina requires that the structures between the outside of the eye and the retina be transparent and able to focus the images entering the eye. Images entering the eye pass through four transparent mediums: the cornea, aqueous humor, crystalline lens, and vitreous humor. An opacity or irregularity in these structures will prevent light and images from properly reaching the photoreceptor cells in the retina. With TBI, damage can occur to the cornea and lens in the eye during the assault to the head and create opacities or irregularities that reduce the quality of the incoming visual input. For example, debris or shrapnel may penetrate the inner layers of the cornea, causing a scar to develop on the cornea. The irregular surface caused by the scar causes the light rays passing through the cornea to be unevenly dispersed, and the person will have blurred, distorted vision.[37] Blunt trauma to the eye can displace the lens, creating a distorted image; it may also induce the development of a cataract that eventually clouds the lens and blurs vision.[83,128]

Corneal scarring and lens displacement immediately impair vision, whereas it may take several months for a cataract to develop and reduce acuity.

Impaired accommodation also diminishes the focusing ability of the eye. Brain injury, disease, and age can disrupt the delicate balance of accommodation, resulting in blurred vision in close-up viewing.[b] Ciuffreda et al.[35] found that accommodative dysfunction was the most commonly identified oculomotor impairment in clients referred for visual examinations after TBI and stroke. Presbyopia creates a nearly universal need for bifocals and reading glasses in older adults. Accommodative dysfunction is also commonly observed in people with Parkinson's disease.[20] Individuals with accommodative dysfunction frequently complain of difficulty reading, reduced concentration, and headache.[2,24,36,37,147] Because the client may demonstrate normal distance acuity but reduced reading acuity, it is important to screen both distant and reading acuity. If there is a significant difference between the two acuities, the client should be referred to an optometrist or ophthalmologist for further evaluation. The eye specialist may prescribe reading glasses and/or eye exercises to strengthen accommodation.[36]

Damage to the retina.

Injury or disease can damage the photoreceptor cells of the retina, preventing these cells from capturing images. Two eye diseases—age-related macular degeneration (AMD) and diabetic retinopathy (DR)—damage the photoreceptor cells in the central (eg, macular/foveal) visual field. AMD is the leading cause of low vision in older adults, and DR is the leading cause of low vision and blindness in individuals younger than age 65.[40] Damage to the central retina diminishes both high- and low-contrast visual acuity, impairing accurate identification of objects. It is not uncommon for an older adult who has been referred for intervention for stroke-related disability also to demonstrate reduced visual acuity from an age-related eye disease.[126] Too often the vision loss resulting from the eye disease is either overlooked or misdiagnosed as impaired attention or cognition associated with the stroke.

Traumatic injuries to the eye can cause retinal hemorrhage or a detachment of retinal cells immediately or several days after the initial trauma.[83,155,156] Retinal detachments usually can be successfully repaired when detected within a few hours of onset. However, if the detachment accompanies a significant brain injury, the trauma team may be focused on sustaining body functions and may not thoroughly assess the eyes for damage. If the trauma client is not sufficiently aware to describe visual symptoms, the detachment may not be diagnosed until after permanent damage has occurred.

Damage to the optic nerve.

Trauma is the most common cause of optic nerve damage in brain injury.[65,128,155,156] Damage can occur from a penetrating injury to the nerve (eg, a bullet wound to the head) or from optic canal fracture associated with facial or blunt forehead fractures.[65] These fractures are most common in children and young adults and usually affect only one of the nerves.[54] Severe closed-head injuries can cause stretching or tearing of the optic nerves, resulting in significant and usually bilateral damage to the nerves. Bilateral optic nerve injury can also result from compression of the nerves from intracranial swelling or hematoma.[65]

Two fairly common neurologic diseases, glaucoma and optic neuritis, can damage the optic nerves. Glaucoma is a collection of optic nerve diseases that usually affect the peripheral visual field first and may progress into the central field, reducing visual acuity.[40,52] Multiple sclerosis can cause demyelination and inflammation of the optic nerve, a condition called optic neuritis. Optic neuritis can cause reduced visual acuity and color vision, visual field deficit, orbital pain, dulled vision, and sensitivity to light.[32]

Damage to posterior cortical processing.

People with injuries to the posterior areas of the cortex, including the occipital lobes and posterior parietal and temporal lobes, can experience a variety of visual disturbances, including blurred vision, reduced contrast sensitivity, a perception of dark or dim vision, light sensitivity, and reduced dark adaptation.[49,83,173] As previously discussed, clients with light sensitivity (eg, photophobia) may be bothered by normal levels of artificial lighting or outdoor environments and avoid these environments or wear sunglasses and wide-brimmed hats. In contrast, people with impaired dark adaptation complain of dark or dim vision and seek additional lighting for tasks and environments. Some people may be able to tolerate and see clearly only within a very small range of lighting conditions.[45]

Occupational Limitations

Reduced visual acuity can cause limitations in a significant number of daily occupations. The severity of the limitation depends on the extent of the acuity loss and whether the impairment is in the central or peripheral field. Central field impairment affects the ability to discriminate small visual details and to distinguish contrast and color. Daily activities that involve reading, writing, and fine motor coordination will be affected, such as meal preparation, medication management, financial management, grooming, and shopping. When the peripheral field is affected the client experiences difficulty with mobility. Peripheral field deficits impair the ability to locate landmarks and obstacles, accurately detect motion, and maintain orientation in the environment. The client will experience difficulty with activities in the community, such as driving, shopping, and participation in social activities.

Evaluation

All OT evaluations begin with observation of the client's performance of daily activities. Clients with reduced acuity often complain of an inability to read print and may report that the print is too small or too faint to read, and that letters are distorted, parts of words are missing, or the words run together and swirl on the page. Clients with impaired contrast sensitivity may complain of an inability to see faces clearly. They may also have difficulty distinguishing between colors of similar hue, such as navy blue and black, and detecting subtle low-contrast features, such as the difference between the last step and the landing when the two are the same color.

When ADL performance suggests impaired acuity, the occupational therapist should screen high- and low-contrast acuity. If it appears that the client has difficulty focusing to see up close, the therapist should screen both distance and reading acuity. Distance acuity charts measure acuity at a distance of 1 meter or greater, and reading acuity charts measure acuity at the typical reading distance of 40 cm (16 inches).[133] Near acuity can be measured using single optotypes or words. It is most often measured using words because reading is the primary activity enabled by near acuity. Reading acuity charts contain sentences in progressively smaller sizes of print. To obtain an accurate measurement, the occupational therapist must be sure that the chart is well illuminated and held at the correct distance. Adequate illumination is important because as illumination decreases, so does acuity (no one can read a letter chart in the dark). Because acuity is depicted as a fraction of distance over letter size (eg, 20/20 or 20/200), the measurement is not accurate unless the viewing distance is precise. All test charts specify a distance at which they are to be used, and this should not be altered.

The client's acuity level is recorded at the smallest line of optotypes that can be read with good accuracy.[133] The client is instructed to read the optotypes on the chart out loud, beginning with the largest line and continuing until the print is too small to see. Clients with brain injury may have deficits in cognition, language, and perception that can interfere with the ability to provide an accurate and timely response in a testing situation. Extra time may be needed for the client to locate the optotype, process the image, and respond. Slowness in responding, therefore, does not necessarily indicate that the client lacks the acuity to identify the optotype.[133] If the client struggles in identifying the optotypes on each line but is accurate, the test should proceed until the client reaches a line where he or she is unable to accurately identify the majority of the optotypes. If the client understands speech but is unable to speak, the therapist can offer a choice (eg, "Is it this, or is it that?" and the client can respond with a nod). If the client has poor scanning and attention, all the optotypes on a line can be covered except one, which the client is asked to identify.

The therapist should always screen acuity using the client's best-corrected vision. Eyeglasses correct for refractive errors, so if the client habitually wears glasses to see distances or for reading, he or she must wear them during the test. Although it seems obvious that every client should be wearing his or her corrective lenses, research has shown that people frequently are admitted to rehabilitation floors without their glasses. Lotery et al.[85] found that more than 25% of clients receiving inpatient rehabilitation after a stroke who routinely wore glasses, did not have them with them, and that among those who did, nearly one-fourth of the eyeglasses were dirty, scratched, or needed repair. Roche et al.[121] evaluated individuals admitted to an orthopedic floor and, like Lotery, found that 25% of the clients did not have their glasses with them in the hospital; of those who did, 85% of the spectacles were dirty or in poor repair.

The most useful chart is one that measures visual acuity as low as 20/1000, so that significant reductions in acuity can be identified. Standard acuity charts measure visual acuity primarily in the range that can be compensated for with eyeglasses and measure nothing below the 20/200 level. Because some conditions (eg, optic nerve damage and macular diseases) can result in profound vision loss (less than 20/400 acuity), it is important to be able to measure acuity in the lower ranges so that appropriate referral and task modifications can be provided to the client. The LeaNumbers Intermediate Low Vision Test Chart (Good-Lite, *http://www.good-lite.com*), which is included in the biVABA, is an example of a test chart that measures visual acuity in the low vision ranges.

Low contrast acuity (contrast sensitivity) also is measured by viewing optotypes printed on a chart held at a specified distance from the client. However, for this type of testing, the optotypes (which may be letters, numbers, symbols, or sine wave gratings) remain the same size but diminish in contrast as the person proceeds down or across the chart. The client reads down the chart as far as possible until the optotype is too faint to be identified. There are many forms of contrast sensitivity tests. The MARS Letter contrast sensitivity chart measures peak contrast sensitivity using letters.[7] The chart is normed for individuals over age 60, and the client's contrast ability can be categorized as normal or as moderate, severe, or profound impairment. The least expensive and most portable test charts are those designed by Dr. Lea Hyvarinen; they include the LeaNumbers Low Contrast Screener (part of the biVABA), the LeaSymbols Low Contrast Screener, and the LeaNumbers and LeaSymbols Low Contrast Tests (Good-Lite). As with high-contrast acuity testing, the test chart must be held at a specific distance and must be well illuminated to obtain an accurate measurement.

It is important to remember that the occupational therapist screens acuity to obtain a general understanding of how well the client is able to see and to determine whether vision is limiting occupational performance. If a significant limitation in acuity is observed on the screening, the occupational therapist should seek referral of the client to an ophthalmologist or optometrist to determine the cause and prognosis of the impairment and whether acuity can be improved using lenses, surgery, or medications.

Intervention

The first step in intervention is to make sure the client is wearing prescribed glasses and that the glasses are clean and in good repair. The second step, especially for older clients, is to seek referral to an optometrist or ophthalmologist if it has been more than 2 years since the client's last refraction. In the study by Lotery et al.,[85] mentioned earlier, the investigators found that half of the participants who wore glasses benefitted from a new refraction. Park et al.[105,106] found that nearly half of the clients referred to optometry from a general inpatient rehabilitation floor in an urban hospital benefitted from updated refraction of their glasses. In this study, the participants had been admitted to the rehabilitation floor with 27 different primary diagnoses, but nearly 75% of the sample had a neurologic condition documented in their medical history. A client with best-corrected acuity in the low vision range (20/60 Snellen acuity or below) should be referred to a low vision rehabilitation program for specialized intervention.

It is important that deficiencies in high-contrast and low-contrast acuity be identified early in the rehabilitation process to obtain an accurate picture of the client's rehabilitation potential. Studies have shown that uncorrected visual impairment may appear as cognitive impairment.[19,60] Using highly educated, healthy, and normally sighted participants with artificially blurred vision, Bertone et al.[19] tested the individuals' ability to complete nonverbal neuropsychological tests commonly used to assess cognitive status in adults. They found that even a slight reduction in acuity (ie, from 20/20 to 20/40) resulted in poorer performance on certain nonverbal tests. The takeaway message for this research is that the client's visual acuity must be determined first, before neuropsychological and reading tests are administered, and that the client must be wearing his or her eyeglasses for the test.

When screening indicates that the client has reduced high-contrast or low-contrast acuity, the occupational therapist should modify the client's environment and tasks to increase the visibility of key features. This is accomplished by using the interventions described in the previous section: increase contrast; reduce pattern; provide good-quality, even illumination; enlarge objects; and provide a structured, predictable environment. In addition to environmental modification, the client may benefit from the variety of services available to assist individuals with vision loss. These services are generally free of charge. The resource librarian in the public library can usually provide contact information, or the OT can contact an advocacy organization, such as the American Foundation for the Blind (*http://www.afb.org*). The following are other examples of available services.

1. The National Library Service for the Blind and Physically Handicapped offers recorded books, magazines, and music through its Talking Books program (*http://www.loc.gov/nls/*). Each state has at least one talking book library.

2. Most states offer radio reading services in conjunction with a university-sponsored public radio station. The person is provided with a dedicated radio that is tuned to the reading service, which provides special programming (eg, reading of portions of the local newspaper each day).

3. Local telephone companies often offer free directory assistance to individuals with disabilities; most pharmacies will provide large-print medication labels, and many businesses will provide large-print bills.

The location of Penny's stroke, in the middle cerebral artery, would not cause a change in visual acuity. However, Penny's diabetes may cause diabetic retinopathy and other eye conditions that can cause significant vision loss. After learning that Penny had diabetes, the optometrist carefully evaluated the health of her eyes and checked her acuity. The optometrist saw changes in the retina that indicated that Penny has macular edema, an indication of early-stage background diabetic retinopathy. The disease has not yet reduced her visual acuity. The optometrist cautioned Penny that she must maintain her blood glucose at the level prescribed by her physician, monitor her diet, and check her blood glucose levels several times a day. The optometrist asked the occupational therapist to evaluate Penny's ability to compensate for the hemianopia when performing diabetes self-management tasks, including drawing insulin, using a glucometer to monitor blood glucose levels, and preparing meals according to her prescribed meal plan.

Oculomotor Function

The purpose of the oculomotor system is to achieve and maintain foveation of an object.[54] That is, the oculomotor system ensures that the target is focused on the fovea of both retinas (to ensure a clear image) and that focus is maintained as long as needed to accomplish the desired goal. This is a daunting task because human beings interact within dynamic, moving environments. An image focused on the fovea is always in danger of slipping off as the head or object is moved. Foveation is achieved and maintained by eye movements that keep the target stabilized on the retina during fixation, gaze shift, and head movement.[54,82]

Another function of oculomotor control is to provide binocular vision. **Binocular vision** ensures perception of a single image even though the brain receives two separate visual images (one from each eye). The process of combining two visual images into one is called **sensory fusion**. For sensory fusion to occur, corresponding photoreceptor cells (eg, cone cells and rod cells) in the two retinas must be stimulated with the same image. If the photoreceptors are stimulated and if the images match in size and clarity, the brain is able to fuse the two images perceptually into one. The eyes must work together in an integrated binocular system to maintain sensory fusion. If the eyes do not align with each other or if there is a significant difference between the eyes in acuity, images may appear blurry or even doubled (eg, diplopia).[54,82,129]

Oculomotor Dysfunction

The pathways controlling eye movements are very complex and involve multiple areas of the brain in the cortex, thalamus, brainstem, and cerebellum.[145] Deficits in oculomotor control after brain injury are common, ranging in prevalence from 50% to 90%.[145] Impairment can result from cranial nerve lesions affecting one or more of the extraocular muscles that control eye movements and/or disruption of the central neural control of the internal and external eye muscles, affecting the coordination of eye movements.[9,51,82,155,156] Either condition can reduce the speed, control, and coordination of eye movements.

Three pairs of cranial nerves control the extraocular muscles: the oculomotor nerve (CN III), the trochlear nerve (CN IV), and the abducens nerve (CN VI). These three nerves are responsible for controlling seven pairs of striated muscles that move the eye.[54,82] When a person who had intact CN function experiences a CN lesion, the muscles innervated by that nerve are weakened or paralyzed, causing a condition known as **paralytic strabismus**.[46,82,127,129] Strabismus means misalignment, and there are several different forms of strabismus.[82,127,129] In paralytic strabismus the eye is unable to move in the direction of the paretic muscles; this disrupts the ability of the eyes to move together. An eye turn may be observed (ie, the eye turns in or out). Because the eyes must always move together and line up evenly to maintain a single visual image, the person experiences diplopia. Diplopia is a primary characteristic of CN lesions.[96,127,129] **Diplopia** creates perceptual distortion, and the performance limitations the client experiences depend on where the diplopia occurs in the focal range (the range in which a person can keep objects in focus). Diplopia occurring near the body disrupts reading and activities requiring eye-hand coordination, such as pouring liquids, writing, and grooming. Diplopia occurring at a distance beyond arm's reach affects walking, driving, TV viewing, and playing sports such as golf and tennis. To eliminate the double image, the client often assumes a head position that avoids the field of action of the paretic muscle.[9,129] For example, a client with a left lateral rectus palsy (CN VI) will turn the head to the left to avoid the need to abduct the eye. A client with paralysis of the right superior oblique muscle (CN IV) will tilt the head to the right and downward to avoid the action of that muscle.[9] Unless oculomotor function is carefully assessed, these alterations in head position may be interpreted as resulting from changes in muscle tone in the neck rather than as a functional adaptation purposely assumed to stabilize vision.

CN lesions are estimated to account for approximately 6% to 12% of the oculomotor impairment that occurs from TBI or stroke, and they are associated with moderate to severe brain trauma.[156] Most oculomotor impairment results from damage to the neural centers that coordinate eye movements. The brainstem, cortex, and cerebellum all exert control over the extraocular muscles via the cranial nerves.[82] Injury in these areas can cause the person to experience difficulty executing and coordinating eye movements even when the cranial nerves are intact.[35,63,70,82,155] The focusing system is the most vulnerable oculomotor system in mild and moderate to severe brain injury.[147] Studies show that nearly half of all those with a brain injury who are referred for visual assessment have complaints related to focusing.[147]

The most commonly identified focusing disorder is **convergence insufficiency**.[2,35,70,147,155] Convergence is the muscle action of moving the eyes inward in adduction. It is one of the three components of accommodation, the process that keeps objects in focus as they come into close view. When convergence insufficiency occurs, clients have difficulty obtaining or sustaining adequate focus during near vision tasks. Clients with this condition often complain of fatigue, eye pain, or headache after a period of sustained viewing in near tasks. Their primary complaint is reading.[24,87,147] As the eye muscles fatigue from the exertion of sustaining convergence during reading, fusion breaks down and the client may experience odd visual phenomena, such as print swirling and moving on the page or the page going blank. Because CN function is usually intact, the client's complaints may be attributed to inattention, lack of effort, or dyslexia rather than oculomotor impairment.

People with oculomotor impairment from TBI often experience multiple changes in vision, including photophobia, convergence insufficiency and other accommodative dysfunctions, visual field deficits, visual inattention and neglect, nystagmus, and difficulties with saccadic and eye pursuit movements.[2,24,87,156] After TBI many people also experience vestibular impairment in conjunction with oculomotor impairment.[131] These conditions occur together and create a very complex case in terms of evaluation and treatment.

It is important to remember that oculomotor impairment also occurs with neurologic diseases, most notably Parkinson's disease and multiple sclerosis, and also Alzheimer's disease. Individuals with Parkinson's disease can experience convergence insufficiency and other accommodative dysfunctions, diplopia, and an increased blink rate associated with blepharitis[20,45]; in addition, they often complain of blurred vision and have difficulty reading. Individuals with multiple sclerosis can experience diplopia from involvement of the cranial nerves and nystagmus, and those with Alzheimer's disease can experience difficulty executing and controlling saccades.[167]

Evaluation

Because a number of factors can disrupt the control of eye movements, considerable skill and expertise are needed to diagnose an oculomotor deficit accurately and to determine the appropriate intervention. It is imperative that the client be referred for diagnosis and management to a neuroophthalmologist or an optometrist who specializes in visual impairment caused by neurologic conditions. The occupational therapist is often one of the first members of the rehabilitation team to observe that the client may have an oculomotor impairment affecting occupational performance. This frequently places the occupational therapist in the position of requesting further evaluation by an eye care specialist. To make an appropriate referral, the occupational therapist must perform a screening to identify patterns of oculomotor dysfunction that may be contributing to the occupational limitations observed in the client.

The occupational therapist uses a "listen and look" approach to screen the client. The therapist *listens* to the complaints voiced by the client or the rehabilitation team and *looks* for changes in oculomotor control that may account for these complaints. This approach is described in the biVABA manual, and the following evaluation steps are from that assessment.[158]

The first step in assessment is to obtain the client's visual history. The history is necessary because adults with childhood histories of oculomotor dysfunction or reduced acuity often display oculomotor abnormalities that they have adapted to and that do not affect functional performance.[147] The client may wear eyeglasses to correct for the deficiencies, and the eyeglasses must be worn during the assessment to obtain accurate results. Questions to ask include whether the client had good vision before the brain injury; has had a prior head injury; has a history of conditions that may affect oculomotor control (eg, congenital strabismus, lazy eye, or amblyopia), and whether he or she currently wears eyeglasses and the purpose of the glasses. Glasses that correct oculomotor deficiencies are generally prescribed to be worn at all times, in contrast to glasses worn to correct acuity just for reading or for distance.

If the client reports diplopia, the therapist should ask about the characteristics of the diplopia. Does it disappear when one or the other eye is closed? This suggests impairment of the extraocular muscles. Do objects double side to side or on top of one another? Is the diplopia present at near distances or at far distances? Is there any area in the range of focus where the client is able to achieve single vision? The answers to these questions may suggest CN involvement (Table 24.1) and also may supply important information about limitations the client may experience in daily activities. The therapist should ask about the client's ability to complete daily activities and look for a pattern, such as difficulty completing activities that require sustained focus in near space (reading, writing, and quilting); whether the client's visual difficulty seems to change with the focal length of the task; whether complaints of fatigue and reduced concentration follow activities that require sustained focusing.

TABLE 24.1

Summary of Oculomotor Deficits Associated With Cranial Nerve Lesions

Oculomotor Nerve III	Trochlear Nerve IV	Abducens Nerve VI
Impaired vertical eye movements	Impaired downward and lateral eye movements	Impaired lateral eye movements
Lateral diplopia for near-vision tasks	Vertical diplopia for near-vision tasks	Lateral diplopia for far-vision tasks
Dilation of pupil and impaired accommodation		Bilateral lesion: Assumes downward head tilt
Ptosis of the eyelid		

After the interview, the therapist should observe the client's eyes and eye movements for deficiencies. The therapist instructs the client to look at a distant target and observes the eyes for asymmetries in pupil size, eyelid function, and eye position. Asymmetries such as a dilated pupil in one eye or a droopy eyelid may indicate CN involvement.[83] Next, the therapist instructs the client to track a moving target (eg, a penlight or pencil topper) vertically, horizontally, and diagonally.[96,127,129] The therapist observes the eyes and notes (1) the symmetry of the eye movement; (2) whether the eyes move the same distance in each direction; and (3) whether the eyes are able to stay on target with a minimum of jerking movements in the middle part of the range. The therapist assesses convergence by instructing the client to track the target as it moves toward the bridge of the nose. The client should be able to easily follow the target inward and be able to repeat this action several times before experiencing stress or fatigue. Difficulty or effort in converging or maintaining convergence while focusing on the target may indicate convergence insufficiency and/or other accommodative dysfunction.[129]

If the client complains of diplopia, the therapist may complete a cover-uncover and/or an alternate cover test to determine which eye is involved and whether the double vision is associated with a phoria or tropia.[127] The suffix *-tropia* is used when there is a noticeable deviation of the position of one eye in relation to the other when the client views an object.[127,129] The suffix *-phoria* is used when there is a deviation of the eye that is held in check by fusion and therefore is not noticeable when the client focuses on an object. These terms are used in conjunction with four prefixes that describe the direction of the deviation: *eso-,* meaning a turning in of the eye; *exo-,* a turning out of the eye; *hypo-,* a turning downward of the eye; and *hyper-,* a turning upward of the eye. *Esotropia,* therefore, describes an observable, inward deviation of the eye commonly described as "crossed eyes," whereas *esophoria* indicates that the eye drifts inward when the client is not focusing on an object but is held in check when the client does focus on an object.[129]

Cover tests are based on the principle that when an eye is required to fixate on an object, it does so with the fovea. If an eye that is not fixating on a target is suddenly required to foveate, it will achieve foveation by making a saccade toward the target.[127] By requiring the client to fixate with both eyes on a target and then covering one of the client's eyes during fixation, the therapist can determine whether the two eyes are aligned in focusing on the target and, if not, which eye has difficulty maintain alignment. Two tests are used: a cover/uncover test, which is completed when a tropia is suspected, and a cross or alternate-cover test, which is completed when a phoria is suspected.[96,129] If the two eyes are aligned equally and fixating on the target, no movement of either eye will be observed when one eye is covered or uncovered. If the eyes are not aligned, the deviating eye will move to take up fixation when the nonaffected eye is covered. Clients with tropias generally complain of constant diplopia when viewing objects, whereas clients with phorias may be bothered only intermittently, usually when they are fatigued or stressed by sustained viewing of a target. Clients with both conditions may experience significant visual stress, which can manifest as headaches, eyestrain, or decreased concentration.[129]

The occupational therapist should compare the information gathered from the screening with observations of occupational performance to determine whether the oculomotor dysfunction is contributing to the client's functional limitations. For example, the presence of convergence insufficiency may help explain the difficulty the client is having in maintaining concentration when reading. When oculomotor deficiencies appear to limit occupational performance, the occupational therapist must seek referral to an ophthalmologist or optometrist, who can determine the cause of the deficiency, the prognosis for improvement, and treatment options.

Intervention

Oculomotor dysfunction usually does not prevent the client from completing an occupation, but it does affect participation in daily activities.[24,45,145,146] The client may experience difficulty coordinating eye movements for reading and other activities; he or she may experience doubling and blurring of visual images and may not be able to sustain focus on near objects or quickly switch between near and far focal distances. These difficulties, especially when combined with photophobia, can cause the client to experience significant visual stress, which may trigger the onset of headache, eyestrain, neck strain, and fatigue.[2,45] The client may begin to avoid participating in activities that trigger visual stress. Many of these activities involve reading (because of the need to sustain a close focal distance) or, like driving, take place in community environments and require the person to adjust to bright and changing lighting. Computer work and viewing television are also often stressful activities because of sustained focus and glare from the screens.

Role of Ophthalmologists and Optometrists

Ophthalmologists and optometrists diagnose the cause of the oculomotor impairment and also offer interventions to reestablish fusion and binocularity through the use of occlusion, application of a prism or lenses, eye exercises, and surgery.[a] The last three interventions are completed only by the eye physicians. Occupational therapists, under the direction of a physician, may apply occlusion. Because most oculomotor dysfunctions resolve without intervention within 6 months of the brain injury,[105] ophthalmologists generally apply either a prism or occlusion to eliminate the client's diplopia during the recuperation period. If the diplopia persists and becomes chronic, the ophthalmologist may recommend surgery by a specialist to reestablish fusion. Optometrists have a different perspective; they believe that control of eye movements and accommodation can be improved through carefully prescribed exercises, which they use in addition to occlusion and prisms to reestablish binocularity.[36] The intervention selected for a client depends on the prognosis for recovery, the client's ability to participate in therapy and her or his financial resources, and the eye specialist providing the consultation.

Occlusion.

Diplopia causes images to double and blur; this distortion creates confusion for the client and limits participation in daily activities. Therefore, diplopia must be eliminated if the client is to benefit fully from rehabilitation. Occlusion can be achieved by assuming a head position or by covering one eye with an opaque or a translucent material.[127,129] Because assuming a deviant head position often affects motor and postural control, the preferred method is to cover one eye. Occlusion of the eye can be achieved through either complete or partial occlusion.[127,129]

With complete occlusion, all the vision in one eye is occluded, often by application of a “pirate patch,” a clip-on occluder, or opaque tape. The challenge with using complete occlusion is that it eliminates all peripheral visual input to one eye, disrupting normal mechanisms for control of balance and orientation to space. This can cause the client to feel off balance and disoriented when navigating environments. Another challenge is that most clients cannot tolerate long periods of occlusion of an eye, especially of the dominant eye, because the other eye becomes fatigued. Therefore, for the comfort of the client, the period of occlusion is alternated between the eyes. Even though altering occlusion reduces fatigue of the working eye, clients often resist having their dominant eye occluded for even short periods because that is the eye used to direct fixation. As a result, the client does not adhere to the occlusion schedule.

Partial occlusion involves covering a portion of the visual field in one eye. Just enough occlusion is applied to eliminate the diplopia without completely covering the eye.[127] Several different types of occluders are used for partial occlusion.[127,129] One technique that can be easily performed by the OT practitioner is to apply a strip of translucent material (eg, 3M Transpore surgical tape) to the central portion of the eyeglass lens (Fig. 24.6). The client is instructed to view a target that is doubling, and the therapist applies the Transpore tape from the nasal rim toward the center of the lens until the client reports that the diplopia is gone when viewing the target. The tape is applied to the nondominant eye for the greater comfort of the client. The width of the tape is gradually reduced as the muscle paresis resolves. Partial occlusion provides a kinder, gentler way to achieve single vision without disrupting balance or orientation. Usually the client is more comfortable and therefore more willing to engage in activities. The main disadvantage of this type of occlusion is that the client must either wear prescription lenses or have tape applied to a pair of frames with plano (nonrefractive) lenses.

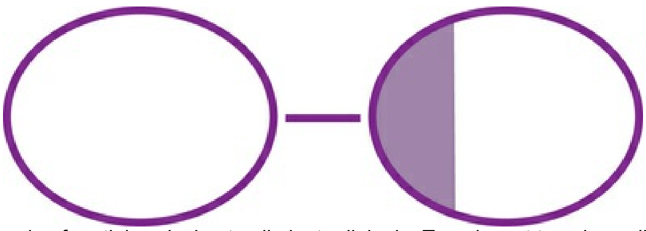

FIG 24.6 Example of partial occlusion to eliminate diplopia. Translucent tape is applied to the nasal portion of the eyeglass lens on the side of the nondominant eye. (From Warren M: Brain Injury Visual Assessment Battery for Adults test manual. visAbilities Rehab Services. http://www.visabilities.com.)

As an OT intervention, occlusion is considered a modification and adaptation intervention approach. The goal is to eliminate the stress caused by the diplopia so that the client is willing to participate in daily activities and therapy. Occlusion has no therapeutic purpose other than to eliminate the double image. However, it is still considered an optometric or ophthalmologic intervention, and as such the occupational therapist should not apply occlusion without a physician's oversight. The referring physician should be consulted and must sign off on use of the modification, just as is done when a splint or sling is applied.

Prisms and lenses.

Ophthalmologists and optometrists may apply a prism to the lens of the client's eyeglasses to reestablish single vision in the primary directions of gaze: looking straight ahead and looking down.[36,83,127,129] Application of a prism displaces the image, causing the disparate images created by the strabismus to fuse into a single image.[129] The prism can be permanently ground into the client's eyeglass lens or temporarily applied to the lens using a plastic Fresnel press-on prism.[127] A prism is used only as long as it is needed to maintain fusion. If the paresis is resolving, the client is gradually weaned from the prism by reducing the dioptic strength of the prism over a period of time commensurate with the rate of recovery. Lenses can boost focusing, and the optometrist or ophthalmologist may use lenses to assist clients who experience accommodative dysfunction from conditions such as convergence insufficiency to achieve and maintain focus with less effort.

Eye exercises.

There is disagreement over whether eye exercises can improve oculomotor control any faster than normal recovery.[90] Traditionally there has been only limited and inconclusive evidence supporting the efficacy of using eye exercises to restore binocular function and improve oculomotor control after adult acquired brain injury.[36,57,70,86] However, several recent, carefully planned studies have shown evidence of the effectiveness of precise exercise protocols for improving vergence and accommodation in people with mild head trauma.[145,146] As an optometric intervention, eye exercises do not fall within the OT scope of practice and should be prescribed and supervised only by an optometrist.

Surgery.

Surgery is recommended when the degree of strabismus is too great to be overcome consistently and easily by fusional effort or when a significant strabismic condition does not resolve within 12 to 18 months.[129] The general approach in surgery is to make the action of one of the extraocular muscles either weaker or stronger by changing the position of its attachment on the eyeball. The position of the eye in the socket is changed by the procedure, and the image is realigned. An ophthalmologist specially trained in strabismus surgery performs this surgery.

Role of the Occupational Therapist

The OT's role is to enable the client to participate in necessary and desired daily occupations despite the challenges and discomfort of oculomotor impairment. It is important to remember that people with oculomotor impairment are not dependent on others to complete daily activities for them. They can complete daily occupations, but if they experience considerable visual stress during certain activities, they will avoid participating in that activity. The occupational therapist works with the client to modify the environment and task and devise strategies that enable the client to complete the activity with the least amount of visual stress. As stated previously, most CN lesions resolve within 6 months. For these clients, the OT's role consists of working with the client and eye physicians to determine the best way to manage the double vision during recovery so the client can participate in daily occupations. For example, the OT may advocate for partial occlusion instead of total occlusion for a client who must navigate community environments.

Other conditions that accompany oculomotor impairment may persist much longer and still be present months to years after the brain injury, even with a mild TBI or concussion.[2,45,87] These conditions include photophobia (light sensitivity), headache (tension and migraine) and blurred vision.[2,45] They can cause significant discomfort, and the client may respond to the discomfort by changing routines and developing habits that limit or avoid participation in certain activities. Giving up valued occupations may lead to depression, which further reduces motivation to participate in daily activities and can lead to a debilitating and self-perpetuating cycle of depression causing activity limitations, which aggravates the depression.[64]

The occupational therapist observes and interviews the client to identify the occupations that cause visual stress, in addition to aspects of the performance patterns, context, and environments that either increase or decrease visual stress for each occupation. The sensory qualities of the physical environment often exert significant influence on the client's level of visual stress. Too much lighting, poor quality or glaring light, and fluctuating lighting may all trigger the onset of headache in clients who are light sensitive. Clients with blurred vision have difficulty seeing low-contrast features and small visual details in tasks and environments. Lots of pattern and clutter in environments force the client to spend more time searching for items. The more stressful provoking features in an environment, the more likely the client will spend as little time as possible engaging in occupations there.

The occupational therapist can suggest ways to make the environment and task less stressful by adding contrast, increasing size, reducing pattern, and finding sources of comfortable lighting. Removing the visual steps to tasks and adding structure to the environment lessen the need to use vision. Changing these parameters facilitates participation by creating an environment and a task that are less stressful and more inviting.

The occupational therapist can also work with the client to establish habits and routines to reduce stress. The client can be taught how to pace participation in a stressful activity to avoid the onset of a debilitating headache. For example, a client who experiences significant visual stress that triggers a headache when shopping for groceries might try shopping for just a few items at a time. This will require more trips to the grocery store, but it significantly reduces the amount of time spent in this stress-provoking environment, which may reduce the incidence of headache. The client also may reduce stress by shopping at a different time of day, perhaps in the early morning, when the client is more rested and the grocery store is less crowded. The use of fitover filters and wide-brimmed hats to control the light entering the eye (discussed in the earlier section on adding adequate, good-quality illumination) can be a helpful modification for clients with light sensitivity.

These interventions teach clients practical ways to manage their visual stress and continue to participate in daily occupations, and in doing so, they help build clients' sense of self-efficacy—that is, that they can control, rather than be controlled by, their symptoms.

Penny reported to the occupational therapist that she had become sensitive to bright lighting in her environment due to the macular edema she had developed from her diabetes. She was especially bothered by the lighting of her church sanctuary, which has very large windows. She stated that she often had to shut her eyes during the service because the light bothered her so much. She hated the thought that other parishioners might think she was sleeping, but if she kept her eyes open, they watered a lot and she was afraid people might think she was crying. "I can't win," she told the therapist. "Sometimes we just don't attend church on bright and sunny days." The therapist took Penny to a room with brightly lit windows and had her try out several pairs of fitover UV filters (NoIR Medical Technologies; http://www.noir-medical.com*) in different tints.*

(Fitover filters, as the name implies, fit over the individual's current glasses.) Penny felt that the filters with a light rose tint provided her with the greatest comfort in the bright light. The therapist lent Penny the filters to try out at church the next Sunday. At the following session, Penny reported that the filters worked well to reduce the glare, but she felt self-conscious wearing them because they were so bulky. The therapist and Penny explored various styles of fitover frames, and Penny ordered a more stylish pair.

Visual Field

The visual field is the external world that can be seen when a person looks straight ahead. It is analogous to the dimensions of a picture imprinted on the film in a camera (with the retina representing the film). The normal visual field extends up to approximately 135 degrees vertically and up to 160 degrees horizontally.[68] The fields of the two eyes overlap, so most of the visual field is binocular and is seen by both eyes (see Fig. 24.1). A small portion of the peripheral field on the temporal side of the face in each eye is monocular and can be seen only by one eye because the bridge of the nose occludes vision in the other eye (see Fig. 24.1). The central visual field is made up of the macula and fovea (Fig. 24.7). The fovea lies at the very center of the macula and provides the highest level of acuity. The central field is packed with cone photoreceptor cells to provide the details and color needed to complete object identification.[142] The remainder of the visual field is the peripheral field. The peripheral visual field is comprised of rod photoreceptors that detect general shapes and movement in the environment and provide background but not detailed vision.

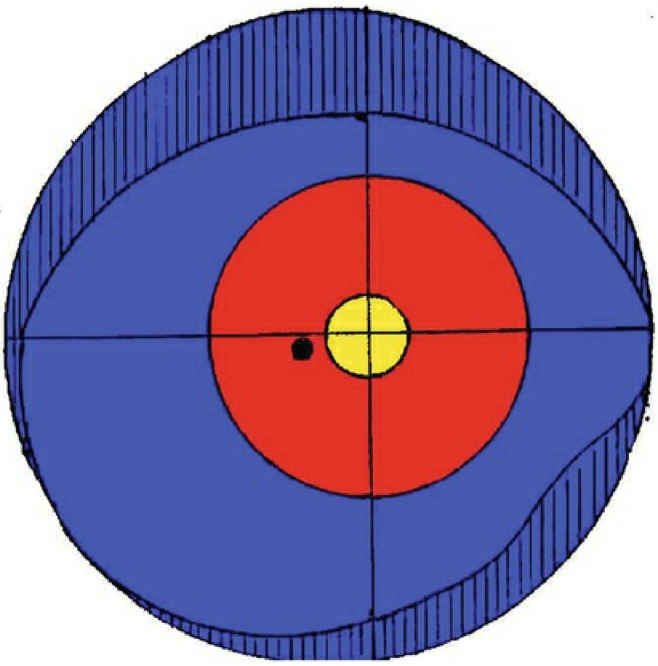

FIG 24.7 Visual field diagram showing the acuity divisions of the visual field of the right eye. The yellow circle in the center represents the fovea, the area of highest visual acuity, which contains only cone photoreceptor cells. The red area depicts the macula, which contains mostly cone photoreceptor cells. Together the macula and fovea comprise the central visual field, which provides detailed vision and color. The blue area depicts the peripheral visual field, which contains the rod photoreceptor cells and provides background vision. The black dot is the blind spot in the temporal portion of the visual field. (Courtesy Josephine C. Moore, PhD, OTR.)

Visual Field Deficits

Damage to the photoreceptor cells in the retina or to the optic pathway that relays retinal information to the cortex for image processing results in a **visual field deficit (VFD)**.[66,142] Fig. 24.1 illustrates this pathway as it changes from the optic nerve to the optic tract to the geniculocalcarine tracts. The location and extent of the VFD depends on where the damage occurs along the pathway. Although any type of VFD is possible after brain injury, homonymous hemianopia (HH) is the most common; it occurs in approximately 30% to 50% of people who have a stroke.[124] In hemianopia (*hemi-* meaning half, *-anopia* meaning blindness), a loss of vision occurs in one-half of the visual field in the eye. *Homonymous* means that the deficit is the same in both eyes. A lesion posterior to the chiasm in the right hemisphere causes a left HH; a lesion in the left hemisphere causes a right HH. Most hemianopias from stroke are caused by occlusion of the posterior cerebral artery, although a middle cerebral artery stroke, such as that experienced by Penny, can also cause this deficit.[124] Hemianopia and other forms of VFDs are also common after a TBI.[24,25,155,156]

Occupational Limitations

Although hemianopia is often considered a mild impairment compared with the dramatic loss of use of the limbs, it can create changes in visual search that significantly limit occupational performance. Research on individuals with hemianopia has shown that visual search toward the blind field is characterized by disorganization, multiple fixations, longer search time, and inability to locate relevant objects.[173] Instead of spontaneously adopting a wider search strategy by turning the head farther to see around the blind side of the field, the person typically turns the head very little and limits visual search to areas immediately adjacent to the seeing side of the body.[173] This ineffective strategy occurs because of the influence of a visual cognitive process called perceptual completion.[66] During normal visual cognitive processing, the frontal lobes visually sample the environment and predict what it looks like.[90,117] This prediction is based partially on incoming visual input from the environment, but it also relies heavily on memory of prior experiences in the environment.[117] Perceptual completion, which is a frontal lobe process, adds significant speed to information processing by enabling an individual to construct a complete visual scene based on partial visual input. As such, it plays an important role in the person's ability to adapt to fast-paced and dynamic environments.[117] However, in the case of significant visual field loss, perceptual completion makes it difficult for the client to determine how the visual field has changed.[39,84]

Because of perceptual completion, the client with a hemianopia is not immediately aware of the absence of vision because he or she perceives a complete visual field, without gaps or missing information.[39,84,132] However, the brain cannot place objects in a visual scene that it does not actually see. Therefore, the client will be unaware of an unanticipated object on the blind side; for example, he or she may run into a recently placed chair on the blind side or may be unable to locate an item unexpectedly placed in the blind field. Until the client becomes consciously aware of the HH, he or she will experience the odd perception of seeing a complete visual scene in which objects always seem to be appearing, disappearing, and reappearing, without warning, on the affected side. Uncertainty regarding the accuracy of visual input from the affected side often causes the client to adopt a protective strategy and attend only to visual input from the intact visual field.[39,173] This behavior can increase the chance of collisions and cause significant limitations in occupations that require monitoring of the entire visual field, such as driving a car or walking through a busy, crowded store.[168] Warren[163] found that 90% of participants with hemianopia from brain injury experienced collisions with unexpected objects on the affected side during ambulation.

Even when the person becomes aware of a hemianopia, visual search into the blind field often is slow and delayed.[39,102,141,173] Again, the culprit is perceptual completion, which eliminates the presence of a marker to indicate the boundary between the seeing and nonseeing fields. Unable to determine the actual border of the seeing field or where a target might be within the nonseeing field, the client naturally slows down when searching the blind field. Instead of making a single saccade to locate the target in the blind field, the person adopts the strategy of making repeated short "stair step" saccades toward the target until it is located.[141,173] Disruption of visual search toward the affected side increases the client's difficulties in navigating and in finding objects in the environment.[39,102,104,173]

When the hemianopia extends into the fovea, a client may miss or misidentify visual details when viewing objects because part of the object falls into the blind field. This can create significant challenges in reading.[a] Normally sighted readers view words through a "window" or *perceptual span* that allows them to see approximately 18 characters (letters) with each fixation of the eye.[118] The reader typically moves from the center of one word to the center of the next using a series of alternating fixations and saccadic eye movements. Each fixation last approximately 250 milliseconds (ms); generally only one fixation is required to decode each word in a text.[118] The brain uses 50 ms to decode the word and 200 ms to plan the saccade to the next word in the text.[153] The saccade of a person reading English moves fixation eight or nine characters over to the right, the typical length of English words. The remaining partially decoded letters on the right side of the perceptual span are used to plan the next saccade.[118] The left side of the span is important for accurate word identification.

Hemianopia reduces the width of the perceptual span on the side of the deficit, causing the client to view only part of a word during a fixation and even miss small words.[80,134,173] For example, a client with a left hemianopia may read the sentence, "She should not shake the juice" as "He should make juice," transforming "she" into "he" and "shake" into "make" and leaving out "not" and "the." Right HH can especially hinder reading because the restriction on the right side of the span not only causes the person to miss letters on the right, it also disrupts the ability to plan the saccade to the next word; as a result, the person lands off center and misses the next word.[80] When these reading errors occur, the client must stop and reread sentences, and this reduces reading speed and comprehension. Clients also experience difficulty accurately reading numbers in series, often with detrimental effects. Whereas context alerts the client to an error when reading because the sentence does not make sense, numbers don't have a precise context, and mistakes can go unnoticed. For example, a bill for $368 may be misread as $68, and the error may be missed until a notice of insufficient payment is received. A recipe calling for 3 tbsp (tablespoons) of sugar may be read as 3 tsp (teaspoons). Clients who make numerical errors quickly lose confidence in their ability to pay bills and balance their checkbook, prepare meals using recipes, or manage their medications, and they may turn over these important daily occupations to someone else.[163]

If the hemianopia occurs on the same side as the dominant hand, the client may have difficulty visually guiding the hand in fine motor activities. The most common performance skill limitation is reduced writing legibility.[163] The client often cannot visually locate and maintain fixation on the tip of the writing instrument as the hand moves into the blind visual field, causing handwriting to drift up and down on the line. Writing over something that was just written and improperly positioning handwriting on a form are also common mistakes. Quilting, hand sewing, pouring liquids, dialing numbers on a smart phone, and other fine motor activities are also frequently impaired.[163]

Functional mobility and reading are the primary performance skills most often disrupted by hemianopia.[163] They are components of important IADLs, including medication management, financial management, meal preparation, home management and yard work, communication management, shopping, and driving and community mobility. For individuals with hemianopia, the more dynamic the environment and the wider the field of view required to complete the occupation, the greater the limitation. Clients generally experience only minor limitations completing basic ADLs, which are performed close to the body, but they report significant difficulty completing at least one IADL.[39,91,104,163,168]

People with hemianopia may report feeling anxiousness when moving in unfamiliar environments.[39,163] Sometimes the anxiety can be so severe that the client experiences an autonomic nervous system panic reaction, becoming nauseated, short of breath, and breaking into a sweat in crowded environments. The anxiety can become debilitating, causing the person to withdraw from community activities and become socially isolated.[104] Some clients report a loss of self-confidence because of their continuous mistakes during the course of a day, and many express that they experience depression because of their limitations, especially their inability to drive and read. They may feel disoriented in community environments because they are unable to scan the moving scene fast enough to identify landmarks and comprehend the visual scene.[173] The combination of anxiety and disorientation may cause the person to avoid navigating community environments alone and to become reliant on others to guide him or her. This can significantly reduce the person's ability to independently meet daily needs, and it also restricts social participation.

Penny reported to the occupational therapist that she was able to successfully complete basic ADLs but has difficulty completing several instrumental ADLs. She states that she reads very slowly and makes frequent mistakes especially when reading numbers. She has difficulty reading bills and financial statements and disclosed that she did not pay her credit card bill correctly one month and was charged a financing fee. She also has difficulty reconciling her checkbook as she may read entries incorrectly and then be unable to find her errors. She estimates that it takes her approximately three times as long to pay bills as it did before her vision loss and she always experiences significant anxiety when completing this task and avoids it until the last minute. Her difficulty reading numbers also creates other challenges when she renews prescriptions for herself and for Pot. She frequently reads the prescription number incorrectly and because of this can no longer use the automated telephone renewal feature and must wait until she can talk to someone in person. This is very embarrassing. She also misread her blood glucometer once and injected insulin when she did not need it, which caused a reaction lasting several hours. She was an avid newspaper reader and read the metro and sports pages to Pot daily, an activity they both enjoyed, as he would recognize some of the names of local *teams and players. She can no longer engage in this daily routine, nor can she read novels to Pot, which was another routine they enjoyed and one that she felt was very therapeutic for Pot.*

Penny reported that she is able to complete meal preparation, although she spends a great deal of time scanning shelves to locate items. She also has difficulty seeing well enough to pour and measure items and occasionally misreads a recipe or sets the wrong time on the microwave. She mentioned that once, she was melting chocolate for a cake batter and set the microwave on 8 minutes, rather than 3, and burned the chocolate. After that, she decided to stop baking for the annual church bake sale, even though she is well known for her delicious chocolate chip cookies.

Penny reported that her greatest limitations involve mobility. She is unable to drive and must depend on others for transportation. When a friend takes her shopping, she has difficulty locating the items she needs and reading the labels. Because she does not want to inconvenience her friend and slow her down, she often comes home with the wrong item or without items because she could not find them. She also admits to feeling very uncomfortable in crowded environments, especially with people moving on her left side. She states that her heart pounds and she feels an overwhelming desire to leave. She is afraid she will collide with someone, as she has experienced several instances of this, and she sometimes experiences disorientation. She and Pot attended religious services regularly before her stroke and a neighbor has offered to provide transportation, but she feels too uncomfortable to make the trip.

When asked about her art, Penny became very quiet and finally stated that she felt that activity was also behind her now. She stated that she had tried drawing again but could not see well enough to complete the intricate line drawings and that she could not find the supplies she needed. Instead of a joyful occupation, drawing had become a very frustrating exercise that reminded her of her disability. She stated that she did not want to resume drawing if she could not do it well.

When asked to prioritize her goals for therapy, she stated driving as the number one goal and reading as the second goal. She wants to accurately complete financial management, meal preparation, and diabetes self-management, and she wants to be able to shop independently, take Pot to appointments, and resume attending church.

Evaluation

The visual field is evaluated using a *perimetry* test.[31] There are many types of perimetry tests, ranging from simple bedside assessments (eg, the confrontation test), which provides a gross indication of field loss, to the precise imaging of a microperimeter.[123,132,151] Availability, cost, and the client's ability to participate in testing often determine the selection of the test. For example, confrontation testing does not incur any expense and can be performed nearly anywhere, whereas microperimetry must be completed by a specially trained technician in a center that has purchased this expensive instrument. All perimetry testing includes three steps, which occur in sequence: (1) the person fixates on a central target; (2) a second target (or targets) of a specific size and luminosity is presented in a designated area of the visual field; and (3) the person acknowledges the second target without breaking fixation on the central target. A static or kinetic test strategy is used to present the target. In static presentation, the target appears in a specified area of the visual field without being shown moving to that location. In a kinetic testing strategy, the target moves in from the periphery until it is identified.[133,173] The number of targets presented during the test can vary from fewer than 10 for a quick screening test to more than 100 for a diagnostic test.

Ophthalmologists and optometrists often use a computerized bowl perimeter, such as the Humphrey Visual Field Analyzer, to obtain a definitive diagnosis of a hemianopia or other field deficit.[133] For this test the client places his or her chin on a chin rest and fixates on a central target inside the bowl-shaped device. As the person fixates on the central target, a second lighted target is displayed inside the bowl in varying locations and intensities. The client responds to each seen target by pushing a small button. For diagnosis of a field deficit, lighted targets are often presented in more than 100 locations in the field using a step-threshold sequence, in which the intensity of the light is incrementally increased if it is not identified on the first presentation. The result is an accurate measurement of the areas of absolute loss (no response) and relative loss (decreased retinal sensitivity) in the field.[133]

All perimetry tests require that the person sustain visual attention over an extended period, and it is impossible to eliminate visual attention from the evaluation process, regardless of the type of perimetry test. Individuals with brain injury commonly experience impaired and limited visual attention, especially in the acute stages of recovery. This means that for many clients with brain injury, it is not possible to successfully administer a diagnostic perimetry test and formally diagnosis the deficit until several weeks to months into the recovery period, depending on the severity of the brain injury.[25,172]

Until the client has sufficient visual attention to complete a diagnostic perimetry test, the occupational therapist can screen for field deficits using simple perimetry tests in combination with careful observation of the client performance in daily occupations. Confrontation testing provides a crude indication of visual field loss.[158] To complete a static confrontation test, the examiner sits in front of the client at a distance of 1 meter and has the client fixate on a centrally placed target (the examiner's nose). The examiner then holds up two targets in each of the four quadrants of the visual field (right upper, right lower, left upper, and left lower). The client indicates whether both targets are visible.[158] To complete a kinetic test, the examiner stands behind the client and moves a target (best target is a penlight) in from the periphery while the client fixates straight ahead on a central target, which is often held by a second examiner, who sits in front of the client and also observes for cheating (eg, breaking fixation on the central target to look for the second target). The client indicates as soon as the target appears by saying “now” or making a hand movement. The examiner moves the penlight in from the left, right, superior, and inferior fields to test these areas. Standardized versions of these tests are included in the biVABA. Because confrontation testing has been shown to be unreliable in detecting all but gross defects,[151] occupational therapists using this form of screening must be careful to correlate their findings with observations of client performance. If the confrontation test shows no deficit but clinical observations suggest that a deficit is present, the clinical observations should carry the greater weight. Client behaviors that suggest the presence of a VFD include changing head position when asked to view objects placed in a certain plane; consistently bumping into objects or missing objects on one side of the field; and making consistent errors in reading, such as missing letters and words on the side of the deficit.[158]

A simple portable perimeter, the Damato 30-Point Multifixation Campimeter provides a more precise alternative to confrontation testing of the central visual field. The campimeter is included in the biVABA and is also distributed by Good-Lite. The test shown in Figs. 24.8 and 24.9 consists of numbered targets to test 30 points in the visual field. The test stimulus is a 6-mm black dot that is shown in the center part of the card. The test uses a unique strategy that relies on moving the eye rather than the target. The client is instructed to fixate on one of the numbered targets. The black dot is then shown in the central window, and the client indicates if it was seen. If the client does not see the black dot, that point in the visual field is recorded as a loss. The test proceeds with the client successively moving the eye to view each numbered target until the entire central field is mapped. A study compared the ability of the Damato campimeter to identify central field deficits against the gold standard Humphrey Field Analyzer and found that the campimeter had a sensitivity of 81% and a specificity of 72%, suggesting good accuracy.[123]

FIG 24.8 Damato 30-point campimeter. The 30 numbers (in light blue) are arranged in a circular pattern on the board. The arm positions the client the correct distance from the chart. The black dot appears in the

window in the center of the chart. (Courtesy Good-Lite, http://www.good-lite.com.)

FIG 24.9 Positions of the therapist and the client for perimetry testing using the Damato campimeter. The therapist moves the black dot into the window in the center of the chart while the client fixates the numbered target. Without breaking fixation on the number, the client indicates when the black dot is seen.

Although spontaneous recovery of some of the visual field has been shown to occur in approximately 50% of those with hemianopia from brain injury,[172] complete recovery of the visual field is uncommon.[173] Most recovery occurs within the first 4 weeks after onset, and the likelihood of improvement significantly decreases beyond 8 weeks.[172] Because of the low rate of complete recovery, hemianopia is generally considered a permanent visual impairment.[172,173] Perimetry tests establish only whether a VFD is present and the size and location of the deficit. To know whether intervention is needed, the occupational therapist must determine whether the client is able to compensate for the field in daily occupations, in addition to the quality and consistency of the compensation. Because reading is so often affected by hemianopia, the therapist should evaluate reading performance.

The Visual Skills for Reading Test (VSRT, *http://www.lowvisionsimulators.com*) assesses the influence of a scotoma (or field loss) in the macula on the visual components of reading, including visual word recognition and eye movement control.[164] The VSRT (often known by its alternative name, the Pepper test) was developed with individuals with central field loss from macular degeneration, but it has been shown to be useful in identifying limitations in reading performance in those with hemianopia.[163] The client is asked to read single letters and words printed on a card. The card contains words that can be misread and still make sense. Because the words don't appear in the context of a sentence, the person must rely solely on vision to identify the word. Three different versions of the test card, in varying font sizes, are included to accommodate clients with reduced acuity and to permit retest. The test measures reading accuracy and corrected reading rate and provides information on the prevalent types of reading errors made by the client. Clients with hemianopia often make errors on the Pepper test consistent with the side of their field deficit.[163] For example, a client with a left hemianopia may read the word “radish” on test form I as “dish,” and a client with a right hemianopia may read the word “mustard” as “must.”

Another test, the Telephone Number Copy (which is part of the biVABA), provides information about the client's accuracy in reading numbers. In this test the client is required to copy down telephone numbers that include numbers with similar configurations, such as 6, 8, 9, and 3.[158] The therapist records the number of errors made in copying the phone numbers, provides the client with this feedback, and instructs the client to locate and correct the errors. Individuals with hemianopia typically make mistakes when reading numbers located on the affected side and often confuse numbers with similar configurations. For example, a client with a left hemianopia may misread the number 9 in the telephone number 938-2020 as an 8 and copy down 838-2020. However, it is expected that the client will be able to use the provided feedback to locate and correct the errors made on the test unless the client's ability to engage visual attention is also impaired.

To effectively compensate for the hemianopia, the client must execute an organized and thorough search of the blind field using the seeing portion of the visual field. This means that a client with a left hemianopia must use the right visual field to search both the left and right fields. Clients with hemianopia demonstrate difficulty searching both *peripersonal space* (the space immediately around the body) and *extrapersonal space* (the space extending from the body into the environment). Deficiencies in searching peripersonal space affect the performance of ADLs completed close to the body, such as grooming, dressing, reading, and writing.[91,163] Deficiencies in searching extrapersonal space have a pronounced impact on mobility and affect activities in outside and community environments, such as driving, shopping, and mowing the yard.[91,163]

To navigate dynamic and complex community environments, the client must use a wide scanning strategy that is initiated on the side of the deficit and executed quickly and efficiently. The client also must be able to rapidly shift attention and search back and forth between the central and the peripheral visual fields to keep track of objects moving within the environment. The ability to compensate for the hemianopia to search extrapersonal space is best evaluated by observing how the client searches during a task involving extrapersonal space. If the client is compensating well for the field deficit, he or she should be able to symmetrically search both the right and left halves of the visual field with equal speed whether stationary or moving.

Computerized light boards can be used to measure and compare the client's response time in searching the right and left halves of the visual field, along with the person's ability to divide attention between the central and peripheral fields.[72] The Dynavision D2 (Dynavision, *http://www.dynavisioninternational.com*) is an example of one of these devices (Fig. 24.10). The Dynavision D2 presents a random visual target (light) that the client must touch to extinguish. As soon as the client extinguishes one target, another appears in a random location on the board. The client must "hit" as many targets as possible during a specific period (called an exercise run). The computer records the client's reaction time in extinguishing the targets in each quadrant of the board to provide an objective measurement of search performance in each portion of the field. Increased reaction time to responding to targets in the blind side of the field indicates reduced compensation for the field deficit. The Dynavision t-scope feature can be added to an exercise run to evaluate the client's ability to divide attention between the central and peripheral areas of the board. The t-scope is a light-emitting diode (LED) panel in the center of the board that can be programmed to display letters, numbers, symbols, subtraction problems, words, or text at either fixed or random intervals during the run. When the t-scope is active, the client must simultaneously extinguish the light targets and identifying optotype that appears in the t-scope, and this can only be accomplished by monitoring both the central and peripheral areas of the board. Occupational therapists without a light board such as the Dynavision can create a task analysis using a laser pointer to observe the client's search capability. The therapist randomly projects the laser beam onto various locations on a blank white wall, and the client locates and touches the projected red or green dot. The therapist notes the strategy and the amount of time the client used to locate the dot.

FIG 24.10 Example of a visual search task using the Dynavision D2. The lights on the board are illuminated one at a time in random patterns. The client must locate the illuminated light and press it to turn it off. As a light is pressed, another light is illuminated. The client strikes as many lights as possible within a specified time. The activity can be used to teach and reinforce efficient search patterns to compensate for visual field deficits and visual inattention. (Courtesy Dynavision International, LLC. http://products.dynavisioninternational.com/products.)

A ScanCourse (part of the biVABA) can be used to determine whether the client executes visual scanning during ambulation.[158] The therapist constructs the course using targets created by placing a 1-inch black, stick-on letter or number on several 3 × 5-inch white index cards. The targets are placed along a hallway in various locations on the left and right sides. The therapist instructs the client to identify the targets as he or she walks through the course and observes the client's accuracy in locating the targets on each side during ambulation. The client is given two trials to complete the scan course. After the first trial, the therapist provides feedback on the client's performance, such as, "You missed three targets on the right side; remember to turn your head to make sure you see all the targets on that side." The client then completes the second trial by reversing and going through the course in the opposite direction. The therapist notes whether the client's performance improves on the second attempt. Clients who are unable to improve performance on the second trial will require substantial support within the environment to scan for safety risks.

The perimetry test performed with Penny showed a complete left hemianopia in both eyes, affecting both the central and peripheral fields. Of particular importance was the finding that the border of the hemianopia split the foveal field in half. This finding suggested to the OT that Penny's perceptual span for reading was probably significantly reduced on the left side, causing her to miss words and letters to the left of fixation. The OT used the Pepper test to confirm this hypothesis. The results of the Pepper test showed that Penny misses letters and words on the left, which reduced her reading accuracy to 83% on the test. Her reading rate was 51 words per minute (normal speed is 250 words per minute).[81] Because Penny had reported difficulty reading numbers accurately, the therapist also administered the Telephone Number Copy test from the biVABA. Penny misread three numbers on this test; she misidentified a 3 as an 8, a 4 as a 1, and a 5 as an 8. She was able to find her errors on the test and correct her mistakes.

The therapist used the Dynavision to observe Penny's ability to search for targets in her visual field. Penny demonstrated a reaction time of 2.35 seconds to locate targets in the left half of the board, compared to 1.1 seconds in the right half of the board. In observing her locate targets on the board, the OT noted that Penny moved her head very slowly to the left side of the board to locate targets and did not turn her head far enough *to see the lighted targets on the outer ring of lights.*

Penny also completed a scan course. On the first pass through the course, she missed 4 of 10 targets on the left side (60% accuracy) but easily identified 10 of 10 targets on the right side (100% accuracy). After receiving feedback on her performance, Penny turned around and walked through the course in the reverse direction. This time she identified 9 of 10 targets (90%) on the left and 10 of 10 targets (100%) on the right. Her performance also indicated that she was able to use feedback to improve her search of the left side of space, thus demonstrating good rehabilitation potential.

Intervention

The performance limitations experienced by people with hemianopia generally fall into two categories: difficulties with mobility and difficulties with reading. Because of the mobility limitation, clients experience difficulty navigating independently and safely engaging in daily occupations completed in dynamic environments, such as driving, shopping, and participating in community events.[91,104,107,163] Resumption of driving may or may not be a goal, depending on the driving laws of the state in which the client lives. The client's challenges in reading result from an inability to adapt the present saccade strategy to the width of the new perceptual span. The client experiences reduced accuracy and reading speed, which limits participation in occupations such as financial management. To overcome reading challenges, the client must develop a new saccade strategy to match the new perceptual span.

To compensate for hemianopia, the client must develop a habit of consciously using head movement to search the visual field on the blind side.[23,77,103,114,124] Because the frontal lobes perform perceptual completion, the client often initially lacks insight into the extent and boundaries of the field deficit. Successful compensation requires the client to believe firmly that the deficit exists and that the visual input from the blind side cannot be trusted. A client able to develop this level of insight usually learns to effectively compensate for the deficit. Therefore, every effort must be made through activities and education to make the client aware of the location and extent of the deficit.

Mobility limitations.

The limitations experienced in mobility occur primarily because the client does not turn the head far enough, fast enough, or often enough toward the blind field to take in the information needed for safe mobility. If the inferior visual field has been affected, as occurs with a hemianopia, the client may also experience difficulty monitoring the support surface on the deficit side. This can result in hesitancy in walking and a tendency to keep the head down and the eyes fixed on the floor directly in front of the client. Although this strategy may keep the client from colliding with objects, it also prevents the client from monitoring the surrounding environment and can add to disorientation during ambulation.

To compensate effectively for the hemianopia, the client must learn to turn the head quickly and completely search the blind visual field. The following are desired outcome behaviors.

1. Initiation of a wide and fast head turn toward the blind field

2. Anticipation of visual input from the blind field, as evidenced by an increase in the number of head and eye movements toward the blind field

3. Execution of an organized and efficient search pattern that begins on the blind side

4. Attention to and detection of visual detail on the blind side

5. Ability to quickly shift attention and search between the central visual field and the peripheral visual field on the blind side

Combining preparatory methods and tasks with occupation-based intervention can be an effective way to elicit these behaviors and develop compensatory strategies. Preparatory tasks focus on increasing the speed, width, and efficiency of the search pattern toward the blind side.[a] Occupational therapists use light boards (eg, the Dynavision) to develop the components of efficient search patterns.[6,72,75] The size of the board automatically elicits the wide head turn needed to search the blind side. The light buttons are identical, which eliminates the need for discrete identification and elicits a more automatic visual search response. Drills on the light board are presented as games of skill, as the client tries to strike as many lighted buttons as possible in the allotted time. This challenges clients to give their best effort each time. The device records and analyzes performance, identifying where deficiencies exist to enable the client to improve performance on the board. The lights can be programmed to move at high speeds, and it is impossible to beat the board, which draws out the competitive nature of the user. In clinics without a Dynavision or similar light board, practitioners can use a laser pointer projected onto the wall and play “tag” games, in which the client attempts to locate the red dot as quickly as possible.

As the basic components of the search strategy are developed, the OT should incorporate them into activities that require combining search with ambulation. Indoor and clinic activities can include completing scan courses (described earlier); activities such as “find red,” in which the client points out every red item in the surrounding environment while navigating toward a destination; and “narrated walks,” in which the client points out landmarks and changes in the environment while navigating toward a destination. These activities reinforce keeping the head up during ambulation to improve orientation and avoid collisions. As skill is developed, practice in dynamic and unfamiliar environments should be added. The client completes activities in stores and malls; for example, he or she turns toward the blind side to identify the number of people standing in an aisle or inside a store while walking by; also, the client locates stores in a mall and specific items in stores using landmarks and organized search strategies.

It is important that the client develop habits and routines to support performance, especially in high-risk community environments. One very important habit is to stop before entering an unfamiliar environment and slowly scan the environment for potential travel hazards, such as temporary and fragile displays and low-contrast features (eg, curb cuts and other subtle changes in the support surface). This habit helps the client build a mental representation of the space before entering and engaging it; it also should increase the client's confidence and reduce the likelihood of an unexpected collision. Another habit is to closely observe unique landmarks. such as a picture on a wall or a change in wall color, to assist in maintaining orientation. Supportive routines include shopping at times of day when the stores are less crowded, choosing well-lighted walkways with minimal obstacles, and arriving early for concerts and other events.

Reading limitations.

The client's primary challenges in reading occur because the client is trying to read using a saccade strategy designed for a wider, unrestricted perceptual span. To improve reading speed and accuracy, the client must learn to adapt the saccade strategy to the new perceptual span. This requires significant practice and can be extremely frustrating for the client. The occupational therapist can help the client put in the required practice time by breaking the reading task down into manageable components. Preparatory interventions using prereading exercises (such as those designed by Warren[161] or by Wright and Watson[169]) and commercially available word and number searches can be used to provide this practice. These exercises are designed so that the client searches for specified letters, numbers, or words on worksheets (Fig. 24.11). The low cognitive requirements of the exercises enable the client to focus on perfecting the saccade strategy. As the client's reading performance improves, the OT should switch to an occupation-based approach and help the client select a large-print book on a familiar topic to transition to reading continuous text. The large-print format reduces the density of the text, requiring less saccade precision, and the familiar subject reduces the cognitive demands on the client. Typically the client is instructed to read a chapter a day. Modifications, such as drawing a bold red line down the margin of the text, can be used as adjuncts to help the client with a left hemianopia find the beginning of a line of text, or to help a client with a right hemianopia find the end of a line of text. Clients who have difficulty staying on line or moving from line to line can use a ruler or card to maintain their place, but such aids should be relinquished as reading performance improves because they slow reading speed. As the client regains skill in reading, the occupational therapist should introduce the materials the client needs to complete reading-dependent occupations, such as financial management, meal preparation, and medication management.

FIG 24.11 Example of a prereading exercise. The client is instructed to cross out all the double numbers on the page. (From Warren M: Pre-reading and Writing Exercises for Persons with Macular Scotomas. visAbilities Rehab Services, http://www.visabilities.com.)

The OT addresses handwriting by teaching the client to slow down and monitor the pen tip as the hand moves across the page and into the blind side. Preparatory tasks that require the client to trace lines and shapes are effective in helping the client learn how to position the paper and pen so that the pen tip stays visible on the line. Practice completing blank checks, addressing envelopes, and filling in a check register helps the client learn to apply handwriting to daily occupations.

It is important that the occupational therapist also modify environments and tasks to increase visibility and structure as described in the overview on intervention at the beginning of this chapter. Adding color and contrast to the key structures in the environment needed for safe navigation and orientation (eg, door frames and furniture) will help the client locate these structures more quickly. Using black felt-tip pens and bold-line paper to heighten the contrast in writing materials will help the client more accurately monitor the pen tip in handwriting. The simple addition of high-quality light often increases speed and reduces errors in reading and improves mobility. Reducing pattern in the environment by eliminating clutter and using solid-colored objects enhances the client's ability to locate items more quickly. Creating a structured, predictable environment reduces the need for constant scanning. All these modifications reduce the amount of effort the client must generate to compensate for the VFD, and they increase the likelihood that the client will participate in the occupation—the ultimate goal.

Penny received 10 1-hour sessions of outpatient OT intervention over a 10-week period. To address her limitations in reading, Penny was given prereading exercises involving letters, numbers, and words to help her modify her saccade strategy to match her reduced perceptual span. She completed the exercises at home for 45 minutes a day. The Pepper test was repeated at 5 weeks; it showed that her reading accuracy had increased to 92% and her reading rate had increased to 72 words per minute. The Telephone Number Copy test was also repeated, and Penny scored 100% accuracy.

As Penny's performance improved, the therapist introduced reading of large-print books with familiar content to begin the transition to reading continuous text. Penny and Pot are fans of the Harry Potter books, so Penny's friend took her to the local library to check out a large-print copy of one of the books she had read before. She read the book daily to Pot for 1 hour. At discharge, the therapist repeated the Pepper test; Penny demonstrated 100% accuracy and a reading rate of 124 words per minute.

The OT made a home visit during the third therapy session to evaluate Penny's environment and to meet Pot. Penny's friend and fellow artist who had been taking her to therapy also attended the session. The assessment showed that Penny's home generally had sufficient lighting, contrast, and organization. However, the small kitchen had only a single small, round ceiling light, which left the countertops and work surfaces poorly lit. In addition, she had deep cupboards packed with food and cookware, and her countertops were cluttered with appliances and food items. Penny's studio, located in a bedroom, was also cluttered and had only overhead lighting and a small table lamp. The OT suggested replacing the small overhead lighting fixture in the kitchen with a large fluorescent fixture and adding fluorescent undercounter lighting. The OT also suggested cleaning out the cupboards and removing rarely used items and expired food from the shelves and then adding a two-tiered cabinet organizer so that foods could be stored one-item deep to make them more visible. The OT demonstrated how this could be accomplished with one of Penny's shelves. The OT also recommended that Penny remove all items from the countertops except those that she used daily. Although Penny was still resistant to resuming her art, the OT made suggestions to improve the lighting in her studio by adding a 50-watt halogen task lamp on her worktable, along with increasing organization and reducing clutter. A low-power magnifying lamp was also recommended to help her see details more clearly. Penny expressed doubt that she could make the recommended modifications, but her friend stated that she would help her, and within 2 weeks, all the recommendations had been implemented. The friend also expressed interest in getting Penny to resume her art and asked for suggestions on how to accomplish this. The OT practitioner suggested that if the detailed drawings Penny had previously completed were still too difficult, even with the studio modifications, maybe she could explore other forms of artistic expression that were not so visually demanding. The next week Penny reported in therapy that she and her friend had attended an art fair over the weekend, and she thought she might experiment with watercolor landscapes, something she had done early in her career. Her friend was coming over to assist her that week.

Penny's ability to complete meal preparation, financial management, and diabetes self-management was addressed through improvement of reading and visual search skills, task and environmental modification, and adaptive equipment. Using a talking calculator to verify numbers helped her reconcile her checkbook. Because of the critical need for accuracy in monitoring blood glucose levels and drawing insulin, she was trained to use a talking glucometer and a nonvisual adaptive device to draw her insulin. The environmental modifications implemented after the home assessment greatly improved her ability to complete meal preparation.

To address mobility, the OT practitioner began by having Penny complete a series of exercises on the Dynavision for the first 20 minutes of each session. The exercises focused on increasing the speed and efficiency of the search pattern she executed to the left and on her ability to shift attention between the center and peripheral areas of the board and complete scanning with cognitive distractions. The OT also used scan courses with targets taped along the hallways of the center, along with "find red" and narrated scanning. As Penny improved on indoor activities, the OT moved outdoors and had Penny navigate sidewalks and areas adjacent to the clinic. The OT taught her that, prior to navigating an unfamiliar environment, she must consciously turn her head widely and survey her surroundings, locating any potential obstacles and identifying landmarks. As her comfort in these environments increased, she was taken on a community outing to her local grocery store to practice the skills she had learned and receive instruction in how to quickly and efficiently scan shelves to locate needed items. Additional community outings were completed in her local mall and in her church. Two weeks prior to discharge, Penny excitedly reported that she and Pot had attended church and afterward had had lunch with friends, with no difficulty.

Driving was addressed throughout the intervention period. The Dynavision exercises Penny completed improved the visual skills she needed for driving, especially speed, flexibility, and width of the search strategy to the left. Limitations experienced by drivers with hemianopia were discussed in conjunction with strategies to compensate for these limitations and vehicle modifications. When Penny had shown sufficient improvement, the 4-minute test on the Dynavision was administered. This test has been shown to be predictive of a person's performance behind the wheel.[73] *A person who scores above 195 on the test is likely to successfully complete an on-road driving assessment. Penny scored 230 on the test and was referred to a driver's program for an evaluation administered by an OT credentialed as a certified driver's rehabilitation specialist (CDRS). Penny passed the driving evaluation and was released to resume driving during daylight hours over familiar routes.*

Visual Attention and Visual Scanning

Visual attention is the ability to observe objects closely to discern information about their features and their relationship to oneself and other objects in the environment. It requires the ability to ignore irrelevant sensory input and random thought processes and to sustain focus for several seconds to several minutes.[117] Visual attention also entails being able to shift visual focus from object to object in an organized and efficient manner. Engagement of visual attention is accomplished through visual scanning or search (these two terms are used interchangeably). Although these two processes are separated in the visual perceptual hierarchy so that they are easier to understand, they cannot be separated in evaluation and intervention. Any change in visual attention will be observed in the client as a change in the scanning pattern used for visual search.

Visual attention is divided into two broad categories: focal (or selective) visual attention and ambient (or peripheral) visual attention. Focal/selective attention enables the person to accurately distinguish visual details such as differences between letters, numbers, and faces. It is used to recognize and identify objects.[53] Ambient/peripheral attention focuses on the location of objects in the environment and their proximity to the person. Its job is to ensure that a person is able to move safely through space and maintain orientation in space; it depends on seeing "the big picture" rather than the details.[53] If humans did not have the capacity for peripheral attention, collisions with objects and disorientation when moving would be the norm. To be able to fully engage and learn from the environment, a person must use these two modes of visual attention simultaneously at all times. The contribution of each is equally important to perceptual processing. Adults without brain injury use an organized, systematic, and efficient pattern to complete visual search.[154,160,162,166] The type of search pattern used depends on the demands of the task.[79] For example, a person would use a linear search strategy to read a book or search for an item on a shelf.

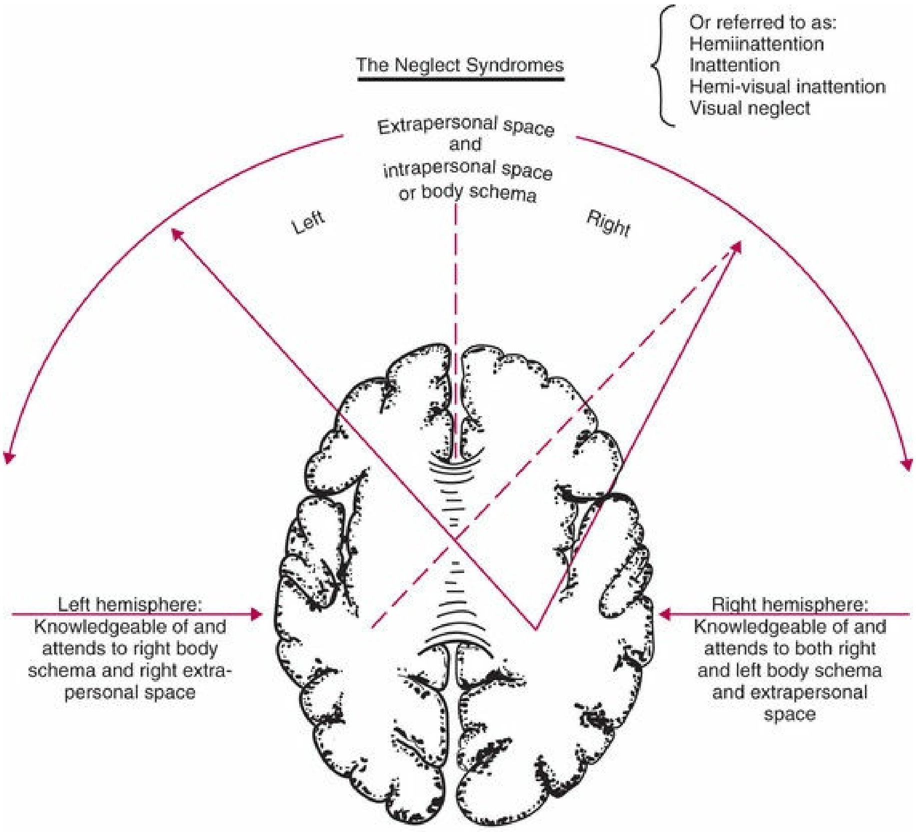
Hemiinattention

Deficits in visual attention commonly occur after brain injury.[53,94] **Hemiinattention** and its most severe form, visual spatial neglect, is one of the most common attention deficits observed in individuals with acquired brain injury from a stroke or head trauma.[12,29,71]

Kerkhoff and Schenk[71] defined hemiinattention as the "impaired or lost ability to react to or process sensory stimuli (visual, auditory, tactile, olfactory) presented in the hemispace contralateral to a lesion of the human right or left cerebral hemisphere." Several key words in this definition delineate the features of hemiinattention. First, ability can be "impaired" or "lost," implying that there are degrees of severity of the condition, ranging from a milder form (impaired) to a severe form (lost). Second, people can have difficulty "reacting" to stimuli (ie, noticing and responding to it) or difficulty "processing" stimuli (ie, using the sensory information to complete a task). Third, people can experience inattention to different kinds of sensory input, not just visual. Finally, people experience impaired attention to incoming sensory input "contralateral" to (on the opposite side of) the location of the lesion. This means that individuals with right hemisphere lesions experience difficulty attending to visual stimuli on the left side of the body midline, and vice versa.

The consensus now is that hemiinattention represents a heterogeneous disorder characterized by a complex and diverse set of behaviors.[a] These behaviors can be generally grouped into three broad categories of impairment: (1) a lateralized bias in attending to and searching space; (2) a nonlateralized impairment in arousal and ability to focus, shift, and sustain attention; and (3) a lateralized inability to map and build internal mental representations of space on the left side of the body.[1,15,58,92,136] The diversity of behaviors associated with hemiinattention results from disruptions in the large distributed network that controls visual attention.[b] The network comprises the frontal, prefrontal, temporal, parietal, and occipital lobes in the cortex and the brainstem, thalamus, and cerebellum. The diverse areas of the network communicate extensively with each other through the long white matter pathways (fasciculi) that connect areas of the brain.[48] Brain injuries can disconnect areas and disrupt network actions at multiple sites, including sites that may not have been directly damaged by the brain injury.[42] This means that hemiinattention is not caused by damage in just one brain area.[1,42]

Hemiinattention is predominantly caused by brain injuries affecting the cortical areas of the right hemisphere.[8,12,58,119] Left hemisphere lesions in the cortex can cause right hemiinattention, but the condition occurs less frequently and with less severe and consistent changes in behavior.[15] Hemiinattention is associated with right hemisphere injuries and probably occurs because of a difference in the way the hemispheres direct visual attention.[48] As Fig. 24.12 shows, the left hemisphere directs attention toward the right half of the visual space surrounding the body, and the right hemisphere directs visual attention toward *both* the right and left halves of space. If a lesion occurs in the left hemisphere, visual attention and search toward the right side are diminished, but some attentional capability is still provided by the right hemisphere. A similar lesion in the right hemisphere may completely eliminate attentional capability toward the left because no other area directs attention toward the left side.



In relation to **movement** and **sensory perceptions** such as vision (visual-spatial and visual-object awareness and recognition), auditory and somesthetic (including body image or schema) cognition and awareness, it appears that the left hemisphere primarily attends to the right extrapersonal space and/or body image parameters while the right hemisphere attends to both right and left extrapersonal space and body image. Thus **left hemisphere lesions** of the 1°, 2° or 3° areas of the cerebral cortex or associated subcortical fiber tracts concerned with visual, auditory, somesthetic, or motor functions rarely result in a neglect syndrome because the right hemisphere can attend to and compensate for the left hemisphere deficit. However, **right hemisphere lesions** of one or more of these functional areas leave the brain unable to attend to or be aware of the left extrapersonal space and body schema. visual field deficits (especially left homonymous hemianopia) always compound the neglect syndrome.

FIG 24.12 Difference between the right and left hemispheres in the direction of visual attention and the relationship of hemisphere lesions to hemiinattention and neglect syndrome. (Courtesy Josephine C. Moore, PhD, OTR.)

Spatial Bias

Spatial bias is the classic behavior associated with hemiinattention.[12] The presence of spatial bias toward the right side changes visual search and creates difficulty exploring the left side of the body. Instead of initiating a symmetrical search pattern beginning on the left and moving to the right, the client with hemiinattention begins on and confines search to the right side of a visual array. This rightward bias creates an asymmetric search pattern, depriving the client of needed information on the left side of objects and visual arrays.

Nonlateralized Attention Deficit

Individuals with persistent (chronic) hemiinattention have difficulty generating adequate levels of alertness and sustaining attention.[120,140,149] The impairment of attention is nonlateralized, meaning that it does not affect attention to one side differently from the other, but instead affects the brain's overall ability to receive and process visual information. The generalized diminishing of attention impairs the ability to attend to specific tasks, and the client often drifts off and loses focus while completing activities.[120]

In addition to difficulty sustaining attention, people with hemiinattention have difficulty disengaging from the object they are focusing on and shifting attention to another object.[44] People with right hemisphere lesions have greater difficulty disengaging from viewing targets located on the right (ipsilesional) side and also experience difficulty engaging attention on targets located to the left.[1] They make fewer visual fixations and slower eye movements to the left, and the result is slowed and incomplete search toward the left half of the body space.[89]

Mental Representation of Space

Mental representations of space are internally generated maps of the space that surrounds the body. The maps are continuously updated as the body moves through environments. People with hemiinattention experience a disruption of the mental representation of space in which objects to the client's left side simply disappear from the client's conception of space. According to Becchio and Bertone,[15] it is as though the mental map of space on the left side did not exist in the past, doesn't exist in the present, and will never exist in the future. As a result, the client doesn't attend to landmarks on the left side and does not build a map of environments on the left side. This diminishes the ability to orient to and maintain orientation in space, and clients are often observed at times to be literally “lost in space” as they try to navigate environments.

Inability to conceptualize space may explain the consistency of the inattentive behavior so often observed in clients with hemiinattention and also the client's lack of insight regarding the missing space.[15] It may also explain another commonly observed behavior associated with hemiinattention, called revisiting, in which the person repeatedly reexamines objects on the right side of a visual array while ignoring objects on the left. For example, if asked to locate a cup of pudding on the left side of the dinner tray, the client will repeatedly search the right side of the tray, even though the pudding cannot be found there.

Hemiinattention often is confused with the presence of left hemianopia. Although both may cause the client to miss visual information on the left side, they are distinctly different conditions and do not have the same effect on performance. When left hemianopia occurs, the client attempts to compensate for the loss of vision by engaging visual attention. The client directs eye movements toward the blind left side in an attempt to gather visual information from that side. Because of the field deficit, however, the client may not move the eyes far enough to acquire the needed visual information from the left side and as a result may miss objects on that side and appear inattentive. In contrast, the client with hemiinattention has lost the cortical attentional mechanisms that drive the search for visual information on the left. The client will make little attempt to search for information on the left side of the visual space. Visual search is most significantly impaired when the two conditions occur together. In this case, the client does not receive visual input from the left side because of hemianopia and does not compensate for the loss of visual input by directing attention toward the left side. The combination of hemiinattention and left hemianopia creates the most severe form of hemiinattention, **visual neglect**.[30] Clients with this condition show exaggerated inattention toward the left half of the visual space surrounding the body and often do not move the eyes past midline toward the left or turn the head toward the left side.[1] Visual neglect may be compounded by neglect of the limbs on the left side of the body or neglect of auditory input from the left side.[71]

Occupational Limitations

Because visual attention is modulated through an extensive neural network involving the entire brain, some capacity for visual attention generally is retained even in cases of severe brain trauma.[53] Conversely, because so many neural structures contribute to attention, changes in visual attention occur even with mild injury. Hemiinattention creates asymmetry and gaps in the visual information gathered through visual search. The incomplete search pattern can create challenges completing tasks that require symmetric attention and search. The client misses needed details on the left, and this can result in confusion when reading and dangerous behavior, such as colliding with objects on the left while navigating through environments.[16,116,152,165] How much the diminishment of visual attention affects occupational performance depends on the circumstances and requirements of tasks. For example, enormous amounts of selective and sustained visual attention are required when the person reads a highly technical textbook, but less when the individual reads an advertisement. Driving requires continuous global attention to monitor the speed and position of other vehicles and objects, in addition to sporadic selective attention to identify landmarks, street signs, and traffic lights.

Evaluation

As a process found at the intermediate level of the visual perceptual hierarchy, visual attention is affected by deficits in the lower level visual functions of visual acuity, oculomotor function, and visual field. Aphasia and motor impairment can also affect performance on visual attention assessments. Therefore, these client factors must be evaluated first, before visual attention is addressed. Because visual search is the outward motor expression of visual attention, it is assessed by observing how the client initiates and carries out visual search on a task. The occupational therapist seeks to answer these questions:

1. Does the client initiate a left-to-right and top-to-bottom search strategy?

2. Does the client execute the search strategy in an organized and efficient manner?

3. Does the client search symmetrically and obtain complete visual information from both sides of the array?

4. Is the client able to sustain visual search, or is there evidence the client drifts off during search?

5. Does the client accurately locate targets?

6. Does the client's ability to search for information decrease as the visual complexity of the task increases?

Cancellation tests are frequently used to evaluate changes in visual search and have been shown to be sensitive to uncovering the spatial bias caused by hemiinattention.[94,154] Cancellation tests are usually paper and pencil tests consisting of rows of single letters, numbers, or symbols. The therapist instructs the client to search through the rows and cross out or cancel a specific target (Fig. 24.13). The therapist records the time required to complete the test and the accuracy of target detection. Adults without brain injury demonstrate specific characteristics of search strategies on cancellation tests that ensure good accuracy and speed completing the test.[162] These characteristics include strategies that are linear, organized, symmetrical, thorough, and consistent. Warren et al.[162] found that the most commonly used strategy on cancellation tasks was a left-to-right and top-to-bottom linear reading strategy, followed by a back-and-forth (left to right then right to left), top-to-bottom strategy. They also found that most people consistently use the same strategy throughout a single cancellation test and a series of cancellation tests.

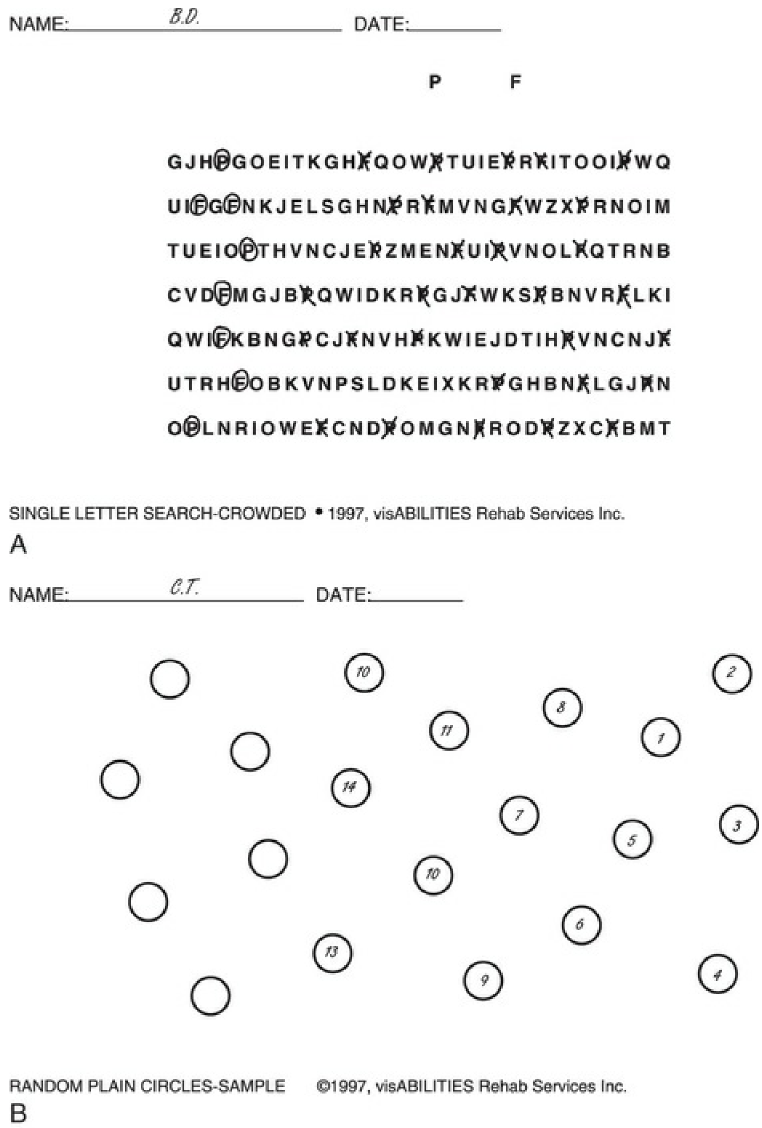


FIG 24.13 Examples of ineffective search patterns used by clients to complete two visual search subtests of the Brain Injury Visual Assessment Battery for Adults. A, An abbreviated search pattern used by a client with left hemianopia when crossing out the letters P and F on the subtest. The client executed an organized left-to-right linear search pattern but failed to locate the beginning of the line on the left side, and consequently failed to cross out targets on that side *(circled letters).* B, An asymmetric and abbreviated search pattern executed by a client with hemiinattention and left hemianopia. The client was asked to number the circles consecutively, choosing any pattern desired. The client began numbering the circles from the right, rather than from the left, and failed to number circles on the left side of the array.

The client with hemianopia may demonstrate an abbreviated search pattern toward the blind side, resulting in omissions of targets on that side of the test. The search pattern may also be executed slowly, especially toward the blind field. However, unless the client's visual attention is diminished, the search pattern should be organized and consistent and the client should thoroughly search and accurately identify the targets in the seen field. The client should also be able to respond to a cue (eg, "Be sure to search the left side") to improve performance. In contrast, individuals with hemiinattention demonstrate an abbreviated search toward the left side with target omissions, but they also often search in a random, unpredictable fashion, reflecting their difficulty in selectively focusing and sustaining attention (see Fig. 24.12).[1,14,26] The organization and accuracy of the search pattern also may deteriorate when they scan more complex visual arrays. Thus, one way to differentiate between left hemianopia and hemiinattention is to observe the search strategies the client uses to complete a cancellation test. Observing the client copy a design also provides information about the ability to conceptualize space on the left side.[1] On a design copy test, the client is shown a simple figure (eg, a house, clock, or flower) and asked to reproduce it.[158] Clients with hemiinattention frequently omit details on the left side of drawings and skew the drawing toward the right side; this suggests both bias against and impaired mental representation of left space.[18]

Determining how the client applies a search strategy to extrapersonal space requires the use of tests that force the client to scan a wider visual field. The ScanBoard (part of the biVABA) consists of a large board (20 × 30 inches) on which 10 numbers are displayed in an unstructured pattern. The board is placed at eye level and centered at the client's midline. The client is asked to scan the board and point out all the numbers he or she sees. The therapist records the pattern the client follows in identifying the numbers. Research using this test has shown that adults without brain injury use an organized, sequential search pattern, beginning on the left side of the board and proceeding in either a clockwise or counterclockwise fashion until all the numbers have been identified.[160] In contrast, adults with deficits in visual attention from brain injury demonstrate disorganized, random, and often abbreviated search strategies, frequently missing numbers on one side of the board.

Light boards (eg, the Dynavision) and the biVABA ScanCourse also assess the client's ability to attend to and search extrapersonal space. Divided attention tasks on the Dynavision using the t-scope feature, or asking the client to complete a cognitive task (eg, reciting the names of states or countries) while striking the lights, provide opportunities to observe the client's ability to rapidly shift attention between divergent tasks. Exercise runs on the light board can also be extended over several minutes, testing the person's ability to sustain attention. On the Dynavision, the computer printout breaks down the client's performance into 1-minute increments, allowing the therapist to determine whether the client is able to consistently sustain attention and performance throughout the 4-minute period.

The information gathered from observing the client complete visual search tests should reveal a pattern of deficiencies in attention and search that affect the client's ability to acquire visual information when completing everyday activities. For example, the client who demonstrates an asymmetric search pattern on a cancellation test, initiating and confining search to the right side, often demonstrates the same asymmetric pattern while searching for grooming items in the bathroom. The client's level of performance depends on the severity of the attention deficit. Clients with mild inattention generally are able to complete basic and habitual daily activities and experience difficulty only on tasks that are unfamiliar or require search of a complex visual array. In contrast, clients with neglect may have difficulty with basic tasks, such as locating all the food on their plate. Combining information from the visual search and ADL assessments enables the therapist to obtain a complete picture of how inattention has affected the client's performance of daily activities.

The physician who referred Penny to the low-vision center noted that she had possible hemiinattention in addition to the left hemianopia. Because hemiinattention can significantly interfere with completion of ADLs, especially driving, it was important to determine how much, if any, of Penny's difficulty scanning was due to inattention. To assess this, Penny was given the visual search subtests from the biVABA, which uses a cancellation format. On the first subtest, Penny missed several of the targets located on the left side of the sheet, demonstrating an abbreviated search pattern toward the left. The therapist provided a verbal cue, "Be sure to look far enough toward the left to see the border of the test." Penny acknowledged the cue and located the rest of the targets on the left; she also made sure to begin her search on the far left side on each of the remaining subtests. She consistently used an organized left-to-right and top-to-bottom search strategy on all seven subtests. She also carefully looked at each target and rechecked her work for accuracy. These observations suggested normal attention capability, which was verified by her performance on other assessments. For example, although she made mistakes in copying numbers on the Telephone Number Copy test, she was able to search and correct her mistakes without assistance. She also missed targets on the left side during her first pass through the ScanCourse, but after receiving feedback, made no errors on her second trial on the course. On the Dynavision she was also able to switch attention easily between the left and right sides of the board, and her ability to search the left side of the board rapidly improved with practice. After analyzing Penny's performance on these assessments, the occupational therapist concluded that because of the severity of her hemianopia, Penny may have appeared to be inattentive toward the left side during the first several weeks after her stroke, when she was unaware of the VFD. However, as she gained awareness of the deficit, she was able to use attention to help compensate for the loss of vision on the left. If Penny's performance had suggested the presence of the hemiinattention, it would not have been appropriate to set a goal to resume driving, and it would have been necessary to explore alternative forms of transportation.

Intervention

The incidence of hemiinattention and neglect has been reported to be as high as 70% in the early stages of recovery from a right hemisphere brain injury.[69] However, most hemiinattention resolves with time and is significantly diminished by 3 months after injury in two-thirds of clients.[29,69] Disruption of the white matter network that connects the frontal, temporal, parietal, and occipital lobes may account for the initially high incidence of neglect right after injury and the good potential for recovery.[48] Individuals with neglect that persists beyond 3 months may have significant and persistent deficits that reflect the presence of structural rather than pathway damage in the brain.[69]

Individuals with hemiinattention/neglect experience difficulty locating and using resources from the environment to complete daily activities. Performance limitations may include difficulty with the following: locating items on the left side; sustaining attention long enough to complete an activity; dividing and shifting attention to be able to multitask; and rapidly and accurately assessing situations in dynamic contexts (eg, the community) because of limitations in working visual memory. Generally, the more dynamic and ambiguous the environment, the greater the limitations experienced by the client because of the demand on visual attention.

Intervention addresses the challenges of spatial bias in attending to and searching space and the impairment in arousal and ability to focus, shift, and sustain attention. Intervention focuses on modifying the environment and task to reduce the contextual demands on the client's visual attention and on enabling the client to engage and sustain attention through the use of compensatory strategies and occupation. Sensory input strategies may also be used as adjuncts to increase attention. These approaches are combined with education delivered to the client through feedback during performance to increase the client's insight into how hemiinattention has affected the ability to complete daily occupations.[74,143,144] Insight is an important prerequisite to developing compensatory strategies because before a client can learn to reorganize visual search, he or she must understand how visual search and attention have changed.[74,143,144] Education begins during the evaluation process, when the occupational therapist alerts the client to deficiencies in the search pattern or through cueing, as the client completes the visual search tests (as was done with Penny), and by providing feedback on the strengths and weaknesses of the client's search pattern on conclusion of the test. The therapist should continue to use every opportunity to educate the client during intervention, using the client's difficulties or mistakes as teachable moments to help the client develop an understanding of capabilities and limitations.[144]

Modification.

All clients benefit from modification of the environment to help them use limited attention capabilities. The environment can be made more visible by reducing factors that place stress on visual processing. These environmental modifications, discussed in the overview on intervention, include reducing pattern, increasing contrast, and maximizing lighting. Minimizing pattern is a key intervention for a client with limited attention. The more densely packed the background pattern, the greater the amount of selective attention needed to locate the desired object. Clients with severe brain injuries may not be able to sustain the effort needed to complete this level of processing and may view their environments as filled with “visual noise” rather than meaningful objects. Reducing the number of distractors in an environment has been shown to improve effectiveness of the search pattern in individuals with neglect.[59,88,139] Improving the quality of lighting and adding contrast to increase the visibility of key features and objects in the environment also make it easier for the client to locate items. Increasing the discriminability of targets has been shown to elicit a more efficient and faster search pattern in those with neglect by creating a “pop out” effect that grabs the person's attention.[95,139] An example of using contrast to create a pop-out effect could be as simple as wrapping a piece of bright orange fluorescent tape around a call button to distinguish it from the bed rail. Adding structure to the environment by finding a place for everything and keeping everything in its place is the final critical piece in creating an attention-promoting environment. All together, these modifications create a more explicit context for the client that enables him or her to make maximum use of limited attentional capabilities to complete occupations. They also create a more inviting context for the client that encourages participation.

Compensation.

Visual scanning training (VST) has been shown to have the strongest evidence for effectiveness in reducing the effect of spatial bias by teaching the client specific compensatory strategies to reorganize and restructure the search pattern.[a] VST uses language and cognition to help the client learn to use a structured search pattern that begins on the left side of a visual array and progresses left to right and top to bottom. This structured pattern helps counteract the client's tendency to restrict visual search to the right side and increases the symmetry of the search pattern. The OT practitioner selects preparatory tasks, activities, and occupations that provide the client an opportunity to practice this compensatory pattern. The following guidelines are helpful in selecting the best visual scanning activities to teach and reinforce use of this structured search pattern.

1. *Select activities that require the client to scan as broad a visual space as possible.* Many daily activities require a person to orient to and work within a broad visual space. To help the client learn to initiate and complete a wide visual search, the working field of the activity should be large enough to require the client either to turn the head or to change body positions to accomplish the task. Many activities and games can be enlarged to require head turning to complete visual search. For example, the therapist can lay out a deck of playing cards face up in rows 3-feet wide and ask the client to use another deck of playing cards to match the cards on the table, turning the pairs over as the match is made. The practitioner ensures that the client initiates a left-to-right, top-to-bottom, organized scanning pattern when searching for the matching cards to complete the task. An occupation approach might involve planting a row of flowers or bulbs along a wide hedgerow in a garden or hanging up sheets on a clothesline.

2. *Select activities that require the client to interact physically with the target*. Attention is more focused when the person must act on what is seen. Games such as solitaire and dominoes, or those played on the Nintendo Wii, along with Dynavision or other light board exercises, are examples of activities with interactive qualities. Occupations such as cooking and laundry require physical interaction and interaction within a wide space.

3. *Select activities that require conscious attention to visual detail and careful inspection and comparison of targets*. To facilitate selective attention, clients should be taught to consciously study objects for their relevant features. Games such as solitaire, double solitaire, Concentration, Connect Four, checkers, Scrabble, and dominoes have these qualities. Large 300- to 500-piece puzzles, word or number searches, crossword puzzles, and needlecrafts (eg, latchet hook) also require selective attention. Throughout performance of these tasks, clients should be encouraged to recheck their work to make sure critical details are not missed.

4. *Use visualization to reinforce the correct search pattern*. Niemeier[98] demonstrated that clients with severe chronic neglect could be taught to search left space through the use of a clever visual imagery technique called the “lighthouse strategy.” A simple line drawing of a lighthouse was positioned in the client's view. The client was told that whenever he or she needed to search for something, to imagine being a lighthouse like the one in the picture and to scan widely from left to right. The lighthouse picture (cue) was always available to the client as he or she practiced scanning activities. The client would be cued to look at the picture and imagine being the lighthouse before completing an activity. Participants in the study required various amounts of rehearsal to learn the strategy, but a statistically significant increase in search performance was found after the training. The findings were replicated in a second study that showed statistically significant improvements in route finding, navigation (with or without a wheelchair), and problem-solving tasks.[99]

In addition to difficulty using a structured, symmetric search pattern, people with hemiinattention often have limited ability to sustain attention. The therapist should engage the client in activities that *require continuous attention over an extended period*. Interventions that use continuously challenging and interactive activities have been shown to increase alertness and the ability to sustain attention.[109,137,140,148,149] A 4-minute run on the Dynavision, combined with the t-scope feature in which a number appears periodically in the center of the board, is an example of a preparatory task that meets this criterion. The client is required to shift attention across the board to strike the light target when it appears, while simultaneously monitoring the center of the board to call out the number when it appears in the t-scope. The client receives auditory feedback each time a light target is successfully struck and visual feedback from a printed analysis of reaction time performance in each quadrant of the board on completion of the run. Fast-paced video games and computer programs that extend over several minutes, such as those played on the Nintendo Wii, are also examples of task that permit the client to practice the ability to sustain and shift attention.

Almost all IADLs require sustained attention for extended periods and can be graded in attentional demand. For example, the therapist might start with preparation of a simple breakfast and progress to preparation of a four-course meal. Tham et al.[143] found that teaching clients with hemiinattention to consciously reflect on how to proceed before beginning an activity, and then to continue to consciously reflect while completing the activity to monitor performance, sustained attention and increased the likelihood of a successful outcome. An example of this approach would be to instruct a client to describe the steps for putting on a shirt, then to describe each step out loud as he or she put on the shirt, and finally to assess his or her own performance to determine whether the shirt had been put on correctly.

Occupation.

It is important to remember that the OT role is to enable the client with hemiinattention and neglect to complete daily occupations and that this goal is often best achieved using occupation. The research on the effectiveness of using motivating activities to improve attention is still limited, but it is growing as researchers are finding that engaging individuals with neglect in emotionally relevant and motivating activities improves attention.[22,74,130,143] Tham et al.[143] found that participation in everyday activities that were personally relevant and meaningful made it easier for clients with neglect to learn compensatory strategies because the client was *interested* in using the strategy to complete the task. Klinke et al.[74] confirmed the importance of using daily activities in a qualitative study of 12 people with chronic neglect. Participants reported that it was easier to attend to concrete and meaningful tasks and tasks that held high emotional relevance. For example, one participant reported how much easier it was to hold her baby and make formula to feed the child than making coffee and holding a coffee cup. Bodack et al.[22] showed improved attention to the left in participants with chronic neglect after having them practice playing scales on a keyboard. The social environment in which the person practices daily activities can also facilitate compensation for neglect.[74,144] Tham and Kielhofner[144] and Klinke et al.[74] found that nurturing and positive responses from staff and family can increase motivation to learn compensatory strategies to increase awareness of the left side.

Participants in the study by Tham et al.[143] also reported that it was easier to apply compensatory strategies when activities involved the use of familiar objects and that repetition (completing the occupation on a daily basis) was important. Practice in applying compensatory search strategies can be easily incorporated into completion of basic ADLs and IADLs. For example, the client might be required to use a left-to-right search strategy when selecting clothes from a closet, searching for items in a refrigerator, or shopping for groceries. The more often the strategy is repeated under varied circumstances, the more the skill is generalized and transferred to new situations.[150] Cafeterias, gift shops, and office areas within the hospital and fast food restaurants and shops surrounding the hospital can be used to expose the client to more demanding visual environments.

Sensory input strategies.

Sensory input strategies attempt to reduce the rightward spatial bias observed in neglect by altering sensory input into the brain.[71] The person responds to the altered sensory input by increasing orientation to the left space. Small studies have shown that, along with constraint-induced therapy and patching, applications of caloric, galvanic, optokinetic, and neck muscle vibration can increase orientation toward the left side in people with neglect.[71,170,174] However, additional research is needed to determine the most appropriate clinical application of these interventions before they can be widely used in rehabilitation.[71] Prism adaptation is the one sensory input strategy that has received significant attention as an intervention to reduce spatial bias. More than 40 studies, including randomized controlled trials, have been published on the use of this intervention in clients with neglect.[97] Although 90% of the studies have shown positive results for ameliorating spatial bias, many of the studies have been criticized because of small sample size, absence of a control group and blinding, and questionable outcome measures.[97] Prism adaptation is considered a promising intervention for reducing spatial bias, but further research is needed to establish the correct protocols to achieve the optimal outcome.[97]

Complex visual processing.

In everyday living, complex visual processing is applied to solve a problem, formulate a plan, or make a decision about a specific situation. The therapist's understanding of the client's visual processing limitations, developed through standardized assessments and observation, is helpful, but it can't predict how the person will actually perform in the context of a practiced and valued occupation. Typically tasks that require complex visual processing also demand complex cognitive processing. To determine the right course and complete a task, a person relies not just on vision, but also on a variety of sensory inputs and memories. The more experience a person has had completing a complex task, the better he or she is at recognizing the pertinent, salient features of a visual scene and recalling and formulating a successful plan when returned to the familiar context of the occupation.[53]

An experienced driver like Penny, who has lived in the same area for many years, would likely drive more competently over the familiar roads she has traveled hundreds of times than in a driving simulator.

Because of the contextual nature of complex visual processing, the best way to evaluate it is to observe the client complete daily tasks requiring this level of processing. Thus, if the client is a teacher planning to return to work, the occupational therapist should assess his or her ability to develop teaching lessons and plans, teach a concept, grade a paper, or perform other aspects of his or her job, preferably at the client's place of employment. The occupational therapist should also simulate as closely as possible the client's natural context for the task. This will require some creativity and effort, but it is the only way to ensure a fair assessment of the client's abilities to determine whether the client is able to resume the desired occupation.

This approach was used to determine whether Penny was safe to resume driving. The occupational therapist and the CDRS who evaluated Penny's ability to resume driving conducted a behind-the-wheel evaluation that required Penny to drive for 60 minutes in various types of traffic. During the evaluation the therapist asked Penny to drive to destinations that she typically traveled to in completing errands, including the grocery store, her church, the physician's office, the library, and the senior center where her painting guild met.

Summary

The brain relies on visual information to anticipate and plan adaptation to the environment and complete daily occupations. Brain injury or disease disrupts the processing of visual information, creating gaps in the visual input sent to the brain. The quality of a person's occupational performance decreases because the brain does not have sufficient or accurate visual information to make decisions.

Penny's left hemianopia, for example, caused her to misread words and sentences because she did not always see letters and words on the left side. This limited her ability to complete daily occupations that relied on reading, such as medication management, shopping, financial management, and meal preparation. Because of her inability to quickly and efficiently scan toward her blind field, she collided with people and objects on the left and experienced disorientation. This affected her ability to navigate environments safely and to drive.

Whether a person's deficit in visual perceptual processing necessitates intervention depends on the person's lifestyle and whether the visual deficit prevents successful completion of daily living activities.

As the primary caregiver for an ailing husband, Penny needed to be able to complete the family finances, drive, and shop; if her husband had been fit, she may not have needed to complete these activities. As a caregiver, she also needed the creative outlet and release that her art provided to help her cope with her additional responsibilities.

The framework for assessment and intervention rests on the concept of a hierarchy of visual perceptual processing levels that interact with and subserve one another. Because of the unity of the hierarchy, a process cannot be disrupted at one level without an adverse effect on all visual processing. Assessment must be directed at measuring function at all process levels, with particular emphasis on the foundation of visual functions and visual attention and scanning.

The absence of visual input on the left side caused Penny to appear to ignore visual stimuli on the left, giving the impression of hemiinattention. Assessment demonstrated that she had normal attentional capability but had not yet learned to compensate for the hemianopia.

The role of the occupational therapist on the rehabilitation team is to ensure that the client is able to participate in daily occupations. That goal may be achieved through interventions that focus on modification, compensation, adaptation and, when appropriate, remediation.

Penny benefitted from a variety of compensatory and remediation strategies aimed at improving her ability to use her remaining right visual field to compensate for the left VFD and to adapt and structure her environment to help her use her remaining vision to complete daily activities.

It is important to remember the most powerful tool in the OT toolkit is modification of the task and environment, to ensure that the client can clearly see and access the key aspects of the task and environment required for successful completion of the occupation. There is no guarantee that the client's visual capabilities will recover, and much more research is needed to determine the most efficacious interventions to restore visual processing capabilities after acquired brain injury. This means that we must work with what the client has and maximize his or her ability to use current visual processing to successfully complete valued occupations—keeping in mind that engagement in daily activities promotes neuroplasticity in the brain and improves the health-related quality of life.[47,64,74,143] It also is important to remember that a team approach is required to address visual impairment from brain injury. The occupational therapist works closely with vision specialists (ophthalmologists and optometrists) and other vision rehabilitation specialists to ensure that the client's vision problems are comprehensively addressed, so that the optimal therapy outcomes can be achieved.

Review Questions

1. What determines whether intervention is needed for a client with a visual impairment?
2. What three aspects of an environment or a task can be modified to increase its visibility for the client with a visual impairment?
3. What prevents a client from automatically compensating for a hemianopia by turning the head farther to see around the blind field?
4. What is the primary compensatory visual search strategy taught to the client with hemiinattention?
5. What is the most crucial lower level visual process that contributes to the ability to perform visual cognitive processing?
6. What changes occur in the visual search pattern of a client with hemiinattention?
7. When would partial occlusion be used with the client? Describe the technique for partial occlusion.
8. How does convergence insufficiency affect reading performance?

Evaluation and Intervention for Perception Dysfunction

Shawn Phipps

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, the student or practitioner will be able to do the following:

1. Describe how perceptual dysfunction affects participation in occupational performance.
2. Identify standardized and functional evaluation tools for visual perception, visual-spatial perception, tactile perception, body schema perception, and perceptual motor skills.
3. Differentiate between remedial and adaptive approaches to intervention for perceptual dysfunction and how they facilitate engagement in occupation.
4. Describe specific occupational therapy interventions for targeted perceptual motor deficits that facilitate improved performance skills, client factors, and participation in occupation.

KEY TERMS

Adaptive approaches
Agnosia
Agraphesthesia
Apraxia
Astereognosis
Body scheme
Color agnosia

Color anomia
Constructional disorder
Dressing apraxia
Figure-ground discrimination
Finger agnosia
Form constancy
Graphesthesia
Ideational apraxia
Ideomotor apraxia
Metamorphopsia
Perception
Praxis
Prosopagnosia
Remedial approaches
Right-left discrimination
Simultanagnosia
Spatial relations
Stereognosis
Stereopsis
Visual-spatial perception

Threaded Case Study

Walt, Part 1

Walt is a 38-year-old male who sustained a traumatic brain injury from a motor vehicle accident, resulting in right frontal, parietal, temporal, and occipital lobe lesions. His occupational profile included a complex and varied occupational history that consisted of full-time work as a graphic artist in a prestigious architectural firm. Walt is a husband and the father of two young children, as well as an accomplished painter.

After the brain injury, Walt's roles as worker, husband, father, and architect were affected because of impairments with motor and process performance skills and client factors, such as perceptual and cognitive dysfunction. Walt was unable to participate in his most valued areas of occupation, including painting, using a computer, sketching, and playing catch with his children. During the evaluation process, his visual foundation skills, including visual acuity, oculomotor control, and visual field function, were found to be intact. However, he demonstrated difficulty initiating motor actions when playing with his children and interpreting visual information for meaningful visual-spatial relationships when painting, sketching, or using the computer. In addition, he exhibits clinical signs of unilateral neglect to the left half of his body and is unable to discriminate between different types of materials through touch alone.

During the initial assessment, the occupational therapist elected to use the Canadian Occupational Performance Measure[64] to obtain client-centered goals that would assist Walt in achieving his occupational performance goals. Walt identified his primary goals in occupational therapy: to submit a painting to a local art gallery, to play with his children, to drive, and to regain computer skills in preparation for resuming part-time work as an architect.

Critical Thinking Questions

1. How would you best evaluate Walt's occupational performance?

2. How would you best evaluate the impact of Walt's perceptual dysfunction on occupational pursuits?

3. How would you assist Walt in achieving his occupational performance goals using remedial and adaptive approaches for his perceptual dysfunction?

"Perception is the gateway to cognition."[15]

Perception is the mechanism by which the brain interprets sensory information received from the environment. This perceived information is then processed by the various cognitive centers in the brain (described in Chapter 26). The individual may then choose to respond with a motor act or a verbal expression. For example, when waiting in a checkout line in a grocery store, a person may observe the array of brightly wrapped candy lining the aisle, may remember the sweet taste of the chocolate, may remember a recent resolution to lose weight, and may choose to resist adding any candy bars to the grocery cart. The person may look over to the next aisle, recognize a neighbor, and begin a conversation. In a few minutes, the person may notice that another register has a shorter line and may choose to move over to that line to be able to complete grocery shopping in a shorter amount of time. Perception of the environment provides the information to enable these response options.

In early development, tactile, proprioceptive, vestibular, and visual perception provide an internalized sense of **body scheme**, which is basic to all motor function.[7,69,109] Highly developed spatial skills are critical to the successful occupational performance of an architect, plumber, designer, or artist.[40] The process of interpreting visual stimuli is a learned skill, as evidenced by blind individuals who, when sight is restored later in life, have difficulty interpreting what they see.[90]

Acquired perceptual deficits are noted in persons with cerebrovascular accident (CVA), traumatic brain injury (TBI), and other neurologic disorders, such as multiple sclerosis and Parkinson's disease.[65,82] Spatial disorders and apraxia of a progressive nature are also seen in Alzheimer's disease.[6,14]

Severe visual perceptual deficits, frequently combined with cognitive impairments, can affect every area of occupation (e.g., activities of daily living [ADLs], instrumental activities of daily living [IADLs], education, work, play, leisure, and social participation) and can present grave safety concerns.[56] For example, an individual who is not able to judge distance and the spatial relationship of his or her foot to the top step of a stairwell may be in danger of a serious fall. Another person who cannot judge the position of the dial on the stove when preparing a meal may cause a fire. It is often the occupational therapy practitioner's role to evaluate safe and independent functioning in valued occupations and to assess visual and perceptual skills using standardized instruments along with observations of occupational performance in context.

This chapter describes the client factors of visual perception, visual spatial perception, tactile perception, body schema perception, motor perception, and the potential deficits in occupational performance that result from impairment to these client factors. Suggestions for standardized and functional assessments are provided, and general occupational therapy (OT) approaches to intervention are reviewed.

General Principles of the Occupational Therapy Evaluation

When evaluating visual perception skills, several assessment tools may be required. The optimal battery of standardized assessment tools requires a verbal response (eg, naming a picture) or a motor response (eg, drawing or constructing) or has flexible response requirements of either mode (multiple choice indicated by verbalizing the number or letter or by pointing to the chosen item). This enables the OT practitioner to assess visual perceptual dysfunction in a client with severe cognitive or communication limitations. With a variety of assessments, the OT practitioner is able to gather information to discriminate between an impairment in the reception of information and an impairment in the motor or verbal output.[25] This information will influence the occupational therapy intervention approach. Observation of the client's occupational performance in context along with analysis of the perceptual-motor demands of functional activities further complement the analysis of perceptual dysfunction obtained from the administration of standardized assessment tools. These data are then integrated to provide a more comprehensive understanding of the deficits in occupational performance. Evaluation methods should be conducted in the specific context of the occupation being performed.

Warren emphasized the importance of using a bottom-up approach to evaluate impairments in visual foundation skills,[99,100] such as visual acuity, oculomotor function, visual field function, visual attention, and visual scanning, prior to evaluating the higher-level visual perceptual skills covered in this chapter. For example, a deficit in visual acuity could be the underlying cause of poor performance on a test of perceptual processing. The normal aging process also results in impairments related to visual foundation areas, and a variety of age-related eye diseases such as macular degeneration, glaucoma, diabetic retinopathy, and cataracts can affect visual acuity or visual field function.[62] It is also possible that performance on global perceptual tests may be affected by deficits in cognitive areas such as attention, memory, or executive function (see Chapter 26). For example, an individual with severely limited attention is unlikely to perform well on many standardized assessments, regardless of the modality or nature of the task. Tsurumi and Todd also analyzed the cognitive skills involved in the commonly used assessments of visual perceptual function and warned that an individual's performance using two-dimensional representations of visual stimuli may not predict the person's performance in a dynamic three-dimensional world.[98]

Arnadottir recommended the observation of ADLs in context to evaluate neurobehavioral dysfunction, including visual perceptual dysfunction and its effect on the performance of tasks essential to functional independence.[5] She maintained that it is preferable for occupational therapists to assess neurobehavioral deficits directly from the ADL evaluation. She developed the Arnadottir OT-ADL Neurobehavioral Evaluation (A-ONE), which evaluates perceptual and perceptual-motor dysfunction in the context of ADLs and functional mobility tasks, including ideational apraxia, ideomotor apraxia, unilateral neglect, body scheme disorders, organization/sequencing dysfunction, agnosia, and spatial dysfunction.[3-5]

Toglia's multicontext treatment approach focuses on remediating and compensating for perceptual and cognitive impairments by generalizing functional skills across multiple contexts.[96] Visual processing strategies, task analysis, incorporating the specific learning needs of the client, establishing a criterion for the transfer of learning, metacognitive training, and practicing in multiple environments are key components of Toglia's approach. This approach also assists the client with TBI or stroke to gain self-awareness of perceptual and cognitive strengths and weaknesses to promote the use of strategies for remediation or compensation of skills across multiple contexts.[97] Toglia's Dynamic Object Search Test is one assessment that can be used to determine a client's abilities in visual processing, visual scanning, and visual attention.[96]

Another occupation-based assessment tool that can be used to determine the impact of deficient performance skills on functional tasks is the Assessment of Motor and Process Skills (AMPS).[38] This standardized assessment evaluates the performance skills necessary for engagement in areas of occupation by assessing 16 motor skills and 20 process skills (eg, temporal organization, organizing space and objects). Each performance skill is evaluated in the context of client-identified and culturally relevant IADLs from a list of standardized activities at various levels of difficulty. The AMPS has a high rate of reliability and validity, and the evaluator must be an occupational therapist who has received advanced training and certification to administer this assessment.

The Loewenstein Occupational Therapy Cognitive Assessment (LOTCA)[57] and Rivermead Perceptual Assessment Battery[32,103] provide a comprehensive profile of visual perceptual and motor skills and involve both motor-free and constructional functions. Various other assessment tools require either a verbal or a simple pointing response. The Motor-Free Visual Perception Test, 4th Edition (MVPT-4)[16,24,70], assesses basic visual perceptual abilities. An alternative version of the test presents the multiple choices in a vertical format (MVPT-V) to reduce the interference of hemianopsia or visual inattention.[73] The MVPT-V has been shown to predict on-the-road driving performance and can be used as a screening tool to identify persons who would not be safe drivers.[71] The Test of Visual Perceptual Skills-Upper Level (TVPS-UL)[42] also provides a multiple-choice format and has been normalized for adults. Test items require a higher level of visual analysis compared with the MVPT, and the test is untimed.[16-18] The Hooper Visual Organization Test[53] requires that the individual mentally assemble fragmented drawings of common objects. The Minnesota Paper Form Board Test[66] is a high-level assessment of visual organization, requiring mental rotation of fragmented geometric shapes.

General Approaches to Occupational Therapy Intervention

An underlying assumption about perceptual-motor function is that perceptual deficits will adversely affect occupational performance. Further, it is assumed that remediation of or compensation for perceptual deficits will improve occupational performance.[74] In her critical analysis of approaches for treating perceptual deficits, Neistadt described two general classifications: the adaptive and the remedial.[74] **Adaptive approaches** provide training in occupational performance to facilitate the client's adaptation to unique contextual environments.[2] In contrast, **remedial approaches** seek to produce some change in central nervous system (CNS) functions.[74] The effectiveness of the various approaches to the remediation of perceptual deficits has not been well documented and requires further scientific investigation.[33,74,89]

The OT practitioner may use one approach or a combination of approaches when designing an intervention plan to address the effects of visual perceptual dysfunction. The remedial and adaptive approaches can be used along a continuum, beginning with remediating basic visual perceptual skills and gradually incorporating compensatory techniques as the deficits persist.[58] The occupational therapy literature suggests specific activities for the intervention of perceptual deficits, but protocols for the use of such activities require further research.[109] For measuring the effectiveness of occupational therapy intervention, criteria are needed for successful performance, task grading, objective methods of evaluating performance, and guidelines for task modification.[75] In the absence of objective criteria, the occupational therapist relies on empirical methods to measure and document functional improvement. Several studies have demonstrated the relationship between perceptual deficits and functional performance.[8,32,88,89]

Remedial Approaches

Remedial, or transfer of learning, approaches assume that multiple practice opportunities with a particular perceptual skill will produce carryover of performance to similar activities or tasks requiring comparable perceptual skills.[74] For example, practice in reproducing pegboard designs for spatial relations training could carry over to dressing skills that require spatial judgment (such as orienting a blouse sleeve to an arm and discriminating between right and left shoes). The capacity for persons to improve their performance on perceptual tests following perceptual training has been documented.[47] However, additional research has also shown that remedial strategies for optimizing perceptual skills may not be as effective as using occupation-based interventions in context to promote changes in perceptual awareness and abilities.[33,68,76,77,109]

Adaptive Approaches for Perceptual Dysfunction

Adaptive approaches are characterized by the repetitive practice of targeted occupational performance tasks that help the person with neurologic dysfunction gain independence by utilizing alternate strategies to compensate for perceptual impairments.[74] The therapist does not retrain specific perceptual skills when utilizing an adaptive approach. Rather, the person is made aware of the problem and is instructed on adaptive strategies to compensate for the perceptual deficit during occupational performance. For example, if the client has difficulty with dressing due to impaired body schema, the therapist may set up a regular dressing routine and provide cues with repetitive practice on how to compensate for the perceptual challenges in context. With these adaptations, the client may learn to dress independently. Adaptation of the physical environment or the specific activity demands (eg, objects used in the environment and their properties) is another way to compensate for a perceptual deficit. For example, if an individual has difficulty discriminating a white shirt against the white sheets of the bed, the therapist may encourage the person to select a patterned shirt or may lay the white shirt on a colored towel or bedspread to provide a contrasting background.

Evaluation and Intervention of Specific Perceptual Impairments

Visual Perception Disorders

Visual perception disorder impairs the person's ability to recognize and identify familiar objects and people.[108] Although these individuals may have intact visual anatomic structures, objects and people may appear distorted, or larger or smaller than they actually are due to neurologic damage. These individuals also have difficulty interpreting the meaning of objects in their environment, such as signs and maps. In addition, they can have difficulty recognizing, identifying, or remembering the names of colors in their environment. These visual perception disorders can lead to safety problems in dynamic environments and may affect social skills, as the person has difficulty recognizing family members, friends, and coworkers.

Threaded Case Study

Walt, Part 2

Walt presents with a visual perception disorder. He has difficulty recognizing and differentiating the faces of his two children; he also has difficulties identifying the differences in the brushes he uses for painting. He requires verbal cues to identify the unique features that distinguish the faces of his two children and to identify the appropriate paintbrush to use during an art project. He also has difficulty identifying and recognizing the significance of various traffic signs, which would prevent him from driving safely.

Agnosia

Visual object recognition refers to the ability to verbally identify objects via visual input. An impairment in this area is called **agnosia**, and it is caused by lesions in the right occipital lobe or posterior multimodal association area.[54,65] The individual with agnosia can demonstrate normal visual foundation skills. The inability to name objects is not caused by a language deficit, as noted in aphasic disorders. Rather, the person is unable to recognize and identify an item using only visual means. If the person holds the object, he or she can identify it via tactile input or by olfactory means if the object has a distinguishable odor, such as a flower or an onion.[91]

Agnosia is assessed by asking the individual to identify five common objects by sight, such as a pencil, a comb, keys, a watch, and eyeglasses. If the client demonstrates word-finding difficulties, the occupational therapist can offer a choice of three answers and ask the client to indicate the correct choice through a head nod (yes or no). If the client is unable to name four out of the five objects, visual agnosia may be indicated.

OT intervention for visual agnosia focuses on adaptive or compensatory methods of keeping frequently used objects, such as a hairbrush, in consistent locations and teaching the client to rely more heavily on intact sensory modalities, such as stereognosis and tactile discriminatory touch, to seek and find desired items for functional use.[54] Remedial approaches can include having the client practice identifying objects that are needed for occupational performance, such as a paintbrush for Walt, or using nonverbal, tactile-kinesthetic guiding during occupations.[108] Following the activity, the occupational therapist can have the client practice naming the items that were used. Current research has found that efforts to remediate object recognition have met with limited success.[55]

Color Agnosia and Color Anomia

Color agnosia refers to the client's inability to remember and recognize the specific colors for common objects in the environment.[50] For example, Walt was unable to recognize the color of the paints he was using during his landscape painting. He confused the green paint he was using to paint the grass with the blue paint he intended to use for the sky. Alternatively, **color anomia** refers to the client's inability to name the color of the objects. Although these clients understand the differences between the colors of objects, they are unable to name the object accurately. For example, Walt was able to recognize the color red but was not able to name it as such.

To assess color agnosia, the occupational therapist can present the client with two common objects that are accurately colored and two objects that are not accurately colored and then ask the client to pick out the objects that are not accurately colored. If the client is unable to choose the objects that are inaccurately colored, color agnosia may be clinically present.

To assess color anomia, the occupational therapist can ask the client to name the color of various objects in his or her environment. If the patient has aphasia, the therapist will ask him or her to nod yes or no after offering the patient choices of colors. If the client is unable to correctly name the colors of various objects, color anomia may be present.

OT intervention for color agnosia and color anomia will focus on providing the client with opportunities to recognize, identify, and name various colors of objects in his or her environment. Intervention is best provided in a familiar context and can be incorporated functionally during occupational performance. For example, while Walt is painting a landscape, the therapist would provide verbal cues that assist him in recognizing, identifying, and naming the various colors of paint he is using.

Metamorphopsia

Metamorphopsia refers to the visual distortion of objects, such as the physical properties of size and weight.[108] For example, when Walt was playing sports with his two children, he could not distinguish among the basketball, the football, the baseball, or the volleyball. Each of the balls appeared heavier, lighter, larger, or smaller than they actually were, making it difficult to distinguish the differences between them through observation alone.

Assessment for metamorphopsia includes presenting the client with various objects of different weights and sizes (e.g., balls, drinking glasses filled with water, puzzle pieces). The client is asked to place each object in order according to size or weight through observation alone. Metamorphopsia may be indicated if the client is unable to determine the weight and size of the various objects.

OT intervention for metamorphopsia includes providing the client with opportunities to practice distinguishing objects in the natural environment through intact sensory modalities (eg, tactile-kinesthetic-proprioception). The functional use of objects during occupational performance will provide the client with feedback about the sizes and shapes of different objects. The occupational therapist should also provide specific verbal descriptors of the object when using this approach. Other treatment modalities include puzzles, board games, and computer games that help the client to gain experience distinguishing the sizes and shapes of different objects.

Prosopagnosia

Prosopagnosia refers to an inability to recognize and identify familiar faces caused by lesions of the right posterior hemisphere.[19,54,91] The individual with prosopagnosia may have difficulty recognizing his or her own face, the faces of family members and friends, or the faces of recognizable public figures because the person cannot recognize the unique facial expressions that make each face different. When attempting to identify family members and acquaintances, the person may compensate by relying on auditory cues such as the sound of the family member's voice or a distinctive feature such as long, wavy hair.

Brain lesions can also impair the ability to interpret facial expressions, which can have significant social consequences.[21,106] For example, one client tended to be very suspicious of others. He was observed to have difficulty describing the expressions of various persons depicted in photographs. Because he had immigrated to the United States from another country, his difficulty was originally thought to be a result of cultural differences. He was asked to bring in a newspaper that he regularly received from his native country. The captions of the photographs were occluded, and he was asked to describe the emotional expressions of the persons shown. He was then asked to translate the photo captions and became aware that he was unable to discriminate the emotions apparent on the faces.

A standardized test of facial recognition[12] is available, which presents a multiple-choice matching of faces presented in front view and side view and under various lighting conditions. Informal functional assessments could include having the client identify the names of the people in photographs, with family members at a dinner table (eg, Walt's two children side by side), or by having the client identify his or her own face in a mirror. Photographs of famous public figures could also be used during the assessment. If aphasia is present, the client can communicate through gestures, such as head nodding (eg, yes or no) in response to a multiple-choice format. If the client is unable to identify him- or herself or family members, prosopagnosia may be present. A formal test of facial expression discrimination is not available in the literature,[65] but an informal assessment is possible using pictures and photographs of familiar people.

OT interventions for prosopagnosia include remedial approaches such as providing face-matching exercises.[108] Adaptive approaches include providing pictures of family members and famous people with names and assisting the client to associate the family member's face with other unique characteristics and features, such as weight, height, mannerisms, accents, and hairstyle.

Simultanagnosia

Simultanagnosia refers to the inability to recognize and interpret a visual array as a whole, and it is caused by lesions to the right hemisphere of the brain.[35] Clients with simultanagnosia are able to identify the individual components of a visual scene, but they are unable to recognize and interpret the gestalt of the scene. For example, Walt is able to identify the flowers and the trees in one of his paintings, but he is not able to recognize and interpret this painting as the landscape surrounding the family home where he grew up.

Assessment includes presenting the client with a photograph that has a detailed visual array (eg, Walt's family photograph at the beach), asking the client to describe the scene in detail, and assessing whether the client can describe the scene as a whole. Many clients will be able to identify specific features of the visual array (eg, the sand castle) but cannot describe the context or meaning of the whole scene (eg, a family trip to the beach). Simultanagnosia is clinically significant when the client cannot recognize and interpret a visual array as a whole.

OT intervention focuses on helping the client to construct the meaning of a visual array through verbal cues and therapeutic questions to facilitate abstract reasoning. Intervention is best provided in familiar contexts, such as a client's home, work setting, or during a community outing to the shopping mall.

Visual-Spatial Perception Disorders

Visual-spatial perception refers to the capacity to appreciate the spatial arrangement of one's body, objects in relationship to oneself, and relationships between objects in space. Various efforts have been made to subdivide spatial skills into components, but authors acknowledge that spatial skills cannot be isolated easily from one another.[22] It is generally acknowledged that the right hemisphere, which controls spatial abilities, tends to function in the gestalt, whereas the left hemisphere tends to focus on discrete details.[65]

Visual-spatial perception occurs instantaneously to support safe and effective occupational performance. Because of this rapid simultaneous processing of visual and spatial information, it is possible to react quickly to another driver's actions to avoid a collision when operating a motor vehicle. An individual with a mild visual-spatial perception impairment may need additional time to perform a task but processes the information correctly, possibly by compensating with verbal analysis of the perceptual components. Severe impairment may result in an incorrect response despite additional time used in attempting to solve the problem.

Visual-spatial skills are not limited to the visual domain.[63] Sounds can be localized in space, and the mobility and daily occupations of blind individuals are heavily dependent on the tactile appreciation of the spatial arrangements of objects.[83] For example, a blind person's ability to navigate through a familiar room requires awareness of the layout of each piece of furniture in the physical environment and continual shifting of the individual's *cognitive map* while changing positions in the room.

As a pencil rolls across a desktop, it is the skill of visual-spatial perception that enables a person to appreciate the relative orientation of the pencil to the table surface as the pencil nears the edge and is about to fall to the floor. Fig. 25.1 illustrates the complexity of visual-spatial perceptual function.

Threaded Case Study

Walt, Part 3

Walt presents with visual-spatial perception dysfunction. He has difficulty distinguishing the right and left sides of his body and often confuses right and left when given directions. He frequently gets lost and requires a family member to be with him at all times when he is in unfamiliar community environments. When painting, Walt has also been observed to have difficulty distinguishing the foreground and the background in his paintings and is unable to determine the differences between the amounts of paint in each of the cups next to him. In addition, he is often observed missing the canvas in front of him when attempting to apply the paint.

FIG 25.1 Visual-spatial functions in real life. Note that all components of spatial functions can be found in this scene.

Figure-Ground Discrimination Dysfunction

Figure-ground discrimination allows a person to perceive the foreground from the background in a visual array.[108] For example, Walt is unable to locate a particular painting utensil from the other writing utensils in the pencil holder, thereby demonstrating difficulty distinguishing the targeted object from the background.

Figure-ground discrimination can be assessed functionally in a variety of contexts. During a dressing activity, you may ask the client to identify the white undershirt located on top of his or her white sheets. In the kitchen, you can ask the client to pick out all of the spoons from a disorganized utensil drawer. Figure-ground discrimination dysfunction may be indicated if the client is unable to discriminate the foreground from the background in a complex visual array.

Using a remedial approach, intervention for figure-ground discrimination dysfunction should focus on challenging the client to localize objects of similar color in a disorganized visual array.[108] The task could be incorporated contextually into meaningful occupation. For example, the therapist working with Walt may have him localize the exact pencil he would like to use for his sketch drawings. The task can be downgraded by making the visual array less complex and upgraded by making the visual array more complex.

An adaptive approach to intervention would focus on modifying the environment to increase the organization of common functional objects (eg, placing only the most necessary objects needed for self-care), decreasing the complexity of the visual array that the client has to discriminate (eg, have only one paintbrush in front of Walt at a given time), or marking common objects with colored tape so that objects are easily distinguished from one another, particularly when the objects are of a similar color.[107]

Toglia's multicontextual approach may be used to help the client gain self-awareness of his or her figure-ground discrimination dysfunction and develop effective organizational and visual scanning strategies for discriminating the foreground and background in the environment.[96] This intervention approach also focuses on the generalization of skill to multiple functional contexts by using strategies that the client has identified as effective in locating objects in the environment.

Form-Constancy Dysfunction

Form constancy is the recognition of various forms, shapes, and objects, regardless of their position, location, or size.[108] For example, a person can perceive all of the pencils on a desk, in various sizes or in various positions in the pencil holder.

To assess form constancy, ask the client to identify familiar objects in his or her environment through observation alone when those objects are placed upside down or on their side. For example, in the kitchen, you may ask Walt to identify a cup that is turned upside down or a toaster oven that is placed on its side. Form-constancy dysfunction may be indicated if the client is unable to identify objects in a position that varies from the norm.

Intervention for form-constancy dysfunction includes using tactile cues that will help the client to feel objects in various positions and thereby learn their constancy despite their position, size, or location. Activities can be graded from positioning all objects in an upright position to placing objects in odd positions. Intervention is best provided with common objects that the client utilizes in everyday occupational performance.

Position in Space

Position in space, or **spatial relations**, refers to the relative orientation of a shape or object to the self. It is this component of perception that allows a person to recognize that the tip of the pencil is pointed away from him, and so directs the hand to effectively grasp the pencil.

To assess position in space, have the client place common objects in relation to the self or other objects using the following directional terms: top/bottom, up/down, in/out, behind/in front of, and before/after. For example, the occupational therapist can ask Walt to place his paintbrush on top of his computer or his basketball behind his back. Position-in-space dysfunction may be indicated if the client is unable to discern the relationships of objects to the self or other objects through directional terms.

Intervention for position in space includes providing the client with opportunities to experience the organization of objects in the environment to the self. For example, Walt could practice placing various objects in relation to one another in a graphic design program on the computer so that directional concepts of up/down, in/out, behind/in front of, and before/after can be reinforced.

Right-Left Discrimination Dysfunction

Right-left discrimination is the ability to accurately use the concepts of right and left.[108] An individual with right-left discrimination dysfunction may confuse the right and left side of his or her body or confuse right and left in directional terms when navigating through the environment.

To assess right-left discrimination, the occupational therapist asks the client to point to various body parts (eg, left ear) or assess the client's ability to accurately navigate the environment through verbal commands using right and left (eg, turn right at the end of the hallway). Right-left discrimination dysfunction may be indicated if the client is unable to differentiate between right and left in relation to his or her body and the environment.

Intervention for right-left discrimination focuses on assisting the client to practice reciting right and left while interacting with his or her own body (eg, "I am now placing my right arm into the shirt sleeve") or the environment (eg, "I am now turning left at the stop sign"). Remediation of right-left discrimination can significantly improve topographical orientation as the client learns to navigate in a more dynamic home and community environment.

Stereopsis

Stereopsis is the inability to perceive depth in relation to the self or in relation to various objects in the environment.[108] Depth perception is critical to function in a three-dimensional world and to safety in driving and community mobility. Clients with visual dysfunction in one eye or who wear an eye patch to compensate for double vision may demonstrate stereopsis, because binocular visual input from both eyes is required to perceive depth.

To assess depth perception, the occupational therapist places a variety of common objects on a table surface and asks the client to identify which object is closer and which object is farther away.

In a community context, the client may also be assessed functionally by asking him or her to identify buildings or landmarks that are closer or farther away. Stereopsis may be indicated if the client is unable to judge the distance between objects in the environment.

Computer-assisted software has been created that can help the client to develop depth perception by judging the relative distance of objects in relation to one another on a computer screen.[108] Tactile-kinesthetic approaches also help the client judge distances through the use of tactile input.[1]

Tactile Perception Disorders

Impairment in tactile perception involves tactile discriminative skills of the second somatosensory area of the parietal lobes.[72] These skills require a higher level of synthesis than the basic tactile sensory functions of light touch and pressure described in Chapter 23.

Threaded Case Study

Walt, Part 4

Walt presents with an impairment in tactile perception. He is unable to identify the objects he uses for painting by touch alone. He is unable to discriminate between different types of materials or different forms and shapes by tactile means and must compensate visually to determine the objects he is using during occupational performance.

Stereognosis

Stereognosis, also known as tactile gnosis,[27] is the perceptual skill that enables an individual to identify common objects and geometric shapes through tactile perception without the aid of vision. It results from the integration of the senses of touch, pressure, position, motion, texture, weight, and temperature and is dependent on intact parietal cortical function.[44] Stereognosis is essential to occupational performance because the ability to "see with the hands" is critical to many daily activities. It is the skill that makes it possible to reach into a handbag and find a pen and to find the light switch in a dark room. Along with proprioception, stereognosis enables the use of all fine-motor activities without the need to concentrate visually on the objects being manipulated. Examples of stereognosis are knitting while watching television, reaching into a pocket for house keys, and using a fork to eat while engaged in conversation.

A deficit in stereognosis is called **astereognosis**. Persons who have astereognosis must visually monitor the use of their hands during activities. Thus they must be slow and purposeful in their movements and generally tend to be less active.

The purpose of a stereognosis test is to assess a client's ability to identify common objects and perceive their tactile properties.[10,26,49,60] A means to occlude the person's vision is needed, such as a curtain, patch, or folder as described in Chapter 23. Typical objects that could be used for assessment include a pencil, pen, a pair of sunglasses, a key, nail, safety pin, paper clip, metal teaspoon, quarter, nickel, and a button. Any common objects may be used, but it is important to consider the client's social and ethnic background to ensure that he or she has had previous experience with the objects. Three-dimensional geometric shapes (eg, a cube, sphere, or pyramid) can also be used to assess shape and form perception.

The evaluation should be conducted in an environment that has minimal distractions. The therapist should sit across from the client being tested. The client's vision is occluded, with the dorsal surface of the hand resting on the table. Objects are presented in random order. Manipulation of objects is allowed and encouraged. The therapist assists with the manipulation of items in the client's hand if the person's hand function is impaired. The client should be asked to name the object, or, if he or she is unable to name the object, to describe its properties. Clients with aphasia may view a duplicate set of test objects after each trial and point to a visual choice. The person's response to each of the items presented is scored. The therapist notes if the object is identified quickly and correctly, if there is a long delay before the object is identified, or if the individual can describe only properties (eg, size, texture, material, and shape) of the object. The therapist also notes if the person cannot identify the object or describe its properties.

Eggers has described a graded intervention program for astereognosis.[34] Initially, the client manipulates the object while looking at it and making noise with the object such as tapping it on the tabletop. This approach allows the client to see and hear an object while feeling it for the benefit of intersensory facilitation; then vision is occluded during the tactile exploration. Finally, a pad is placed on the tabletop so that both auditory and visual clues are eliminated and the person relies on tactile-kinesthetic input alone. The program for tactile-kinesthetic reeducation begins with gross discrimination of objects that are dissimilar—for example, smooth and rough textures or round and square shapes. Next, the client is asked to estimate quantities (such as the number of marbles in a box) through touch. Then the client must discriminate between large and small objects hidden in sand and progress to discriminating between two- and three-dimensional objects. Finally, the client is required to pick a specific small object from among several objects.

Farber also described a treatment approach to retrain stereognosis for adults and children with central nervous system dysfunction.[37] First, the client is allowed to examine the training object visually as it is rotated by the therapist. The client is then allowed to handle the object in the less affected hand while observing the hand. In the next step, the client is allowed to manipulate the object with both hands while looking. Then the object is placed in the affected hand and the client manipulates the object while looking at it. The individual may place the hand in a mirror-lined, three-sided box to increase visual input during these manipulations. This sequence is then repeated with the client's vision occluded. Once several objects can be identified consistently, two of the objects may be hidden in a tub of sand or rice. The client is then asked to reach into the tub and retrieve a specific object. If the sensation of the sand or rice is overstimulating or disturbing, the objects can be placed in a bag.[37]

Graphesthesia

An additional assessment of tactile perception that measures parietal lobe function is the test for **graphesthesia**, or the ability to recognize numbers, letters, or forms written on the skin.[23,44,80] The loss of this ability is called **agraphesthesia**. To assess graphesthesia, the examiner occludes the client's vision and traces letters, numbers, or geometric forms on the fingertips or palm with a dull-pointed pencil or similar instrument. The client tells the occupational therapist which symbol was written.[80] If the client has aphasia, pictures of the symbols may be provided for the individual to indicate a response after each test stimulus. Agraphesthesia is clinically indicated if the client is unable to state or identify the symbol written on the palm of the hand.

OT intervention for agraphesthesia focuses on providing the client with opportunities for tactile discrimination through the use of his or her hands. The therapist can grade the intervention from tracing letters and numbers to words and geometric forms on the palm of the hand. With vision occluded, the client can also practice writing his or her name in the opposite palm.

Body Schema Perception Disorders

Following a CVA or TBI, a person's sense of his or her body's shape, position, and capacity frequently is distorted. This is known as a disorder of body schema, or autotopagnosia.[11] This condition can be noted in attempts to draw a human figure (Fig. 25.2) or in a person's unrealistic expectations of performance abilities.[65] The disorder can affect the egocentric perception of one's own body or of another person's body.[79,82] A person may neglect one side of the body or demonstrate generally distorted impressions of the body's configuration. The person may confuse his or her body with that of another, such as the person who thought that the therapist had stolen her wedding ring, not realizing that the hand she was viewing was her own. **Finger agnosia**, or the inability to discriminate the fingers of the hand, can also be part of the disorder.[11] An impaired body scheme will also affect participation in occupation and performance skills.[89]

FIG 25.2 Example of a body schema perception disorder. Drawing on the left is the person's first attempt to draw a face. The occupational therapist asked the person to try again. The second effort is the drawing on right.

Body schema perception disorders can be assessed by asking the individual to draw a human figure (see Fig. 25.2) or point to body parts on command (eg, "Touch your left hand" and "Touch your right knee"). Finger agnosia is evaluated by occluding the person's vision and asking him or her to name each finger as the therapist touches it. Unilateral body neglect can be observed functionally during occupational performance as the client ignores the affected limb or states that a body part is not his or her own. A body schema perception disorder may be clinically indicated if the client is unable to correctly identify parts of his or her body.

A remedial approach to intervention for body schema perception disorders should focus on providing the client with opportunities to reinforce body knowledge through tactile and proprioceptive stimulation.[108] For example, while Walt is dressing or painting, the occupational therapist can have him incorporate his affected left upper extremity into the activity and verbally acknowledge that this is in fact his left arm and hand being used. Tactile-kinesthetic guiding or constraint-induced movement therapy strategies can also be used if the client has difficulty initiating the use of the affected limb. As the client incorporates the use of the affected limb into occupational performance, he or she will begin to gain perceptual awareness of his or her body and the relationship between various body parts.

Threaded Case Study

Walt, Part 5

Walt demonstrates unilateral inattention to the left side of his body and his environment. He demonstrates asymmetric visual scanning to the left side of his environment, misses details in his drawings on the left, and routinely neglects the functional use of his left upper extremity during functional tasks. He often states that his left arm is owned by someone else and has difficulty holding a painting utensil because of impairments with spatial relationships between his fingers.

Motor Perception Disorders

Praxis is the ability to plan and perform purposeful movement. **Apraxia** has been classically defined as a deficit in "the execution of learned movement which cannot be accounted for by either weakness, incoordination, or sensory loss, or by incomprehension of or inattention to commands."[43] The disorder can result from damage to either side of the brain or to the corpus callosum,[51,105] but it is more frequently noted with left hemisphere damage.[52] Apraxia is often seen in persons with aphasia; however, not all aphasic persons are apraxic, nor are all apraxic persons aphasic.[48,51] This type of dysfunction may occur after CVA or TBI. Progressive apraxia is also noted with degenerative disorders such as Alzheimer's disease.[45,51,81] (See also Chapters 33, 34, and 35.)

Apraxia has been strongly correlated with dependence in areas of occupation.[93,101] For example, in a severe case of apraxia, Ms. S initially required total assistance with basic activities of daily living (BADLs). Ms. S was fully cognizant of ongoing events but could not direct her arm and leg movements in a way that would assist the nursing staff during dressing. When asked to pick up a pencil, Ms. S walked around all four sides of the table in an attempt to position her hand correctly to grasp the object. She could describe the desired action in words ("I want to pick up the pencil between my thumb and index finger, with the lead point of the pencil close to the tips of my fingers") but reported after returning to her seat that her hand never "looked like it was in the right position" to take hold of the pencil.

The categories of apraxia are difficult to differentiate, and authors differ in their use of terms.[94] The principal types recognized in the literature are ideational apraxia, ideomotor apraxia, dressing apraxia, and constructional disorder. Because the distinction between ideational and ideomotor apraxia is often perplexing, some authors recommend simply using the term *apraxia*.[61,65]

Threaded Case Study

Walt, Part 6

Walt presents with a motor perception disorder that affects his motor planning. When given a shirt to don, Walt attempts to put his legs through the sleeves of the shirt. During drawing and painting activities, he seems to hesitate and is unable to initiate a motor plan without physical cues. He knows that he is painting and knows what he would like to paint, but he is unable to translate this idea into a motor action. Walt is also unable to operate the mouse on the computer for a graphic design activity because of his difficulty with motor planning. In addition, when given a three-dimensional craft project, he is unable to use effective problem-solving strategies during the construction of the design.

Ideational Apraxia

Ideational apraxia is a conceptual deficit seen as an inability to use real objects appropriately.[28,31,48] More recent authors suggest the use of the term *conceptual apraxia*.[52,81] The individual also may have difficulty sequencing acts in the proper order,[51] such as folding a sheet of paper and inserting it into an envelope. The individual may use the wrong tool for the task or may associate the wrong tool with the object to be acted on, such as by attempting to write with a spoon.[51] This deficit has significant functional implications in a variety of areas of occupation.

Ideomotor Apraxia

Ideomotor apraxia is an inability to carry out a motor act on verbal command or imitation. However, the person with ideomotor apraxia is able to perform the act correctly when asked to use the actual object.[30,51,84] For example, a person is unable to mime the action of brushing his or her teeth on request but is observed using a toothbrush correctly when performing grooming activities in context. Observation of the person in areas of occupation is critical to the identification of ideomotor apraxia. Impairments are demonstrated only in the testing environment and appear to have little functional impact, as compared with ideational apraxia.[94]

Dressing Apraxia

Another category of motor perception disorders recognized in the literature is **dressing apraxia**. Dressing apraxia contributes to the inability to plan effective motor actions required during the complex perceptual task of dressing one's upper and lower body. The classification of dressing impairment as a form of apraxia has been questioned because the difficulties in ADLs are considered to be caused by perceptual or cognitive dysfunction[20,101,109] (if apraxia is not noted in other activities) or are seen as an extension of an ideational or ideomotor apraxic disorder.

General Principles in the Assessment and Treatment of Apraxia

It is important that assessments of sensory function, motor control, and dexterity are completed before the test of praxis because deficits in these areas would complicate any assessment of apraxia. If a person has a hemiplegia, the unaffected hand is used for testing. Input from the speech-language pathologist is important for establishing an individual's capacity for basic comprehension via words or gestures. Because of the frequent association of apraxia with aphasia and left hemisphere brain damage, an apraxia screening is included.

The literature[20] offers several apraxia assessments used in research, such as the Florida Apraxia Screening Test (FAST),[87,88] the Movement Imitation Test,[29,30] and the Use of Objects Test.[29] The Loewenstein Occupational Therapy Cognitive Assessment (LOTCA)[57] includes a praxis subsection, as does the Rivermead Perceptual Assessment Battery,[103] both of which serve as screening tools for the disorder. The Santa Clara Valley Medical Center Praxis Test and the Solet Test for Apraxia are two additional evaluation tools developed by occupational therapists.[108]

A thorough assessment includes functional items presented, such as those shown in Table 25.1,[51] and involves both transitive movements (actions involving both tool and use, such as writing with an imaginary pen) and intransitive movements (movements for communication, such as waving farewell). Lists of gestures used in assessment are noted in several studies.[20,51,85,87,104]

TABLE 25.1

Elements of a Comprehensive Apraxia Assessment

Test Condition	Example
Gesture to command	"Show me how you would take off your hat." (transitive)
	"Show me how you would throw a kiss." (intransitive)
Gesture to imitation	"Copy what I do." *Therapist shrugs shoulders.* (intransitive) *Therapist flips an imaginary coin.* (transitive)
Gesture in response to seeing the tool	"Show me how you would, seeing the tool, use this object." *Therapist provides screwdriver for display.*
Gesture in response to seeing the object upon which the tool works	"Show me how you would use this object." *Therapist provides screwdriver and block of wood with screw partially inserted.*
Actual tool use	"Show me how you would use this object." *Therapist provides screwdriver for use.*
Imitation of the examiner using the tool	"Copy what I do." *Therapist makes stirring motion, using a spoon.*
Discrimination between correct and incorrect pantomimed movements	"Is this the correct way to blow out a match?" *Therapist pantomimes holding a match in an unsafe manner (eg, match held upside down, with the head of the match near the palm of hand).*
Gesture comprehension	"What object am I using?" *Therapist pantomimes shaving face with a razor.*
Serial acts	"Show me how you would open an imaginary can of soda, pour it into a glass, and take a drink."

From Heilman KM, Rothi LJG: Apraxia. In Heilman KM, Valenstein E, editors: *Clinical neuropsychology*, New York, 1993, Oxford University Press.

Returning to the case of Ms. S, she was first treated for her severe apraxia by being instructed to practice basic motor movements, then she followed a developmental sequence to more advanced functional motor activities. For example, following repetition of basic movement patterns, the client with apraxia progressed to coloring geometric shapes on note cards (felt-tip markers were initially placed in a vertical stand for easy grasp) and gradually to writing exercises. Independent telephone use was important to Ms. S, so a large calculator was used for keystroke practice. She gradually progressed to a disconnected telephone and then to a functional telephone. By the termination of the intervention program, Ms. S was independent in most areas of occupation, although additional time was needed for each activity.

For another client with apraxia, the clinical reasoning process was used in planning the treatment, beginning with spoken instruction for each sequence in the task, written or pictorial instructions, and visual monitoring of her limbs throughout each aspect of the task.[20] Another case study of apraxia treatment involved conductive education—that is, breaking the task into smaller units and verbally guiding the sequence.[76] The individual improved on targeted tasks, but minimal generalization was noted in everyday occupations across various contexts.

OT interventions for dressing apraxia involve problem solving with the client on effective dressing strategies, such as distinguishing between right and left or from front to back on specific clothing items. An effective strategy is to have the client position the garment the same way each time (eg, positioning a shirt with the buttons faceup and pants with the zipper faceup). Labels, small buttons, or ribbons can be used as cues to differentiate the front from the back of the garment.[108,109]

Constructional Disorder

The term **constructional disorder** is now favored over the previously used term *two- and three-dimensional constructional apraxia* because the deficit does not clearly fall within the definition of apraxia.[13,20,65] Many occupations depend on visuoconstructional skills, or the ability to organize visual information into meaningful spatial representations. Constructional deficits refer to the inability to organize or assemble parts into a whole, as in putting together block designs (three dimensional) or drawings (two dimensional). Constructional deficits can result in significant dysfunction in occupations that require constructional ability, such as dressing, organizing food in a refrigerator, following instructions for assembling a toy, and loading a dishwasher.[78,95] Fig. 25.3, which shows evidence of left inattention, also demonstrates constructional deficits. An individual acts on his or her contextual environment based on the information he or she perceives. Therefore deficits in perception become more apparent when a person interacts with the environment in maladaptive ways.

FIG 25.3 Example of a two-dimensional constructional disorder and left-sided inattention in a drawing of a house by a retired architect who suffered a right CVA.

Traditional tests of constructional abilities in a two-dimensional mode are the Test of Visual-Motor Skills for Adults,[41] the administration of the Benton Visual Retention Test,[92] and the Rey Complex Figure assessment.[65] The latter two tests also are used to evaluate visual memory skills. Use of the Rey Complex Figure has been suggested for a quick screening of visual perceptual function.[67] The Three-Dimensional Block Construction[8] involves the use of various blocks to copy a design from a three-dimensional model. Nonstandardized tests that may be used are drawing, constructing matchstick designs, assembling block designs, or building a structure to match a model.[108] In daily living, occupations such as dressing or setting the table require constructional skills. To perform such tasks successfully, an individual must have integrated visual perception, motor planning, and motor execution.[9,46,75,102,109]

Several studies have gathered data on the constructional skills of unimpaired subjects for use as a normative reference for persons with CVA and TBI.[36,75] In a study of constructional abilities in the well elderly, Fall demonstrated that results are influenced by the type of test administration.[36] Subjects tended to score higher on tests that used three-dimensional models as guides for construction than on those that used photographs or drawings. The implications of this finding for occupational therapists are that (1) the type of test administration affects scores, and (2) in teaching persons with constructional disorders, models or demonstrations of desired performance are likely to produce better results than would photographs or drawings.[36]

The remedial approach to intervention involves the use of perceptual tasks such as paper and pencil activities, puzzles, and three-dimensional craft projects to improve constructional skills. The adaptive approach includes participating in occupational performance and developing compensatory approaches to the functional performance skill impairments. Many areas of occupation are suitable for the treatment of constructional deficits, such as folding towels, setting the dinner table, and weeding the garden.

Behavioral Aspects of Perceptual Dysfunction

Some degree of accurate self-awareness and recognition of the effect of the disability on one's functioning is needed if the person is to invest energy in the therapy process.[39] An individual who is unaware of perceptual deficits may be a serious safety risk and may attempt occupations that are well beyond present physical abilities. Denial is often noted in early stages of recovery from CVA or TBI and may serve as a protective coping mechanism that allows the individual to gradually absorb the effect of the injury on his or her functioning. A person's innate trust in the accuracy of perceptions often is a basis for unrealistic self-confidence; demonstrating to the individual that his or her perceptions are now distorted and no longer trustworthy can profoundly affect the person's sense of self. An occupational therapist needs to be respectful and sensitive to the individual's sense of self and be prepared to aid the client in understanding the changes in perceptual capacity and in reestablishing an accurate sense of self. Several questionnaires are available to assess an individual's self-awareness.[59] The questionnaires typically are issued to the person with deficits as well as to a family member or close acquaintance. The discrepancies in the two questionnaires are used as a measure of the accuracy of the individual's insight and serve as the basis for intervention. The individual's behavior may also be the result of a disorder in executive function.[59] (See Chapter 26 for additional discussion of this possibility.)

An individual who has some degree of awareness of the disability often is depressed, which seems an appropriate response given the effect of perceptual impairments on participation in occupational roles. The occupational therapist needs to recognize and appreciate this emotional response and assist the individual in achieving an emotional balance to reestablish quality of life through celebrating progress in therapy while acknowledging the impact of the perceptual impairments on participation in occupation.[39,86] (See also Chapter 6 on the social and psychological aspects.)

Threaded Case Study

Walt, Part 7

1. How would you best assess Walt's occupational performance?
   Walt's performance in his most valued occupations has been affected because of visual perceptual impairment. A combination of skilled observation and formal assessments, such as the A-ONE[3-5] and the AMPS,[38] could be used to assess Walt's occupational performance in a variety of functional contexts. In addition to evaluating occupational performance, these assessments can also appraise Walt's specific perceptual functioning. The Canadian Occupational Performance Measure can also be used to evaluate the client's primary goals in occupational therapy and set the stage for an occupation-based and client-centered approach to intervention.

2. How would you best assess Walt's perceptual function?
   Throughout the chapter, a variety of assessment tools have been presented to evaluate visual perception, visual-spatial perception, tactile perception, body schema perception, and motor perception. In addition, other comprehensive perceptual tests—such as the Motor Free Visual Perceptual Test, Revised,[24] the Dynamic Object Search Test,[96] the TVPS-UL,[42] the Lowenstein Occupational Therapy Cognitive Assessment,[57] the Rivermead Perceptual Assessment Battery,[32,103] the Minnesota Paper Form Board Test,[66] and the Hooper Visual Organization Test[53]—could be used to assess global areas of visual processing and perceptual functioning.

3. How would you assist Walt in achieving his occupational performance goals using remedial and adaptive approaches for his perceptual dysfunction?
   To assist Walt in achieving his occupational performance goals of submitting a painting to a local art gallery, playing with his children, driving, and regaining computer skills in preparation for resuming part-time work as a graphic artist at an architectural firm, the therapist would need to use a combination of remedial and adaptive approaches to treat his perceptual impairments. This chapter outlines a variety of intervention possibilities for Walt. The evidence shows that the most successful outcomes for treating visual perceptual impairments are through occupation-based

activities that have meaning and offer the client the opportunity to generalize functional skills to multiple contexts through the remediation and adaptation of perceptual dysfunction.[33,68,76,77,109]

Review Questions

1. Describe the effects of visual perception, visual-spatial perception, tactile perception, body schema perception, and motor perception on occupational performance.
2. Compare the advantages and disadvantages of formal perceptual testing and functional assessment in the context of occupational performance.
3. Describe one assessment used to test perceptual impairments in the following areas: visual perception, visual-spatial perception, tactile perception, body schema perception, and motor perception.
4. Describe the two approaches to treatment of perceptual deficits, and give one example of an occupational therapy intervention for each.
5. Describe an intervention for each of the following types of perceptual dysfunction: visual perception, visual-spatial perception, tactile perception, body schema perception, and motor perception.

Evaluation and Treatment of Limited Occupational Performance Secondary to Cognitive Dysfunction

Glen Gillen

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, the student or practitioner will be able to do the following:

1. Understand the interplay between cognition and performance in areas of occupation.
2. Choose appropriate standardized, reliable, and ecologically valid tools to measure baseline cognitive status and client progression.
3. Understand the impact of impaired client factors and performance skills on performance in areas of occupation.
4. Develop an evidence-based treatment plan to maximize participation in chosen occupations for individuals with cognitive dysfunction.

KEY TERMS

Anterograde amnesia
Areas of occupation
Arousal
Attention
Attentional switching or alternating attention
Awareness deficits
Client-centered approach
Cognitive Orientation to Daily Occupational Performance (CO-OP)
Cognitive rehabilitation/retraining model
Declarative memory
Distractibility
Divided attention
Dynamic Interactional Model
Dysexecutive syndrome
Ecological validity
Episodic memory
Explicit memory
Field-dependent behavior
Implicit memory
Long-term memory (LTM)
Metacognition
Metamemory
Neurofunctional approach
Nondeclarative memory
Procedural memory
Prospective memory
Quadraphonic approach
Retrograde amnesia
Selective attention
Self-awareness
Semantic memory
Short-term memory
Sustained attention (vigilance)
Task-oriented approach
Unilateral neglect
Working memory

Threaded Case Study

Jane, Part 1

Jane, age 28, is 6 months from completing her master's degree in social work. She was recently married and lives in a ranch-style house in the suburbs. Approximately 1 week ago, she told her husband, Gary, that she was feeling "off." Later in the day she told him that she had the worst headache of her life (ie, a "thunderclap headache"). She began vomiting and, according to Gary, became confused, so he took her to the hospital. The medical team determined that Jane had sustained a subarachnoid hemorrhage secondary to a ruptured cerebral aneurysm. She had emergency surgery, which involved a craniotomy and clipping of the aneurysm. On postoperative day 8, she was transferred to the brain injury rehabilitation unit at the hospital.

Jane's occupational profile was determined her first day on the rehabilitation unit through interviews with Jane (who was quite drowsy and distracted), Gary, and Jane's sister, Paula. Gary described Jane as “fiercely independent” and reluctant to ask for help. It was determined that, in addition to being a “grade A graduate student,” Jane had shared housekeeping responsibilities with Gary, maintained the family garden, was an avid reader of fiction, was responsible for paying the monthly bills online, and loved to cook. Currently Jane could not participate fully in any of these occupations. Her biggest goal has been graduating on time. She has spent a tremendous amount of time and money getting through graduate school. Also, since high school she has been a volunteer working with impoverished children in urban areas. Gary stated that Jane was pursuing a social work degree to build her skills and “give her credibility,” so that she could continue to serve these children.

Gary and Paula expressed concern that Jane did not know what day it was, did not remember who had visited earlier in the day, and was slow to respond to questions, to which she sometimes gave inaccurate answers. During the interviews, Jane spent much of the time sleeping. She did not know why she could not “just go home.”

Critical Thinking Questions

1. How would you structure Jane's initial evaluation to determine the reasons she cannot currently engage in the occupations meaningful to her? What assessments would you choose, and how would you prioritize them?

2. What are appropriate goals for Jane?

3. What interventions would you use to ensure that Jane meets her initial goals? What is the starting point for intervention?

Cognition and Occupational Therapy

The American Occupational Therapy Association (AOTA) asserts that occupational therapists and occupational therapy assistants, through the use of occupations and activities, facilitate individuals' cognitive functioning to enhance occupational performance, self-efficacy, participation, and perceived quality of life. Cognition is integral to effective performance across the broad range of daily occupations such as work, educational pursuits, home management, and play and leisure. Cognition also plays an integral role in human development and in the ability to learn, retain, and use new information in response to changes in everyday life.

American Occupational Therapy Association[4]

Occupational therapy is one of several professions (eg, psychology, psychiatry, neuropsychology, speech-language pathology, and neurology) involved in working with those who are cognitively impaired. However, the approach of occupational therapy to this area of practice is unique and differentiated from other disciplines.[4] The clinical focus of what most professions call cognitive rehabilitation or working on cognition is better described by occupational therapists (OTs) as the process of improving participation and quality of life for individuals with cognitive impairments. In terms of maintaining this unique focus, the reader should consider the following points related to the process and domain of the practice of occupational therapy as they relate to this area of practice.

- Evaluations and assessments should focus on clients' performance of relevant occupations. Simultaneously (as described later), the OT documents what impairment or patterns of impairment in client factors and performance skills are interfering with occupational performance and participation.[11]
- Goals should be related to improving performance in **areas of occupation**, as described by the current version (2014) of the OT Framework, "Occupational Therapy Practice Framework: Domain and Process," third edition (OTPF-3).[3]
- Interventions should consist of primarily graded relevant occupations being performed in natural contexts.
- The outcomes of OT intervention for individuals with cognitive impairment should document improved performance in areas of occupation.

Although these points may seem obvious, until recently this area of OT practice focused primarily on impairments in client factors, and the focus of intervention involved the use of contrived "cognitive tasks." Outcomes were measured on the basis of tests of cognition that were not related to daily performance. It was assumed that remediation of an identified impairment or impairments would generalize into the ability to perform meaningful, functional activities. In general, this assumption has not been supported by empirical research.[43] It has become clear that this approach is not consistent with current approaches to occupational therapy.[3] Current practice embraces interventions that focus on strategies for living independently, with a purpose, and with improved quality of life, despite the presence of cognitive impairments. Likewise, outcome measures that focus on documenting improved functioning outside a clinic environment and those that include test items focused on performing functional activities are being embraced.[43] This chapter focuses on areas of occupation, client factors, and performance skills[3] and their relationships (Table 26.1).

TABLE 26.1

Summary of the OTPF-3 Domains Related to Cognition and Occupation

Domain	Examples
Performance in areas of occupation	Activities of daily living (ADLs), instrumental activities of daily living (IADLs), education, work, play, leisure, rest and sleep, and social participation
Client factors (body functions)	**Specific Mental Functions**
	• Higher level cognitive: Judgment, concept formation, executive functions, metacognition, cognitive flexibility, insight • Attention: Sustained, selective, and divided • Memory: Short-term, long-term, working memory • Perception: Discrimination of sensations • Thought: Control and content of thought, awareness of reality versus delusions, logical and coherent thought
	Global Mental Functions
	• Consciousness: State of awareness and alertness

	• Orientation: Orientation to person, place, time, self, and others • Temperament and personality: Extroversion, introversion, agreeableness, conscientiousness, emotional stability, openness to experience, self-control, self-expression, confidence, motivation, impulse control, appetite
Performance skills	*Process skills:* Observed as a person (1) selects, interacts with, and uses task tools and materials; (2) carries out individual actions and steps; and (3) modifies performance when problems are encountered. Examples include pace, heeds, attends, chooses, uses, handles, inquirers, initiates, continues, sequences, terminates, search/locates, and gathers.

Adapted from the American Occupational Therapy Association: Occupational therapy practice framework: domain and process, ed 3, *Am J Occup Ther* 68:S1–S48, 2014.

Overview of Models Guiding the Practice of Occupational Therapy

Various models that guide this OT practice area have been described in the literature. (The reader is referred to Katz for a comprehensive description of these models.[54])

A common theme in OT practice addressing cognitive impairment is maintaining a client-centered approach when providing rehabilitation services. As Law et al.[61] noted, such an approach "embraces a philosophy of respect for, and partnership with, people receiving services. A **client-centered approach** fosters an active partnership where the client joins with the OT to design and implement an intervention program to best meet the client's unique needs."

Van den Broek[117] specifically recommended using a client-centered approach as a way to enhance rehabilitation outcomes. He stated that treatment failure may occur secondary to practitioners focusing interventions on what they *believe* the client needs, rather than what the client *actually* wants. Another argument for using a client-centered approach to guide the focus of intervention in cognitive impairment is that the interventions typically used for individuals with cognitive dysfunction are notoriously difficult to generalize to other real-world settings and situations. For example, strategies taught to accomplish a specific task (eg, using an alarm watch to maintain a medication schedule for those with memory loss) will not necessarily generalize or "carry over" to another task, such as remembering therapy appointments. Finally, in a large number of clients, the level of brain damage precludes generalizing of learned tasks.[74] This issue of task specificity related to treatment interventions must always be considered by practitioners working with clients who have cognitive dysfunction. A client-centered approach helps ensure that the outcomes, goals, and tasks used as the focus of therapy are at least relevant, meaningful, and specific to each *client,* in addition to the *caretaker* or *significant others,* despite their potential lack of generalizability in individuals with cognitive impairment.

Dynamic Interactional Model

The **Dynamic Interactional Model** views cognition as a product of the interaction among the person, activity, and environment.[113] Therefore, performance of a skill can be promoted by changing either the demands of the activity, the environment in which the activity is carried out, or the person's use of particular strategies to facilitate skill performance.[113,114] Toglia described several constructs associated with this model, including the following:

- Structural capacity, or physical limits in the ability to process and interpret information
- Personal context, or characteristics of the person, such as coping style, beliefs, values, and lifestyle
- **Self-awareness**, or understanding one's own strengths and limitations, in addition to metacognitive skills, such as the ability to judge the demands of tasks, evaluate performance, and anticipate the likelihood of problems
- Processing strategies, or underlying components that improve the performance of tasks, such as attention, visual processing, memory, organization, and problem solving
- The activity itself with respect to its demands, meaningfulness, and how familiar the activity is
- Environmental factors, such as the social, physical, and cultural aspects

Toglia summarized her conclusions in this way:

To understand cognitive function and occupational performance, one needs to analyze the interaction among person, activity, and environment. If the activity and environmental demands change, the type of cognitive strategies needed for efficient performance changes as well. Optimal performance is observed when there is a match between all three variables. Assessment and treatment reflect this dynamic view of cognition.[113]

This approach may be used with adults, children, and adolescents.

Toglia used the Dynamic Interactional Model to develop the Multicontext Treatment Approach.[113,114] Combining remedial and compensatory strategies, this approach focuses on teaching a particular strategy to perform a task and practicing this strategy across different activities, situations, and environments over time. Toglia summarized the components of this approach:

- Awareness training or structured experiences should be used in conjunction with self-monitoring techniques so that clients may redefine their knowledge of their strengths and weaknesses.
- A personal context strategy should be used. The choice of treatment activities is based on the client's interests and goals. Particular emphasis is placed on the relevance and purpose of the activities. Managing monthly bills may be an appropriate activity for a single person living alone, whereas crossword puzzles may be used as an activity for a retiree who previously enjoyed this activity.
- Processing strategies should be practiced during a variety of functional activities and situations. (Toglia defines processing strategies as strategies that help a client control cognitive and perceptual symptoms such as distractibility, impulsivity, inability to shift attention, disorganization, attention to only one side of the environment, or a tendency to overly focus on one part of an activity.)
- Activity analysis should be used to choose tasks that systematically place increased demands on the ability to generalize strategies that enhance performance.
- Transfer of learning occurs gradually and systematically as the client practices the same strategy during activities that gradually differ in physical appearance and complexity.
- Interventions should occur in multiple environments to promote generalization of learning.

Quadraphonic Approach

The **quadraphonic approach** was developed by Abreu and Peloquin[1] for use with individuals who were cognitively impaired after brain injury. This approach is described as including both a “micro” perspective (a focus on the remediation of subskills, such as attention and memory) and a “macro” perspective (a focus on functional skills, such as activities of daily living [ADLs] and leisure activities). The approach supports the use of remediation and compensatory strategies.

The micro perspective incorporates four theories:

1. The *teaching-learning theory* describes how clients use cues to increase cognitive awareness and control.

2. The *information processing theory* describes how an individual perceives and reacts to the environment. Three successive processing strategies are described, including detection of a stimulus, discrimination and analysis of the stimulus, and selection and determination of a response.

3. The *biomechanical theory* explains the client's movement, with an emphasis on integration of the central nervous system (CNS), musculoskeletal system, and perceptual-motor skills.

4. The *neurodevelopmental theory* addresses the quality of movement.

The macro perspective involves the use of narrative and functional analysis to explain behavior based on the following four characteristics:

1. Lifestyle status or personal characteristics related to performing everyday activities

2. Life stage status (eg, childhood, adolescence, adulthood) and marriage

3. Health status (eg, presence of premorbid conditions)

4. Disadvantage status, or the degree of functional restrictions resulting from impairment

Cognitive Rehabilitation/Retraining Model

The **cognitive rehabilitation/retraining model** is used for adolescents and adults with neurological and neuropsychological dysfunction.[12] Based on neuropsychological, cognitive, and neurobiologic rationales, this model focuses on cognitive training by enhancing clients' remaining skills and teaching cognitive strategies, learning strategies, or procedural strategies.

Neurofunctional Approach

The **neurofunctional approach** is applied to those with severe cognitive impairments secondary to brain injuries.[38,39] This approach focuses on training clients in highly specific compensatory strategies (not expecting generalization) and specific task training. Contextual and metacognitive factors are specifically considered during intervention planning. The approach does not target the underlying cause of the functional limitation, but rather focuses directly on retraining the skill itself.

Task-Oriented Approach

Although usually discussed in relation to motor control dysfunction, the **task-oriented approach** has potential application for individuals with cognitive dysfunction.[84] Mathiowetz[69] has discussed this approach in detail. Summary points related to the adoption of a framework for this approach include evaluating the following areas in the order shown[69,70]:

1. Role performance (social participation): Identify past roles and whether they can be maintained or need to be changed; determine how future roles will be balanced

2. Occupational performance tasks (areas of occupation)

3. Task selection and analysis: Determine the client factors, performance skills and patterns, and/or contexts and activity demands that limit or enhance occupational performance

4. Person (client factors, performance skills and patterns): Cognitive (orientation, attention span, memory, problem solving, sequencing, calculations, learning, and generalization); psychosocial; and sensorimotor

5. Environment (context and activity demands): Including physical, socioeconomic, and cultural

In terms of intervention, Mathiowetz and Bass-Haugen[70] and Mathiowetz[69] recommended the following:

- Help clients adjust to their role and to limitations in performing tasks.
- Create an environment that uses the common challenges of everyday life.
- Practice functional tasks or close simulations to find effective and efficient strategies for performance.
- Provide opportunities for practice outside therapy time.
- Remediate a client factor (impairment).
- Adapt the environment, modify the task, or use assistive technology.

Cognitive Orientation to Daily Occupational Performance

The **Cognitive Orientation to Daily Occupational Performance (CO-OP)** model was developed for children with developmental coordination disorder. More recently, it has been used with neurological and adult clients with various types of dysfunction.[81] CO-OP is a:

- client-centered problem-solving and
- performance-based intervention

The goal is performance acquisition through a process of guided discovery of strategies that enable learning of skills. Strategies may be global and provide a general method of approaching any problem (ie, *goal, plan, do, check*), or they may be domain specific (ie, relating to one area of dysfunction only, such as attention to doing).

Choosing Appropriate Assessments

It is important to reiterate that OT outcomes should be focused on areas of occupation. We will use Jane's case to illustrate this point.

Potential (noninclusive) outcomes for Jane, based on the OT Framework, may include the following[3]:

- Outcome 1: After occupational therapy, Jane has improved her scores on a standardized memory scale (decreased impairment in client factors), but the changes are not detected on measures of instrumental activities of daily living (IADLs) and quality of life (stable performance in areas of occupation).
- Outcome 2: After occupational therapy, Jane has no detectable changes on the standardized memory scale (stable impairment in client factors), but changes are detected on measures of IADLs and quality of life (improved performance in areas of occupation).
- Outcome 3: After occupational therapy, Jane has detectable changes on the standardized memory scale (decreased impairment in client factors), and changes are detected on measures of IADL and quality of life (improved performance in areas of occupation).

Of the three outcome scenarios, outcome 1 is the least desirable. In the past this type of outcome may have been considered successful (ie, "Jane's memory has improved"). This outcome may be indicative of an intervention plan that is overly focused on attempts to remediate memory skills (eg, memory drills, computerized memory programs) without consideration of generalization to real-life scenarios. If a change at the impairment level of function does not translate or generalize to improved ability to engage in meaningful activities, participate successfully in life roles, or enhance quality of life, the importance of the intervention needs to be reconsidered. Outcomes 2 and 3 are more clinically relevant and arguably more meaningful to Jane and her family, and they represent more optimal results of structured OT services. Outcome 2 may have been achieved by focusing interventions on Jane's chosen tasks. Interventions such as teaching compensatory strategies, including the use of assistive technology, may have been responsible for this outcome. Jane is able to engage in chosen tasks despite stable impairments in memory.

Outcome 3 represents improvement (decreased impairment, improved performance of activities, and improved quality of life) across multiple health domains. Although this outcome may be considered the optimal result, the relationships among the three measures are not clear. Clinicians may assume that the improved status detected by the standardized measure of memory was also responsible for Jane's improved ability to perform household chores and child care. This reasoning is not necessarily accurate, however. The changes in the health domains may in fact occur independently of each other. In other words, Jane's improved ability to manage her household after participating in treatment may be related to the fact that the interventions specifically included teaching Jane strategies to manage her household. Similar to outcome 2, this positive change may have occurred with or without a documented improvement in memory skills.

When choosing assessments, the OT should place particular emphasis on the **ecological validity** of an instrument. This term refers to the degree to which the cognitive demands of the test theoretically resemble the cognitive demands in the everyday environment (this is sometimes called *functional cognition*). A test with high ecologic validity identifies difficulty performing real-world functional and meaningful tasks. Ecologic validity also refers to the degree to which existing tests are empirically related to measures of everyday functioning through a statistical analysis.[22]

In terms of a starting point (ie, which areas of occupation should serve as the basis for assessment), as stated earlier, a client-centered approach is necessary. This can be assessed formally by using the Canadian Occupational Performance Measure[61] (COPM) or informally through an interview with the client and/or significant others. The clinical context must also be considered. OTs working in an acute care setting may be focused on areas such as basic mobility (moving in bed and transfers), bedside self-care, IADLs that can be performed at the bedside (eg, money management, medication management), and sedentary leisure activities (eg, reading fiction, doing crossword puzzles). Those working in the home setting may focus on intervention related to community reintegration, more complex IADLs, and returning to work. The OT uses observation skills to determine which underlying cognitive (and other) deficits are interfering with functional performance by using error analysis. In other words, errors in performance (occupational errors[8]) are allowed to occur as long as they are safe and not severe enough to halt performance. Árnadóttir[9] gives the following example of this technique related to observing errors during grooming and hygiene:

Dysfunctions of global and specific mental functions with an effect on grooming and hygiene tasks include ideational apraxia, organization and sequencing problems related to activity steps, impaired judgment, decreased level of arousal, lack of attention, distraction, field dependency, impaired memory, and impaired intention. Ideational apraxia may appear during grooming and hygiene activities; an individual may not know what to do with the toothbrush, toothpaste, or shaving cream or may use these items inappropriately (eg, smear toothpaste over the face or spray the shaving cream over the sink). An individual with organization and sequencing difficulties only may have the general idea of how to perform but may have problems timing and sequencing activity steps. Such a client may not complete one activity step before starting another or may perform activities too quickly as a result of problems in timing activity steps, resulting in a poor performance.

Lack of judgment may appear as an inability to make realistic decisions based on environmental information, providing that perception of those impulses is adequate. An individual so affected may leave the sink area without turning off the water taps or may leave the washcloth in the sink, not noticing that the water level is increasing and threatening to overflow.

Field dependency has an attention component and a perseveration component. Individuals with this dysfunction may be distracted from performing a particular task by specific stimuli that they are compelled to act on or incorporate into the previous activity. For example, if an individual with field dependency sees a denture brush while washing the hands, that person may incorporate the brush into the activity and scrub the hands with the denture brush.

An individual with short-term memory problems may not remember the sequence of activity steps or instructions throughout activity performance. The therapist may have to remind an individual several times to comb the hair, even though the individual does not have comprehension problems.

Lack of initiation may occur during performance of grooming and hygiene tasks; the individual may sit by the sink without performing, even after being asked to wash. With repeated instructions to begin, the individual may indicate that the activity is about to start, yet nothing happens. After several such incidents and if the therapist asks for a plan, the individual may state a detailed plan of action in which the water will be turned on, the washcloth will be picked up and put under the running water, soap will be put on the cloth, and washing will begin. The individual has a plan of action but cannot start the plan. This impairment also may be associated with ideational problems.

Traditionally, practitioners and researchers involved in working with those who are cognitively impaired use standardized measures of cognitive impairment (ie, standardized tests to determine impairments in attention, memory, executive functions, and so on) as the primary outcome measure to document the effectiveness of interventions. These measures tend to be categorized as "pen and paper" or "tabletop" assessments, and they have low ecologic validity compared to assessments that use relevant occupations in naturalistic contexts. Although standardized assessments are one important level of measurement, it is critical that clinical programs and research protocols not only include, but also *focus on* measures of activity, participation, and quality of life as key outcomes. As stated, positive changes in these measures are more relevant than an isolated change in an impairment measure; the change in impairment must be associated with a change in other health domains. The individual receiving services, family members, and third-party payers are all likely to be more satisfied with changes in these arguably more meaningful levels of function. Table 26.2 suggests instruments for documenting successful clinical and research outcomes related to improving function in those with functional limitations secondary to the presence of cognitive impairments. (For a thorough review of performance-based measures, see Law et al.[62])

TABLE 26.2

Examples of Instruments for Documenting Improved Participation in Individuals With Functional Limitations Secondary to Cognitive Impairments and Ineffective Performance Skills

Instrument	Description
Standardized, valid, and reliable measures of quality of life	Measures life satisfaction and well-being. Examples include the Medical Outcomes Study 36-Item Short-Form Health Survey, World Health Organization Quality of Life Scale, and Reintegration to Normal Living.
Standardized, valid, and reliable	Measures performance in areas of occupation. Examples include the Functional Independence Measure (FIM), the (Modified) Barthel Index, and

measures of areas of occupation (eg, BADLs, IADLs, leisure, work)	the Lawton Instrumental Activities of Daily Living Scale.
Standardized, valid, and reliable measures of participation	Measures involvement in life situations. Examples include the Activity Card Sort, Community Integration Questionnaire, and the Canadian Occupational Performance Measure.
Comprehensive Measures to Simultaneously Assess Activity/Participation and Underlying Impairments or Subskills	
Árnadóttir OT-ADL Neurobehavioral Evaluation (more recently referred to as the ADL-Focused Occupation-Based Neurobehavioral Evaluation [A-ONE])[8-11]	A performance-based tool that uses structured observations of upper and lower body dressing, grooming, hygiene, feeding, transfers, mobility, and communication to detect underlying impairments that interfere with function. Examples of impairments include decreased organization and sequencing, short- and long-term memory loss, decreased alertness and arousal, impaired attention, performance latency, confusion, perseveration, distractibility, and impaired initiation, insight, and judgment.
Assessment of Motor and Process Skills (AMPS)[33]	A client-centered performance assessment of both BADLs and IADLs with emphasis on IADL tasks. The AMPS entails the client choosing to perform two or three tasks in collaboration with a therapist from a list of 125 standardized tasks. It evaluates motor and processing skills that affect function. Processing skills are observable actions that a person uses to (1) select, interact with, and use tools and materials; (2) carry out individual actions and steps; and (3) modify performance when problems are encountered. Processing skills should not be confused with cognitive skills.
Brief Measure of Cognitive Functional Performance	
Kettle Test[51]	A brief, performance-based assessment of an IADL task designed to tap into a broad range of cognitive skills. The task consists of making two hot beverages that differ in two ingredients (one for the client and one for the therapist). The electric kettle is emptied and disassembled to challenge problem-solving skills and safety/judgment, and additional kitchen utensils and ingredients are placed as distracters to increase demands on attention.
Assessing Executive Function Impairments	
Executive Function Performance Test (EFPT)[14]	Assesses deficits in executive function during the performance of real-world tasks (cooking oatmeal, making a phone call, managing medications, and paying a bill). The test uses a structured cueing and scoring system to assess initiation, organization, safety, and task completion and to develop cueing strategies. More recently tasks were added to create the Alternate EFPT (aEFPT). These include making pasta, calling a doctor's office, sorting medication into a 7-day pill sorter, and ordering a specific item from a catalog.[48]
Weekly Calendar Planning Activity[116]	The calendar planning activity is a higher level simulated IADL task that involves entering 17 appointments and errands into a weekly schedule. It was designed to be sensitive to the effects of executive dysfunction in that it requires planning, organization, and multitasking abilities. In addition to entering appointments, the person must monitor time, keep track of rules, inhibit distractions, and deal with schedule conflicts.
Multiple Errands Test[2,27,59,100]	A multitasking assessment that challenges multiple executive functions. Tasks include purchasing three items, picking up an envelope from reception, using a telephone, mailing the envelope, writing down four items (eg, price of a candy bar), meeting the assessor, and informing the assessor that the test has been completed.
Executive Function Route-Finding Task[18]	Uses naturalistic observations of route finding to detect dysexecutive symptoms.
Complex Task Performance Assessment[127,128]	An assessment that simulates the task of working in a library. The two primary work tasks are (1) Current Inventory Control and (2) Telephone Messaging. These tasks are administered simultaneously.
Behavioural Assessment of the Dysexecutive Syndrome (BADS)[124]	This battery is designed to assess capabilities typically required in everyday living. It includes six subtests that represent different executive abilities, such as cognitive flexibility, novel problem solving, planning, judgment and estimation, and behavioral regulation. It uses *simulated* everyday tasks.
Assessing Memory Loss	
Rivermead Behavioral Memory Test—Third Edition[126]	An ecologically valid test of everyday memory. Uses *simulations* of everyday memory tasks. Modifications are available for those with perceptual, language, and mobility impairments.
Cambridge Behavioural Prospective Memory Test/Cambridge Prospective Memory Test[47]	An objective test of prospective memory
Assessing Impairments in Attention	
Test of Everyday Attention[94]	Considered an ecologically valid test for various types of everyday attention, such as sustained attention, selective attention, attentional switching, and divided attention. Includes several subtests. It is one of the few tests of attention that *simulates* everyday life tasks. The test is based on the imagined scenario of a vacation trip to the Philadelphia area of the United States.
Moss Attention Rating Scale[50,123]	An observational test of disordered attention that currently includes 22 items. It produces three factor scores and a total score.
Rating Scale of Attentional Behaviour[82]	A short assessment of attention-based impairments that is rated through practitioners' observations of the client's behavior.

BADLs, Basic activities of daily living; *IADLs*, instrumental activities of daily living.

It also is clinically useful to use self-reporting or caregiver reporting measures for clients with cognitive dysfunction. The rationale for this type of assessment is multifold:

- Comparing self-reports with observed performance provides the OT with critical information on the awareness of the severity of impairment and functional status.
- Comparing self-reports and caregiver reports is helpful for getting a "snapshot" of how clients perform in their own environments, which may or may not be congruent with observed performance in an OT clinic.
- It is important that clients and caregivers see benefit from the OT services provided. It is problematic if the OT is documenting improvements that cannot be detected by those to whom services are provided (Table 26.3).

TABLE 26.3

Examples of Self-Reporting and/or Caregiver Reporting Measures

Instrument	Description
Attention Rating and Monitoring Scale[23]	A self-report measure of the frequency of everyday problems related to impairments in attention.
Cognitive Failures Questionnaire[19]	A self-report measure of the frequency of lapses in attention and cognition in daily life. It includes items related to memory, attention, and executive dysfunction.
Prospective Memory Questionnaire[49]	A behaviorally anchored, self-rated evaluation of prospective memory.
Comprehensive Assessment of Prospective Memory[89,95-112,119]	An assessment of prospective memory related to BADLs and IADLs.
Everyday Memory Questionnaire[97,109,110]	A subjective report of everyday memory; a metamemory questionnaire. It is self-reported or reported through a proxy.
Prospective and Retrospective Memory Questionnaire[57,102]	A measure of prospective and retrospective failures in everyday life. It is self-rated or proxy rated. Published norms.
Dysexecutive Questionnaire (part of the Behavioral Assessment of the Dysexecutive Syndrome [BADS] test battery)[20,125]	A 20-item questionnaire sampling everyday symptoms associated with impairments in executive functions. Versions for self-rating and rating by significant others are available.
Behavior Rating Inventory of Executive Function—Adult Version[96]	A measure that documents an adult's executive functions or self-regulation in his or her everyday environment. It includes both a self-report and an informant report.

BADLs, Basic activities of daily living; *IADLs*, instrumental activities of daily living.

Returning to the case study: the OT had access to Jane's acute care medical record. He noted that the day before Jane was transferred to the in-client rehabilitation unit, the neurology resident administered the Mini-Mental State Examination (a brief, 30-item questionnaire used by multiple disciplines to screen for cognitive impairment). She scored 20 of 30, which is indicative of moderate cognitive impairment. Jane had difficulty on the specific items of orientation, attention and calculation, and recall. An assessment required in most in-client rehabilitation units is the Functional Independence Measure (FIM). This tool measures the client's ability to complete specific self-care and mobility tasks, and scoring is based on caregiver burden related to these tasks. The FIM provides information related to *what* tasks Jane requires assistance with. Jane's OT used this opportunity to also document *why* Jane requires assistance with the FIM tasks. He used the error analysis approach described earlier and objectified his findings with the ADL-Focused Occupation-Based Neurobehavioral Evaluation (A-ONE). Jane required minimal physical assistance to *initiate* each FIM task but needed consistent verbal cues to *organize and sequence* the FIM tasks. Additional verbal cues were required to maintain *alertness,* to stay on task secondary to *distractibility,* and to compensate for *short-term memory deficits,* most notably keeping in mind and remembering the tasks the OT had asked her to demonstrate.

Managing Cognitive Dysfunction That Limits Occupational Performance: Assessment and Interventions

The American Occupational Therapy Association (AOTA) has organized the interventions that OTs may use for clients with performance deficits secondary to cognitive impairment into categories, discussed in the following sections.[4]

Global Strategy Learning and Awareness Approaches

Global strategy learning focuses on improving awareness of cognitive processes and assisting clients to develop higher order compensatory approaches (eg, internal problem solving and reasoning strategies), rather than attempting to remediate basic cognitive deficits. This approach enables clients to be able to generalize the application of these compensatory strategies to novel circumstances.

Domain-Specific Strategy Training

Domain-specific strategy training focuses on teaching clients particular strategies to manage specific perceptual or cognitive deficits, rather than being taught the task itself.

Cognitive Retraining Embedded in Functional Activity

In **cognitive retraining**, cognitive processes are addressed in the context of the activity. An example would be working on attention skills while relearning how to use a computer program. The retraining is context specific.

Specific-Task Training

Specific-task training assists clients to perform a specific functional behavior. In specific-task training, the therapist attempts to circumvent the cognitive deficit that hampers performance by teaching an actual functional task. The person can perform the occupation despite having a cognitive impairment.

Environmental Modifications and Use of Assistive Technology

OT intervention involves addressing the complexity of activity demands and altering environmental contexts to enhance the match between the client's abilities and the environmental demands. This includes technology such as cognitive prosthetics (eg, smart phones, pagers, and alarm watches).

Impact of Awareness Deficits on Daily Function

Management of **awareness deficits** may be considered a *foundational* intervention for clients with cognitive dysfunction.[43] Findings from standardized assessments of awareness may dictate the overall management of a client's functional limitations (discussed later). Different terminology and definitions related to limited self-awareness are used in the literature, including lack of insight, lack of or impaired self-awareness or unawareness, anosognosia, and denial. Nonimpaired self-awareness has been defined as "the capacity to perceive the self in relatively objective terms, while maintaining a sense of subjectivity."[87-89] The terms *impaired self-awareness* and *anosognosia* are used interchangeably; Prigatano[86] defined this condition as a clinical phenomenon in which a person "does not appear to be aware of impaired neurological or neuropsychological function, which is obvious to the clinician and other reasonably attentive individuals. The lack of awareness appears specific to individual deficits and cannot be accounted for by hyperarousal or widespread cognitive impairment."

Other authors reserve the term *anosognosia* for describing unawareness of physical deficits only (ie, not including cognitive impairments), such as "anosognosia for hemiplegia" or "anosognosia for hemianopia."

Although impaired self-awareness and anosognosia have clearly been used as overlapping terms in the literature, the term *denial* must be considered separately. Crosson et al.[26] defined psychological denial as “a subconscious process that spares the client the psychological pain of accepting the serious consequences of a brain injury and its unwanted effects on his or her life.” Complicating the matter is the fact that impaired self-awareness and denial may occur together. Differentiation between denial (a psychological method of coping) and neurologically based lack of awareness is difficult because some individuals have both types of clinical manifestations.[88]

The pyramid model of self-awareness was developed by Crosson et al.[26] This model includes three interdependent types of awareness:

1. *Intellectual awareness:* The ability to understand at some level that a function is impaired. At the lowest level, one must be aware that one is having difficulty performing certain activities. A more sophisticated level of awareness is to recognize commonalities between difficult activities and implications of the deficits; it refers to knowing that you have a problem. In the case study, Jane was demonstrating substantial impairment in intellectual awareness on the acute service. Her family reported that she kept repeating, “Why can't I go home? I'm fine.” The OT on the rehabilitation service noted that Jane consistently reported that she understood she had had a “stroke.” In addition, Jane was reporting that “simple” tasks seemed to take a long time and that she keeps “losing her train of thought.” Jane is showing signs of emerging (albeit still severely impaired) intellectual awareness.

2. *Emergent awareness:* The ability to recognize a problem when it is actually happening. Intellectual awareness is considered a prerequisite to emergent awareness in this model because one must first recognize that a problem exists (knowing that you are experiencing a problem when it occurs). Emergent awareness is included in the concept of online awareness or monitoring of performance during the actual task.

3. *Anticipatory awareness:* The ability to anticipate that a problem will occur as the result of a particular impairment in advance of actions. Anticipatory awareness is included in the concept of online awareness.

Individuals with brain injury or cognitive deterioration may be impaired across all three awareness domains[75] or may have better skills in one or more domains of awareness. Crosson et al.[26] further applied this model to the selection of compensatory strategies and categorized compensations appropriate to each type of awareness. They classified compensatory strategies according to the way their implementation is triggered:

- *Anticipatory compensation:* Applied only when needed. This term refers to implementation of a compensatory technique by anticipating that a problem will occur (ie, requires anticipatory awareness). An example is a person who needs groceries for the week and who is aware that busy environments present a greater challenge to his existing memory and attention deficits; therefore, he decides to defer shopping until 7 p.m., when the local store is not as busy.
- *Recognition compensation:* Also applied only when needed. This term refers to strategies that are triggered and implemented because a person recognizes that a problem is occurring (ie, requires emergent awareness). An example is a client who asks a person to speak more slowly because she realizes she is not processing information quickly enough and is having difficulty following the conversation.
- *Situational compensation:* Applies to compensatory strategies that can be triggered by a specific type of circumstance in which an impairment may affect function. The client is taught to use these strategies consistently, every time a particular event occurs. An example is a student with memory impairments after a traumatic brain injury (TBI) who tape-records all lectures in class. Although recording may not be necessary at times (eg, for a particularly slow-moving lecture with limited content), the strategy is used anyway because this type of compensation does not rely on the client's judgment. Intellectual awareness is necessary to use this strategy because one must be aware that a deficit exists to integrate a strategy for overcoming it.
- *External compensation:* Triggered by an external agent or involves an environmental modification. Examples include alarm watches, posted lists of steps related to meal preparation, and so on.

This pyramid model was constructively criticized and expanded on by Toglia and Kirk.[115] Their model, the Dynamic Comprehensive Model of Awareness, suggests a dynamic rather than a hierarchic relationship. The model proposes a dynamic relationship among knowledge, beliefs, task demands, and the context of a situation based on the concept of **metacognition**. This model differentiates between metacognitive knowledge, or declarative knowledge, and beliefs about one's abilities before performing the task (incorporating aspects of intellectual awareness) and online monitoring and regulation of the performance of a task (ie, during task performance), which integrates aspects of emergent and anticipatory awareness.

Fleming and Strong[35] discussed a three-level model of self-awareness:

1. Self-awareness of the injury-related deficits themselves, such as cognitive, emotional, and physical impairments (ie, knowledge of deficits)

2. Awareness of the functional implications of deficits for independent living

3. The ability to set realistic goals; the ability to predict one's future state and prognosis

Most authors recommend that self-awareness be evaluated *before* an intervention program is initiated that focuses on retraining living skills. The findings from standardized evaluations of self-awareness will clearly guide the choices of intervention. For example, a person who exhibits insight into an everyday memory deficit may be a candidate for teaching compensatory strategies, such as using a diary or notebook (discussed later). However, a person who does not realize that he or she has severe unilateral neglect (a lateralized attention deficit) may not be able to learn compensatory strategies and thus may require environmental modifications (eg, all clothing hung on the right side of the closet) to improve everyday function.

In addition, ascertaining the level of insight into a disability is one factor that may determine how motivated a client is to participate in the rehabilitation process. In the most simplistic interpretation, the client must be aware and concerned about a deficit in everyday function to be motivated to participate in what may be a long and difficult rehabilitation process. Returning to the case study, Jane has goals of returning to school and engaging in complex ADLs on returning home. It is imperative that Jane continue to gain insight so that she can implement strategies to compensate for her persistent deficits. Examples of strategies to return to school may include tape-recording lectures, having a note-taker assigned so Jane can fully attend to the lecture, switching to a part-time school schedule, and using electronic aids to organize her day and assignments.

A variety of assessment measures are typically recommended for ascertaining a person's level of self-awareness, including questionnaires (self or clinician rated); interviews; rating scales; functional observations; comparisons of self-ratings and ratings made by others (eg, significant others, caretakers, or rehabilitation staff); and comparisons of self-ratings and ratings based on objective measures of function or cognitive constructs. No method is universally accepted for assessing the construct of awareness or lack thereof. In addition, naturalistic observations can provide further information related to how decreased awareness is interfering with the performance of everyday tasks. Table 26.4 presents examples of standardized assessments of awareness.

TABLE 26.4

Examples of Standardized Tests of Awareness

Test	Description
Assessment of Awareness of Disability[60]	An assessment based on a semistructured interview that is used in conjunction with the Assessment of Motor and Process Skills (AMPS). It consists of general and specific questions related to the activity of daily tasks, and the interview is conducted after performance of the AMPS.
Awareness Interview[7]	A tool used to evaluate awareness of cognitive and motor defects after cerebral infarction, dementia, or head trauma. Operationally, the authors defined unawareness as a discrepancy between the client's opinion of his or her abilities in the interview and his or her abilities as measured by neuropsychological and neurological examinations.
Awareness Questionnaire[101]	A measure of impaired self-awareness after traumatic brain injury (TBI). The instrument consists of three forms (one form is completed by the client, one by a significant other, and one by a clinician). The self-rated and family/significant others forms contain 17 items, and the clinician form contains 18 items. The client's ability to perform various tasks after the injury, compared with before the injury, is rated on a 5-point scale.
Driving Awareness Questionnaire (DriveAware)[55]	A tool consisting of five questions; the client's responses are compared with the clinician's ratings according to a structured marking guide. The clinician's rating is based on information in the referral and observation of performance on other off-road tests.
Client Competency Rating Scale (PCRS)[85]	A tool that evaluates self-awareness after TBI. It is a 30-item self-report instrument that uses a 5-point Likert scale (1 = can't do and 5 = can do with ease) to self-rate the degree of difficulty in a variety of tasks and functions. More recently, Borgaro and Prigatano[17] developed a modified yet still psychometrically sound version of the PCRS for use in an acute in-client neurorehabilitation unit. This version retains 13 items from the original PCRS.
Self-Awareness of Deficits Interview[35]	An interviewer-rated structured interview is used to obtain quantitative and qualitative data on the status of self-awareness after brain injury. Specifically, it assesses a client's level of intellectual awareness (the ability to understand that a function is decreased from the premorbid level and to recognize the implications of the deficits).
Self-Regulation Skills Interview[78]	A semistructured, clinician-rated interview based on the model by Crosson et al.[26] discussed earlier. The tool includes six questions that assess metacognitive or self-regulation skills.

Although most researchers and scholars agree that interventions focused on improving awareness are critical for maximizing rehabilitation and that greater awareness of deficits is associated with better treatment outcomes,[76] others have documented functional changes through task-specific treatment without concurrent improvement in awareness. Overall, there is a lack of empirical studies that have examined the effectiveness of various interventions aimed at improving awareness. In addition, many of the published studies have not included functional outcomes. As a starting point in managing awareness, the entire team should encourage clients to predict their level of performance before any observed performance in areas of occupation. Those with brain injury or cognitive deterioration most often *underestimate* their level of cognitive impairment and *overestimate* their level of function. Practitioners should leave time at the end of each session to compare actual performance with predicted performance. This comparison of predicted versus actual performance is critical and should be done with all functional tasks. Examples of predictions include questions such as, "How long will the task take?" "How many times will you need to ask for help?" "How many times will the therapist need to physically help you?" and "How many times will the therapist need to verbally help you?" The goal is to reduce the discrepancy between the prediction and the actual performance.

It is important for the OT to remember that the verbal or physical cues used to support participation in meaningful occupations are not provided simply to support the completion of tasks. Cues are used to facilitate insight and to encourage the client to solve problems by developing new strategies to overcome deficit areas (Table 26.5).

TABLE 26.5
Prompts to Promote Awareness of Errors During Functional Activities

Prompt	Rationale
"How do you know this is the right answer/procedure?" or "Tell me why you chose this answer/procedure."	Refocuses the client's attention to task performance and error detection. Can the client self-correct with a general cue?
"That's not correct. Can you see why?"	Provides general feedback about an error but is not specific. Can the client find the error and initiate correction?
"It is not correct because …"	Provides specific feedback about an error. Can the client correct the error when it is pointed out?
"Try this [strategy]" (eg, going slower, saying each step aloud, verbalizing a plan before starting, or using a checklist)	Provides the client with a specific, alternative approach. Can the client use the strategy given?
The task is altered. "Try it another way."	Modifies the task by one parameter. Can the client perform the task? Begin again with grading of prompting described previously

From Brockmann-Rubio K, Gillen G: Treatment of cognitive-perceptual impairments: a function-based approach. In Gillen G, Burkhardt A, editors: *Stroke rehabilitation: a function-based approach,* ed 2, St Louis, 2004, Mosby, pp 427–446. Also, modified from Toglia JP: Attention and memory. In Royeen CB, editor: *AOTA self-study series: cognitive rehabilitation,* Rockville, MD, 1993, American Occupational Therapy Association; and Toglia JP: Generalization of treatment: a multicontext approach to cognitive perceptual impairment in adults with brain injury, *Am J Occup Ther* 45:505, 1991.

Tham et al.[111] developed an intervention to improve awareness related to the effect of neglect (a lateralized attention deficit) on functional performance. Purposeful and meaningful (for the participant) daily occupations were used as therapeutic change agents to improve awareness of disabilities. Specific interventions included encouraging participants to choose motivating tasks as the modality of intervention and discussions about task performance. Examples included the following:

- Encouraging participants to describe their anticipated difficulties
- Linking their earlier experiences of disability to new tasks
- Planning how they would handle new situations
- Asking participants to evaluate and describe their performance
- Asking participants to think about whether they could improve their performance by performing the task in another way
- Providing feedback about the difficulties observed, including verbal feedback, discussion, and the use of compensatory techniques that could improve performance of the task
- Providing opportunities for further practice of the task by using newly learned compensatory techniques
- Using video feedback to improve awareness
- Using interviews to reflect on and heighten awareness

With this approach, awareness of disabilities and ADL ability improved in all four participants; unilateral neglect decreased in three participants; and sustained attention improved in two participants. The authors concluded that training to improve awareness of disabilities might improve the ability to learn the use of compensatory techniques for performing ADLs by clients with unilateral neglect.

Fleming et al.[34] completed a pilot study examining the effect of an occupation-based intervention program on the self-awareness and emotional status of four men after acquired brain injury. Each participant received an individualized program that focused on the performance of three client-chosen occupations (eg, writing a job application, budgeting, meal preparation, playing lawn bowling, cooking with one hand) for which they had decreased awareness, according to significant others. The intervention was based on Toglia's multicontextual approach, described earlier.[112] Techniques included providing a nonthreatening environment to build positive therapeutic alliances; having the participants analyze their underlying skills, self-predict, and self-evaluate before and after the occupation; setting "just the right challenge"; supported and structured occupational performance; education on brain injury; timely and nonconfrontive verbal feedback in a sandwich format (negative comments are preceded and followed by positive feedback); and video feedback.

Repeated measures of participants' self-awareness and emotional status were performed before and after intervention and analyzed descriptively. The authors found that their results indicated preliminary support for the effectiveness of the program in facilitating participants' self-awareness, although baseline and follow-up data indicated a complex and inconsistent picture. Of note is that slightly increased anxiety was found to accompany improvements in participants' self-awareness in all four cases, and slight increases in depressive symptoms were noted in three participants. These findings are consistent with the literature discussed earlier that focused on the relationships between emotional status and awareness and on the interconnections between denial and self-awareness (Box 26.1).

Box 26.1

Suggestions for Improving Awareness

- Have clients perform tasks of interest and then provide them with feedback about their performance. The goal is to have clients monitor and observe their behavior more accurately so that they can make more realistic predictions about future performance and also gain insight into their strengths and weaknesses.
- Encourage self-questioning during a task and self-evaluation after a task (eg, "Have I completed all of the steps needed?").
- Provide methods of comparing functioning before and after injury to improve awareness.
- Use prediction methods. Have the client estimate various task parameters (eg, difficulty, time needed for completion, number of errors, and/or amount of assistance needed before, during, or after a task) and compare those estimates with the actual results.
- Help clients develop and appropriately set their personal goals.
- Allow clients to observe their own performance during specific tasks (ie, via videotape) and compare the actual performance with what the client had stated he or she could do.
- Use group treatments and peer feedback, which allow one person to receive feedback on performance from multiple individuals.
- Use role reversals: the therapist performs the task and makes errors, and the client must detect the errors.
- Develop a strong therapeutic alliance that is open and based on trust—this is critical in managing both denial and lack of self-awareness. Coach clients to make better choices and understand how defensive strategies affect daily function.
- Use familiar tasks, graded to match the client's cognitive level ("just the right challenge"), to develop self-monitoring skills and error recognition.

- Educate both the client and family members or significant other about the client's deficit areas.
- Integrate experiential feedback experiences. This method (also called "supported risk taking" and "planned failures") is used during daily activities to gently demonstrate impairments. The therapist must provide high levels of support during this intervention.
- Monitor for increased signs of depression and anxiety as awareness increases.
- Increase mastery and control during performance of daily tasks to increase awareness.
- Use emotionally neutral tasks to increase error recognition.
- Use tasks that offer "just the right challenge" to increase error recognition/correction.
- Provide feedback in a sandwich format; that is, negative comments are preceded and followed by positive feedback.

Jane's OT administered the Self Awareness of Deficits Interview. Gary was present for this session. Jane reported that she was not any different now from what she was like before her hospitalization, that her brain injury had not had any effect on everyday life, and that she hoped to be ready to graduate and look for her first job as a social worker in the next 6 months. The findings and ratings were indicative of severely limited self-awareness. The OT consistently used the time needed to complete a task as the prediction that Jane would make before each task. The OT chose time as the predictor because Jane had poor initiation, was disorganized, and repeated steps of the tasks. Such behavior increased the amount of time needed to complete tasks. Jane consistently predicted length of time based on her preinjury status. When the OT compared the predicted time with the actual time, Jane reacted with disbelief. As sessions progressed, Jane began to increase her accuracy in reporting the time needed for each task (increased awareness). As her awareness increased, the OT noted that Jane was frequently teary. The OT notified the team that although Jane was developing a better understanding of her current functional status, she required increased emotional support from the team and monitoring for increased levels of depression and anxiety.

Impact of Attention Deficits on Daily Function

Attention in its various forms is one of the most important and basic functions of the human brain, and it constitutes the basis for other cognitive processes. Integrity of the attention system is considered a prerequisite for all other higher cognitive systems, such as memory, executive functions, and so on.[80] In particular, basic memory functions (eg, working memory) are dependent on intact attention processes.[23] If a person does not attend to incoming information and cannot hold information in mind, information will not be remembered and cannot be used to guide appropriate behavior or successfully complete daily activities.[72] Attention skills serve as a cognitive foundation and are a prerequisite for engaging in most if not all meaningful activities; also, any impairment in attention processes will result in observable difficulties in everyday life, which may in fact reduce quality of life. Terminology related to attention impairments is shown in Table 26.6.

TABLE 26.6

Terms Related to Attention Impairments

Attention is the voluntary control over more automatic brain systems to be able to select and manipulate sensory and stored information briefly or for sustained periods.[79]		
Attention Component	**Definition**	**Functional Examples**
Arousal	A state of responsiveness to sensory stimulation or excitability[122]; it is dependent on a widely distributed neural network, including the prefrontal areas and neurotransmitter systems.[115]	• Decreased responsiveness to incoming visual, auditory, or tactile cues during performance of a task • Requires noxious or extreme sensory stimuli (eg, a cold washcloth applied to the face) to elicit a behavioral response
Selective attention	The type of attention involved in the processing and filtering of relevant information in the presence of irrelevant stimuli[93]; the efficiency with which people can search and focus on specific information while ignoring distracters.[94] Because selective attention is critical for encoding information into memory, retaining and manipulating information in working memory, and successfully executing goal-directed behavior, a deficit in selective attention could contribute to the numerous cognitive deficits observed in individuals with neurological impairments.[93] This skill is linked to the prefrontal and underlying anterior cingulated areas.	• Attending to one conversation during a party • Studying outside with the noise of traffic and children playing • Attending to a therapist's instructions and cues in a crowded therapy clinic • Making dinner while the children watch TV in the background • Playing a board game during recess
Sustained attention (vigilance)	Supports tasks that require vigilance and the capacity to maintain attention over time[6]; often measured by the time spent on a task.[121] In adults this component is linked to prefrontal function in the right hemisphere, and impairment is linked to white matter damage.[94]	• Being able to attend to long conversations, instructions, class lessons, TV shows, or movies • Playing a game of chess • Balancing a checkbook • Watching your child on the playground
Attentional switching or alternating attention	The ability to switch attention flexibility from one concept to another; related to cognitive flexibility. The ability to change attentive focus in a flexible or adaptive manner.[5] The ability to move between tasks with different cognitive requirements. This skill appears to be a function of the prefrontal cortex and the posterior parietal lobe, thalamus, and midbrain.[73]	• While typing a paper, a friend comes into your room to discuss a completely different topic; when the conversation is over, you return to typing • Cooking, taking care of a crying child, and then returning to cooking • A unit clerk at the hospital alternating between flagging orders on the medical chart, answering the phone, and writing down phone messages
Divided attention	Dividing attention between two or more tasks simultaneously; dual tasking or multitasking; the capacity to attend to two competing stimuli simultaneously.[6] Deficits occur when limited attentional resources are divided between two tasks.	• Making toast and tea at the same time • Texting while carrying on a conversation • Playing cards while discussing the events of the day
Distractibility	A breakdown in selective attention; an inability to block out environmental or internal stimuli when trying to concentrate on performing a particular task; a symptom of prefrontal damage, particularly the dorsolateral cortex.[68]	• Noise in the hallway takes away your attention while taking notes in class • Inability to attend during a therapy session because of being distracted by watching someone else's session
Field-dependent behavior	Distracted by and acting on an irrelevant impulse that interferes with performance of an activity and takes over goal-directed activity; includes both an attention and a perseveration component.[8]	• While performing oral care, a person becomes distracted by a light switch; the person then stops the oral care activity while turning the light switch on and off (ie, not relevant to the task at hand)
Unilateral neglect (a lateralized attention deficit)	See Chapter 33	See Chapter 33

Adapted from Gillen G: *Cognitive and perceptual rehabilitation: optimizing function*, St Louis, 2009, Mosby.

Compared to controls, impaired attention results in increased rates of off-task behavior during performance of a task (eg, looking up and away from the task at hand, engaging in unsolicited conversations). Individuals with impairments in attention are markedly less attentive than controls both in the presence of distractions (noise, movements) and in their absence.[121] Further compounding this problem is a relationship between attention impairment and awareness of errors. McAvinue et al.[71] investigated the processes of error awareness and sustained attention in individuals with TBI. They found the following:

- In comparison to controls, participants with TBI displayed reduced sustained attention and awareness of error.
- The degree of error awareness strongly correlated with sustained attention capacity, even when the severity of injury was controlled for.
- Error feedback significantly reduces errors.
- TBI leads to impaired sustained attention and error awareness.

The finding of a significant relationship between error awareness and sustained attention deficits in clients with TBI suggests that a link may exist between these two processes.

Posner and Peterson[83] proposed the existence of three main functionally and anatomically distinct attentional control subsystems:

1. An orienting system related to sensory events that relies on the posterior brain areas (superior parietal lobe and temporoparietal junction, in addition to the frontal eye fields). This system is involved in the selection of relevant sensory information. This subsystem brings attention to a specific location in space and generates perceptual awareness. It reflects involuntary orienting or automatic processing. The performance of this system is determined by the reaction time in responding to the detection of stimuli.

2. An executive system focused on selection and involving multiple structures (anterior cingulate, lateral prefrontal cortex, and basal ganglia). This system is responsible for exercising control over lower level cognitive functions and resolving conflicts. The system is prominent in detecting signals for focal or conscious attention. A breakdown in this system results in difficulty managing tasks that require divided attention, screening out interfering stimuli, and responding to novelty.

3. An alerting or sustained attention system involving the frontoparietal regions that is responsible for achieving and maintaining sensitivity to incoming stimuli. Impairments related to this system result in short attention spans.

Dockree et al.[28] summarized the following points:

- Attention deficits are among the most commonly observed deficits after brain injury.
- Damage to the frontal lobes of the brain, particularly the white matter connecting the frontal, parietal, and striatal regions, is partly responsible for these deficits.
- Frontal lobe damage in clients with a brain injury results in a tendency to drift from intended goals and increases the frequency of action slips that were unintended.
- Self-reports from clients with TBI revealed that problems with attention and concentration rate among the highest complaints in this group of clients.

The usual and customary tests of attention include pen and paper measures or laboratory-type tasks, such as the Paced Auditory Serial Addition Test, Trail Making Test Part A, and Wisconsin Card Sorting Task. As discussed earlier, when these measures are used, the question of ecologic validity arises regarding the difficulty generalizing the results to everyday living tasks. (Suggested assessments are described in Tables 26.2 and 26.3.) Impairments in attention are manifested as observable errors during performance of tasks and should be documented as such.

In their meta-analysis of attention rehabilitation after an acquired brain injury, Park and Ingles[79] examined two approaches to treating attention deficits:

- *Directly retraining the damaged cognitive function or direct cognitive retraining.* This approach is used under the assumption that practice of carefully selected exercises promotes recovery of damaged neural circuits and restores function in the impaired attentional processes themselves, along with a further assumption that the tasks mediated by those circuits are performed in a way similar to that used by individuals without brain damage. Intervention is then based on a series of repetitive exercises or drills in which clients respond to visual or auditory stimuli. This intervention has received the most attention in the literature with respect to interventions for those with impairments in attention.
- *Having clients learn or relearn how to perform specific skills of functional significance (ie, specific skill training).* The premise here is that that through carefully structured practice of a specific skill that is impaired as a result of brain damage, it is possible for individuals to compensate and develop alternative neuropsychological processes that rely on preserved brain functions (ie, individuals learn to perform the skill in a way that is different from the way used by individuals without brain damage). In terms of intervention, attention is trained either concurrently with or in the context of the specific skills. In addition, this approach applies behavioral principles and an understanding of how the impairment in attention affects the various skills.

Park and Ingles[79] concluded that specific skills training significantly improved the performance of tasks requiring attention. In comparison, the cognitive retraining methods (ie, those focused on improving impairments in attention out of context) included in the meta-analysis did not significantly affect outcomes. Further analysis revealed that overall performance improved in 69% of the participants who received specific skills training (eg, driving, ADLs), whereas performance improved in only 31% of those not so trained. In terms of effect size, the improvements in cognitive functions after direct retraining were small, whereas the improvements in performance after specific skills training were medium or large. These findings demonstrated that acquired deficits in attention are treatable by specific skills training. The authors also proposed clinical implications of their study, including the following:

- The learning that occurs as a function of training is specific and does not tend to generalize or transfer to tasks that differ considerably from those used in training. This specificity of improvement was demonstrated in both the cognitive retraining studies and the specific functional skill-retraining studies.
- Performance of a task after training will improve to the extent that the processing operations required to complete that task overlap with the processes engaged during training (ie, performance will improve after training if the training task is similar to the targeted outcome measure).
- Many survivors of brain injury are impaired when performing controlled cognitive processes but not when performing automatic processes. Controlled processing is heavily involved in the early stages of learning a skill and is less involved as a skill becomes more routine with practice. Therefore, training programs that reduce the requirement for controlled processing during learning may be the most effective. Examples of reducing the demands of controlled processing include breaking down a complex functional skill into simpler components, providing practice on these components, and structuring training in such a way that performance feedback can be more easily interpreted. The authors recommended the technique of "shaping" as a way to train people with controlled processing deficits because shaping links the difficulty of a task to the person's performance. As a result of using the technique of shaping, the person may make fewer errors and be able to interpret feedback more easily.
- Rehabilitation procedures should be based on a set of learning principles.

Strategies aimed at modification of task and environments have proved to be beneficial for individuals with cognitive impairment (Box 26.2). Specific strategies include the following:

- *Time pressure management (TPM).* Fasotti et al.[32] noted that after severe closed head injury, deficits in the speed of processing information are common and result in a feeling of "information overload" in the performance of daily tasks. The authors tested TPM as an approach for managing slow information processing. TPM uses alternative cognitive strategies to support participation in real-life tasks. The overall focus is to teach people to give themselves enough time to deal with life situations. Specific strategies used to prevent or manage time pressure include enhancing awareness of errors and deficient performance, self-instruction training (eg, trying to focus, not getting distracted by outside sounds and other information, not getting distracted by irrelevant thoughts, and trying to imagine things that are being said), optimizing planning and organization, rehearsing task requirements, modifying the task environment, and using an overall strategy of "Let me give myself enough time."
- *Self-instruction statements.*[119] Such statements can be suggested to improve listening and to ask for repetition if attention strays:

- "To really concentrate, I must look at the person speaking to me."
- "I must also focus on what is being said, not on other thoughts that may want to intrude."
- "I must concentrate on what I am hearing at any moment by repeating each word in my head as the person speaks."
- "Although it is not horrible if I lose track of a conversation, I must tell the person to repeat the information if I have not attended to it."

Box 26.2

Strategies for Practitioners and Caretakers in Managing Deficits in Attention

- Avoid overstimulating/distracting environments.
- Face away from visual distracters during tasks.
- Wear earplugs.
- Shop or go to restaurants at off-peak times.
- Use filing systems to enhance organization.
- Label cupboards and drawers.
- Reduce clutter and visual distracters.
- Use self-instruction strategies.
- Use time pressure management strategies.
- Teach self-pacing strategies.
- Control the rate of incoming information.
- Self-manage effort and emotional responses during tasks.
- Teach monitoring or shared attentional resources when multitasking.
- Manage the home environment to reduce auditory and visual stimuli. Keep radios and phones turned off. Close doors and curtains. Keep surfaces, cabinets, closets, and refrigerators organized and uncluttered.
- Use daily checklists for work, self-care, and instrumental activities of daily living.

Data from Cicerone KD: Remediation of "working attention" in mild traumatic brain injury, *Brain Inj* 16:185–195, 2002; Fasotti L, et al: Time pressure management as a compensatory strategy training after closed head injury, *Neuropsychol Rehabil* 10:47–65, 2000; Michel JA, Mateer CA: Attention rehabilitation following stroke and traumatic brain injury: a review, *Eura Medicophys* 42:59–67, 2006; and Webster JS, Scott RR: The effects of self-instructional training on attentional deficits following head injury, *Clin Neuropsychol* 5:69–74, 1983.

From Gillen G: *Cognitive and perceptual rehabilitation: optimizing function,* St Louis, 2009, Mosby.

A case study by Webster and Scott[120] demonstrated positive effects of this approach both immediately after treatment and at the 18-month follow-up; the client demonstrated improved attention, which resulted in increased recall, increased sexual function, and improved job performance.

- *Self-management strategies.* Sohlberg and Mateer[105] suggest the use of three self-management strategies:

1. *Orienting procedures*. Clients are encouraged to consciously monitor activities to prevent or control a lapse in attention. They are taught to ask themselves orienting questions at various intervals (possibly reminded by an alarm watch): "What am I currently doing?" "What was I doing before this?" and "What am I supposed to do next?"

2. *Pacing*. Pacing is used to decrease task demands. Scheduling uninterrupted work times is one example. Other examples are setting realistic expectations, building in breaks, and self-monitoring fatigue and attention.[105]

3. *Key ideas log*. Clients are taught to quickly write or tape-record questions or ideas to address later so that the task at hand is not interrupted.

Because there is insufficient evidence to support the use of remediation-based approaches to attention training to improve occupational performance,[44] strategy training is considered a practice standard for the post-acute period of rehabilitation by the American Congress of Rehabilitation Medicine.[24] Intervention should focus on strategy training to compensate for attention deficits in functional situations.

Impact of Memory Deficits on Daily Function

Memory impairment is one of the most common consequences of brain injury and degenerative cognitive disorders. The severity and type of memory loss vary according to the structures affected. Human memory is composed of multiple and distinct systems, which the individual needs to support daily activities and participate in the community (Table 26.7).[107] Examples include remembering your significant other's birthday, remembering to take your medications, remembering to feed the dog, remembering how to type, remembering events that occurred during a vacation, and so on. Even this "simple" list of memory tasks requires intact functioning of multiple memory systems and includes knowledge of facts and events, procedures, and future intentions. Clearly, memory serves as a key cognitive support to facilitate independent living.

TABLE 26.7

Terms Related to Memory Impairments

Term	Definition	Examples of Everyday Behavior
Anterograde amnesia	A deficit in new learning; an inability to recall information learned *after* acquired brain damage; an inability to form new memories after brain damage occurs	Not able to recall staff names, easily gets lost secondary to topographic disorientation, not able to recall what occurred in therapy this morning, difficulty learning adaptive strategies to compensate for loss of memory
Retrograde amnesia	Difficulty recalling memories formed and stored *before* the onset of disease; may be worse for recent events than for substantially older memories	Inability to remember autobiographic information (address, social security number, birth order), not able to remember historical events (war, presidential elections, scientific breakthroughs) and/or personally experienced events (weddings, vacations)
Short-term memory	Storage of limited information for a limited time	Difficulty remembering instructions related to the use of adaptive equipment, not able to remember the names of someone just introduced at a dinner party, not able to remember "today's specials" in a restaurant
Working memory	Related to short-term memory; refers to actively manipulating information in short-term storage through rehearsals	While playing a board game, unable to remember and use the rules of the game; not able to perform calculations mentally while balancing the checkbook; difficulty remembering and adapting a recipe
Long-term memory (LTM)	Relatively permanent storage of information with unlimited capacity	May affect declarative memory of knowledge, episodes, and facts or nondeclarative memories such as those related to skills and habits
Nondeclarative memory	Knowing *how* to perform a skill, retain previously learned skills, and learn new skills; a form of LTM; also called **procedural memory**	Driving, playing sports, hand crafts, learning to use adaptive equipment or a wheelchair for activities of daily living
Declarative memory	Knowing that something was learned; verbally retrieving a knowledge base (eg, facts) and remembering everyday events; includes episodic and semantic information; a form of LTM	See episodic and semantic memory
Episodic memory	Autobiographic memory for contextually specific events and personally experienced events; a form of declarative LTM	Remembering the day's events, what one had for breakfast, occurrences on the job, and the content of therapy sessions
Semantic memory	Knowledge of the general world and facts, linguistic skill, and vocabulary; may be spared after injury; a form of declarative LTM	Remembering the dates of holidays, the name of the president, dates of world events
Explicit memory	Memories of events that have occurred in the external world; information about a specific event at a specific time and place	Remembering places and names and various words (see declarative memory)
Implicit memory	Memories necessary to perform events and tasks or to produce a specific type of response; does not require conscious retrieval of the past; knowledge is expressed in performance, without the person being aware of having it	Memory of skills, habits, and subconscious processes (see nondeclarative memory)
Prospective memory	Remembering to carry out future intentions	Remembering to take medications, return phone calls, buy food, pick up the children from school, mail the bills; a critical aspect of memory to support everyday life
Metamemory	Awareness of one's own memory abilities	Knowing when you need to compensate for memory capacity (eg, making a list of errands or a shopping list, writing down a new phone number or driving directions); recognizing errors in memory, and so on

Data from Baddeley AD: The psychology of memory. From Gillen G: *Cognitive and perceptual rehabilitation: optimizing function,* St Louis, 2009, Mosby.

The steps or stages of memory have been well documented (Table 26.8).[13,105] The flow of these stages is:

Attention → Encoding → Storage → Retrieval

TABLE 26.8
Stages of Memory

Stage	Description	Neuroanatomic Areas of Function
Attention	Processes that allow a person to gain access to and use incoming information; includes alertness, arousal, and various attention processes (eg, selective attention)	• Brainstem • Thalamic structures • Frontal lobes
Encoding	How memories are formed; an initial stage of memory in which the material to be remembered is analyzed (visual vs. verbal characteristics); correct analysis of the information is required for proper storage	• Dorsomedial thalamus • Frontal lobes • Language system (eg, Wernicke's area) • Visual system (eg, visual association areas)
Storage	How memories are retained; transfer of a transient memory to a form or location in the brain for permanent retention and access	• Hippocampus • Bilateral medial temporal lobes
Retrieval	How memories are recalled; search for or activation of existing memory traces	• Frontal lobe

Data from Sohlberg MM, Mateer CA: Memory theory applied to intervention. In Sohlberg MM, Mateer CA, editors: *Cognitive rehabilitation: an integrative neuropsychological approach*, New York, 2001, Guilford Press.

Traditional measures of memory have tended to be tabletop laboratory-style tools. Contrived tasks commonly used are remembering a string of numbers, a list of words, or the details of a drawn figure and/or paired associate learning (ie, requiring a person to recognize or recall recently presented material). How the results of these tests relate to everyday memory function is not clear, and associations between scores on this type of test and reports of everyday memory failure are not strong.[109] Similarly, functional gains do not always correlate with improvement in memory processes based on objective testing.[91]

A comprehensive evaluation of how impairments in memory affect everyday function includes the use of standardized assessments, nonstandardized observations, standardized self-reports, and standardized reports of caregivers and significant others. (Tables 26.2 and 26.3 provide descriptions of recommended assessments.) The Contextual Memory Test is a useful screening tool.[112] It allows practitioners to objectify three aspects of memory and screen for possible further evaluation:

1. Awareness of memory: Using general questioning before the assessment, predicting performance before assessment, and estimating memory capacity after performance.

2. Recall of 20 line-drawn aspects: Immediate and delayed (15 to 20 minutes) recall.

3. Strategy use: Probes the use of memory strategies and determines the ability to benefit from strategy recommended by the practitioner.

Interventions focused on individuals with memory deficits can be categorized as (1) restorative approaches to improve underlying memory deficits, (2) strategy training, (3) use of nonelectronic memory aids, and (4) use of electronic memory aids or assistive technology. Techniques aimed at improving the underlying memory impairment (eg, memory drills) have been unsuccessful in terms of generalization to meaningful activities. In other words, an improvement may be detected on a laboratory-based measure of memory without a corresponding change in daily function or subjective memory reports.

The most promising interventions to improve function in those with memory deficits rely at least partially on compensatory techniques (Box 26.3). When a compensatory approach is used, choosing the correct system of compensation is critical. Kime[58] suggests a comprehensive evaluation that includes:

- Severity of the injury
- Severity of the impairment in memory
- Presence of comorbid conditions, including physical impairments, language deficits, and other cognitive deficits
- Social supports

- Client's needs (eg, Will the system be used for work, home management, or other occupations?)

Box 26.3

Suggestions for Working With Individuals With Working Memory Deficits

- Keep directions and instructions short.
- Use real-world functional tasks for training (eg, adding up monthly bills rather than practicing rote strings of numbers).
- Speak slowly, but not exaggeratedly so.
- Stress target words during training to help the person realize the key part of the instruction. In addition, put key information at the beginning and end of sentences.
- Increase the automaticity of a response through extra practice and rehearsal (eg, learning to transfer from a wheelchair to a bed).
- Use part-whole learning, or break down a task into components to promote overlearning of the components.
- Teach rehearsal strategies.

Data from Parente R, et al: Retraining working memory after traumatic brain injury, *NeuroRehabilitation* 13:157–163, 1999.

The following sections discuss specific evidence-based interventions.

Memory Notebooks and Diaries

The use of memory notebooks and diaries has been documented to improve orientation and to support everyday living tasks, such as morning ADLs and simple IADLs.[98] Sohlberg and Mateer[103,104] published a systematic, structured training sequence for teaching individuals with severe memory impairments to independently use a compensatory memory book. The training sequence they proposed incorporates principles of learning theory in addition to procedural memory skills, which may be preserved in many clients with even severe memory impairments. Donaghy and Williams[29] suggested that the diary or notebook include a pair of pages for each day of the week. The notebook is set up to aid scheduling of things to do in the future and to record activities done in the past. For each pair of pages, the left-hand page contains two columns, one with a timetable for the day and the other for to-do items. The right-hand page contains the memory log. A "last week" section at the back stores previous memory log entries. A full year calendar allows appointments to be recorded. Ownsworth and McFarland[77] compared two approaches to memory diary training:

- *Diary-only training*. This approach focuses on functional skill building and compensation-based, task-specific learning. The subjects were taught a behavioral sequence consisting of making a diary entry, checking it, and using the information as needed.
- *Diary and self-instructional training*. This approach emphasizes training of the subject's capacity for the higher level cognitive skills of self-regulation and self-awareness. The subjects were taught a ***WSTC*** strategy:

W: What are you going to do?

S: Select a strategy for the task.

T: Try out the strategy.

C: Check how the strategy is working.

The authors found that during the treatment phase, those in the diary and self-instruction training group consistently made more diary entries, reported fewer memory problems, compensated better through use of strategies, and made more positive ratings associated with the efficacy of treatment. Possible sections for a memory notebook are included in Table 26.9.

TABLE 26.9

Sections of a Memory Notebook

Section	Purpose
Daily log	Used to record, store, and retrieve information about daily activities; forms for charting hourly information and scheduling appointments; forms for prioritizing a list of tasks
Calendar	Used to record appointments and retrieve information about important meetings and upcoming events
Names	Used to record, store, and retrieve identifying information and "name drawings" of new people
Current work	Used to record specific procedures for work assignments that may be needed at a later date
Personal notes	Used to record important personal information (eg, personal goals, autobiographic information); also used to record addresses, birthdays, and similar information

From Schmitter-Edgecombe M, et al: Memory remediation after severe closed head injury: notebook training versus supportive therapy, *J Consult Clin Psychol* 63:484–489, 1995.

Errorless Learning

Errorless learning is a strategy that is in contrast to trial-and-error learning or errorful learning. Interventions using an errorless learning approach are based on differences in learning abilities. It is typical for people with impairments in memory to more successfully remember their own mistakes as results of their own action than they are to remember corrections of their mistakes by explicit means (eg, a therapist's cue). In other words, people may remember their mistakes, but not the correction. With errorless learning a person learns something by saying or doing it rather than by being told or shown by someone. A meta-analysis of errorless learning for treating memory loss conducted by Kessels and de Haan[56] documented a large and statistically significant effect size for errorless learning treatment. In addition, no significant effect size was demonstrated for the vanishing cues method (ie, teaching a skill by fading cues over time). It should be noted that the majority of studies analyzed used laboratory-type impairment measures such as word lists, face-name associations, and the like.

Assistive Technology

The literature focused on using technology to improve daily function in those with memory loss is substantial and consistently documents improvement in specifically trained tasks (eg, managing medication, morning routines, and IADLs). A variety of devices have been used (Box 26.4).

Box 26.4

Assistive Technology for Individuals With Memory Loss

- Handheld computers
- Smart phones
- Paging systems
- Voice recorders
- Personal digital assistants
- Alarm watches
- Electronic pillboxes
- Microwave with preset times

- Adaptive stove controls that turn off an electric stove after a certain period or when the heat becomes excessive
- A phone with programmable memory buttons (affix pictures to the buttons)
- A phone with buttons programmed to speak the name of the person being called
- A device for locating keys
- A recording to cue a behavioral sequence, such as morning care

From Gillen G: *Cognitive and perceptual rehabilitation: optimizing function,* St Louis, 2009, Mosby.

Equipment that formerly was specialized (eg, paging systems and handheld computers) continues to become commonplace; therefore, there is a larger population who may be amenable to using devices to compensate for memory loss. Typical smart phones have endless possibilities in terms of being used to cue performance of tasks in those with impaired memory. Examples include calendar functions, alarm functions, shopping list applications, dictation systems, map functions, contact lists, and others.

Mnemonics

Mnemonics is a broad term that refers to any strategy used to remember something, including rhymes, poems, acronyms, and imagery techniques. Examples include "Thirty days hath September …" (rhymes or poems to remember how many days are in each month), the acronym ROYGBIV to remember the colors of the spectrum, and imagining placing the items you want to remember in specific locations in a room with which you are familiar (method of loci).

Hux et al.[53] assessed the effectiveness of three frequencies of intervention sessions focused on using mnemonics and visual imagery strategies to recall names of people: once per day, two times per week, and five times per day. The subjects included seven men who had sustained a TBI, ranging in age from 28 to 40 years. The results showed that sessions held daily and twice a week were more effective than sessions held five times a day. Mnemonics and visual imagery strategies were effective for 4 of the 7 participants, regardless of the frequency of intervention sessions. More research is required to determine whether mnemonic strategies are generalizable to untrained tasks and also who is an appropriate candidate. At this point it seems that mnemonics are best suited for remembering specific and limited types of information (eg, staff names).

Task-Specific Training

A series of experiments by Giles and Morgan[40] documented improved daily function in those with severe memory loss using the following interventions:

- An intervention program consisting of chaining nine discrete activities (eg, shaving, oral care) by using linking phases. The phrases linked the performed activity to the one that immediately followed (eg, "teeth cleaned, now shave"). The person was then asked to repeat the phrase as a cue to initiate the activity, which was followed by the behavioral techniques of verbal praise and a tangible reward.
- An intervention consisting of a cued ADL sequence determined by the client's preinjury habits and responsiveness to cueing. Washing and dressing were conceptualized as a 16-step program in which the staff would cue the next step if behavior compatible with the next step in the sequence was not evident within approximately 5 seconds of completion of the previous step, or if behavior incompatible with production of the next step in the behavioral chain was demonstrated. Although the client's physical and cognitive status remained unchanged during the program, which lasted for 12 treatment days, he did become independent in washing and dressing. Initially requiring 25 to 30 instructions, in addition to physical assistance, to perform the tasks, the client progressed to independence. Independence was maintained at the 6-month follow-up.[42]

Giles et al.[41] presented further support for these specific retraining protocols. Four clients were treated with the aforementioned washing and dressing protocol. Three had sustained a TBI, and one had brain injury after cerebral bleeding. All had moderate to severe memory loss. The training program consisted of behavioral observation, task analysis, consistent practice, and cue fading. The

Adaptive Behavior Scale was used to measure change in behavior. The authors found that three subjects achieved rapid independence in washing and dressing (requiring 20 days, 37 days, and 11 days of treatment), and one did not show significant clinical improvement. Of note was that all clients admitted to the facility during a 3-year period who required retraining in washing and dressing were treated with the same protocol. The authors further concluded that the consecutive series design prevented researchers from selecting clients they believed were good treatment candidates; therefore, the findings supported the general applicability of the training program. Box 26.5 presents strategies for significant others.

Box 26.5

Strategies for Significant Others of Individuals With Memory Loss

- Understand that in many cases the impairment may not be reversible.
- Become familiar with the specific type of compensatory memory strategies that have been prescribed.
- Keep daily schedules as consistent as possible. Stick with habits and routines.
- Simplify the environment by reducing clutter and keeping the living areas organized.
- Reduce excessive environmental stimuli.
- Help by organizing calendars and having clocks and reminders arranged around the house.
- Be proactive in identifying potential safety issues.
- Use short, direct sentences.
- Make sure the most important information comes at the beginning of the sentence.
- Highlight, cue, and emphasize key aspects of communication (eg, repeat, point, and so on).
- Avoid conversations that rely on memory (ie, keep conversations in the present).
- Repetition of sentences may be inevitable.
- Summarize conversations.
- Remember that in many cases intelligence may remain intact.
- Keep "a place for everything, and everything in its place."
- Use photographs, souvenirs, and other appropriate items to help the person access memories.
- Understand that fatigue, stress, sleep disorders, and depression can exacerbate memory loss.
- Keep back-up items (eg, glasses, spare keys).
- Help create to-do lists. Remind loved ones to check off a task or highlight it when it has been completed.
- Label items, drawers, and shelves.

From Gillen G: *Cognitive and perceptual rehabilitation: optimizing function*, St Louis, 2009, Mosby.

Strategy Training

In addition to the strategies discussed previously, Stringer and Small[108] tested an approach called

Ecologically Oriented Neurorehabilitation of Memory, a treatment program that provides a four-step compensatory strategy based on the acronym WOPR: write–organize–picture–rehearse. Performance measures on everyday memory simulations for six declarative memory tasks and one prospective memory task were used as outcome measures. Clients in all three diagnostic groups and at all levels of severity showed significant improvement in memory performance.

Impact of Executive Dysfunction on Daily Function

Executive functions is an umbrella term that refers to complex cognitive processing requiring the coordination of several subprocesses to achieve a particular goal.[30] This term has been defined as "a product of the coordinated operation of various processes to accomplish a particular goal in a flexible manner"[37] or "those functions that enable a person to engage successfully in independent, purposive, self-serving behavior."[66] These higher order mental capacities allow a person to adapt to new situations and achieve goals. They include multiple specific functions, such as decision making, problem solving, planning, task switching, modifying behavior in light of new information, self-correction, generating strategies, formulating goals, and sequencing complex actions. Unfortunately, the published literature is not consistent on whether a particular function is an executive function. Table 26.10 gives an in-depth list of the 20 most commonly reported dysexecutive symptoms and the reported frequencies of these symptoms. Clearly, these executive functions support engagement in daily life activities and participation in the community; they are most important during new, nonroutine, complex, and unstructured situations (Table 26.11).

TABLE 26.10

Frequency of Reporting of Dysexecutive Symptoms[a]

Symptom	Clients Reporting Problem (%)	Caregivers Reporting Problem (%)	Rank of Disagreement[b]	Scaled Disagreement in Rank[c]
Poor abstract thinking	17	21	16.5	−9
Impulsivity	22	22	19.5	−10
Confabulation	5	5	19.5	+3
Planning	16	48	1	+8
Euphoria	14	28	5	+7
Poor temporal sequencing	18	25	15	−8
Lack of insight	17	39	3	+5
Apathy	20	27	13	−5
Disinhibition (social)	15	23	13	−3
Variable motivation	13	15	18	−7
Shallow affect	14	23	10.5	+1
Aggression	12	25	6	+6
Lack of concern	9	26	4	+9
Perseveration	17	26	10.5	−1
Restlessness	25	28	16.5	−6
Can't inhibit responses	11	21	9	+4
Know-do dissociation	13	21	13	−2
Distractibility	32	42	8	+1
Poor decision making	26	38	7	−3
Unconcern for social rules	13	38	2	+10

[a]Only ratings of 3 or 4 (of a maximum of 4) for each item on the Dysexecutive Questionnaire were considered to indicate a problem. These ratings correspond to classification of the symptom as "often observed" or "very often observed." These results are based on data gathered as part of the study by Wilson et al.

[b]This number represents the rank size of the disagreements (in proportions reporting the symptom) between clients and controls, in which 1 represents the greatest disagreement (ie, 1 means that caregivers reported this symptom much more often than clients did).

[c]This number reflects the relative disagreement in rank frequency of reporting between clients and controls, scaled from −10 to +10, with 0 being absolute agreement in rank position of that symptom. On this scale, −10 means that the symptom was commonly reported by clients but not by caregivers, and +1 means that the symptom was frequently reported by caregivers, but it was relatively uncommon for clients to report it.

From Burgess PW, Simons JS: Theories of the frontal lobe executive function: clinical applications. In Halligan PW, Wade DT, editors: *Effectiveness of rehabilitation for cognitive deficits*, Oxford, UK, 2005, Oxford University Press.

TABLE 26.11

Examples of Executive Functions Related to Daily Life: Preparing a Salad

Executive Function	Associated Tasks
Initiation	Starting the task at the appropriate time without overreliance on prompts
Organization	Organizing the work space and performing the task efficiently (eg, gathering the necessary vegetables at the same time from the refrigerator)
Sequencing	Sequencing the steps of the task appropriately (eg, gathering tools and vegetables, washing vegetables, chopping and slicing vegetables, combining vegetables in a bowl, adding dressing)
Problem solving	Solving the problem of using a knife that is too dull to slice

From Gillen G: *Cognitive and perceptual rehabilitation: optimizing function*, St Louis, 2009, Mosby.

Recent studies examining meal preparation abilities in those with frontal lobe involvement have supported the importance of executive functions in everyday activities. Godbout et al.[45] examined executive functions and ADLs in 10 clients with excised frontal lobe tumors and 10 normal controls by means of a neuropsychological test battery, a script generation task, and a complex multitask ADL (planning and preparing a meal). The clients manifested numerous basic executive deficits on the pen and paper tests, were unimpaired on the script generation task (despite an aberrant semantic structure), and demonstrated marked difficulties in the meal preparation task. The authors concluded that the difficulties observed in performing a lengthy, complex, multitask ADL can be explained by impairment of several executive functions, generalized slowness in performance, and paucity of behavior.

Similarly, Fortin et al.[36] investigated executive functions in performing ADLs in 10 clients with frontal lobe lesions after a mild to severe closed head injury (CHI), compared with 12 normal controls, by means of a neuropsychological test battery, a script recitation task, and simulation of a complex multitask ADL. These authors found that the groups did not differ on any neuropsychological test by nonparametric testing. However, the clients with CHI manifested marked anomalies in the meal preparation task. Although small sequences of actions were easily produced, large action sets could not be executed correctly. The authors concluded that an outstanding deficit in strategic planning and prospective memory appears to be an important underpinning of the impairment in ADLs observed in clients with CHI with frontal lobe lesions. It also has been found that components of executive functioning (eg, categorization and deductive reasoning ability) in individuals with brain injury are good predictors of IADL functional performance.[46]

Lezak[65,66] classified the various forms of executive disorders into a four-part schema:

1. *Volition and goal formulation:* Including self-awareness, initiation, and motivation

2. *Planning:* Including the ability to conceptualize change, be objective, conceive alternatives, make choices, develop a plan, and sustain attention

3. *Purposive action:* To implement plans for achieving goals, including productivity, self-regulation, switching, and sequencing of actions

4. *Performance effectiveness:* Including quality control, self-correction, monitoring, and time management

Cicerone et al.[24] also presented a schema for executive functions. It includes four domains based on anatomy and evolutionary development:

1. *Executive cognitive functions* (dorsolateral prefrontal cortex): Involved in the control and direction (planning, monitoring, activating, switching, inhibiting) of lower level functions. Working memory and inhibition mediate executive functions.

2. *Behavioral self-regulatory functions* (ventral/medial prefrontal area): Involved in emotional processing and behavioral self-regulation when cognitive analysis, habit, or environmental cues are not sufficient to determine the best adaptive response.

3. *Activation-regulating functions* (medial frontal areas): Activation through initiative and energizing behavior. Pathology results in a decrease in activation and drive, also known as apathy and abulia.

4. *Metacognitive processes* (frontal poles): Personality, social cognition, and self-awareness as reflected by accurate evaluation of one's own abilities and behavior, rather than objective evaluation or reports by significant others.

People with impairments in executive functions, or **dysexecutive syndrome**, have impaired judgment, impulsiveness, apathy, poor insight, and lack of organization, planning, and decision making, in addition to behavioral disinhibition and impaired intellectual abilities. Specific behavioral characteristics include impulsivity, poor attention, erratic response, lack of flexibility, and poor self-control.[90,106] Of note is that people with impaired executive function may perform normally on pen and paper tests of cognition but unfortunately are found to have catastrophic everyday problems that are particularly evident in situations requiring multitasking and planning.[100]

The usual and customary tests of executive dysfunction include pen and paper measures or laboratory-type tasks, such as the Wisconsin Card Sorting Task, Trail Making Test, and Stroop Test, among others. As discussed earlier, the question of ecologic validity arises when these measures are used, in addition to difficulty generalizing the results to everyday living tasks. These measures have only a low to moderate relationship to everyday skills.

Additionally, the standard clinical tests used to assess executive impairments are considered too structured and rater led; therefore, they fail to capture the common problems of initiation, planning, and self-monitoring. (Recommended instruments are summarized in Tables 26.2 and 26.3.)

Interventions for dysexecutive syndrome (Box 26.6) continue to be tested empirically.

Box 26.6

Categories of Intervention for Clients With Impaired Executive Function

- *Environmental modifications:* Examples include using antecedent control, manipulating the amount of distractions and structure in the environment, organizing work and living spaces, and ensuring balance of work, play, and rest, among others.
- *Compensatory strategies:* Examples include the use of external cueing devices (eg, checklists, electronic pagers) and the use of reminder systems and organizers.
- *Task-specific training:* Training of specific functional skills and routines, including task modifications.
- *Training in metacognitive strategies to promote a functional change by increasing self-awareness and control over regulatory processes.* Such strategies include self-instruction strategies, teaching problem solving, and goal management training.

Because executive functions act as a manager of other cognitive processes, such as attention, memory, and language,[67] some of the interventions previously described in this chapter are appropriate for those with dysexecutive symptoms, including TPM,[32] self-instruction training,[25] WSTC strategy,[63] external cueing devices (eg, paging systems, recorded instructions, and checklists),[21,31,99] and manipulation of environmental variables with a focus on level of distraction.[52] Other examples of specific interventions that have been tested and shown to be effective are described in the next three sections.

Problem-Solving Training

The aim of problem-solving training is to substitute a participant's impulsive approach to problem solving with a verbally mediated systematic analysis of the goal and the means by which it may be achieved.[118] von Cramon et al[118] encouraged participants to act in a manner attributed to an intact executive system, with a focus on five aspects of problem solving:

1. *Problem orientation or identifying and analyzing.* The difficulty in general recognition of a task or situation as a problem was the focus. The participant's tendency to oversimplify problems and neglect relevant information was addressed.

2. *Problem definition and formulation.* Participants learned to survey information by reading and rereading directions and formulated questions to augment their understanding of the problem. Main and relevant points were written down. A focus was to teach participants to discriminate between relevant and irrelevant information.

3. *Generating alternatives and solutions.* Participants were asked to generate as many solutions as possible for a given problem. This was done individually, followed by the participants sharing solutions. The goal was to make participants aware that there were more solutions available than they had originally thought.

4. *Decision making.* Solutions were discussed, and the pros and cons of the solutions were weighed. The feasibility of the solutions was also considered.

5. *Solution verification and evaluation.* Participants learned to recognize faulty solutions, self-correct errors, and return to other hypotheses. The focus here was on increased sensitivity to errors and discrepancies.

Others have recommended using problem-solving strategies such as stop and think; asking clear thinking questions; thinking your way through each step; defining the problem; using clear thinking questions to produce, evaluate, and examine the utility of as many alternative solutions as possible; and emotional self-regulation strategies.[92] These problem-solving skills are then reinforced by role playing and the practice of demanding real-life examples.

Goal Management Training

This intervention is aimed at decreasing disorganized behavior and improving the client's ability to maintain intentions in goal-directed behavior (goal management).[64] Such disorganization results in neglect of daily goals, such as never cleaning the house, forgetting to pack a lunch, or never getting around to making a shopping list—all of which compromise functional independence. Goal management training entails five stages that correspond to key aspects of goal-directed behavior:

Stage 1: *Orienting and assessing the current state.* Stop current activity and direct awareness toward the task.

Stage 2: *Select the main goal.*

Stage 3: *Partition the goals and make subgoals.*

Stage 4: *Rehearse the steps necessary to complete the task.* Encode, rehearse, and retain goals and subgoals.

Stage 5: *Monitor the outcome.* Compare the outcome of action with the stated goal.

These steps are taught using errorless techniques, and the cues for each stage are gradually faded to make sure the person maintains nearly perfect performance.

Metacognitive Training

Birnboim[15] and Birnboim and Miller[16] tested the effectiveness of a metacognitive therapeutic approach in 10 people with multiple sclerosis and executive dysfunction. This approach focused on the metacognitive aspects of behavior and assumed that metacognitive aspects can and should be learned explicitly through a structured process. Phases of the process included the following:

1. *Understanding:* The participant had to recognize his or her specific metacognitive deficits (eg, not planning). This was achieved by confronting various tasks in the clinic to increase awareness.

2. *Practice:* Efficient and specific strategies that the participant and therapist identified together (eg, set priorities) were learned and practiced.

3. *Transfer:* Participants and their therapists considered when and where these strategies could be applied in real-life situations.

Computer strategy games (eg, Mastermind) and tabletop exercises were used during the first two phases of the training. Individualized daily activities were the focus of the generalization phase (eg, specific work tasks). Positive results were noted on a strategy application test, tests of attention, memory tests, tests of executive function, and most important, the Occupational Therapy

Functional Assessment Compilation Tool, which showed an improved occupational role.

Summary

Jane's case will serve as a summary and a conclusion. Jane's initial evaluation was structured to first and foremost foster a client-centered approach to ensure that her OT sessions were tailored to her goals. Gary, Jane's husband, was also involved in this process because Jane was demonstrating poor self-awareness related to her functional limitations. Gary reported that he worked full-time and that Jane would be alone for part of the day. He stated that he would help in any way needed, but he was concerned that helping with self-care would change the dynamic in their new marriage, and he wanted self-care to be a focus of occupational therapy. Jane reported that she felt "humiliated" when staff members had to help her with personal needs, such as ADLs. Jane was also focused on (sometimes perseverating on) finishing school. It was determined that morning OT sessions would focus on self-care, and afternoon sessions would focus on school skills.

As described earlier, the standardized FIM (required on most units) was administered. The FIM findings were supplemented by the standardized A-ONE, which documented the reasons for Jane's limited performance in areas of occupation. Because it was quickly apparent the Jane was not aware of her limitations (one of Gary's greatest concerns), the standardized Self Awareness of Deficits Interview was also administered as a priority. The OT performed nonstandardized assessments of school tasks. To assess performance, the OT requested that Gary bring in Jane's current semester work and supplies at the end of the second week of therapy. The OT was able to document Jane's reading comprehension, ability to attend to lectures (Jane always recorded lectures, and Gary was able to locate the recordings), ability to structure note taking, and use of her laptop for e-mail functions. Deficits were noted in the areas of sustained attention, short-term memory, and being distracted by environmental stimuli.

The OT, along with Jane and Gary, set the following short-term goals, which focused on documenting improvements in areas of occupation.

Week 1

1. Jane will complete upper body dressing with one tactile cue for initiation and no more than two verbal cues for sequencing.

2. Jane will complete grooming tasks (oral hygiene and hair care) with one tactile cue for initiation and the use of a checklist outlining the steps of the tasks.

3. Jane will persist in feeding herself for 10 minutes after one tactile cue for initiation.

Week 3

1. All self-care tasks except for bathing will be completed with no more than one general verbal cue and external cueing devices as needed.

2. Jane will accurately write down three key points from a 10-minute lecture with one general verbal prompt to stay on task.

3. Jane will retrieve her email from her laptop with no more than one verbal cue for sequencing.

In terms of interventions to meet the aforementioned goals and others, the general treatment approach chosen by Jane's OT was the multicontext approach described earlier. This model was chosen primarily because of its emphasis on awareness training so that Jane could redefine her knowledge of her strengths and weaknesses. The OT hypothesized that improving awareness would be the starting point for intervention because he felt confident that if Jane were aware of her errors, he could teach her strategies that would allow her to meet her goals. In addition, the choice of intervention activities was based on Jane's interests and goals (school tasks, reading fiction, cooking). Various processing strategies were practiced during a variety of functional activities and situations. Processing strategies were chosen to allow Jane to control the cognitive symptoms detected on her assessment. As Jane's awareness improved, the OT was vigilant in monitoring her for signs of depression and anxiety. Jane's OT began to place emphasis on teaching specific strategies to keep Jane “on task” (sustained attention), in addition to determining which external cueing devices would allow Jane to stay organized and perform the steps of various tasks in the proper sequence. The OT planned interventions to occur in multiple environments (bedside, OT clinic, hospital gift store, staff office, hospital library) to promote generalization of learning.

Review Questions

1. Name the three levels of the pyramid model of self-awareness.
2. How does the concept of ecologic validity relate to cognitive assessment?
3. List some of the rationales for using self-report/caregiver report measures for individuals with cognitive impairment.
4. How does the OT approach for individuals with cognitive impairments differ from that used by other disciplines?

Eating and Swallowing*

Jerilyn (Gigi) Smith

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, the student or practitioner will be able to do the following:

1. Name and locate oral structures concerned with eating and swallowing.
2. Name and describe the stages of normal eating and swallowing.
3. List the components of the swallowing assessment.
4. Name and describe normal and abnormal oral reflexes.
5. Describe the role of the occupational therapist in the clinical assessment of eating and swallowing.
6. Describe four steps in the swallowing assessment.
7. Describe the appropriate progression of foods and liquids in the assessment and intervention of deglutition and dysphagia.
8. Name two types of tracheostomy tubes, and list the advantages and disadvantages of each.
9. List symptoms of swallowing dysfunction.
10. Identify basic intervention goals for clients with eating and swallowing dysfunction.
11. Describe the roles of the dysphagia team members.
12. Describe proper positioning for safe feeding and swallowing.
13. Describe two methods of nonoral feeding.
14. List principles of oral feeding.
15. List and describe intervention techniques for the management of eating and swallowing dysfunction.

KEY TERMS

Anticipatory phase
Aspiration
Bolus
Compensatory strategies
Deglutition
Dysphagia
Dysphagia diet
Dysphagia team
Eating
Esophageal phase
Feeding
Fiberoptic endoscopy
Gastrostomy tube
Hyoid bone
Instrumental assessment
Larynx
Nasogastric tube
Oral phase
Oral preparatory phase
Pharyngeal phase

Pyriform sinuses
Sulcus
Swallow response
Tracheostomy
Valleculae
Velopharyngeal port
Velum
Videofluoroscopy

Threaded Case Study

Mattias, Part 1

Mattias, a 65-year-old man, experienced a right cerebrovascular accident (RCVA) 3 days ago, which resulted in left hemiplegia. During his occupational therapy evaluation of activities of daily living (ADLs), it was determined that Mattias had difficulties with self-feeding, chewing, and swallowing at meals. He had frequent episodes of coughing, pocketing food in the left cheek, and often had food on the left side of his face. His oral intake is below the normal calorie range at this time. He complains that he chokes on many foods, including water.

An occupational profile provided the following background information. Mattias is married and has two daughters. Until onset, he was working full time as a vice president for marketing in the computer industry. He and his wife are active socially in their golf and tennis club. They also entertain with frequent dinner parties and both are exceptional cooks. Their oldest daughter is engaged and planning to be married in 4 months.

During the occupational therapy assessment, Mattias was asked to prioritize his concerns regarding his occupational performance. Mattias wants to be able to attend and participate in his daughter's wedding in 4 months. His goal is to be able to escort her down the aisle. He wants to be able to eat and drink without concerns about choking or coughing, particularly because he and his wife were going to prepare the dinner for the wedding rehearsal party. He also wants to be able to make and drink a toast to his daughter and her new husband without risk of choking. He had planned to work to the end of the year and then retire. Upon retirement he and his wife planned to travel to Italy to attend a 1-week cooking class.

Critical Thinking Questions

1. What evaluations would you perform to develop an intervention plan for his eating and swallowing needs based on the information described?

2. What interventions would you consider to address his goal to participate in his daughter's wedding?

3. How does context influence Mattias' need to eat safely and eat a variety of foods? How would you incorporate this knowledge into your intervention plan?

4. How would you systematically grade the challenges in the intervention program for Mattias?

Ethical Considerations

Continuing education and special training are required for competence in assessing and intervening with clients who have dysphagia.

Eating is the most basic activity of daily living, necessary for survival from birth until death. Eating occurs throughout life in a variety of contexts and in every culture and is an essential activity of daily living that facilitates an individual's basic survival and well-being.[3] Although eating and **feeding** are closely related, these terms are not synonymous. The Occupational Therapy Practice Framework: Domain and Process, Third Edition (OTPF-3) defines feeding as “the process of setting up, arranging, and bringing food (fluids) from the plate or cup to the mouth; sometimes called self-feeding" and swallowing/eating is defined as "keeping and manipulating food or fluid in the mouth and swallowing it" (p. S19).[3] Swallowing is a complicated act that involves moving food, fluid, medication, or saliva through the mouth, pharynx, and esophagus into the stomach.[5] Feeding, eating, and swallowing are influenced by contextual issues, including psychosocial, cultural, and environmental factors.[5] **Dysphagia** is a medical term that means difficulty with swallowing. This difficulty can occur at any stage (oral, pharyngeal, or esophageal) of the swallow. Dysphagia is not a primary medical diagnosis; rather it is a symptom of underlying disease and is often identified by its clinical characteristics.[33]

Feeding, eating, and swallowing are within the domain and scope of practice of occupational therapy, and occupational therapists are trained to assess and provide intervention for the performance issues involved in these activities.[3,4] *Performance skills* such as motor and praxis, sensory-perceptual, emotional regulation, and cognitive skills; *client factors* such as muscle strength, endurance and motor control, muscle tone, normal and abnormal motor reflexes, respiratory system function, and digestive system function; *activity demands* such as social demands relating to the social environment and cultural contexts, sequence and timing, and required body functions and structures; and *performance patterns* including the habits, routines, and rituals that may interfere with the eating process are assessed. The *contexts* and *environments,* including those that are cultural, personal, and social, that may influence the client's successful engagement in eating are also assessed.[5]

This chapter provides the occupational therapist with a foundation for the assessment and intervention process of the adult client with eating and swallowing dysfunction. Conditions that can result in eating and swallowing problems include cerebral vascular accident (CVA), traumatic brain injury, brain tumor, anoxia, Guillain-Barré syndrome, Huntington's disease, Alzheimer's disease, multiple sclerosis, amyotrophic lateral sclerosis, Parkinson's disease, myasthenia gravis, poliomyelitis, postpolio syndrome/muscular atrophy, and quadriplegia. Anatomic or developmental dysphagia is not discussed in this chapter.

Anatomy and Physiology of Normal Eating Swallow

Deglutition, the normal consumption of solids or liquids, is a complex sensorimotor process involving the brainstem, the cerebral cortex, six cranial nerves, the first three cervical nerve segments, and 48 pairs of muscles.[30,48] A normal swallow requires all of these structures to be intact (Fig. 27.1). Therefore occupational therapists who work with clients with eating and swallowing problems must have a thorough understanding of the anatomy and physiology of all phases of the swallow (Table 27.1). The eating and swallowing process can be divided into four stages: oral preparatory phase, oral phase, pharyngeal phase, and esophageal phase (Fig. 27.2).[5,48] An additional phase, the anticipatory phase, will also be discussed.

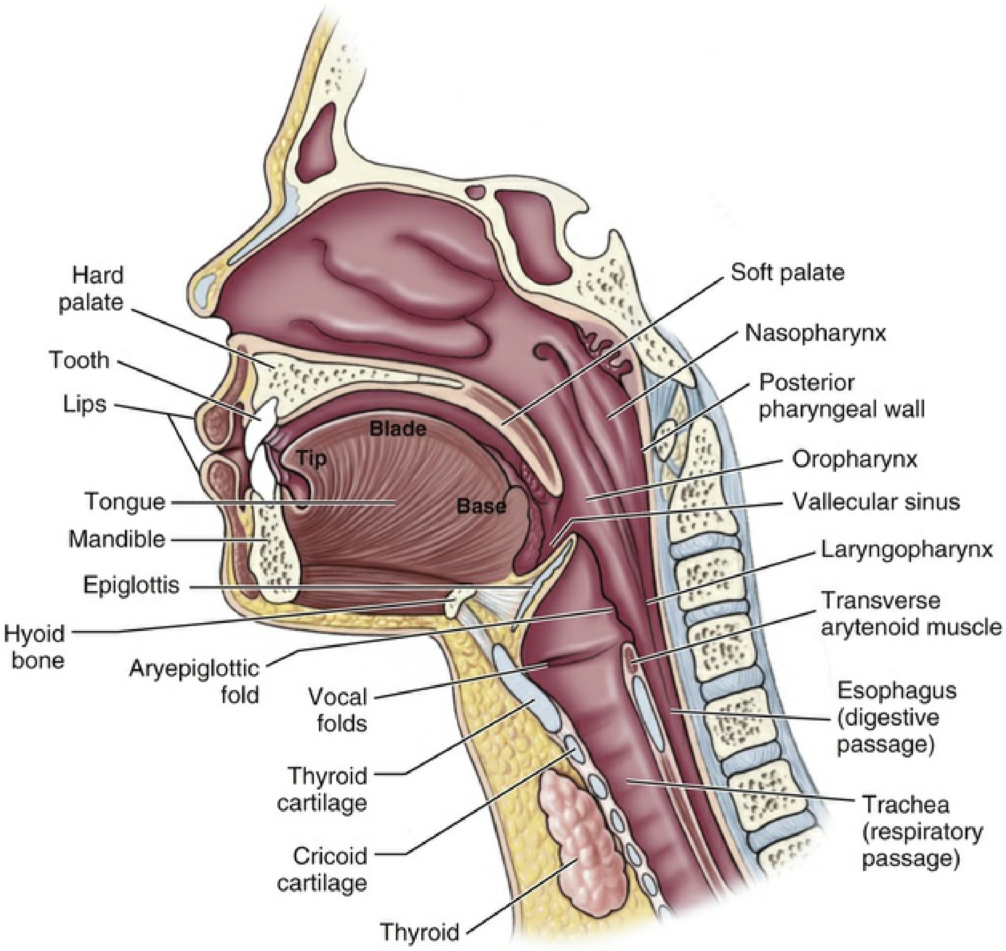

FIG 27.1 Oral structures, swallowing mechanism at rest. (From Herlihy B: *The human body in health and illness*, ed 5, St. Louis, 2014, Saunders.)

TABLE 27.1
Swallowing Process

Oral Preparatory Stage				
Structure	**Muscle**	**Movement**	**Cranial Nerve**	**Sensation**
Jaw	Pterygoideus medialis	Opens jaw	←Trigeminal (V) →	Face, temple, mouth, teeth, mucus
	Pterygoideus medialis and lateralis	Protrudes lower jaw; moves jaw laterally		
	Masseter	Closes jaw		
	Digastricus, mylohyoideus, geniohyoideus	Depresses lower jaw		
Mouth	Orbicularis oris	Compresses and protrudes lips	←Facial (VII)	
	Zygomaticus minor	Protrudes upper lip		
	Zygomaticus major	Raises lateral angle of mouth upward and outward (smile)		
	Levator anguli oris	Moves angle of mouth straight upward		
	Risorius	Draws angle of mouth backward (grimace)		

	Depressor labii inferioris	Draws lower lip downward and outward		
	Mentalis	Protrudes lower lip (pouting)		
	Depressor anguli oris	Draws down angles of mouth		
Tongue	Superior longitudinal	Shortens tongue; raises sides and tip of tongue	Facial (VII) →	Taste, anterior two thirds of tongue
	Transverse	Lengthens and narrows tongue	←Glossopharyngeal (IX) →	Taste, posterior third of tongue
	Vertical	Flattens and broadens tongue	←Hypoglossal (XII)	
	Inferior longitudinal	Shortens tongue; turns tip of tongue downward		
Oral Stage				
Tongue	Styloglossus	Elevates and pulls tongue posteriorly	←Accessory (XI)	
	Palatoglossus	Elevates and pulls tongue posteriorly; narrows fauces (faucial arches)		
	Genioglossus	Depresses, protrudes, and retracts tongue; elevates hyoid	←Hypoglossal (XII)	
	Hyoglossus	Depresses and pulls tongue posteriorly		
Soft palate	Tensor veli palatini	Tenses soft palate	←Trigeminal (V) →	Mouth
	Levator veli palatini	Elevates soft palate	←Accessory (XI)	
	Uvulae	Shortens soft palate		
Pharyngeal Stage				
Fauces (Faucial Arches)	Palatoglossus	Narrows fauces	←Vagus (X) →	Fauces
	Membranes of pharynx			
	Palatopharyngeus	Elevates larynx and pharynx		
Hyoid	Suprahyoideus	Elevates hyoid anteriorly, posteriorly	←Trigeminal (V)	
	Stylohyoideus			
	Sternothyroideus	Depresses thyroid cartilage	←Cervical 1,2,3	
	Omohyoideus	Depresses hyoid		
Pharynx	Salpingopharyngeus	Pharynx elevation	←Glossopharyngeal (IX)	
	Palatopharyngeus	Pharynx elevation		
	Stylopharyngeus	Pharynx and larynx elevation		
	Constrictor pharyngeus	Sequentially constricts the superior nasopharynx, oropharynx, laryngopharynx	←Vagus (X) →	Laryngeal and nasal pharynx
	Membranes of pharynx			
	Constrictor pharyngeus medius			
	Constrictor pharyngeus inferior			
	Cricopharyngeus	Relaxes during swallow; prevents air from entering esophagus		
Larynx	Aryepiglotticus	Closes inlet of larynx	←Vagus (X) →	
	Membranes of larynx			
	Thyroepiglotticus			
	Thyroarytenoideus	Closes glottis; shortens vocal cords		
	Arytenoid-oblique, transverse	Adducts arytenoid cartilages		
	Lateral cricoarytenoid	Adducts and rotates arytenoid cartilage		
	Vocalis	Controls tension of vocal cords		
	Postcricoarytenoideus	Widens glottis		
	Cricothyroideus-straight, oblique	Elevates cricoid arch		
Esophageal Stage				
Esophagus	Smooth	Peristaltic wave	←Vagus (X)	

Data from Finsterer J, Griswold W: Disorders of the lower cranial nerves, *J Neurosci Rural Pract* 6:377–391, 2015; Groher M: Normal swallowing in adults. In Groher M, Crary M, editors: *Dysphagia: clinical management in adults and children,* ed 2, St. Louis, 2016, Elsevier; Gutman SA, Schonfeld AB: *Screening adult neurologic populations,* ed 2, Bethesda, MD, 2009, American Occupational Therapy Association.

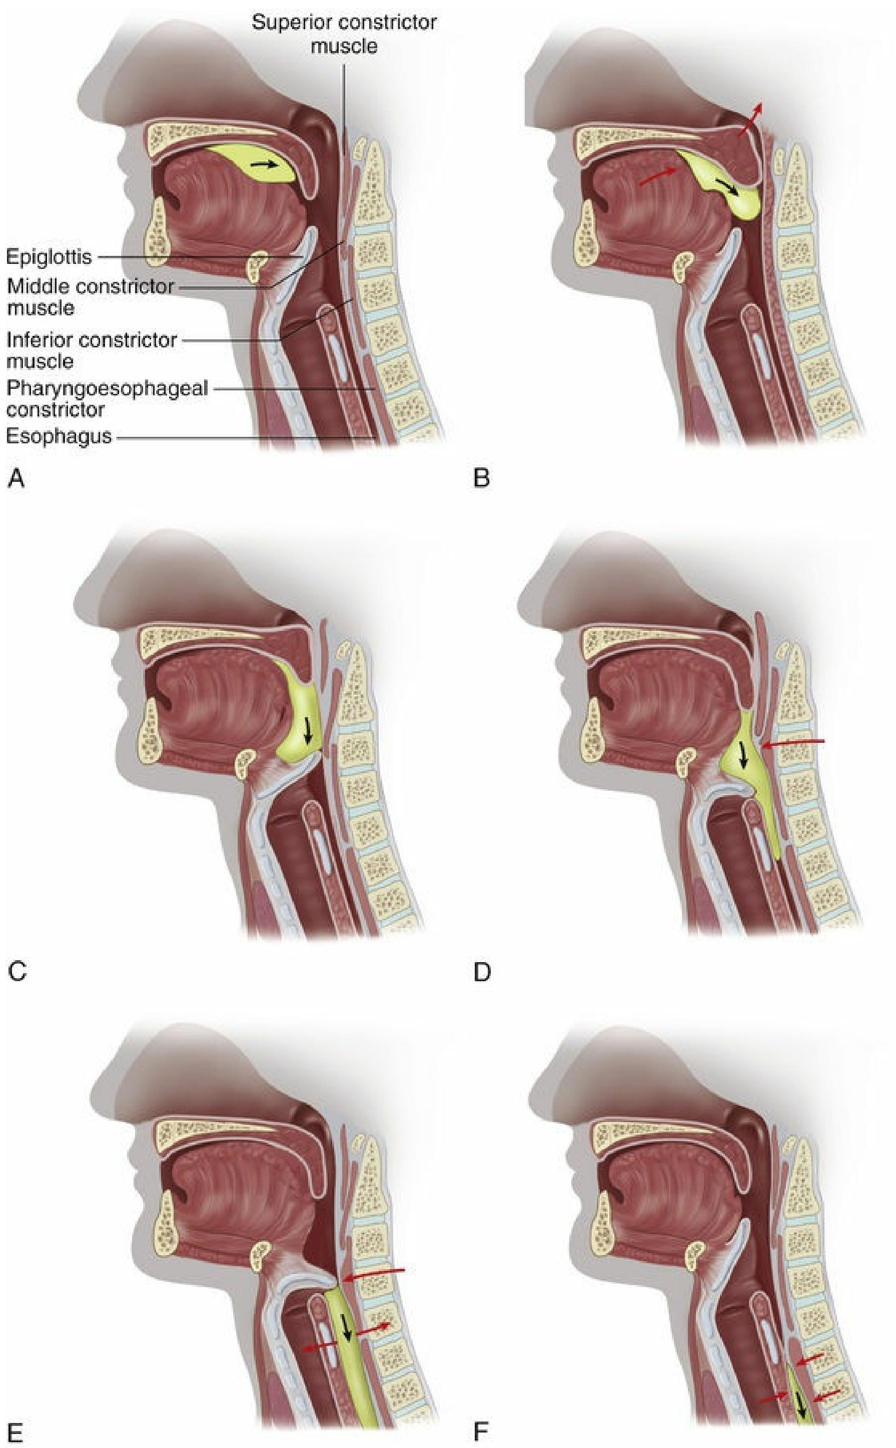

FIG 27.2 **A,** A bolus of food (yellow) is pushed against the hard palate and posteriorly toward the oropharynx by a stripping action of the tongue against the palate. (Black arrows indicate movement of the bolus.) **B** to **E,** The soft palate is elevated, closing off the nasopharynx, and the pharynx is elevated by the palatopharyngeal and salpingopharyngeal muscles. Successive contractions of the pharyngeal constrictors (**C** and **D**) force the bolus through the pharynx and into the esophagus. As this occurs, the epiglottis is bent down over the opening of the larynx, largely by the force of the bolus pressing against it. (Red arrows indicate muscle movement.) **E,** The tonically active pharyngoesophageal constrictor relaxes (outward direction red arrows), allowing the bolus to enter the esophagus. **F,** During the esophageal phase, the bolus is moved by successive contractions of the esophagus toward the stomach. (From Schapira AHV: *Neurology and clinical neuroscience,* Philadelphia, 2007, Mosby.)

Anticipatory Phase

Psychological factors, social interactions, a poor dining environment, and cultural differences contribute to feeding difficulties. The psychological, emotional, and social aspects surrounding mealtime can have a huge impact on an elderly individual's participation in the feeding process as well as on oral intake. Factors to be considered that may have an effect on the **anticipatory phase** include the variety of foods offered, presentation of food, seating during meals, mealtime atmosphere, respect of caregivers for food preferences,[15] and mealtime habits and routines.

The anticipatory phase begins even before the client enters the dining area. The client's expectations of the eating experience will influence his or her reaction to the dining environment and to the foods presented. Appetite/hunger; the sensory qualities of the food; the sensory qualities of the utensils, cups, and plates; the client's motivation to eat; and cognitive awareness of the eating activity will all have an impact on the degree to which the client engages in the feeding process. The anticipatory phase is an important precursor to successful eating. The occupational therapist can be instrumental in identifying environmental modifications that can positively influence the client's response to the eating experience.

Oral Preparatory Phase

In the **oral preparatory phase** of the swallow, food is masticated by the teeth and gums (if necessary) and manipulated by the lips, cheek, and tongue to form a **bolus** of appropriate texture for swallowing.[5,52] Visual and olfactory information stimulates salivary secretions from three pairs of salivary glands. Saliva is mixed with the food to prepare the bolus for the swallow. As tactile contact is made with the food, the jaw comes forward to open. The lips close around the glass or utensil to remove the food or liquid. The labial musculature forms a seal to prevent any material from leaking out of the oral cavity. This phase reflects the close relationship between feeding and eating. As Mattias brought food to his mouth, he did not have symmetrical lip closure on utensils or a glass, and often food or fluid would dribble from the left side of his mouth.

As chewing begins, the mandible and tongue move in a strong, combined rotary and lateral direction. The upper and lower teeth shear and crush the food. The tongue moves laterally to push the food between the teeth. The buccinator muscles of the cheeks contract to act as lateral retainers, to prevent food particles from falling into the **sulcus** between the jaw and cheek.[48] The tongue sweeps through the mouth, gathering food particles and mixing them with saliva. Recall that Mattias frequently had food remaining in his cheek after swallowing. This pocketing of food in the cheek may occur from diminished motor control of the tongue to manipulate the bolus or may indicate diminished sensory appreciation for food remaining in the sulcus. Sensory receptors throughout the oral cavity carry information of taste, texture, and temperature of the food or liquid through the seventh and ninth cranial nerves to the brainstem. The chewing action of the mandible and tongue is repeated rhythmically, repositioning the food until a cohesive bolus is formed. The length of time needed to form a bolus one can safely swallow varies with the viscosity of the food. A short time is needed for soft foods, and a longer time is needed for more textured or dense foods.[78] Large amounts of thick liquids or thick and dense foods require the tongue to divide the food into smaller parts to be swallowed one at a time. The posterior portion of the tongue forms a tight seal with the **velum**, preventing slippage of the bolus or liquid into the pharynx.[48] Foods that are a mixture of liquid and solids (such as soup with chunks of vegetables) require greater oral motor control and often present more difficulty for clients with oral preparatory phase swallowing problems.

In preparation for the next stage, the solid or liquid bolus, having been formed into a cohesive and swallowable mass, may be held between the anterior tongue and palate, with the tongue tip either elevated or dipped toward the floor of the mouth.[48] The tongue cups around the bolus to seal it against the hard palate. The **larynx** and the pharynx are at rest during this phase of the swallowing process, and the airway is open.

Threaded Case Study

Mattias, Part 2

As Mattias brought food to his mouth, he did not have symmetric lip closure on utensils or a glass, and often food or fluid would dribble from the left side of his mouth. Mattias frequently has food remaining in his cheek after swallowing.

Problems at the oral preparatory phase can disrupt the normal swallow sequence. Mattias has problems with this phase of the eating process. Of additional concern to Mattias is the embarrassment of having food or fluid dribble from the left side of his mouth. His decreased sensory awareness compromises his ability to notice foods/fluids and use a napkin to wipe the remaining food from his face.

Oral Phase

The **oral phase** of swallowing begins when the tongue initiates posterior movement of the bolus toward the pharynx.[48] The tongue elevates to squeeze the bolus up against the hard palate and forms a central groove to funnel the bolus posteriorly. As the viscosity of the food increases, the amount of pressure created by the tongue against the palate increases. Thicker foods require more pressure to propel them efficiently through the oral cavity.[48]

The oral phase of the swallow is voluntary, requiring the person to be alert and involved in the process. A normal voluntary oral phase is necessary to elicit a strong **swallow response** during the pharyngeal stage that follows. This stage of the swallow requires intact labial musculature to maintain food or liquid inside of the oral cavity, intact lingual movement to propel the bolus toward the pharynx, intact buccal musculature to prevent material from falling into the lateral sulci, and the ability to comfortably breathe through the nose. The oral phase takes approximately 1 second to complete with thin liquids and slightly longer with thick liquids and textured foods.

Threaded Case Study

Mattias, Part 3

Mattias is alert but has difficulties maneuvering food within his mouth during the oral phase. His ability to chew textured foods is compromised, and he requires additional time to chew foods. This contributes to the decreased oral intake.

Pharyngeal Phase

Voluntary and involuntary components are necessary for a normal swallow. Neither mechanism alone is sufficient to produce the immediate, consistent swallow necessary for normal eating.[48] The **pharyngeal phase** marks the beginning of the involuntary portion of the swallowing process.

This phase of swallowing begins when the bolus passes any point between the anterior faucial arches and where the tongue base crosses the lower rim of the mandible into the pharynx, marking the start of the involuntary component of the swallow.[48,69] After the swallow response has been triggered, it continues with no pause in bolus movement until the total act has been completed. The pharyngeal swallow is controlled by central pattern-generating (CPG) circuitry of the brainstem and peripheral reflexes.[42] Within the medulla oblongata the medullary reticular formation is responsible for screening out all extraneous sensory patterns and for responding only to those patterns that indicate the need to swallow. The reticular formation also assumes control of all motor neurons and related muscles needed to complete the swallow. Higher brain functions such as speech and respiration are preempted.

When the swallow response is triggered, several physiologic functions occur simultaneously. The velum elevates and retracts, closing the **velopharyngeal port** to prevent regurgitation of material into the nasal cavity. The tongue base elevates to direct the bolus into the pharynx. The hyoid and the larynx elevate and move anteriorly. There is closure of the larynx at the vocal folds, the laryngeal entrance, and the epiglottis to prevent material from entering the airway. The pharyngeal tube elevates and contracts from the top to the bottom in the pharyngeal constrictors, using a squeezing motion to move the bolus through the pharynx toward the esophagus. The bolus passes through the pharynx, dividing in half at the **valleculae** and moving down each side through the **pyriform sinuses** toward the esophagus. The upper esophageal sphincter (UES) relaxes and opens, allowing the material to enter the esophagus.[31,48] This movement must be rapid and efficient so that respiration is interrupted only briefly. The pharyngeal phase of the swallow takes approximately 1 second to complete for thin liquids.

Threaded Case Study

Mattias, Part 4

Mattias frequently coughs, indicating difficulties with the timing and coordination of the pharyngeal phase. His problems swallowing water may indicate diminished laryngeal elevation and decreased airway protection during the swallow.

Esophageal Phase

The **esophageal phase** of the swallow starts when the bolus enters the esophagus through the cricopharyngeal juncture or UES. The esophagus is a straight tube, approximately 10 inches long, that connects the pharynx to the stomach. The pharynx is separated from the esophagus by the UES. The lower esophageal sphincter (LES) separates the esophagus from the stomach. During the swallow, the strong muscles of the esophagus contract and the bolus is transported through the esophagus by peristaltic wave contractions. The overall transit time needed for the bolus to reach the stomach varies from 8 to 20 seconds. As the food enters the esophagus, the epiglottis returns to the relaxed position, and the airway opens.[31,48]

Threaded Case Study

Mattias, Part 5

Mattias complains of frequently coughing and choking on food and fluid. This may be due to problems with the preoral, oral, pharyngeal, or esophageal phase of eating. As you read the section on eating and swallowing assessment, use the case presentation of Mattias and consider what assessment results you would look for to identify which phase is producing the episodes of coughing and choking.

Eating and Swallowing Assessment

When a physician refers a client for occupational therapy, a thorough eating and swallowing assessment for possible dysfunction must be completed. The occupational therapist reviews the client's medical history and assesses the client's perceptual and cognitive skills; physical control of head, trunk, and extremities; oral structures; oral motor control; sensation; and swallowing ability.

Medical Chart Review

A review of the client's medical chart before initiating the bedside assessment reveals important information. The therapist should take note of the client's diagnosis, pertinent medical history (including prior incidents of **aspiration**), prescribed medications, and current hydration and nutritional status.

The medical diagnosis may indicate the etiology or cause of the client's eating or swallowing problems. For example, a diagnosis of a neurologic disorder such as a CVA or a degenerative disease/disorder should alert the therapist that eating or swallowing problems may exist.[61,75] It is important to know whether problems developed suddenly or gradually. The therapist should seek information regarding the duration of the client's swallowing difficulties and note any secondary diagnoses that could contribute to dysphagia, such as gastrointestinal or respiratory problems or changes in medication. A diagnosis of dehydration, weight loss, or malnutrition may indicate a chronic problem with deglutition.

Particular attention should be paid to reported episodes of pneumonia or aspiration (entry of food or material into the airway below the level of the true vocal folds). Aspiration pneumonia occurs when food or material enters into the lung and can be a serious medical complication that is identified by x-ray and treated with antibiotics.[30] Possible predictors of aspiration pneumonia include the need for frequent suctioning, chronic obstructive pulmonary disease (COPD), congestive heart failure (CHF), use of a feeding tube, weight loss, swallowing problems, multiple medications, and eating dependence.[2,43,74] An elevated temperature may also indicate that a client is aspirating.

An examination of the client's current hydration and nutritional status provides valuable information about the client's ability to manage oral intake. This information can be found in the dietary section of the chart or in the nursing progress notes in the intake and output (I & O) record. An altered diet texture (pureed food or thickened liquids) alerts the therapist to a potential problem with the client's ability to safely eat a regular diet. The presence of an intravenous (IV) fluid may indicate dehydration. Weight loss is frequently a result of a swallowing or feeding problem. Consideration should be given to prescribed medications that may alter the client's alertness, orientation, saliva production, appetite, and muscle control. The nursing notes may also indicate whether the client coughs or chokes when taking medications. How the client receives nutrition is also important—for example, the presence of a nonoral feeding device such as a **nasogastric tube** (NG tube) or **gastrostomy tube** (G tube) is often an indication of a serious dysphagia problem.

Occupational Profile

In the beginning of the evaluation process, the therapist obtains information from the client to develop the occupational profile. Information gathered for the profile is designed to help the therapist understand what is meaningful and important to the client.[3] Prior eating habits and routines and the importance of eating to the client (and the client's family or significant other) are essential to know so that interventions can be established to meet the client's needs. The occupational therapist must take into consideration the cultural values, beliefs, habits, and routines of the client revolving around food and eating. The client may have strong feelings about particular foods, food temperatures, or food textures. Food and food preparation methods may be symbolically meaningful to clients and may have a strong impact on the client's oral intake. The presentation of food may have a significant influence on the individual's desire to eat. Most adults have firmly rooted routines surrounding the activity of eating. For example, an elderly person may eat a late breakfast, a larger meal at midday, and only a light meal in the evening. He or she may watch TV while eating. This routine can be severely disrupted in an institutionalized setting.

OT Practice Notes

It is important to know the previous habits and routines of the individual and to incorporate them into the intervention program. The therapist must also be sensitive to cultural issues that revolve around eating and foods.

Threaded Case Study

Mattias, Part 6

The intervention program is developed based on information provided to the therapist in the occupational profile. Mattias clearly identified his intervention priorities and discussed his concerns about participating in his daughter's wedding. The issues related to eating and drinking are closely tied to the cultural and social expectations for the father of the bride.

Cognitive-Perceptual Status

The client's cognitive and perceptual abilities are assessed to determine the degree to which the client can actively participate in an eating and swallowing assessment and intervention program. The therapist should establish whether the client is alert, oriented, and able to follow simple directions, either verbal, with demonstration, or with manual guidance. It is important to assess the client's memory to determine if he or she will be able to recall strategies for safe eating. The therapist should also evaluate the client's visual function, visual-perceptual skills, and motor planning skills, as they are important for independent feeding. An individual who exhibits confusion, dementia, poor awareness of the eating task, poor attention span, or impaired perception or memory will require close supervision during eating for safe consumption.[14,16,47]

Physical Status

Control of head and trunk is an important component of a safe swallow. To assess head control, the therapist asks the client to turn the head from side to side and up and down. The therapist assesses the client's range of motion and motor control. Assessment should include the quality of head movement without physical assistance or support initially and with assistance, if needed. The therapist should also gently move the client's head passively from side to side and up and down to look for stiffness or abnormal muscle tone. Poor head control may indicate decreased strength, decreased or increased muscle tone, or decreased awareness of posture. Appropriate head control is necessary to provide a stable base for adequate jaw and tongue movement, allowing an optimal swallow response. Head control is also necessary to anatomically position the client in the safest posture to reduce the risk of aspiration.

In assessing the client's trunk control, the therapist observes whether the client is able to sit in the upright position in midline with equal weight bearing on both hips. The therapist assesses the client's ability to maintain the midline position independently when involved in eating and whether he or she requires the use of postural supports (such as wheelchair trunk supports or a lap board) or physical assistance. It is also important to determine if the client can return to midline if a loss of balance occurs. To participate in an eating and swallowing intervention program, the client must maintain an upright position with the head and trunk in midline to provide correct alignment of the swallowing structures and reduce the risk of aspiration caused by poor positioning. The client's endurance for sitting upright and participating in an eating activity is assessed, and the impact of fatigue on the swallow is determined.

Threaded Case Study

Mattias, Part 7

Mattias is able to independently sit in a chair and at the side of the bed. His head control appears adequate, but he tends to sit shifted to his right side, and his head is most often facing to the right side instead of positioned in midline. This indicates poor trunk and head alignment and can impact eating.

Oral Assessment

Outer Oral Status

The face and mouth are sensitive areas to assess. Most adults are cautious about or even threatened by having another person touch their face. Therefore each step of the assessment process should be carefully explained prior to touching the client, using terms that the individual understands. The therapist also should tell the client how long he or she will be touching the face—for example, “For a count of three.” The therapist assesses the outer oral structures, including the facial musculature and mobility of the cheeks, jaw, and lips. Working within the client's visual field, the therapist moves his or her hand(s) slowly toward the client's face. This allows the individual time to process and acknowledge the approach.

Sensation.

Indications of poor oral sensation include drooling, food remaining on the lips, and food falling out of the mouth without the client being aware that this is happening. To assess the client's awareness of touch, the therapist occludes the client's vision and uses a cotton-tipped swab to gently touch different areas of the face. The individual is asked to point to where he or she was touched. If pointing is difficult, the client is asked to nod or say yes or no when touched. The client with intact sensation responds accurately and quickly.

The client's ability to sense hot and cold should be assessed. The therapist may use two test tubes, one filled with hot water and one with cold water. A laryngeal mirror that is first heated and then cooled using hot and cold water may also be used. The client's face or lips are touched in several places, and the client is asked to indicate whether the touch was hot or cold. An aphasic client or a client with cognitive impairment may have difficulty responding accurately. In this instance, the therapist must make an assessment from clinical observations.

Poor sensory awareness can affect the client's ability to move facial musculature appropriately. The client's self-esteem may be affected, especially in social situations, if decreased awareness causes the client to ignore saliva, food, or liquids remaining on the face or lips.

Threaded Case Study

Mattias, Part 8

Consider Mattias and his personal goal of eating at his daughter's wedding rehearsal dinner. The diminished sensation around Mattias' face will need to be addressed to avoid his embarrassment during this important event. Strategies that promote compensatory habit formation should be used, such as having Mattias wipe his face after every second or third bite of food to remove any food on his face. This strategy provides further sensory input to the face in addition to decreasing the potential embarrassment of having food remain on his face.

Musculature.

An assessment of the facial musculature provides the therapist with information about the movement, strength, and tone available to the client for chewing and swallowing. The therapist first observes the client's face at rest and notes any visible asymmetry. If a facial droop is obvious, the therapist should observe whether the muscles feel slack or taut. A masked appearance, with little change in facial expression, may also be observed. The therapist should observe whether the client appears to be frowning or grimacing with the jaw clenched and the mouth pulled back.

The therapist tests the facial musculature by asking the client to perform the movements listed in Table 27.2. The therapist should note how much assistance the client needs to perform these movements. As the client moves through each task, symmetry of movement is assessed. Asymmetry could indicate weakness or increased tone. Musculature is palpated for abnormal resistance to the movement.

TABLE 27.2

Outer Oral Motor Assessment

Function	Instruction to Client	Testing Procedure*
Facial expression	"Lift your eyebrows as high as you can."	Place one finger above each eyebrow. Apply downward pressure.
	"Bring your eyebrows toward your nose in a frown."	Place one finger above each eyebrow. Apply pressure outward.
	"Wrinkle your nose upward."	Place one finger on tip of nose and apply downward pressure.
	"Suck in your cheeks."	Apply pressure outward against each inside cheek.
Lip control	"Smile."	Observe for symmetric movement. Palpate over each cheek.
	"Press your lips together tightly and puff out your cheeks."	Place one finger above and one finger below lips. Apply pressure, moving fingers away from each other; check for ability to hold air.
	"Pucker your lips as in a kiss."	Apply pressure inwardly against lips (toward teeth).
Jaw control	"Open your mouth as far as you can."	Help patient maintain head control. Apply pressure from under chin upward and forward.
	"Close your mouth tightly. Don't let me open it."	Help client maintain head control. Apply pressure on chin downward.
	"Push your bottom teeth forward."	Place two fingers against chin and apply pressure backward.
	"Move your jaw from side to side."	Place one finger on left cheek and apply pressure to right.

*Apply resistance only in the absence of abnormal muscle tone.

Data from Avery W, et al: *Dysphagia care and related feeding concerns for adults,* ed 2, Bethesda, MD, 2010, American Occupational Therapy Association; Gutman SA, Schonfeld AB: *Screening adult neurologic populations,* ed 2, Bethesda, MD, 2009, American Occupational Therapy Association.

If the client is able to hold the position at the end of the movement, the therapist applies gentle pressure against the muscle to determine strength. An individual with normal strength is able to hold the position throughout the applied resistance. The person who is only able to hold the position briefly against pressure may have adequate strength for chewing and swallowing but may require an altered diet.

Oral reflexes.

A client who has sustained damage to brain-stem or cortical structures may demonstrate primitive oral reflexes that will interfere with a dysphagia-retraining program. The presence of the rooting, bite, or suck-swallow reflex, normal from 0 to 5 months of age, will interfere with oral motor control in adults. Persistence of these primitive oral reflexes interferes with the client's isolated oral motor control, which is needed for chewing and swallowing. The gag, palatal, and cough reflexes should be present in adults and contribute to airway protection. The absence or impairment of these important reflexes may interfere with a safe swallow. Specific assessment techniques are presented in Table 27.3.

TABLE 27.3

Oral Reflexes

Reflex	Assessment	Functional Implications
Rooting (0–4 months)	Stimulus: touch client on right or left corner of mouth	Limits isolated motor control of lip muscles
	Response: client moves lips and head in direction of stimulus	Moves head out of midline, which alters alignment of swallowing mechanism
Bite (4–7 months)	Stimulus: touch crowns of teeth with unbreakable object Response: client involuntarily clamps teeth shut	Prevents normal forward, lateral, and rotary movements of jaw necessary for chewing
Suck-swallow (0–4 months)	Stimulus: introduction of food and liquid Response: sucking	Prevents development of normal voluntary swallow
Tongue thrust (abnormal)	Stimulus: introduction of food and liquid	Interferes with ability to keep lips and mouth closed
	Response: tongue comes forward to front of teeth	Prevents tongue from propelling food to back of mouth in preparation for swallow; prevents formation of bolus, loss of tongue lateralization
Gag (0–adult)	Stimulus: pressure on back of tongue Response: tongue humping, pharyngeal constriction	Protects airway (not always present in normal adult); hypersensitive gag reflex can interfere with chewing, swallowing
Palatal (0–adult)	Stimulus: stroke along faucial arches Response: constriction of faucial arches; elevation of uvula	Protects airway, closes off nasal passages, triggers swallow response

Data from Avery W, et al: *Dysphagia care and related feeding concerns for adults,* ed 2, Bethesda, MD, 2010, American Occupational Therapy Association; Logemann J: *Evaluation and treatment of swallowing disorders,* Austin, TX, 1998, Pro-Ed.

Intraoral Status

An assessment of the client's intraoral status includes an examination of oral structures, including the tongue and palatal function. The therapist first explains each procedure to the client, then works within the client's visual field and gives the person time to process the instructions found in Table 27.4.

TABLE 27.4

Intraoral Motor Assessment

Function	Instruction to Client	Testing Procedure*
Tongue		

Protrusion	"Stick out your tongue."	Apply slight resistance toward the back of the throat with tongue blade after client exhibits full range of motion.
Lateralization	"Move your tongue from side to side."	Apply slight resistance in opposite direction of motion with tongue blade.
	"Touch your tongue to your inside cheek—right, then left; move your tongue up and down."	Using finger on outside of cheek, push against tongue inwardly.
Tipping	"Touch your tongue to your upper lip."	With tongue blade between tongue tip and lip, apply downward pressure.
	"Open your mouth. Touch your tongue behind your front teeth."	With tongue blade between tongue and teeth, apply downward pressure on tongue.
Dipping	"Touch your tongue behind your bottom teeth."	With tongue blade between tongue and bottom teeth, apply upward pressure.
Humping	"Say, 'ng'; say, 'ga.' "	Observe for humping of tongue against hard palate. Tongue should flow from front to back.
	"Run your tongue along the roof of your mouth, front or back."	Observe for symmetry and ease of movement.
Swallow		
Hard palate	"Open your mouth and hold it open."	Using flashlight, gently examine for sensitivity by walking finger from front to back.
Soft palate	"Say, 'ah' for as long as you can (5 seconds). Change pitch up an octave."	Observe for tightening of faucial arches, elevation of uvula. Using laryngeal mirror, stroke juncture of hard and soft palate to elicit palatal reflex. Observe for upward and backward movement of soft palate.
Hyoid elevation (base of tongue)	"Can you swallow for me?"	Place finger at base of client's tongue underneath the chin, and feel for elevation just before movement of the larynx.
Laryngeal		
Range of motion	"I am going to move your Adam's apple side to side."	Grasp larynx by placing fingers and thumb along sides. Move larynx gently side to side; evaluate for ease and symmetry of movement.
Elevation	"Can you swallow for me?"	Place fingers along the larynx: first finger at hyoid, second finger at top of larynx, and so on. Feel for quick and smooth elevation of larynx as the client swallows.
Cough		
Voluntary	"Can you cough?"	Observe for ease and strength of movement, loudness of cough, swallow after cough.
Reflexive	"Take a deep breath."	As client holds breath, using palm of hand, push downward (toward stomach) on the sternum. Evaluate strength of reaction.

*Apply resistance in absence of abnormal muscle tone.

Data from Avery W, et al: *Dysphagia care and related feeding concerns for adults*, ed 2, Bethesda, MD, 2010, American Occupational Therapy Association; Gutman SA, Schonfeld AB: *Screening adult neurologic populations*, ed 2, Bethesda, MD, 2009, American Occupational Therapy Association.

Standard precaution techniques are used throughout the assessment and include the use of examination gloves and careful hand washing. The therapist should check for allergies to latex before examining the person's mouth and use an examination glove made of appropriate material for an intraoral examination. The therapist must place only a wet, gloved finger or dampened tongue blade into the client's mouth. The mouth is normally a wet environment, and a dry finger or tongue blade can be uncomfortable. After a count of three, the therapist removes the finger and allows the client to swallow the secretions that may have accumulated.

Dentition.

Because the adult uses teeth to shear and grind food during bolus formation, it is important for the therapist to assess the condition and quality of the client's teeth and gums. Poor dental status or inadequate denture fit can contribute to dysphagia, discomfort or pain with swallowing, dehydration, malnutrition, low dietary intake, poor nutritional status, and weight loss.[21,58]

For assessment purposes, the mouth is divided into four quadrants: right upper, right lower, left upper, and left lower. The therapist notes whether the client's gums are bleeding, tender, or inflamed and whether the gums feel spongy or firm. Loose teeth and sensitive or missing teeth are also noted.

OT Practice Notes

The therapist should avoid placing his or her finger between the client's teeth until it has been determined that the client does not have a bite reflex.

After assessing the gums, the therapist turns over his or her finger, slides the pad of the finger against the inside of the client's cheek, and gently pushes the cheek outward to feel the tone of the buccal musculature. The therapist notes whether the cheek is firm with an elastic quality, too easy to stretch, or tight without any stretch. The therapist observes the condition of the inside of the client's mouth, checking for bite marks on the tongue, cheeks, and lips. Next, the therapist should remove the finger from the client's mouth, allow or assist the client to swallow saliva, and assist the client to move the lip and cheek musculature into the normal resting position. This procedure is repeated for each quadrant.

If the client has dentures, the therapist must determine whether the fit is adequate for chewing. Because dentures are held in place and controlled by normal musculature and sensation, changes in these areas, or marked weight loss, affect the client's ability to use dentures effectively for eating. Dentures should fit over the gums without slipping or sliding during eating or talking. Clients should always wear well-fitting dentures during oral intake. A dental consultation may be needed to ensure appropriate fit if dentures cannot be held firmly with commercial adhesive creams or powders. Loose dentures or teeth may necessitate changes in food consistencies that the client may have otherwise managed. Clients who have gum or dental problems require appropriate follow-up and excellent oral hygiene to participate in a feeding and eating program. Poor oral hygiene can lead to the development of bacteria, which, if aspirated, contributes to the increased risk of pneumonia.[9,46,53]

Tongue movement.

The tongue has a critical role in the normal chewing and swallowing process. Controlled lingual movement is necessary to assist in the preparation and movement of food in the mouth.[37,72] The extrinsic muscles of the tongue control the position of the tongue in the oral cavity, and the intrinsic muscles are responsible for changing the shape of the tongue, which is necessary in propelling the bolus posteriorly.[68] Lingual discoordination is one of the most commonly reported problems affecting the oral stage of swallowing.[77] A thorough assessment of the tongue's strength, range of motion, control, and tone is an important component of the swallowing assessment.

The client is asked to open the mouth, and the therapist assesses the appearance of the tongue using a flashlight and notes whether the tongue is pink and moist, red, or heavily coated and white. A heavily coated tongue decreases the client's sensations of taste, temperature, and texture and may indicate poor tongue movement or be a sign of infection.

When examining the shape of the tongue, the therapist notes whether it is flattened, bunched, or rounded. Normally, the tongue is slightly concave with a groove running down the middle. The therapist observes the tongue at rest in the mouth and determines whether it is in the normal position of midline, resting just behind the front teeth, retracted or pulled back away from the front teeth, or deviated to the right or left side. A retracted tongue may indicate an increase of abnormal muscle tone or a loss of range of motion as a result of soft-tissue shortening. The client exhibiting tongue deviation with protrusion may have muscle weakness on the affected side, causing the tongue to deviate toward the unaffected side because the stronger muscles dominate. The client also may have abnormal tone, causing the tongue to deviate toward the affected side.

Using a wet gauze pad to grasp the tongue gently between the forefinger and thumb, the therapist pulls the tongue slowly forward. Next, the therapist walks a wet finger along the tongue from front to back to determine whether the tongue feels hard, firm, or mushy. The tongue should feel firm. An abnormally hard tongue may be the result of increased muscle tone, and a mushy tongue is associated with low muscle tone. The right side of the tongue is compared with the left side for symmetry.

While continuing to grip the tongue between forefinger and thumb, the therapist assesses the client's range of motion by moving the tongue forward, side to side, and up and down. The tongue with normal range will move freely in all directions without resistance. Moving the tongue through its range, the therapist can simultaneously evaluate tone. As the therapist gently pulls the tongue forward, he or she determines whether it is easily moved or whether resistance is noted. A tongue pulling back against the movement indicates increased tone. A tongue that seems to stretch too far beyond the front teeth indicates decreased tone. When moving the tongue side to side, the therapist notes whether it is easier to move in one direction or the other. Increased tone makes it difficult for the therapist to move the tongue in any direction without feeling resistance against the movement. Clients who are confused or apraxic may resist this passive motion but not have abnormal tone.

To assess the tongue's motor control (strength and coordination), the therapist asks the client to elevate, stick out, and move the tongue laterally (see Table 27.4). If the client has difficulty understanding verbal directions, the therapist can use a wet tongue blade to guide the client through the desired movements.

Poor muscle strength or abnormal tone decreases the tongue's ability to sweep the mouth and gather food particles to form a cohesive bolus. If the tongue loses even partial control of the bolus, food may fall into the valleculae, the pyriform sinuses, or the airway, possibly leading to aspiration before the actual swallow.[48] The back of the tongue must also elevate quickly and strongly to propel the bolus past the faucial arch into the pharynx to trigger the swallow response.[31] The client with poor tongue control may not be a candidate for eating or may need altered food or liquid textures. Close supervision by an experienced therapist is required for a client with impaired tongue control to participate in eating.

Threaded Case Study

Mattias, Part 9

Mattias had decreased tongue mobility and control. When he protruded his tongue, it was deviated toward the left, which indicates diminished motor control on the left side of his tongue. An additional indication of diminished tongue control is the pocketing of food in his mouth following a swallow.

Clinical Assessment of Swallowing

Because aspiration is a primary concern in swallowing, the occupational therapist must carefully assess the client's ability to swallow safely. A swallow screening should be conducted as soon as medically appropriate followed by a more comprehensive assessment.[11] Before the therapist presents the client with material to swallow, he or she should assess the client's ability to protect the airway. The client must have an intact palatal reflex, elevation of the larynx, and a productive cough. The purpose of a productive cough is to remove any food or liquid from the airway.[43] Individuals with a weak or nonproductive cough are at a higher risk for aspiration.[35,73] Directions for assessing all the components of the swallow are described in Table 27.4. The therapist should note the speed and strength of each component. The client with intact cognitive skills may accurately report to the therapist where and when difficulty occurs with the swallow.

The occupational therapist integrates all the information from the assessment process. Clinical judgment plays an important role in the accurate assessment of dysphagia.[5,22] The following questions should be asked:

1. Is the client alert and able to participate in a swallowing assessment?

2. Does the client maintain adequate trunk and head control, with or without assistance?

3. Does the client display adequate tongue control to form a cohesive bolus and move the bolus through the oral cavity?

4. Is the larynx mobile enough to elevate quickly and with sufficient force during the swallow?

5. Can the client handle saliva with minimal drooling?

6. Does the client have a productive cough, strong enough to expel any material that may enter the airway?

If the answer is yes to all of these questions, the therapist may assess the client's oral and swallow control with a variety of food consistencies.

The therapist should request an assessment tray from dietary services. The following foods are merely suggestions and the therapist must consider cultural factors and medical conditions that influence the selection of foods. For example, a vegetarian or a person who is lactose intolerant will require an appropriate selection of foods. The tray should contain a sample of foods of various textures including pureed food such as pudding or applesauce, soft foods such as a banana or macaroni and cheese, and a mechanical soft-textured food such as ground tuna with mayonnaise or chopped meat with gravy. The tray should also include a thick drink such as nectar blended with half of a banana for a 7-ounce drink; a semithick drink such as fruit nectar or a yogurt drink; and a thin, flavored liquid such as juice and water.

To minimize the risk of aspiration, pureed foods are chosen for clients with decreased oral motor control and chewing difficulties or apraxia. Clients who have poor endurance, breathing difficulties, or have difficulty attending to the task of eating may also require pureed foods. Soft foods are more easily formed into a bolus and require less chewing than regular or ground textures for clients who have impaired oral motor control. Soft foods are also easier for the client to keep in a cohesive bolus as they are moved through the oral cavity. Ground foods allow the therapist to assess a client's ability to chew, form a cohesive bolus, and move it in the mouth. Thick liquids move more slowly from the front of the mouth to back, giving the client with a delayed swallow or impaired oral motor skills more time to control the liquid until the swallow response is triggered. Thin liquids are the most difficult to control because they require intact oral motor strength and coordination, and an intact swallow to prevent aspiration.

For the client who appears to have some ability to chew, the therapist should start with pureed and soft textures. Solid textures may be introduced next if the client is able to safely and efficiently swallow the pureed and soft food textures. The following procedures should be completed after each swallow of food or liquid:

1. The therapist places a small amount ($\frac{1}{3}$ teaspoon) of food or liquid on the middle of the client's tongue. The client is asked to swallow. Two to three bites are presented of each texture to check for fatigue in controlling that texture.

2. The therapist palpates for the swallow by placing the index finger at the hyoid notch, the second finger at the top of the larynx, and the third finger along the midlarynx. The therapist can feel the strength and smoothness of the swallow and can note whether the client requires subsequent or additional swallows to clear the bolus.[43] The therapist evaluates oral transit time by noting when food entered the mouth, when tongue movement was initiated, and when the elevation of the hyoid notch was felt, which indicates the beginning of the swallow process. The therapist can time the swallow from the time that hyoid movement begins to when laryngeal elevation occurs, indicating triggering of the swallow response.[48] A normal swallow takes only 1 second to complete for thin liquids and slightly longer for textured foods.

3. The therapist asks the client to open the mouth to check for remaining food. Food is commonly seen in the lateral sulci, under the tongue, on the base of the tongue, and against the hard palate.[48] Food remaining in the mouth indicates decreased or impaired oral transit skills. The client who exhibits oral motor deficits has increasing difficulty with chewing, shaping a bolus, and moving the bolus in the oral cavity as textured foods are introduced.

4. The therapist asks the client to say "ah." By listening carefully, the therapist can assess the client's voice quality and classify the sound production as strong, clear, gurgly, or gargling.[48]

A gurgly voice may result from a delayed swallow response, which allows material to collect in the larynx prior to the initiation of the swallow. The therapist asks the client to take a second "dry" swallow to clear any pooling of material. Asking the client to say "ah" again enables the therapist to assess whether the voice quality remains gurgly or wet-sounding for any length of time after the dry swallow. In addition, the therapist asks the client to pant for a few seconds. This will shake loose any material that may remain in the pyriform sinuses or valleculae. If the voice is still gurgly, the therapist should be concerned with the possibility that material has come into contact with or is sitting on the vocal cords.[48]

A client with an impaired swallow may aspirate immediately or may pool liquids in the pyriform sinuses and valleculae, which, when full, overflow into the laryngeal vestibule and down into the trachea. If a client continues to have a gurgling or gargling voice after a second dry swallow or has substantial coughing with any of the liquid consistencies, the assessment should be discontinued.

If the client has significant coughing episodes, particularly before the therapist feels the initiation of the swallow (elevation of hyoid notch) with all consistencies, then he or she should not continue to present food. Strategies and techniques to facilitate a safe swallow are appropriate to introduce at this point. If the client continues to have significant coughing or other signs that may suggest aspiration, a **videofluoroscopy** swallow study is indicated.[25,65]

A client with central nervous system damage and impaired sensation may have difficulty with a pureed food because it does not stay together as a bolus. The weight of soft foods, denser than a pureed food, may trigger the swallow response. If the client continues to cough even with soft foods, the swallow assessment should be discontinued. In this instance, a videofluoroscopy swallow study is indicated. If a client is having difficulty at this level, only a prefeeding intervention program should be considered.

A client who has difficulty managing solid consistencies may or may not have difficulty with liquids. To assess the client's swallow with liquids, the therapist starts with a thickened (thick) nectar, then a pure nectar (semithick), and finally a thin liquid such as water or juice (see Table 27.8, presented later in the chapter). Small amounts of the liquid are placed on the middle of the client's tongue with a spoon. The therapist proceeds by following the four-step sequence described earlier for solid foods. The therapist assesses the client's skill at moving material from front to back, the time of oral transit and swallow, and the voice quality after each swallow. Each liquid consistency is assessed for two or three swallows to check for fatigability. If the client tolerates and swallows liquids by spoon without difficulty, the therapist assesses the client's ability to tolerate liquids from a cup or with a straw. The client's voice quality is checked following each swallow.

The therapist must also assess the client's ability to alternate between liquids and solids, which occurs naturally during meals. The therapist presents the client with an easily managed food bolus, followed by the safest type of liquid tolerated, and then assesses the client's ability to safely swallow when the consistency of the food is changed.

A client with a **tracheostomy** tube in place can be assessed as previously described. The same criteria must be met before the therapist assesses the client's eating and swallowing of food or liquids. The therapist must have a thorough understanding of the types of tracheostomy tubes and varied functions. The therapist must also be aware that clients who have had a tracheostomy tube, especially those on ventilation for any length of time, may experience changes in the swallowing mechanism such as muscle atrophy, decreased sensation, and laryngeal damage.[13]

Threaded Case Study

Mattias, Part 10

Although Mattias had frequent episodes of coughing during the bedside evaluation, no gurgly or raspy vocal quality was noted during speech. He is able to clear material from his vocal folds with a strong protective cough. He is able to swallow his secretions, but drooling was noted from the left corner of his mouth, which indicates diminished sensation.

Because Mattias is able to safely manage a modified diet texture using positioning strategies and does not have signs and symptoms of aspiration, a videofluoroscopy was not deemed necessary.

Two main types of tracheostomy tubes exist: fenestrated and nonfenestrated.[48] A fenestrated tube (Fig. 27.3) is designed with an opening in the middle to allow increased air flow. This type of tube is frequently used for clients being weaned from a tube because it allows a client to breathe nasally as he or she relearns a normal breathing pattern. Placement of an inner cannula piece into the tracheostomy tube allows the fenestrated opening to be closed off. With the inner cannula removed, a trachea button may be used to allow the client to talk. A nonfenestrated tube has no opening. A fenestrated tube is preferred for treating a client with dysphagia.

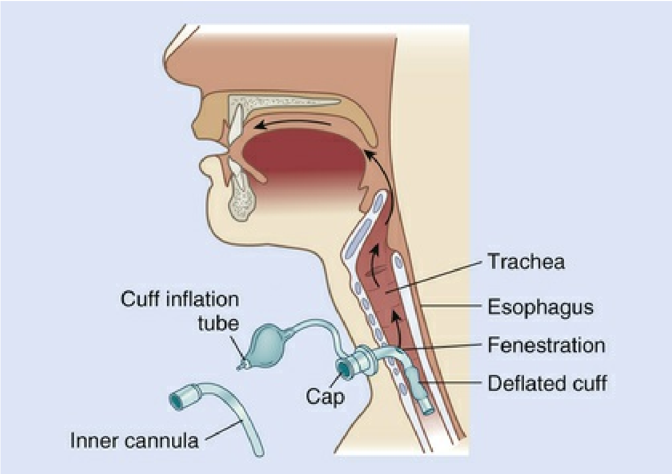

FIG 27.3 Fenestrated tracheostomy. (From Lewis SL, et al: *Medical-surgical nursing: assessment and management of clinical problems*, ed 9, St. Louis, 2014, Mosby.)

A tracheostomy tube may be cuffed or uncuffed. A cuffed tube has a balloon-like cuff surrounding the bottom of the tube (Fig. 27.4). When inflated, the cuff comes into contact with the trachea wall, preventing the aspiration of secretions into the airway. A cuffed tube is used in cases in which aspiration has occurred. The therapist should consult with the client's attending physician to see whether the client is still at risk of aspiration or if it is safe to deflate the cuff for an eating and swallowing assessment.

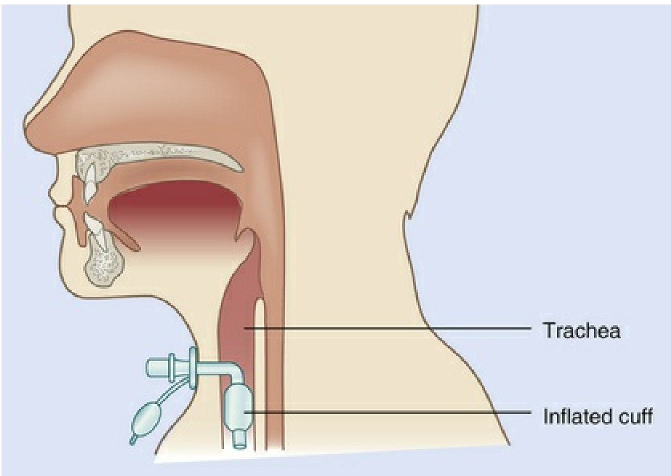

FIG 27.4 Cuffed tracheostomy. (From Lewis SL, et al: *Medical-surgical nursing: assessment and management of clinical problems,* ed 9, St. Louis, 2014, Mosby.)

The presence of a tracheostomy tube may affect a client's ability to swallow because laryngeal elevation is impeded due to the presence of the tube, loss of upper airway sensitivity, inability of the larynx to effectively close during the swallow, and reduced subglottal air pressure atrophy of the laryngeal muscles due to disuse.[32] Despite these challenges, studies have found that a tracheostomy does not necessarily increase the risk of aspiration in chronically dysphagic patients.[40,44]

Before the therapist presents food or liquid to the client with a tracheostomy who has a fenestrated tube, the inner cannula should be in place. If the client has a cuffed tube, the therapist should thoroughly suction orally and around the cuff, present food, and slowly deflate the cuff while suctioning to prevent substances from penetrating the airway. The airway again needs to be suctioned orally and through the tracheostomy to ensure that all secretions have been cleared.[48]

After presenting food or liquids, the therapist should assess oral transit skills and the pharyngeal swallow as previously described. Blue food coloring may be added to food or liquids presented orally if the client is not allergic to dyes. This can help the therapist identify aspirated material in the trachea. The client or the therapist can use a gloved finger to cover the trachea opening and thereby achieve a more normal tracheal pressure, which has been shown to improve the pharyngeal swallow.[34]

If the tracheostomy tube is cuffed and inflated during the assessment, the cuff is slowly deflated after the client has swallowed. The airway is suctioned through the tracheostomy tube to determine whether any material entered the airway. The swallow assessment should not be continued if material is found in the trachea.[48] When the assessment is complete, the airway is thoroughly suctioned. The inner cannula is removed from the fenestrated tube, or the cuff is inflated to the level prescribed by the physician.

The client's performance on the swallowing assessment determines whether he or she is able to participate in a feeding program and which diet texture is the most appropriate to ensure a safe, efficient swallow. The safest consistency is that which the client is able to chew, move through the oral cavity, and swallow with the least risk of aspiration.

Indicators of Eating and Swallowing Dysfunction

Symptoms of oropharyngeal dysphagia include (but are not limited to) the following:

1. Difficulty with bringing food to the mouth

2. Difficulty or inability to shape food into a cohesive bolus-prolonged chewing

Loss of food or liquids from the mouth; drooling

Loss of food or liquids from the nose (nasal regurgitation)

3. Coughing or frequent throat clearing before, during, or after the swallow

4. Wet or gurgling voice quality after eating or drinking

5. Changes in mealtime behaviors

Food residue remaining in the mouth (cheeks, gums, teeth, tongue)

Loss of appetite; dehydration or weight loss

Discomfort or pain when swallowing

Difficulty breathing while eating

Unusual head or neck movements when swallowing

6. Delayed or absent swallow response

7. Weak cough

8. Reflux of food after meals

Heartburn

Changes in eating—for example, eating slowly or avoiding social occasions

Food avoidance

Prolonged mealtimes

Recurrent episodes of pneumonia

Aspiration

Swallowing dysfunction can lead to aspiration of food or liquid into the airway. Aspiration can occur at any point during the swallowing process (Fig. 27.5). The following are acute symptoms of aspiration that may occur before, during, or after the swallow:[48]

1. Any change in the client's color, particularly if the airway is obstructed

2. Prolonged coughing or choking

3. Gurgling voice and extreme breathiness or loss of voice

4. Excessive secretions

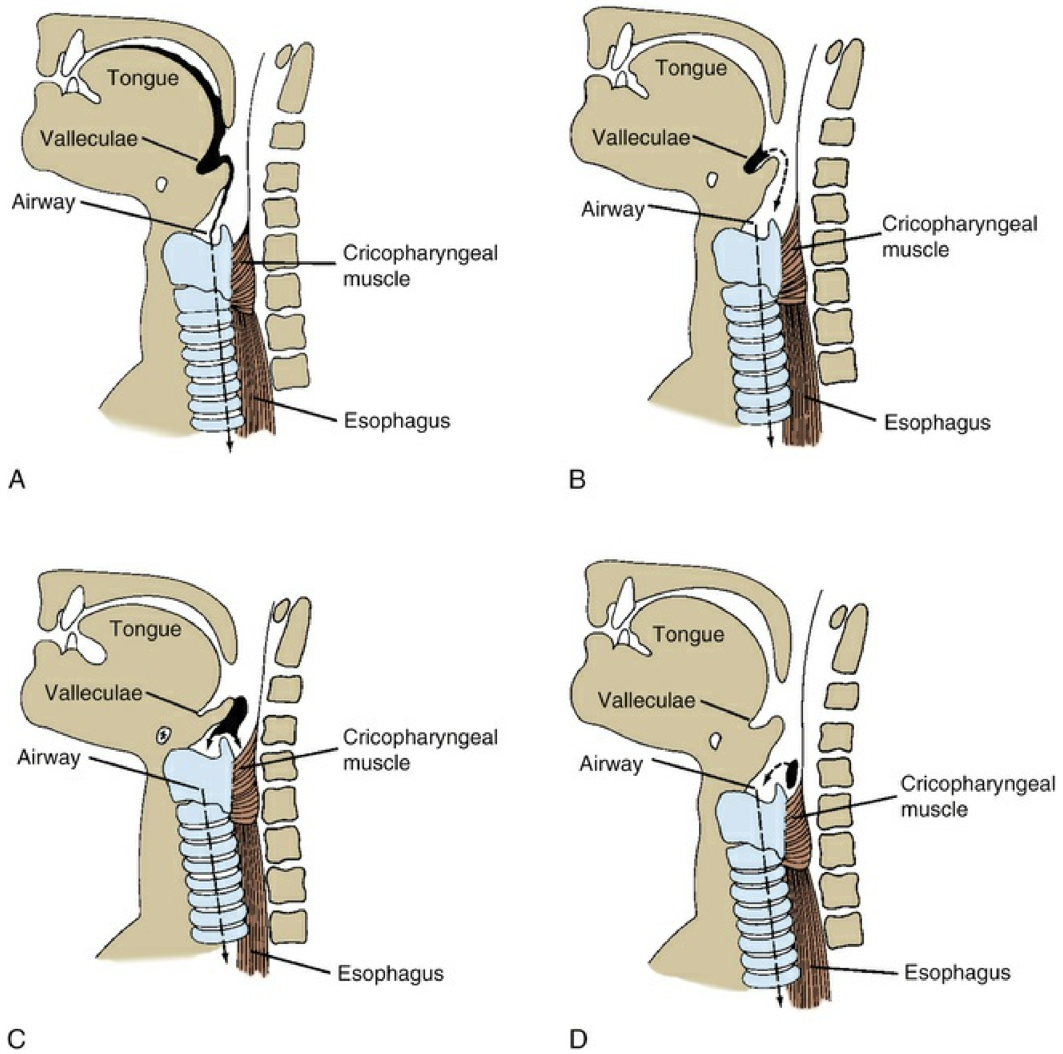

FIG 27.5 Types of aspiration. **A,** Aspiration before swallow caused by reduced tongue control. **B,** Aspiration before swallow caused by absent swallow response. **C,** Aspiration during swallow caused by reduced laryngeal closure. **D,** Aspiration after swallow caused by pooled material in pyriform sinuses overflowing into airway. (From Logemann J: *Evaluation and treatment of swallowing disorders,* San Diego, 1998, College-Hill Press.)

Many individuals with dysphagia silently aspirate, which means they show no clinical symptoms of aspiration during swallowing. For these individuals, aspiration and the etiology of aspiration can only be determined through an instrumental assessment.

During the 24 hours immediately after the swallow, the therapist and medical staff must observe the client for additional signs of aspiration. Aspiration pneumonia is a lung infection requiring medical intervention that may result from aspiration during swallowing. Clinical signs include fever, shortness of breath with a rapid heart rate, mental confusion, and incontinence, although not all of these symptoms are always present, especially in older clients.[30] If aspiration pneumonia develops, the client must be reevaluated for a change in diet levels or taken off the feeding program, if necessary. An alternative feeding method may be necessary to ensure adequate hydration and nutrition.

Instrumental Assessment

Instrumental assessments are important techniques for evaluating biomechanical and physiologic function and for determining swallow safety as well as assessing the effects of **compensatory strategies** (ie, posture and bolus texture) on swallowing. They are performed in conjunction with the clinical bedside assessment to rule out or identify silent aspiration. Silent aspiration may not always be accurately identified solely through a clinical bedside assessment. Studies have shown that 2% to 25% of clients with acute stroke[52] and up to 50% or more with neurologic impairment[12,29,45] are found to be silent aspirators during the instrumental assessment. Aspiration can occur before the swallow because of poor tongue control, pooled material in the valleculae, or a delayed or absent swallow response. Poor laryngeal closure can result in aspiration during the swallow. Aspiration after the swallow is the result of pooled material in the pyriform sinuses or in the valleculae overflowing into the trachea. Understanding why a client is aspirating can help the occupational therapist plan appropriate intervention. Instrumental evaluations provide valuable information about a client's swallow during a specific period of time, under specific conditions. They allow the therapist to try different intervention strategies and to assess the results of these strategies on the swallow. This information is considered part of the complete evaluation process, which includes the bedside assessment and client performance during intervention sessions and meal activities.

The two most common instrumental evaluations used, videofluoroscopy swallow study (VFSS) and fiberoptic endoscopy (FEES), are described next.

Ethical Considerations

Instrumental assessment procedures require advanced knowledge and training in techniques, purpose, and indications for use. Only occupational therapists who have these advanced skills may use instrumental evaluation procedures.[5]

Assessment With Videofluoroscopy

The videofluoroscopic swallow study (VFSS) is the most commonly used instrumental assessment tool to examine oropharyngeal swallowing disorders.[25,35,48] This assessment uses fluoroscopy to capture the client's swallow with a variety of foods and textures. The VFSS allows the therapist to see the client's jaw and tongue movement, measure the transit times of the oral and pharyngeal stages, observe the stages of the swallow, note any residue in the valleculae and the pyriform sinuses after the swallow, and identify aspiration.[49,57] With videofluoroscopy, the therapist can determine the anatomic or physiologic cause of aspiration. Various compensatory techniques may also be assessed to determine if the airway can be protected and if swallow function can be improved, which may allow the therapist to initiate a feeding program.[48,49] Videofluoroscopy, in conjunction with the clinical assessment, may be used to select appropriate intervention techniques and assist the therapist in determining the safest diet level to help the client achieve a safe swallow.

The VFSS is conducted in the hospital radiology department. The radiologist, the radiology technician, and the swallowing therapist are present during the evaluation. Equipment necessary for the VFSS includes the fluoroscopy x-ray machine, a monitor for viewing the movement of the bolus in real time. The images are usually videotaped or digitally recorded to allow the radiologist and the therapist to review the recording in slow motion or frame by frame for more in-depth analysis. Other pieces of equipment normally available in a radiology department are lead-lined aprons, lead-lined gloves, and foam positioning wedges. Although VFSS subjects the client to radiation, the doses are relatively small and are considered to be safe,[41,57] with the benefits of assessing oropharyngeal swallow biomechanics and intervention strategies outweighing the minimal risk of exposure to radiation.

The client is positioned to allow a lateral view, with the fluoroscopy tube focused on the lips, hard palate, and posterior pharyngeal wall. The lateral view is most frequently used because it allows the therapist to evaluate all four stages of the swallow. This view clearly shows the presence of aspiration. A posterior-anterior view also may be needed to evaluate asymmetry in the vocal cords and pooling of the valleculae or pyriform sinuses.

During the VFSS, the therapist presents the client with food or liquid to which barium paste or powder has been added.[48,49] The barium contrast allows the bolus to be visible on videofluoroscopy. The therapist mixes or spreads small amounts of paste or powder onto or into each food or liquid consistency. Premixing the consistencies with the barium paste or powder prevents time-consuming interruptions during the actual assessment procedure.

Food and liquids are presented in the same sequence used for the clinical assessment. Starting with pureed foods, the client is given $\frac{1}{2}$ to $\frac{1}{3}$ teaspoon at a time of each consistency and asked to swallow when instructed. Liquids are tested separately, beginning with the thickened substance. Material is given in small amounts to reduce the risks of aspiration. An experienced dysphagia therapist may choose to use only foods or liquids that the client had difficulty with during the clinical examination, rather than to proceed through the entire sequence. The therapist continues to present each consistency to determine if the client can swallow safely and efficiently without aspirating. If aspiration occurs, the therapist should try compensatory strategies and reassess with the same texture. If aspiration occurs while using the strategies, the assessment with this texture is discontinued.

The videofluoroscopy procedure can also be used to observe for fatigue of the oral or pharyngeal musculature or the swallow reflex. The client is asked to take repeated or serial swallows of solids and liquids. The therapist also assesses the client's ability to control mixed consistencies of solids and liquids such as soups with broth and bits of vegetables, as well as the client's ability to alternate between solids and liquids. The solid and liquid consistency that the client manages without aspiration is selected as the starting point for eating and swallowing intervention. A client who aspirates on pureed or soft foods is not suited for an oral program. The client who aspirates on thick liquids is not a candidate for liquid intake.

VFSS is a valuable tool to be used in conjunction with the clinical examination. It can provide the therapist with additional information regarding the client's difficulties. By identifying silent aspiration, the therapist can feel comfortable with the decisions made in determining a course of treatment. The therapist must keep in mind that VFSS records the client's performance in an isolated instance and is not a conclusive indicator of the client's potential ability in a feeding program. Many factors may interfere with an individual's ability to participate in a VFSS, including a poor level of awareness, impaired cognitive status, or inability to consent.[19] A second VFSS may be indicated in some situations to reevaluate a client who previously was initially unable to safely swallow on video but now shows signs of readiness to participate in a feeding program.

When the results of a VFSS test are documented, foods that were presented, problems that occurred at each stage, and the number of swallows taken to clear the food or liquid are recorded. The therapist also should document compensatory strategies or facilitation techniques that worked effectively to elicit a safe swallow or reduce aspiration risk.

Assessment With Fiberoptic Endoscopy

Fiberoptic endoscopy (FEES) is a nonradioactive alternative to the VFSS. FEES allows for direct assessment of the motor and sensory aspects of the swallow. It can be repeated as often as necessary without exposure to radiation. FEES has been shown to be highly effective in detecting aspiration and critical features of pharyngeal dysphagia.[8,10,38,45]

The equipment needed for a FEES includes a flexible fiberoptic nasopharyngolaryngoscope, a portable light source, a video camera, a video recorder, and a monitor. Placed on a rolling cart, this system can be brought directly to the client's bedside. The therapist passes a flexible fiberoptic tube through the nasal fossa, along the floor of the nose through the velopharyngeal port, ending in the hypopharynx. The scope allows the therapist to observe the oral cavity, the base of the tongue, and the swallowing structures. The client is given foods and liquids. As the client the swallows, the therapist is able to observe on the monitor tongue movement, pharyngeal and laryngeal function both before and after the swallow, and assess for penetration and aspiration.[23] The results of a thorough assessment determine the course of intervention to increase a client's ability to safely eat. Upon completion of the entire dysphagia assessment, the therapist should clearly document the client's strengths, major problems, goals and objectives, and intervention plan. The objectives should be concise and measurable. The intervention plan should include the type of diet needed, the training and facilitation that the client requires, positioning techniques to be used during feeding, and the type of supervision that must be provided. Recommendations should be communicated to the appropriate nursing and medical staff.

Intervention

Because a client may display more than one problem at each stage of deglutition, the intervention program for eating and swallowing problems is multifaceted. Intervention for the client with dysphagia involves trunk and head positioning techniques to facilitate oral performance, improve pharyngeal swallow, and reduce the risk of aspiration. The occupational therapist uses clinical reasoning skills to evaluate the interplay of physical, cognitive, environmental, and sociocultural factors that have an impact on feeding, eating, and swallowing.[5] Clients with severe problems can require a prolonged course of intervention before they reach optimal recovery.

Intervention falls into two broad categories: rehabilitation techniques and compensatory strategies. Rehabilitation techniques include the use of exercise to improve strength and function. Oral motor exercises are specifically designed to improve the strength and coordination of facial musculature, the tongue, and jaw. An effortful swallow in which the client is instructed to swallow with maximal effort either with or without food has been shown to increase tongue base retraction and oral and pharyngeal pressure to improve the swallow.[18,27] Other swallowing maneuvers such as the effortful swallow, the Mendelsohn maneuver, the Masako maneuver, and the Shaker head lift are rehabilitative techniques used to physically change swallow function. Compensatory swallowing strategies increase swallow safety and decrease the client's symptoms, such as aspiration, but do not change the physiology of the swallow. Postural techniques such as those listed in Table 27.5 have been found to redirect bolus flow and reduce aspiration risk.[6] Rehabilitative techniques and compensatory strategies are often both used during the client's therapy program.

TABLE 27.5

Postural Techniques Used in Dysphagia Management

Problem	Posture	Rationale
Impaired oral transit	Head back	Utilizes gravity to clear oral cavity
Delay in triggering of pharyngeal swallow	Chin down	Widens valleculae to prevent bolus from entering airway; narrows airway entrance; pushes epiglottis posteriorly
Residue in valleculae after the swallow	Chin down	Pushes tongue base backward
Reduced laryngeal closure	Chin down, head rotated to weak side	Narrows laryngeal entrance, increases vocal fold closure
Reduced pharyngeal contraction (residue in pharynx)	Lying down on side	Eliminates gravitational effect in pharynx
Unilateral oral and pharyngeal weakness	Head tilt to stronger side	Directs bolus down stronger side
Cricopharyngeal dysfunction (residue in pyriform sinuses)	Head rotated	Pulls cricoid cartilage away from posterior pharyngeal wall, reducing resting pressure in cricopharyngeal sphincter

Adapted from Logemann J: *Evaluation and treatment of swallowing disorders*, Austin, TX, 1998, Pro-Ed.

Goals

The overall goals of occupational therapy in the remediation of eating and swallowing dysfunction are as follows[3,4,6,42]:

1. Facilitation of appropriate positioning during eating

2. Improvement of motor control at each stage of the swallow, through normalization of tone, facilitation of quality movement, and strengthening of oral musculature

3. Maintenance of an adequate hydration and nutritional intake

4. Prevention or reduction of aspiration risk

5. Reestablishment of oral eating to the safest, optimum level on the least restrictive diet

Team Management

Because of the complex nature of dysphagia treatment, the client's optimal progress is facilitated by the use of a team approach.[11,51] The **dysphagia team** should include the client's attending physician, the occupational therapist, the dietitian, the nurse, the physical therapist, the speech-language pathologist, the radiologist, and the client's family. Each professional contributes expertise to facilitate client improvement. All members of the dysphagia team should have the training and knowledge necessary to work with clients with dysphagia. Interdepartmental in-service education is frequently required so that team members have a similar frame of reference.

The occupational therapist's role is to select, administer, and interpret assessment measures; develop specific intervention plans; and provide therapeutic interventions.[5] The American Occupational Therapy Association [AOTA] has prepared a document, *Specialized Knowledge and Skills in Feeding, Eating, and Swallowing for Occupational Therapy Practice,* that describes the knowledge and skills that occupational therapists and occupational therapy assistants should have to provide comprehensive feeding, eating, and swallowing management and services which includes developing and implementing an intervention plan designed to improve swallowing skills.[5] The occupational therapist may also be responsible for coordinating the team effort, which includes obtaining physician's orders as needed, communicating with other team members and staff, providing family education to ensure proper follow-through, and selecting the appropriate diet.

The attending physician's role involves the medical management of the client's health and safety. The physician gives the orders for clinical and instrumental assessments and approves intervention and program recommendations. He or she oversees all decisions regarding treatment for diet level selection, oral and nonoral feeding procedures, and the progression of treatment as recommended by the team. The physician also reinforces the course of treatment with the client and the family.[33]

The dietitian is responsible for monitoring the client's caloric intake. This member of the dysphagia team makes recommendations to ensure that the client receives a balanced, nutritional diet in accordance with the medical condition. The dietitian is involved in suggesting types of feeding formulas for the nonoral client. Diet supplements to augment oral intake may be recommended. In conjunction with the dysphagia team, the dietitian ensures that the client receives the proper food and liquid consistencies. Additional training may be necessary for the dietary staff, because **dysphagia diets** vary from traditional medical diets.

The client's physical therapist is involved in muscle reeducation and tone normalization techniques. The client receives treatment in balance, strength, and control. The physical therapist and the occupational therapist collaborate on positioning options. The physical therapist is involved in increasing the client's pulmonary status for breath support, chest expansion, and cough.

The role of the speech-language pathologist (SLP) involves reeducating the oral and laryngeal musculature used in speaking, voice production, and swallowing. The SLP is a key member of the dysphagia team.[6]

The nurse is another important member of the dysphagia team. The nursing staff is responsible for monitoring the client's medical and nutritional status. Nurses who are available on a 24-hour basis in the hospital setting and who are trained in dysphagia screening are in a key position to administer initial swallowing screenings.[39] The nurse usually is the first to notice changes in the client's condition, such as an elevated temperature; an increase in pulmonary congestion; and an increase in secretions, which indicates swallowing dysfunction.[33] The nurse informs the physician and the dysphagia team of these changes. The nurse records the client's oral and fluid intake and notifies the dysphagia team when the client's nutritional status is adequate or inadequate. The nursing staff members administer supplemental tube feedings that have been ordered by the physician; the staff also provides oral hygiene, tracheostomy care, and supervision for appropriate clients during meals.[33,39]

The client's family is included on the team to act as program supporters. Families frequently underestimate the danger of aspiration. Therefore both the family and the client must be educated, beginning with the first day of assessment. The family and client should understand which food consistencies are safe to eat and which foods must be avoided.[2,4]

The roles of the team members may vary from one treatment facility to another. Designated roles must be clearly defined to ensure a coordinated team approach. Therapists who are responsible for direct treatment should have advanced knowledge and training in dysphagia treatment procedures.

Positioning

Proper positioning is essential when working with the client who has dysphagia. This is an important role for the occupational therapy practitioner as a member of the dysphagia team. The client should be positioned symmetrically with normal alignment between the head, neck, trunk, and pelvis. The ideal position is as follows:

1. The client is seated on a firm surface, such as a chair.

2. The client's feet are flat on the floor.

3. The client's knees are at 90-degree flexion.

4. There is equal weight bearing on both ischial tuberosities of the hips.

5. The client's trunk is flexed slightly forward (100-degree hip flexion) with the back straight.

6. Both of the client's arms are placed forward on the table.

7. The head is erect, in midline, and the chin is slightly tucked (Fig. 27.6).

FIG 27.6 Proper head position for a client with aphasia.

For the client who may be restricted to bed but is able to sit in a semireclined position, the same positioning principles apply: equal weight bearing on both ischial tuberosities for the hips, the trunk flexed slightly forward (100-degree hip flexion) with the back straight, knees slightly flexed, and both arms placed forward on a bedside table. The head and neck should be aligned appropriately to reduce the risk of aspiration.

For the client who must remain completely supine in bed, oral feeding is usually contraindicated. If the client can be positioned side-lying in bed, appropriate head and neck alignment must be achieved before the assessment of feeding skills. The client's knees and hips should be slightly flexed and trunk aligned while supported in the side-lying position. The use of additional pillows, rolls, and supports may be required to maintain the appropriate alignment.

A client who has difficulty moving into the correct position or maintaining the position presents a challenge to the occupational therapist. A careful analysis of the client is needed to determine the major problem preventing proper positioning. Poor positioning may be a result of decreased control, strength or balance secondary to hypertonicity, hypotonicity, or weakness or poor body awareness in space secondary to perceptual dysfunction (Fig. 27.7). After the cause is identified, the therapist develops intervention to address the specific problems. Treatment suggestions are described later in this chapter.

FIG 27.7 Positioning of the client with dysphagia. **A,** Incorrect positioning. **B,** Correct positioning.

Fig. 27.8 shows different supportive positions that allow the therapist to help the client maintain head control. Correct positioning allows more appropriate muscular action, which thereby facilitates quality motor control and function of the facial musculature, jaw and tongue movement, and the swallowing process, all of which minimize the potential for aspiration.

Threaded Case Study

Mattias, Part 11

Mattias was able to sit in a chair and responded well to physical prompts to sit aligned with both arms supported on the tabletop. Although he was concerned that resting his arms on the table was impolite, his therapist suggested using a chair with armrests. He typically would slightly extend his neck when attempting to swallow foods, and using the technique of a slight chin tuck diminished the coughing and choking episodes when he ate textured foods.

FIG 27.8 Different supportive positions allow the therapist to help the client maintain head control. **A-B,** Side hold position for clients requiring maximum to moderate assistance. **C,** Front hold position for clients requiring minimal assistance. **D,** Turning the head toward the more involved side for an individual who sustained a CVA.

Oral Hygiene

Oral care by nursing and therapy team members prevents gum disease, the accumulation of secretions, the development of plaque, and the aspiration of food particles that remain after eating. Poor or inadequate oral hygiene has been linked with healthcare-associated pneumonia, respiratory tract infections, and influenza in elderly people.[9,20,56] The client who is hypersensitive or resistant to having anything in the mouth may require intervention from the occupational therapist. Preparation steps may include firmly stroking outside the client's mouth or lips with the client's or therapist's finger. Sensitive gums can also be firmly rubbed, preparing the client for the toothbrush.

For cleaning purposes, the mouth can be divided into four quadrants. A toothbrush with a small head and soft bristles is used to clean each quadrant, starting with the top teeth and moving from front to back. When brushing the bottom teeth, the therapist brushes from back to front. Next, holding the toothbrush at a vertical angle, the therapist brushes the inside teeth downward from gums to teeth. Finally, the cutting surfaces of the teeth are brushed. An electric toothbrush can be more effective, if the client can tolerate it.

After each procedure the client is allowed to dispose of secretions. After brushing, the client is carefully assisted in rinsing the mouth. If the client can tolerate thin liquids, small amounts of water can be given. Having the client flex the chin slightly toward the chest helps prevent the water from being swallowed. The therapist can help the client expel the water by placing one hand on each cheek and simultaneously pushing inward on the cheeks while the chin remains slightly tucked. If the client has no ability to manipulate liquids, a dampened sponge toothette can be used.

Oral hygiene for the nonoral or oral client can be used as effective sensory stimulation of touch, texture, temperature, and taste. It can be used to facilitate beginning jaw and tongue movements and to encourage an automatic swallow.[20] Lack of oral stimulation over a prolonged time leads to hypersensitivity within the oral cavity. Clients who display poor tongue movement or decreased oral sensation and who are able to eat frequently have food remaining on their teeth or dentures or between the cheek and gum. A client with decreased sensation is not aware of the remaining food. A thorough cleaning should follow each time the client eats.

Nonoral Feedings

A client who aspirates more than 10% of food or liquid consistencies or whose combined oral and pharyngeal transit time is more than 10 seconds, regardless of positioning or facilitation techniques, is an inappropriate candidate for oral eating.[48] This client needs a nonoral nutritional method until eating and drinking capability is regained. Clients who lack the endurance to take in sufficient calories also may require nonoral feedings or supplements.

The two most common procedures for nonoral feedings involve the nasogastric tube (NG tube) and the percutaneous endoscopic gastrostomy (PEG).[31] The NG tube is passed through the nostril, through the nasopharynx, and down through the pharynx and esophagus to rest in the stomach. The NG tube is a temporary measure that should not be used for longer than 1 month.[30] The NG tube has several advantages:

1. The NG tube can be inserted and removed nonsurgically.

2. The NG tube allows the physician to choose between continuous or bolus feedings (a feeding that runs no more than 40 minutes).

3. The NG tube allows the therapist to begin prefeeding and feeding training while the tube is in place.

4. The NG tube provides full nutrition and hydration if necessary and keeps the digestive system active, which is important for moving to oral feedings.

The NG tube also has some disadvantages:[30,48,59,62,63]

1. It can desensitize the cough reflex and the swallow response.

2. It can interfere with a positioning program (the client needs to be elevated to 30 degrees during feeding).

3. It can increase aspiration risk, pharyngeal secretions, and nasal reflux.

4. It can decrease the client's self-esteem.

5. It can be uncomfortable.

6. It distends pharyngeal esophageal segment and upper esophageal sphincter; it may promote reflux.

7. It can cause nasal ulceration.

Placement of a PEG is a minor surgical procedure. The client receives a local anesthetic, and a small skin incision is made to create an external opening in the abdominal wall. A tube is passed through the opening into the stomach. A PEG offers several advantages:

1. Using a PEG allows the physician to choose between continuous or bolus feedings.

2. The PEG provides full nutrition and hydration if necessary and keeps the digestive system active, which is important for moving to oral feedings.

3. It allows the therapist to begin a prefeeding or feeding program while the tube is in place.

4. It carries less risk of reflux and aspiration.

5. It does not irritate or desensitize the swallowing mechanisms.

6. It does not interfere with a positioning program.

7. It can be removed when the client no longer requires supplemental feedings or liquids.

However, use of a PEG also has some disadvantages[30,62,63]:

1. It requires surgical placement.

2. The stoma site can become irritated or infected.

3. Reflux if the stomach fills too fast.

4. The family can perceive the tube as being permanent.

A PEG is the ideal choice for the client who may require tube feeding or supplemental feedings for longer than 1 month.[30]

A commercially prepared liquid formula that provides complete nutrition usually is used for tube feedings. Many types and brands are available. The physician and dietitian determine which formula is best suited to the client. The feedings are administered by either a bolus or a continuous method. A bolus feeding takes 20 to 40 minutes to run through either the NG tube or the PEG. It can be gravity assisted or run through a feeding pump. Bolus feedings can be scheduled at numerous times throughout a 24-hour period.

Continuous feedings, which the client may better tolerate, provide smaller amounts that are administered continuously by a feeding pump. The feeding pump can be set to regulate the rate at which the formula is dripped into the tube. A disadvantage of continuous feedings is that the client must be attached to the feeding pump during tube feedings, which limits mobility.

As a client begins to eat enough to require an adjustment in the intake amount of formula, bolus feedings become the preferred method. A bolus feeding allows the therapist to work with the physician to wean the client from formula feeding. A bolus feeding can be held back before a feeding session, and the number of bolus feedings per day can be decreased as the client improves. If satisfied by the tube feedings, the client will not have an appetite and will have decreased motivation to eat.

As the client improves, oral intake can be increased, and the formula feeding can be used to supplement the client's caloric intake. An accurate calorie count, determined by recording the percentage of oral intake, assists the physician in decreasing the calories received through the tube feedings as the client begins to meet nutritional needs orally. The occupational therapist works closely with the dietitian to ensure that all hydration and caloric needs are being met. If the client has progressed only enough to handle solids, the NG or PEG can be used to meet the client's total or partial fluid requirements. When the client is able to meet nutrition and hydration needs through oral feedings, the NG or PEG can be removed.

Oral Feedings

For a client to be an appropriate candidate for oral feeding, several criteria must be met. The therapist can use the criteria for evaluating a client's swallow with foods or liquids. To participate in an oral feeding program, a client must (1) be alert, (2) be able to maintain adequate trunk and head positioning with assistance, (3) have beginning tongue control, (4) manage secretions with minimal drooling, and (5) have a reflexive cough. The therapist needs to identify the food or liquid consistency that is most appropriate for the client. The safest consistency with which to initiate the oral program is one that enables the client to complete the oral and pharyngeal stages combined in less than 10 seconds and to swallow with minimal aspiration (10% or less).[48] The ultimate goal of an oral feeding program is for the client to be able to safely swallow the least restrictive diet in sufficient amounts to meet nutrition and hydration needs without aspiration.

Diet Selection

For those diagnosed with dysphagia, the texture of their food may need to be modified to help make swallowing safer and more efficient and to help prevent aspiration. A dysphagia diet must be carefully selected to reflect the needs of the client. In general, foods chosen for dysphagia diets should (1) be uniform in consistency and texture, (2) provide sufficient density and volume, (3) remain cohesive, (4) provide pleasant taste and temperature, and (5) be easily removed or suctioned when necessary.[1]

The following foods are contraindicated for dysphagia diets: foods with multiple textures, such as vegetable soup and salads; fibrous and stringy vegetables, meats, and fruits; crumbly and flaky foods; foods that liquefy, such as gelatin and ice cream; and foods with skins and seeds.[1]

The therapist should work closely with the dietitian to identify the appropriate dysphagia diet for the client. Using established dysphagia diets develops a standard for consistently describing which food textures and what foods are allowed at each level. This consistency is critical for client safety. Because many disciplines are involved in the care of an individual with dysphagia, standardized language is needed when describing food and liquid textures to facilitate the diagnostic and nutritional management of the client.[1] The National Dysphagia Diet Task Force (NDDTF) has developed a science-based, multilevel, standardized diet for clients with dysphagia. Once the therapist has determined the appropriate diet level, all members of the team, including the family and the client, should be educated about which foods are acceptable in each level and which foods should be avoided to ensure the client's safety. Liquid diet levels should also be established. When requesting a dysphagia diet, the therapist should specify both levels desired, liquid and solid, because a client may handle each differently.

Diet Progression

Tables 27.6 through 27.8 list foods in three progressive dysphagia levels. These levels reflect the food texture levels recommended by the NDDTF.[1] After mastering level 3 the client may progress to a regular diet. Dysphagia diet level 1 (dysphagia pureed) is for individuals with moderate to severe swallowing difficulty who may have a reduced ability to protect their airway. All foods are pureed. This food group is best for persons with little or no jaw or tongue control, a moderately delayed swallow, and a decreased pharyngeal transit, resulting in pooling in the valleculae and pyriform sinuses. Pureed foods move more slowly past the faucial arches and into the pharynx, which allows time for the swallow response to trigger. Pureed foods should be homogenous, pudding-like in consistency. No coarse textures, raw fruits or vegetables, or nuts are allowed. Any foods that require mastication are not allowed. Level 1 foods are best used only to increase the client's oral intake. It may be difficult to meet caloric and nutrition needs on this diet, and often high-caloric, nutrient-dense foods are recommended. The client should be advanced to the next level as soon as possible.

TABLE 27.6

Dysphagia, Level 1: Dysphagia Pureed

Food Groups	Recommended	Avoid
Cereals and breads	Pureed bread mixes, pregelled slurried breads, pancakes, or French toast	All other breads, rolls, crackers, muffins, etc.
	Smooth, homogenous cooked cereals, creamed wheat or rice, Malto Meal	All dry cereals and any cereals with lumps
	Cereals should have a pudding-like consistency	Oatmeal
Eggs	Custard, pureed eggs	All others
Fruits	Pureed fruits or well-mashed bananas Applesauce	All others—any whole fruits (fresh, frozen, canned)
Potatoes and starches	Mashed potatoes with gravy, pureed potatoes with gravy, butter, margarine, or sour cream Pureed well-cooked noodles, pasta or rice Must be pureed to a smooth, homogenous consistency	All others
Soups	Soups that have been pureed in a blender or strained May need to be thickened Thickened, strained cream	Soups that have chunks or lumps (to a consistency of pureed vegetables)
Vegetables	Pureed vegetables without lumps, chunks, pulp, or seeds	All vegetables that have not been pureed
Meat and meat substitutes	Pureed meat	Whole or ground meats, fish, or poultry
	Pureed poultry with gravy	Cottage cheese, cheese
	Softened tofu mixed with moisture	Peanut butter, unless pureed into foods
	Hummus or other pureed legume spread	
Desserts	Smooth puddings, custards, yogurt, pureed desserts, and soufflés	Ices, gelatins, frozen juice bars, bread and rice pudding, yogurt with fruit
		All other desserts
		These foods are considered thin liquids and should be avoided if thin liquids are restricted:
		Frozen malts, milk shakes, frozen yogurt, ice cream, sherbet, gelatin
Fats	Butter, margarine, strained gravy, sour cream, mayonnaise, cream cheese, whipped topping	All fats with chunky additives

TABLE 27.7

Dysphagia, Level 2: Dysphagia Mechanically Altered Characteristics (Mechanical Soft)

Food Groups	Recommended	Avoid
Cereals and breads	Cooked refined cereals with little texture (eg, oatmeal) Slightly moistened dry cereals with little texture (eg, Corn Flakes, Rice Krispies) Soft pancakes with syrup French toast without crust Graham crackers	Very coarse cooked cereals that may contain seeds or nuts Whole-grain dry or coarse cereals All others
Eggs	Poached, scrambled or soft eggs (egg yolks should be moist and mashable with butter, not runny) Souffles—may have small chunks	Hard cooked or fried eggs
Fruits	Soft canned or cooked fruits without seeds or skin	Fruits with seeds, coarse skins, fibers; fruits with pits, raisins, grapes
	Soft, ripe bananas	
	Baked apple (no skin)	All raw fruits except those listed
Potatoes and starches	Well-cooked, moistened, boiled, baked, or mashed potatoes Well-cooked noodles in sauce	Potato skins and chips, fried potatoes, rice
Soups	Soups with easy to chew or easy to swallow soft meats or vegetables (particle sizes < ½ inch)	Soups that have large chunks of meat or vegetables
	Cream soups	Soups with rice, corn, peas
Vegetables	Soft, well-cooked vegetables; should be easily mashed with a fork	All raw vegetables Cooked corn and peas Broccoli, cabbage, brussels sprouts, asparagus, or other fibrous, nontender cooked vegetables
Meat and meat substitutes	Moistened ground or cooked meat, poultry, or fish; may be served with gravy Casseroles without rice Soft-moist lasagna, moist macaroni and cheese Moist meatballs, meat loaf, or fish loaf Tuna or egg salad without large chunks, celery, or onion Cottage cheese, smooth quiche Tofu All meats or protein substitutes should be served with sauces or moistened to help maintain cohesiveness in the oral cavity	Dry, tough meats (such as bacon, sausage, hot dogs) Peanut butter Dry casseroles Pizza Sandwiches All other cheeses
Desserts	Pudding and custard Soft fruit pies with bottom crust only Crisps and cobblers without seeds or nuts Canned fruit (excluding pineapple) Soft, moist cakes with icing Pregelled cookies or soft moist cookies “dunked” in milk, coffee, or other liquid	Dry, coarse cakes or cookies Anything with nuts, seeds, coconut, pineapple, or dried fruit Rice or bread pudding
Fats	Butter, margarine, strained gravy, sour cream, mayonnaise, cream cheese, whipped topping	All fats with chunky additives

TABLE 27.8

Dysphagia, Level 3: Dysphagia Advanced

Food Groups	Recommended	Avoid
Cereals and breads	All well-moistened cereals Any well-moistened breads, muffins, pancakes, waffles, etc. Add butter, margarine, syrup, etc., to moisten	Coarse or dry cereals such as shredded wheat Dry toast, crackers Crusty bread such as French bread, hard rolls Popcorn
Eggs	Eggs, prepared any way	
Fruits	All canned and cooked fruit	Difficult-to-chew fresh fruits such as apples or pears
	Soft, peeled fresh fruit, without seeds	Stringy, high-pulp fruits such as papaya or pineapple
	Soft berries	Uncooked dried fruit
		Fruit with seeds or coarse skins
Potatoes and starches	All, including rice and fried potatoes	Potato skins
		Tough, crisp-fried potatoes
Soups	All soups except those on the Avoid list	Soups with tough meats Corn or clam chowders Soups with large chunks (>1 inch)
Vegetables	All cooked, tender vegetables	All raw vegetables, except shredded lettuce
	Shredded lettuce	Cooked corn
		Nontender, stringy, cooked vegetables
Meat and meat substitutes	Thin-sliced tender or ground meats and poultry	Tough, dry meats and poultry
	Well-moistened fish	
	Casseroles with small chunks of meat, ground meats, or tender meats	
Desserts	All except those on the Avoid list	Dry, coarse cakes or cookies
		Anything with nuts, seeds, coconut, pineapple, or dried fruit
Fats	All except those on the Avoid list	All fats with chunky additives

Data from American Dietetic Association: National dysphagia diet: standardization for optimal care, Chicago, 2002, American Dietetic Association; American Occupational Therapy Association: AOTA resource guide: feeding and dysphagia, Rockville, MD, 1997, American Occupational Therapy Association; Avery-Smith W: An occupational therapist coordinated dysphagia program *Occup Ther Pract* 3:10, 1998; Community Hospital of Los Gatos, Rehabilitation Services: Dysphagia protocol, Los Gatos, CA, 2003, Community Hospital of Los Gatos; Curran J: Nutritional considerations. Level 2 items are soft foods that stay together as a cohesive bolus; thus the possibility of particles spilling into the airway is decreased. Dysphagia diet level 2 (dysphagia advanced altered) foods are best for clients with a beginning rotary chew, enough tongue control with assistance to propel food back toward the pharynx, and a minimally delayed swallow. Mechanical soft foods reduce the risk of aspiration in individuals who have both a motor and a sensory loss. Mechanical soft foods with a density provide increased proprioceptive input throughout the mouth. Meats should be ground or minced and kept moist with gravies and sauces. These foods also stay together as a cohesive bolus rather than crumbling and falling uncontrolled into the airway. The level 2 diet is for individuals with mild to moderate swallowing difficulties.

Dysphagia diet level 3 (dysphagia advanced) requires that the client be able to chew and have adequate oral motor skills to form a cohesive bolus of textured foods and move the bolus posteriorly in the oral cavity. This food group offers a wider variety of consistencies and food choices. Level 3 is a step down from a regular diet. Level 3 foods work well for the client who has minimal problems with jaw or tongue control and a mildly delayed but intact swallow response. The client who has reached a level 3 diet needs to be concerned with a delayed swallow only when fatigued. Dysphagia level 4 (regular) diet includes all foods.

When a client is ready to progress to the next diet level, the therapist can adjust the meals by requesting one or two items from the higher group, which enables assessment at the new level. This technique is also appropriate for clients who become fatigued. The client is thus able to work with the therapist on the more challenging food items first and continue the meal with foods that are easier as the client begins to fatigue. The therapist also may consider arranging several small meals throughout the day for the client who fatigues, rather than three traditional meals.

Threaded Case Study

Mattias, Part 12

Mattias agreed to eat pureed foods to increase his caloric intake and joked with his wife that his occupational therapist gave him permission to eat ice cream. He was progressed to textured foods (level 2) but continued to use the pureed foods as a supplement because of the effort required to eat a sufficient quantity of textured foods.

After 3 weeks of intervention, Mattias progressed to a level 3 diet, which greatly increased the variety of foods he could eat and increased his overall satisfaction with meal selections. He continued to support caloric intake using foods from both levels 1 and 2 because of motor coordination and fatigue issues. His daughter selected foods for the wedding meal that required minimal chewing, including baked sole and crème brûlée in addition to the wedding cake.

A client should progress to a regular diet when oral motor control is within functional limits, allowing the client to chew and form any consistency of food into a bolus and propel it back toward the faucial arches. The client at this level should be able to swallow all food and liquid consistencies with only occasional coughing. Continuing dietary precautions for a client with a history of dysphagia include avoiding raw vegetables, stringy foods, and foods containing nuts or seeds.[1]

Many individuals with dysphagia have difficulty with thin liquids, as this texture requires greater oral motor and pharyngeal control as well as an intact swallow response. Increasing the viscosity of the liquid is often used as a strategy to decrease aspiration risk. The liquid progression is divided into four groups: "thin," "nectar-like," "honey-like," and "spoon-thick." Thin liquids include water, coffee, tea, soda or anything else that will quickly liquefy in the mouth. Thin liquids require an intact swallow. Nectar-like liquids are thickened to a consistency that coats and drips off a spoon, similar to unset gelatin. Honey-like liquids have been thickened to a honey consistency; the liquid flows off a spoon in a ribbon, like honey. Spoon-thick liquids are thickened to a pudding consistency and remain on the spoon in a soft mass.[1] The liquid consistency chosen depends on the client's swallowing problem. Examples of liquids in these levels are given in Table 27.9.

TABLE 27.9

Liquids

Liquid Level	Examples
Thin	Water, ice chips Coffee, tea Milk Hot chocolate Fruit juices Broth or consommé Gelatin dessert Ice cream Sherbet
Nectar-like	Nectars Extra thick milkshake Extra thick eggnog Strained creamed soups Yogurt and milk blended V-8 juice
Honey-like	Nectar thickened with banana Nectar thickened with pureed fruit Regular applesauce with juice Eggnog with baby cereal Creamed soup with mashed potatoes Commercial thickener
Spoon-thick	Commercial thickener

Data from American Dietetic Association: National dysphagia diet: standardization for optimal care, Chicago, 2002, American Dietetic Association; American Occupational Therapy Association: AOTA resource guide: feeding and dysphagia, Rockville, MD, 1997, American Occupational Therapy Association; Avery-Smith W: An occupational therapist coordinated dysphagia program *Occup Ther Pract* 3:10, 1998; Community Hospital of Los Gatos, Rehabilitation Services: Dysphagia protocol, Los Gatos, CA, 2003, Community Hospital of Los Gatos; Curran J: Nutritional considerations. In Groher M, editor: *Dysphagia: diagnosis and management*, ed 3, Newton, MA, 1997, Butterworth-Heinemann; Rader T, Rende B: *Swallowing disorders: what families should know*, Tucson, AZ, 1993, Communication Skill Builders.

Thick liquids are the appropriate choice for clients with cognitive problems that interfere with bolus preparation, moderate to severely impaired oral motor skills, markedly delayed swallow response, or diminished ability to protect the airway.[54] A thick liquid moves more slowly through the oral cavity, which allows the client with impaired motor skills to have greater control of the bolus, preventing it from entering the pharynx and open airway before the swallow has been triggered. Videofluoroscopic studies show higher aspiration rates for thin liquids compared to thicker liquid consistencies for individuals with dysphagia.[55] Care must be taken when a client is on modified liquids to ensure that adequate hydration is maintained. Many clients dislike thickened liquids and do not take them in sufficient amounts, putting them at risk for dehydration.

Thickened liquids are made by adding thickening agents such as banana, pureed fruit, yogurt, dissolved gelatin, baby cereal, cornstarch, or a commercial thickener to achieve the appropriate viscosity. The thickened drink or soup should stay blended and not separate or liquefy. It is important that everyone involved in the client's care understand what constitutes the various liquid levels so that the correct amount of thickening agent is added. Commercially prepared thickened liquids (all levels) are available for use in the hospital setting and at home. Using a commercially prepared product guarantees the proper viscosity.

Principles of Oral Feeding

The therapist should incorporate certain principles into the oral feeding program. An important aspect of the oral preparation stage is looking at, recognizing, and reaching for food. The client must actively participate in the eating process. Food should be presented within the client's visual field. If the client has a severe visual field deficit or unilateral neglect, the therapist must help the client to scan the plate or tray visually.

When physically possible, the client should feed himself or herself, even if assistance is necessary. If the client does not have a normal hand-to-mouth movement pattern, the therapist must help the client achieve one by guiding the extremity in the correct pattern. Abnormal movement of the upper extremity influences abnormal movement in the trunk, head, face, tongue, and pharynx and decreases the client's ability to safely swallow.

If the client is not capable of self-feeding, the therapist can keep the client actively involved by allowing the client to choose which food or liquid is preferred for each bite. Food is presented by moving the utensil slowly from the front, toward the mouth, so that the client can see the food the entire time. The client should be allowed as much control of the eating situation as possible.

For adults, eating is a social activity shared with friends and family. A normal dining environment facilitates normal eating. If the client has difficulty in this environment, intervention can be directed toward reducing distractions and identifying environmental modifications that will allow the client to be successful. Cultural preferences must be taken into account when selecting foods and dining settings. The client's normal eating habits and routines should be considered in the development of the eating program. Special care must be taken to obtain this information during the initial assessment.

The occupational therapist must continually assess the client's positioning, muscle tone, oral control, and swallow. If the client displays poor oral motor skills, the therapist assesses for food pocketing after every few bites. The rate of the client's intake is monitored. The therapist should determine when too much food is in the mouth and when the client puts food into the mouth before the previous bite has been cleared. The therapist feels for the swallow with a finger at the hyoid notch if the client displays abnormal laryngeal movement or a delayed swallow.[43] The therapist also assesses the client's voice quality upon completion of the swallow to assess for possible penetration into the laryngeal vestibule.

The frequency with which the therapist must check each component depends on the skill level and performance of the client. The more difficulty the client exhibits, the more frequent the assessment. The therapist may find it necessary to assess after each bite or sip, after a few bites or sips, or after each food item. Use of skilled observational skills allows the therapist to make the appropriate clinical decision. Specific techniques for assessment during feeding trials can be found in the swallowing assessment section of this chapter. After completing the feeding process, the client should remain in an upright position for 15 to 30 minutes to reduce the risk of refluxing food and of aspirating small food particles that may remain in the throat.

The therapist must observe the client for signs of aspiration while eating and monitor for the development of aspiration pneumonia over time. Clients vary in the amount of aspiration they can tolerate before developing aspiration pneumonia, according to age, health, and pulmonary status. The signs of acute and chronic aspiration were outlined previously.

When a client with compromised swallow function is participating in oral feedings, careful monitoring of the nutritional status is necessary. Nutrient requirements and fluid intake needs are determined by a nutrition assessment.[17,60] Nutritional deficiency is a concern, especially for older individuals, and places the client at risk for adverse health outcomes such as decreased functional ability and increased use of healthcare services.[17] The client's caloric needs are determined by the dietitian and the physician and depend on the client's height, weight, activity level, and medical condition. Caloric and fluid intake is monitored by having the physician order a calorie count and a liquid intake and output hydration count (I and O). Each person who works with the client with oral intake should record the percentage of each item the client eats or drinks. The dietitian converts the percentages into a daily calorie total. The client also should be monitored for physical signs of nutritional deficiency and dehydration. These symptoms include weakness, irritability, depression, decreased alertness, changes in eating habits, hunger, thirst, decreased turgor, and changes in amounts or color of urine. If a client is not able to take in the necessary calories, supplemental feedings are necessary to make up the difference.[28] The physician and dietitian decide on the number of supplemental feedings.

Techniques for the Management of Dysphagia

Tables 27.10 through 27.13 provide intervention techniques for the management of dysphagia. These techniques are not intended to be used in all situations. Each client presents a different clinical picture and may display one deficit or a combination of deficits. After careful assessment, the therapist must determine the primary cause of the client's deficits and intervene accordingly. The occupational profile determines the focus of occupational therapy services and identifies the importance of dysphagia intervention within the client's priorities.

TABLE 27.10

Dysphagic Treatment: Oral Preparatory Stage

Structure	Symptoms	Problem	Prefeeding Technique	Feeding Technique
Trunk	Leaning to one side	Decreased trunk tone Ataxia Increased trunk tone Poor body awareness in space	Facilitate trunk strength Exercises at midline Have client clasp hands, lean down, and touch foot, middle, other foot; rotate trunk with hands clasped and shoulders flexed to decrease or normalize tone	Assist client to hold correct position; assist with head control Assist client to hold correct feeding position; provide with perceptual boundary; consider lateral trunk support
	Hips sliding forward out of chair	Increased tone in hip extensors Poor body awareness in space	See previous entry Provide firm seating service	Adjust positioning so that client leans slightly forward at hips, arms forward on table
Head	Inability to hold head in midline	Decreased tone Weakness	Facilitate strength through neck and head exercises in flexion, extension, and lateral flexion	Assist with head control
	Inability to move head	Increased tone Poor range of motion	Tone reduction of head, shoulders, and trunk Facilitate normal movement Myofascial release techniques Soft tissue mobilization	Assist with head control
Upper	Spillage of	Decreased tone	Facilitate increased tone through weight bearing, sweeping, or tapping	Guide client through correct movement pattern

extremity	food from utensils	Apraxia Decreased coordination	muscle belly of desired muscle	Provide adaptive equipment or utensils as needed
	Inability to self-feed	Increased tone Abnormal movement patterns Weakness or decreased motor control	Reduce proximal tone with scapula mobilization, weight bearing through arm strengthening exercises Facilitation of normal movement	Guide client through correct movement pattern Provide adaptive equipment or utensils as needed
Face	Drooling, food spillage from mouth	Decreased lip control Poor lip closure secondary to decreased tone, poor sensation Apraxia	Place a wet tongue blade between client's lips; ask client to hold tongue blade while therapist tries to pull it out Vibrate lips with back of electric toothbrush down cheek and across lips Lip exercises: movements described in outer oral motor evaluation; client performs repetitions two to three times daily Blow bubbles into glass of liquid with straw	Using side handgrip for head control, the therapist approximates lip closure by guiding and assisting with jaw closure Have client use a straw when drinking liquids until control improves Place food to unimpaired side Use cold food or liquids
		Decreased sensation	Fan lips so that client feels drool or wetness on lips or chin to increase awareness	Teach client to pat mouth (versus wiping mouth) and chin every few bites or sips
Tongue	Pocketing of food in cheeks or sulci Poor bolus formation	Poor tongue control for lateralization or tipping Decreased tone Poor sensation	Tongue exercises: use movements described in inner oral motor evaluation	Avoid crumbly foods Stroke client's outside cheek where pocketing occurs with index finger back and up toward client's ear; instruct client to check cheek for pocketing
	Retracted tongue	Increased tone Retracted jaw	Tongue range of motion: wrap tip of tongue in wet gauze; gently pull tongue forward, side to side and up and down; move slowly Pull tongue wrapped in wet gauze forward past front teeth, using index and middle fingers to vibrate tongue back and forth sideways to decrease tone and facilitate protrusion	Avoid crumbly foods Reduce tone as needed during meal Double swallow Resist head flexion to facilitate jaw closure Resist head extension to facilitate jaw opening

Data from Daniels S, Huckabee ML: *Dysphagia following stroke (clinical dysphagia),* ed 2, San Diego, CA, 2013, Plural Publishing; Logemann J: *Evaluation and treatment of swallowing disorders,* ed 2, Austin, TX, 1998, Pro-Ed.

TABLE 27.11

Dysphagic Treatment: Oral Stage

Structure	Symptoms	Problem	Prefeeding Technique	Feeding Technique
Tongue	Slow oral transit	Poor anterior to posterior movement; decreased tone, poor sensation	Practice "ng-ga" sounds	Tuck chin toward chest
	Tongue retraction	Increased tone	Grasping tongue wrapped in gauze, pull it forward past front teeth; use finger or tongue blade to vibrate base of tongue back and forth sideways Improve tongue range of motion	Position food in center, midtongue Avoid crumbly foods Use cold or hot foods instead of warm Correct positioning Place index finger at base of tongue under chin; stroke up and forward
	Slow oral transit time Inability to channel food back toward pharynx	Inability to form central groove in tongue Apraxia	Grasping tongue wrapped in gauze, pull forward to front teeth; stroke firmly down middle of tongue with edge of tongue blade	Tuck chin toward chest Position food in center, midtongue Avoid crumbly foods Use cold or hot foods instead of warm Correct positioning Place index finger at base of tongue under chin; stroke up and forward
	Repetitive movement of tongue; food is pushed out front of mouth	Tongue thrust	Facilitate tongue retraction to bring tongue back into normal resting position; vibrate on either side of the frenulum found inside the mouth, under the tongue with finger Increase jaw control; teach isolated tongue movements	Correct positioning Place food away from midline of tongue toward back of mouth Provide downward and forward pressure to back of tongue with spoon after food placement
	Food falls off tongue into sulci or food remains on tongue without the client's awareness	Poor sensation	Ice tongue with ice chips placed in gauze to prevent ice chips from slipping into pharynx Brush tongue with toothbrush to stimulate receptors	Use foods with high viscosity or density Alternate presentation of cold and hot foods during meal
	Slow oral transit time; food remains on hard palate; coughing before swallow	Poor tongue elevation; decreased tone	Ask client to practice "k," "g," "n," "d," and "t" sounds Lightly touch tongue blade or soft toothbrush to roof of mouth at back of tongue; instruct client to press spot with tongue; resist movement with blade or brush to increase strength Vibrate tongue at base below chin; provide quick stretch by pushing down on base of tongue	Correct positioning With finger under chin at base of tongue, move finger upward and forward to facilitate elevation Avoid crumbly foods Double swallow
	Slow oral transit time Food remains on back of tongue because client is unable to elevate tongue to push food to hard palate Coughing before the swallow Retracted tongue	Decreased sensation Increased tone Decreased range of motion Soft tissue shortening	Tone tongue with gauze reduction; grasping wrapped tongue forward with around tip, pull finger or tongue blade Apply pressure to base of tongue right to left Grasping base of tongue under chin between two fingers, move it back and forth to decrease tone Tone reduction Range of motion exercises Place a variety of tastes on lips to facilitate tongue licking lips	Adjust correct positioning by increasing forward flexion at hips, arms forward to decrease tone Reduce tone as needed; give client breaks because tone increases with effort With finger under chin at base of tongue, move finger upward and forward to facilitate tongue elevation

Data from Logemann J: *Evaluation and treatment of swallowing disorders,* ed 2, Austin, TX, 1998, Pro-Ed; Wheeler-Hegland K, et al: Evidence-based systematic review: oropharyngeal dysphagia behavioral treatments. Part II—impact of dysphagia treatment on normal swallow function, *J Rehabil Res Dev* 46:185–194, 2009.

TABLE 27.12

Dysphagia Treatment: Pharyngeal Stage

Structure	Symptoms	Problem	Prefeeding Technique	Feeding Technique
Soft palate	Tight voice; nasal regurgitation Air felt through nose or mist seen on mirror when client says "ah" Decreased tone Nasal speech	Increased tone Decreased tone Rigidity	Facilitate normal head/neck positioning Have client tuck chin into therapist's cupped hand, then push into hand as therapist applies resistance; client says, "ah" afterward; speed and height of uvula elevation should increase; follow by thermal application	Facilitate normal head and neck positioning With head and neck in midline, have client tuck chin slightly to decrease rate of food entering into pharynx
	Delayed swallow	Decreased triggering of swallow response	Thermal application: using a laryngeal mirror #00 after being placed in ice water or chips for 10 seconds, touch base of faucial arch; repeat up to 10 times; process can be repeated several times a day	Alternate presentation of food; start with a very cold substance, then warm; cold substance can increase sensitivity of faucial arches; tuck chin slightly forward to prevent bolus entering airway
Hyoid	Delayed elevation of hyoid bone Poor tongue elevation	Delayed swallow Incomplete swallow	Increase tongue humping because elevation of tongue and hyoid stimulates triggering of response	Place index finger under chin at base of tongue and push up forward to facilitate tongue elevation
	Tongue retraction	Abnormal tongue tone; poor	Tone reduction	

		range of motion		
Pharynx	Coughing after swallow	Decreased pharyngeal movement Penetration into laryngeal vestibule	None	If appropriate, alternate presentation of liquid with stage II or stage III solids; liquid material moves solids through pharynx
	Coating of pharynx seen on videofluoroscopy Gurgling voice	Pharyngeal weakness	Isometric or resistive head and neck exercises	Have client take second dry swallow to clear valleculae and pyriform sinuses Tilt head to stronger side Supraglottic swallow
	Seen on videofluoroscopy, anteroposterior view; material residue seen on one side; weak or hoarse voice	Unilateral pharyngeal movement	None	Compensatory technique for clients with low tone: have client turn head toward affected side during swallow to prevent pooling in affected pyriform sinuses; evaluate technique against its effect on client positioning and tone in trunk, upper extremities
Larynx	Coughing, choking after swallow	Decreased laryngeal elevation Decreased tone Weakness	Quickly ice up sides of larynx; ask client to swallow; assist movement by guiding larynx upward Vibrate laryngeal musculature from under chin, downward on each side to sternal notch	Teach client to clear throat immediately after swallow to move residual Use supraglottic swallow, Mendelsohn maneuver, effortful swallow
	Noisy or audible swallow	Increased tone Rigidity Uncoordinated swallow	Range of motion—place fingers and thumb along both sides of larynx and gently move it back and forth until movement is smooth and easy tone decreased Using chipped ice, form pack in washcloth and place around larynx for 5 min	Placing fingers and thumb along both sides of larynx, assist client with upward elevation before swallow Double swallow
Trachea	Continuous coughing before, during, after swallow	Aspiration—before: poor tongue control; during: delayed swallow response; after: decreased pharyngeal movement	Teach client how to produce a voluntary cough; ask client to take a deep breath and cough while breathing out; therapist uses palm of hand to push downward (toward stomach) on the sternum	Encourage client to keep coughing; facilitate reflexive cough; push downward on sternum as client breathes out; suction client if problem increases Push into client's sternal notch to assist with cough
	Client grabs or reaches for throat Reddening in the face No voice or cough	Blocked airway	None	Perform Heimlich maneuver Seek medical assistance

Data from Crary M: Imaging swallowing examinations: videofluoroscopy and endoscopy. In Groher ME, Crary MA: *Dysphagia: clinical management in adults and children,* ed 2, St. Louis, 2016, Elsevier; Logemann J: *Evaluation and treatment of swallowing disorders,* Austin, TX, 1998, Pro-Ed; Wheeler-Hegland K, et al: Evidence-based systematic review: oropharyngeal dysphagia behavioral treatments. Part II—impact of dysphagia treatment on normal swallow function, *J Rehabil Res Dev* 46:185–194, 2009.

TABLE 27.13

Dysphagia Treatment: Esophageal Stage

Structure	Symptoms	Problem	Prefeeding Technique	Feeding Technique
Esophagus	Frequent regurgitation of food or liquid and coughing or choking after the swallow: material collecting in a side pocket in esophagus	Esophageal diverticulum	Requires a medical diagnosis; problem can be seen through traditional barium x-ray examination Surgical correction is needed	Report symptoms to medical staff (therapist cannot treat)
	Regurgitation of food, coughing, or choking on food after the swallow: inability of food to pass through the pharynx, esophagus, or stomach	Partial or total obstruction of the pharynx or esophagus Impaired esophageal peristalsis	Requires a medical diagnosis; problem can be seen through traditional barium x-ray examination Surgical correction is needed	Report symptoms to medical staff (therapist cannot treat)

Data from Crary M: Imaging swallowing examinations: videofluoroscopy and endoscopy. In Groher M, Crary M, editors: *Dysphagia: clinical management in adults and children,* ed 2, St. Louis, 2016, Elsevier; Logemann, J: *Evaluation and treatment of swallowing disorders,* Austin, TX, 1998, Pro-Ed.

Intervention for clients with dysphagia is multifaceted and may involve rehabilitative techniques and compensatory strategies. It is essential to have an excellent understanding of the underlying problems causing the swallowing disorder so that an intervention program can be designed that directly addresses these problems. The overarching goal of dysphagia intervention is the resumption of safe oral intake with the least restrictive diet. The therapist should strive toward facilitating the return of normal eating habits and routines for each client. Establishing proper positioning for safe swallowing is often the first therapeutic intervention in dysphagia management. This may involve the use of positioning equipment, therapeutic exercises to improve trunk and head control, and mechanical positioning by feeding staff.

When a client is unable to orally manage food, an *indirect swallowing intervention* program is initiated. Indirect intervention does not involve the ingestion of food or liquid. Indirect intervention techniques include facilitation of tone and movement for hypotonic muscles, desensitization for hypersensitive areas of the face and oral cavity, sensory stimulation to heighten sensation and proprioception, range-of-motion and gentle resistive exercises to strengthen weak oral and pharyngeal musculature, swallowing stimulation (without food), and oral motor exercises and tasks.[24]

Intervention for swallowing performance is called *direct intervention* because it involves the ingestion of food or liquid. These interventions are aimed at facilitating oral performance, improving the pharyngeal swallow, and reducing the risk of aspiration. Examples include compensatory swallowing techniques and strategies, thermal or tactile stimulation, gradation or alteration of the bolus size/texture/consistency, or method of food presentation and specialized positioning.

Compensatory techniques are introduced to improve swallow safety by helping to control the flow of food and liquid and reduce the risk of aspiration. They do not change the physiology of the individual's swallow. Compensatory strategies used in dysphagia intervention include (1) postural techniques (for example, turning the head toward the more involved side for an individual who sustained a CVA closes off the weaker pharyngeal wall and allows safer swallowing (see Fig. 27.7, D), (2) techniques to improve oral sensory awareness, (3) modification of bolus volume and speed of presentation, and (4) texture modifications (Box 27.1). Compensatory strategies often allow a client to safely engage in oral eating while continuing to work on remediation of the underlying problems. The client and those involved with assisting the client to eat are trained in the use of these strategies.

Box 27.1

Bolus Textures and Swallow Problems

Texture	Disorders for Which This Texture Is Most Appropriate
Thin liquid	Tongue dysfunction (ROM, strength, coordination)
	Reduced tongue base retraction
	Reduced pharyngeal wall contraction
	Reduced laryngeal elevation
	Reduced cricopharyngeal opening
Thickened liquid	Tongue dysfunction (ROM, strength, coordination)
	Delayed pharyngeal swallow
Pureed	Oral motor impairment
	Delayed pharyngeal swallow
	Impaired cognition
	Decreased endurance
Mechanical soft	Oral motor impairment (decreased chew)
	Decreased endurance

Adapted from Logemann J: *Evaluation and treatment of swallowing disorders,* ed 2, Austin, TX, 1998, Pro-Ed; Crary MA: Imaging swallowing examinations: videofluoroscopy and endoscopy. In Groher M, Crary M, editors: *Dysphagia: clinical management in adults and children,* ed 2, St. Louis, 2016, Elsevier.

Rehabilitative or remediation techniques include oral motor, range-of-motion exercises, oral motor strengthening exercises, bolus control exercises, vocal fold adduction and laryngeal elevation exercises, neuromuscular electric stimulation, and exercises to improve pharyngeal pressure.[11,67,70,71] Swallow maneuvers may also be introduced to improve laryngeal closure and bolus movement through the pharynx. See Box 27.2 for examples of swallow maneuvers.

Box 27.2

Techniques to Improve Oral Sensory Awareness

- Downward pressure of metal spoon on tongue during presentation of food
- Cold bolus
- Sour bolus
- Larger bolus
- Bolus that requires chewing
- Thermal-tactile stimulation*

*Tactile stimulation provided directly to the anterior faucial arch using a cold, size 00 laryngeal mirror prior to the presentation of the bolus. This technique heightens oral awareness and provides an alerting sensory stimulus to the cortex and brainstem to facilitate the triggering of the swallow response.

Adapted from Logemann J: *Evaluation and treatment of swallowing disorders,* ed 2, Austin, TX, 1998, Pro-Ed.

The therapist continually assesses the client's response to intervention and makes necessary modifications to the eating and swallowing program. The therapist must develop excellent clinical observation skills. For complex clients, the clinician should seek a consultation with an experienced dysphagia therapist. To develop expertise in dysphagia management, it is recommended that the therapist seek continued education in this area.

Summary

Eating is the most basic activity of daily living. Several performance components are required for the client to eat and swallow effectively. Dysphagia refers to difficulty with swallowing or an inability to swallow. The occupational therapist is trained to assess and provide intervention for many of the problems that interfere with normal eating. An understanding of the normal anatomy and physiology of swallowing and advanced training in eating and swallowing disorders are required to effectively treat dysphagia.

Assessment of the client with dysphagia includes testing of head and trunk control, sensation, perception, cognition, intra and outer oral structures, oral reflexes, and swallowing. Instrumental assessment may also include videofluoroscopy or fiberoptic endoscopy.

Several members of the rehabilitation team are involved in the treatment of the client with dysphagia. Positioning, selection of appropriate feeding procedures, diet texture selection, diet progression, and special techniques to facilitate normal patterns of swallowing are part of the intervention plan. The social, cultural, contextual, and psychological aspects of eating are also important considerations in the intervention program.

Case Study

Nick

Nick is a 65-year-old man who suffered a right cerebrovascular accident (CVA) with left hemiplegia 2 weeks ago. He has a PEG in place for nutrition. He recently retired from his position as vice president of a local marketing company. Nick lives with his wife. He and his wife have two grown children living in the area. Before the onset of the CVA, Nick was independent in all ADLs and instrumental activities of daily living (IADLs). He was an active member of the community.

Results of the occupational therapy evaluation indicate that Nick needs moderate to maximum assistance in dressing, toileting, bathing, eating and swallowing, and transfers. The clinical assessment of eating indicates that the client has a mild to moderate increase in jaw and facial tone with poor rotary chew, poor isolated tongue control, and a mild increase in laryngeal tone with delayed swallow.

The videofluoroscopy confirmed that the client had a mildly delayed swallow with minimal pooling in the valleculae and pyriform sinuses. Aspiration was less than 10% on pureed foods. The occupational therapist saw the client three times a week for 6 weeks. A summary of evaluation results and a treatment plan are shown in Fig. 27.9.

DYSPHAGIA EVALUATION AND INTERVENTION PLAN	
Name: N.X. **Dx:** R CVA **Age/Onset:** 65 y/o male, 1 week ago	
Medical hx: Elevated BP x 5 years. Elevated blood lipids. Otherwise unremarkable. Independent in ADL & IADL prior to onset. No previous swallowing problems. Previously ate a regular diet.	
Current nutritional status:	NG tube, NPO until swallowing evaluation
Mental status:	
Alert/oriented	Oriented to self only
Direction following	Follows 1-2 step directions well
Physical status (symmetry, control, tone)	
Head control	Slight increase in tone with head turning.
Trunk control	Poor trunk control. Leans to the right, unable to bring self to midline
Endurance	Fatigues after 20 minutes of activity
Respiratory	No SOB noted
Outer oral status:	
Facial expressions	Flat affect. Unable to mimic facial expressions. Drooping right side
Jaw movement	Poor rotary chew pattern, poor jaw glide, uses up and down movement
Lip movement	Asymmetrical purse and retract, poor lip compression with closure
Sensation	Decreased-absent touch on right side
Abnormal reflexes	Absent
Inner oral status (symmetry, control, tone)	
Dentition	Dentures, fit well
Tongue	
Appearance	White coating, deviated to right
Tone	Hypotonic
Movement: Protrusion	To just past lips, poor anterior to posterior sweep on palate
Lateralization	Reduced ROM both sides, deviated to right at rest
Elevation	With effort, fatigues with repetition
Soft palate/gag reflex:	Uvula rises symmetrically but with slight delay "ah". Gag present
Cough (reflexive/voluntary):	Weak voluntary cough to command
Swallow:	
Spontaneous	Intact
Voluntary	Slight delay with effort
Laryngeal movement	Mild reduction in laryngeal excursion
Food management:	
Puree	Requires verbal cues to attend to food in mouth. Increased oral transit
Mechanical soft	Requires increased effort, verbal cues, transit time, residuals after sw.
Regular	Not tested
Liquids: Thick	With straw, 5 second delay, no cough
Semi-thick	With straw, 5 second delay, cough; by spoon, 5 second delay, no cough
Thin	Not tested
Required assistance with feeding to utilize strategies (chin tuck, clearing swallow). Decreased sensory awareness of food and liquid in mouth. Weak cough reduces airway protection. Limited amounts of PO provided during testing.	

DYSPHAGIA EVALUATION AND INTERVENTION PLAN

Major problems:

1. Poor sitting balance
2. Poor endurance for eating
3. Weak cough
4. Impaired cognition for attention and awareness of food in mouth
5. Decreased intra-oral and extra-oral sensation
6. Poor isolated tongue movements for lateralization, elevation and protrusion
7. 3-second delay in pharyngeal swallow as per videofluoroscopy evaluation
8. 5-10% residuals in valleculae and pyriform sinus after the swallow as per videofluoroscopy

Recommendations/methods:

(positioning, diet texture modifications, environmental modifications, sensory stimulation, compensatory strategies to improve pharyngeal swallow, client/caregiver training)

1. Positioning – Upright on a solid seating surface, feet flat on the floor, trunk and head in midline, arms supported with slight forward flexion at hips
2. Diet texture – Pureed and mechanical soft (finely chopped) foods, nectar thick liquids. P.O. intake with nursing or therapist only
3. Environmental modifications – quiet eating environment without distractions
4. Alternate cold, frozen textured liquid with food to increase sensory awareness in the mouth.
5. Small frequent meals
6. Oral motor exercises to increase tongue ROM and strength
7. Chin tuck during swallow to reduce risk of aspiration due to delayed swallow
8. Clearing (double) swallow to clear pharyngeal residuals
9. Monitor for signs of aspiration
10. Check mouth for pocketing or residuals after oral intake
11. Advance diet texture as client status improves

Long term goals:

1. Good trunk and head control for safe eating
2. Good awareness of food and liquid in mouth – no food/liquid loss from mouth during eating
3. Good attention to task of eating in a variety of eating environments without verbal cues
4. Improved endurance for eating so that client can eat a full meal without signs of fatigue
5. Adequate strength and coordination of oral musculature to safely manage a soft diet
6. Able to safely drink thin liquids via straw and cup
7. Able to meet nutrition and hydration needs P.O.
8. No signs or symptoms of aspiration
9. Safe eating with caregivers

FIG 27.9 Dysphagia evaluation and intervention plan.

The client responded well to treatment. The PEG was removed after 5 weeks. The client achieved all treatment goals by the time of discharge. He went home with family supervision for correct diet, positioning, and swallowing techniques during meals. The client was referred to home health occupational therapy for 2 to 3 weeks for ADLs and home modification so that he could achieve independence at home. The client returned for follow-up outpatient visits.

Review Questions

1. List the components of dysphagia.
2. List the four stages of swallowing and the characteristics of each.
3. List the physiologic functions that occur when the swallow response triggers, and explain why these functions are necessary.
4. Why is it necessary to assess a client's mental status during a dysphagia evaluation?
5. Describe what the therapist should look for when evaluating the trunk and head during the dysphagia evaluation.
6. What information can the therapist gain when assessing the client's facial motor control?
7. How does poor tongue control contribute to aspiration?
8. Name the components required to protect the airway.
9. What is the safest food sequence to follow for a swallowing evaluation?
10. Describe the finger placement that a therapist can use to feel the strength and smoothness of the swallow.
11. Why should the therapist assess voice quality after a swallow?
12. Will a client who has difficulty handling solids also have difficulty with liquids?
13. List the indicators of swallowing dysfunction.
14. List the acute symptoms of aspiration.
15. When is videofluoroscopy necessary?
16. List the types of intervention used with clients with dysphagia.
17. Describe how the client should be optimally positioned for eating and give the rationale
18. What are the indications for placing a client on a nonoral treatment program?
19. Name five important criteria a client must meet to participate in an oral feeding program.
20. List the properties of food preferred for diets for clients with dysphagia.
21. Why is it important to involve the client in the eating process?
22. What are the symptoms of nutritional deficiency?
23. Name three treatment techniques the occupational therapist can use for poor rotary jaw movement and increased tone.
24. Describe two ways a therapist can decrease abnormally high tone in the tongue.
25. Describe thermal application as a treatment technique. For which problem is it used?
26. When is use of the dry swallow technique appropriate?

Pain Management

Joyce M. Engel

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, the student or practitioner will be able to do the following:

1. Differentiate acute from chronic pain.
2. Explain the biopsychosocial model of pain.
3. Describe two common acute and two common chronic pain syndromes.
4. Summarize two approaches to pain evaluation.
5. Describe occupationally based approaches to pain intervention.

KEY TERMS

Acute pain

Biopsychosocial model of pain

Chronic pain

Nociception

Pain

Pain assessment

Pain behavior

Pain intervention

Suffering

Threaded Case Study

Cathy, Part 1

Cathy, a 34-year-old white single woman, sustained a lumbar strain 5 months ago when catching a heavy weight while employed as an electrician. Cathy was initially treated at an emergency room, where narcotics, muscle relaxants, heat application, and bed rest were prescribed. After she persistently complained about pain, she was given pelvic traction and transcutaneous electrical nerve stimulation. Cathy has not returned to work since her injury and described her current lifestyle as sedentary. She described her pain as severe (a "9" or "10" on an 11-point numerical scale, with "0" representing "no pain" and "10" indicating "pain as bad as could be") and almost constant. She reported that prolonged sitting, standing, and ambulation exacerbated pain factors. Cathy described occasional mild pain relief with ibuprofen use and bed rest. Her self-report on the Brief Pain Inventory revealed moderate to high pain interference with instrumental activities of daily living (IADLs) and recreational, social, and work activities. Cathy described using pain-contingent rest and asking for assistance as the means of coping with her pain.

During evaluation, Cathy was found to have decreased active right shoulder range of motion and strength, decreased left lower extremity strength, and muscle spasms throughout the left lumbar paraspinal muscles and into the left buttock. She demonstrated poor body mechanics, poor posture, and mild shortness of breath. Cathy offered numerous verbal complaints of pain and expressed fear that the pain would never go away.

Physical retraining and cognitive behavioral techniques were emphasized in intervention. Cathy participated in generalized mobility, strengthening, and cardiovascular endurance exercises to increase her occupational performance, minimize fatigue, and enhance feelings of well-being. Functional tasks were incorporated into treatment. Cathy was taught how to monitor her daily routine (eg, balance of rest, relaxation, and activity) and modify faulty thinking (eg, catastrophizing, such as thinking there is nothing that can stop the pain). Her daily routine included progressive relaxation rehearsal.

Cathy made good progress in her intervention program, and after 4 weeks she demonstrated normal mobility, strength, and endurance. Bed rest during the day was eliminated. Cathy was taught proper posture and body mechanics and was observed to use them in her routine activities. Although her verbal complaints of pain continued, she stated that she no longer felt the pain was controlling her. Cathy was now ready to progress to a work-hardening program.

Critical Thinking Questions

1. What occupational limitations would you anticipate due to Cathy's injury and pain?
2. How would you approach an occupational therapy evaluation?
3. How would you provide an occupation-based intervention program to meet Cathy's occupational performance needs?
4. What problems in social participation do you anticipate due to the level of pain Cathy experiences on a daily basis?

Pain is a primary reason for seeking healthcare. An estimated one in four adult Americans reported experiencing a daylong pain episode within the past month, with 10% stating the pain lasted at least 1 year.[59] Chronic pain affects more than 100 million Americans, over 30% of the U.S. population.[39] This is more than the combined number of persons with diabetes, heart disease, and cancer in the United States.[1] Despite people's use of pain medications, two-thirds of individuals experiencing chronic pain cannot perform routine occupations.[1] At least $100 billion is spent each year on direct medical expenses, lost income, and lost productivity let alone the inestimable costs of human suffering.[2] The obligation to manage pain and relieve a client's suffering is fundamental to healthcare.[20] Pain may coexist with a medical condition (eg, arthritis) or a rehabilitative procedure (eg, splinting), and it may be the primary complaint (eg, low back pain) or a secondary disability (eg, chronic pain in persons with cerebral palsy). Occupational therapy practitioners may suspect that pain is impeding the client's progress but are unsure about how to best evaluate the condition and intervene. This chapter defines pain, discusses the **biopsychosocial model of pain**, describes common pain syndromes, outlines assessment procedures, and proposes interventions.

Definitions of Pain

Pain is defined as an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage.[56] This definition conveys that pain is a subjective and multifaceted experience. Individual variables such as mood, attention, prior pain experiences, and familial and cultural factors are known to affect one's experience of pain.[4,53]

There are many types of pain, yet most investigators differentiate acute from chronic nonmalignant pain, which is critical for selecting appropriate assessment and intervention strategies. **Acute pain** and its associated physiologic, psychological, and behavioral responses are typically caused by tissue irritation or damage related to injury, disease, disability, or medical or rehabilitative procedures. It has a well-defined onset and serves a biologic purpose by directing attention to injury, irritation, or disease and signaling the need for immobilization and protection of a body part.[54] Fortunately, acute pain is predictable and usually responds to medication and treatment of its underlying cause.[36]

In contrast, **chronic pain** (or *persistent pain*) continues for more than 12 weeks. It may begin as acute pain or may be more insidious and endure beyond the point at which an underlying pathologic condition can be identified.[58] Increased sympathetic nervous system activity does not continue. Chronic pain does not appear to serve a biologic purpose. It is unpredictable and not amenable to routine interventions. Chronic pain typically produces significant chances in quality of life (eg, mood, thoughts, attitudes, lifestyle, and environment).[76] As pain progresses from acute to chronic, factors other than tissue damage or irritation (eg, personality changes) become prominent. Our client, Cathy, is now experiencing chronic pain that is negatively impacting her occupational performance.

Biopsychosocial Model of Pain

Occupational therapy has long embraced the biopsychosocial model for its emphasis on the interaction of the individual's body, mind, and environment.[57] Conceptualizing pain using a biopsychosocial model can clarify the complex, multifaceted nature of pain that is critical to accurate evaluation and effective intervention.[26,80] Loeser and Fordyce[48] suggested the phenomenon of pain could essentially be divided into four distinct domains: nociception, pain, suffering, and pain behavior (Fig. 28.1).

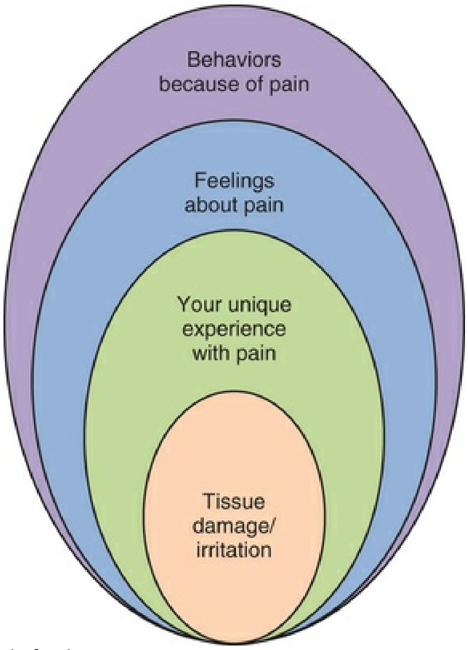

FIG 28.1 Loeser's model of pain. (Adapted from Loeser JD: Concepts of pain. In d'A Stanton-Hicks M, Boas R, editors: *Chronic low back pain*, New York, 1982, Raven Press.)

Nociception is the detection of tissue damage by transducers in the skin and deeper structures, as well as the central transmission of this information by A-delta and C fibers in the peripheral nerves. Nociception is the body's message to do something or avoid doing something for pain relief. For example, you are working at your desk and have ignored the tingling in your hand and wrist for weeks; today, however, you experience a sharp pain shooting through your wrist and up through your arm, signaling carpal tunnel syndrome. **Pain** is the perceived noxious input to the nervous system. Specifically, it is an unpleasant sensory and emotional experience. In the previous example, it is the feeling of the sharp pain that is likely signaling carpal tunnel syndrome. **Suffering** is the negative affective response to pain. For example, chronic pain is often associated with depression, dysthymic disorder, fear, anxiety, substance abuse/dependence, and insomnia.[74] Suffering is personal. The individual knows the impact of pain on his or her body, sense of self, social responsibilities, and daily occupations. Finally, **pain behavior** is what an individual says or does (eg, moaning) or does not say or do (eg, engage in occupations, attend a job) that communicates to others the presence of pain. Pain behaviors are observable and are influenced by familial, cultural, and environmental consequences. This model purports that one can experience or demonstrate some domains of the model in the absence of other domains. In chronic nonmalignant pain, pain behaviors and suffering often exist in the absence of nociception.[24,48,81]

Consider our client, Cathy, as she continues to experience pain and also expresses fear that the pain will never go away. In that sense she is captive to her pain experience.

Pain Syndromes

The evaluation and treatment of pain resulting from trauma, disease, or unknown etiology are significant healthcare concerns. The following sections describe common pain syndromes, their etiology, and typical interventions.

Headache Pain

Recurrent headaches are one of the most common pain problems. Migraines affect approximately 12% to 15% of the general population. More than half of people with headaches do not seek treatment because they perceive the problem as too trivial, have concerns about medication side effects, and believe no adequate treatment is available.[50]

Migraine headaches are characterized by recurrent pain episodes varying in frequency, duration, and intensity. Migraines may occur when the individual oversleeps, is tired, skips meals, overexerts, is stressed, or is recovering from stress.[30] The pain is typically unilateral and pulsatile and may be accompanied by anorexia, nausea, vomiting, neurologic symptoms (eg, sensitivity to light and sound), and mood changes (eg, irritability).[50] A strong genetic predisposition exists for migraines. Experimental evidence supports the role of serotonin in the incidence of migraines. Stress, attention, the environment, and mood (eg, anxiety) affect these headaches.

Tension-type headaches (TTHs) are the most common headache disorder. Approximately 73% of adult Americans experience one or more tension headaches in a year.[9] These headaches are typically of mild-to-moderate intensity. The pain is bilateral and of a pressing character and does not have associated symptoms. Precipitating headache factors include situational stress, missed meals, sleep deprivation, and noxious stimuli (eg, heat exposure).[50] TTH has been attributed to a disorder of central nervous system (CNS) modulation. Simple analgesics (eg, acetaminophen) are standard treatment. Headaches are often controlled with lifestyle management and medication.

Low Back Pain

Low back pain (LBP) is the second most common pain complaint among the adult population. Approximately 3% to 7% of people in Western industrialized countries experience chronic LBP. Job absenteeism, loss of productive activity, and decreased participation are common consequences.[78] Clients may restrict occupational engagement due to a fear that the etiology of pain, the interventions, and the restricted social consequences can be harmful. The most common causes of LBP are injury (eg, lifting) and stress, resulting in musculoskeletal and neurologic disorders (eg, muscle spasm and sciatica). Back pain also may result from infections, degenerative diseases (eg, osteoarthritis), rheumatoid arthritis, spinal stenosis, tumors, and congenital disorders.[66] LBP tends to improve spontaneously over time.[79] Numerous schools of thought govern interventions. Functional restoration is key for the client with chronic back pain. Medication management, physical therapy (eg, exercise, massage, traction), and self-care education are common treatment approaches. Once significant back pain has lasted for 6 months, however, the chance that the client will return to work is only 50%[16] (see Chapter 41).

Threaded Case Study

Cathy, Part 2

Cathy's LBP has significantly compromised her ability to engage in occupations. She has not returned to work since her injury and is at risk for never being gainfully employed in the future. Cathy is no longer able to engage in her preferred recreational activities, dancing and bowling. Her ability to care for her personal activities of daily living (ADLs) is compromised, and she has difficulty stepping in and out of the tub and even bending over to turn the faucet handles to regulate the water temperature. She must request assistance when grocery shopping because bending and reaching for items increases the pain. Cathy even reports that getting in and out of her car is difficult and requires planning and care.

Arthritis

Approximately one-third of all American adults experience joint pain, swelling, or limited mobility due to arthritis.[46] Osteoarthritis (OA), the most common form of arthritis, is a degenerative joint disease characterized by a progressive, dull ache and swelling, typically affecting the fingers, elbows, hips, knees, and ankles. Movement may exacerbate OA. Degeneration of the articular cartilage leading to joint pain, reduced mobility, and swelling occurs, typically affecting weight-bearing joints in persons after age 45.[28,70]

Rheumatoid arthritis (RA) affects 1% to 2% of Americans, with women more often affected.[28] It usually has a slow insidious onset, characterized by aches, pains, swelling, and stiffness. Any joint may be involved, but usually there is a symmetric pattern affecting the fingers, wrists, knees, ankles, and cervical spine. This systemic disease involves remissions and exacerbations of destructive inflammation of connective tissue, especially in the synovial joints.[70] The Arthritis Foundation supports self-management (eg, exercise, relaxation, problem solving strategies) of the disease.[49] (See Chapter 38 for more information on arthritis.)

Complex Regional Pain Syndrome

The incidence of complex regional pain syndrome (CRPS) has been reported as 25.2 new cases per 100,000 annually.[35] CRPS is characterized as a continuous, severe burning pain that results from trauma, postsurgical inflammation, infection, or laceration to an extremity, causing a cycle of vasospasm and vasodilation. Pain, edema, shiny skin, coolness of the hand, and extreme sensitivity to touch occur. An individual experiencing CRPS may also have excessive sweating or dryness. The key feature of CRPS is continuous, intense pain out of proportion to the severity of the injury (if an injury has occurred), which worsens over time. Exacerbating pain factors include movement, cutaneous stimulation, and stress.[43,83] Occupational therapy (OT) treatment strives to normalize sensation, reduce edema, and increase mobility, strength, and endurance while decreasing guarding and restoring routine activities. Simultaneously clients often receive physical therapy, psychotherapy, pharmacotherapy, recreational therapy, and vocational rehabilitation.[35]

Myofascial Pain Syndrome

Muscle pain is common across all age groups, with the elderly most often affected. Myofascial pain refers to a large group of muscle disorders defined by the presence of trigger points (ie, localized areas of deep muscle tenderness). Pressure on the trigger point elicits pain to a well-defined distal area. Myofascial pain is perceived as a continual dull ache often located in the head, neck, shoulder, and low back areas. The trapezius muscle is one of the most commonly affected muscles. The pain may result from sustained muscle contraction or from an acute strain caused by a sudden overload or overstretching of the muscles in the head, neck, shoulder, or lower back regions.[31,69] Physical therapy, needling therapies (ie, insertion of a solid needle for relief of muscular pain), manual therapies, and modalities are common treatment approaches.[13]

Fibromyalgia

The prevalence of fibromyalgia ranges from 0.7% to 3.2% in the adult population. Fibromyalgia is widespread musculoskeletal pain in the muscles, ligaments, and tendons. Skeletal muscles have been implicated as the cause of fibromyalgia, but no specific abnormalities have been identified. Abnormalities of the neuroendocrine system, autoimmune dysfunction, immune regulation, cerebral blood flow difficulties, and sleep disturbances have been suggested.[37] Genetic factors, physical trauma, peripheral pain syndromes, infections, hormonal changes, and emotional distress are capable of triggering fibromyalgia. Pharmacologic therapies, cardiovascular exercise, and cognitive behavior therapy have all proved beneficial.[10]

Cancer Pain

Clients with cancer often have multiple pain problems that are frequently undertreated. Cancer pain varies greatly in frequency, duration, and intensity. In the initial and intermediate stages, 40% to 50% of clients experience moderate to severe pain. About 60% to 90% of clients with advanced cancer have pain. Cancer pain may result from tumor progression, interventions (eg, surgery, chemotherapy, and radiation), infection, or muscle aches when clients decrease their activity.[72]

Disability-Related Pain

Pain is a significant problem for many persons with physical disabilities,[15] including cerebral palsy,[18] spinal cord injury,[12] limb deficiency,[34] and multiple sclerosis.[32] Physiologic changes resulting from the disability and psychosocial factors (eg, negative thoughts) are known to influence the intensity and impact of pain in many persons with chronic pain as a secondary condition to their disability.[42] Data support the use of relaxation training, hypnosis, and medication management.

Evaluation

Referral for an OT evaluation is made when pain interferes with the client's occupational performance. As a member of an interdisciplinary or multidisciplinary team, the occupational therapist focuses the evaluation on factors that contribute to the client's pain perception and pain interference. Before the occupational therapy program is implemented as well as throughout the interventions, performance should be measured objectively to determine the client's occupational profile and the value of those occupations.[33] Factors that may contribute to pain perception, occupational role disruption, decreased occupational performance, and diminished quality of life should be identified. In addition, pain intensity should be recognized as the fifth vital sign and assessed on a regular basis.[2]

The occupational therapist performs a pain evaluation, viewing pain as a complex phenomenon involving psychological arousal, sensations of noxious stimulation, tissue damage or irritation, behavioral changes, complaints of distress, and the social environment. Self-report measures are the most common type of **pain assessment** because pain is considered to be a subjective experience.[77] The clinical interview focuses on the client's identification of pain onset, location(s), frequency, intensity, duration, exacerbating and relieving pain factors, past and current pain treatments, mood, and occupational performance. A verbal rating scale (VRS), 0-10 numeric rating scale (NRS), or visual analog scale (VAS) (Box 28.1) may be used to assess self-reports of pain intensity.[61,77] These instruments have strong psychometric properties and high utility. A VRS of pain intensity consists of a list of 4 to 15 verbal descriptors and a corresponding number (eg, 0 = no pain, 1 = mild pain, 2 = moderate pain, and 3 = severe pain). This is an easy-to-use scale, but it might have a lengthy list of verbal descriptors and the client may not find a descriptor on the list that matches his or her experiences.[41]

Box 28.1

Examples of Pain Intensity Scales

Simple Descriptive Pain Intensity Scale*					
No pain	Mild pain	Moderate pain	Severe pain	Very severe pain	Worst pain possible

0-10 Numeric Pain Intensity Scale*										
0	1	2	3	4	5	6	7	8	9	10
No pain					Moderate pain					Worst pain possible

Visual Analog Scale (VAS)†	
No pain	Pain as bad as it could possibly be

*If used as a graphic rating scale, a 10-cm baseline is recommended.

†A 10-cm baseline is recommended for VAS scales.

From U.S. Department of Health and Human Services, Acute Pain Management Guideline Panel: *Acute pain management in adults: operative procedures. Quick reference guide for clinicians,* AHCPR Pub No. 92-0019, Rockville, MD, 1995, U.S. Government Printing Office.

The NRS consists of a range of numbers, typically 0 (“no pain”) to 10 (“worst pain possible”) (see Box 28.1). The client selects which one number is most representative of his or her pain intensity. Use of the 0-10 NRS is highly recommended. Pain ratings in the 1 to 4 range have minimal impact on functional performance and are labeled “mild” pain. Ratings of 5 or 6 (“moderate” pain) indicate that pain has a greater impact on functioning. Ratings of 7 to 10 (“severe” pain) have the greatest impact on performance.[14]

The VAS consists of a horizontal or vertical line, typically 100 mm long, with each end of the line labeled with descriptors representing the range of pain intensity (eg, “no pain” and “pain as bad as can be”). The client draws a mark on the line that represents his or her pain intensity and the distance measured from the “no pain” anchor to the mark becomes that individual's pain score. It should be noted some individuals have difficulty understanding and completing the measure.[41]

For both the NRS and VAS, decreases or increases between 30% and 35% appear to indicate a meaningful change in pain. Clients tend to prefer VRSs and NRSs over VASs.[41] It has been recommended that both clinicians and researchers use the 11-point NRS so that comparisons between studies can be made.[14] When occupational therapy services were initiated for Cathy, the therapist used a NRS to determine the existence and intensity of the pain Cathy experienced on a daily basis.

Pain behaviors are often targeted in evaluation and intervention.[23] Pain behaviors include guarded movement, bracing, posturing, limping, rubbing, and facial grimacing[44] and are in response to pain, suffering, and distress. The University of Alabama Pain Behavior Scale[64] is an example of a standardized rating scale that is a reliable, valid, and easy method for documenting observable behaviors. Analysis of the client's pain behaviors before, during, and after intervention with and without a significant other present can provide valuable information about the role of situational and learned factors in the individual's pain perception, as well as responses to intervention. Healthcare utilization and medication use are additional clinically relevant pain behaviors.[74] Merskey[55] cautioned practitioners not to provide treatment for reducing pain behaviors in lieu of attempts at alleviating the pain. Evaluation that focuses solely on pain behavior may lead to the inaccurate conclusion that pain behavior suggests malingering, lack of motivation, or hypochondriasis.

The primary focus of the occupational therapist is occupational performance. The client may complete daily activity diaries as an assessment technique and outcome measure.[21] With this technique, the client records hourly entries of time spent in sitting, standing, reclining, and engaging in productive activities, and these behaviors may be corroborated by trained staff or significant others. Activity diaries are highly reliable and valid.[23]

The Brief Pain Inventory (BPI)[11] is a reliable and valid instrument that may also be used to measure pain interference. Pain interference is defined as the extent to which pain impacts daily functioning.[41] Clients rate on an ordinal scale how much their pain has interfered with general activity, mood, mobility, work, interpersonal relationships, sleep, enjoyment of life, self-care, and recreation (Box 28.2).

Box 28.2

Pain Interference Scales

A. *In the past week,* how much has pain interfered with your daily activities?

0-10 Numeric Pain Intensity Scale										
0	1	2	3	4	5	6	7	8	9	10
No interference										Unable to carry out any activities

B. *In the past week,* how much has pain interfered with your ability to take part in recreational, social, and family activities?

0-10 Numeric Pain Intensity Scale										
0	1	2	3	4	5	6	7	8	9	10
No interference										Unable to carry out any activities

C. *In the past week,* how much has pain interfered with your ability to work (including housework)?

0-10 Numeric Pain Intensity Scale										
0	1	2	3	4	5	6	7	8	9	10
No interference										Unable to carry out any activities

From National Institutes of Health, National Institute of Child Health and Human Development, National Institute of Neurological Disorders and Stroke: Ongoing research (Grant No. 1 PO1 HD/NS33988), Pain Management.

The responses are averaged to determine the pain interference score. This information may help to determine baseline tolerance levels for occupations that may be addressed in treatment. The BPI can be used with persons with disability-related pain (eg, spinal cord injury, cerebral palsy) as well as an outcome measure.[41] Similarly, the Pain Disability Index (PDI) is a brief, valid, and reliable self-report measure of general and domain-specific pain-related disability. It uses an ordinal scale to measure how disabling pain is with family/home responsibilities, recreation, social activity, occupation, sexual behavior, self-care, and life-support activity.[63]

Similarly, the Canadian Occupational Performance Measure (COPM)[45] can also be used in valid and reliable pain assessment. The COPM detects changes over time in the individual's perceptions of his or her occupational performance in the areas of self-care, productivity, and leisure, as well as the importance of being able to perform these occupations and the level of satisfaction with performance, using 10-point scales. The COPM has good evidence of concurrent criterion validity and sensitivity to change. It is especially helpful in collaborative functional goal setting.[65]

Finally, evaluation must acknowledge that cultural disparities in pain experiences exist. Differences in pain experiences have been found between whites and African Americans. For example, African Americans report a poorer quality of life with increasing levels of pain, disability, symptoms, and emotional distress as compared to whites. Women are known to report more pain than men. It should also be noted that persons with a lower socioeconomic status tend to be sicker and overall have more chronic health problems.[60] Lastly, pain frequently has been overlooked and therefore undertreated in children and the elderly.[73] These differences have been attributed to numerous causes such as limited access to healthcare and poor coping skills.

Threaded Case Study

Cathy, Part 3

Cathy had indicated that her pain and the fear associated with the pain severely limited her ability to engage in several occupations. She had not returned to work and had greatly decreased social activities. Her contact with friends was limited to infrequent phone conversations and occasionally a friend would stop by to visit. Prior to her injury she regularly went out with friends to movies and to go dancing and bowling, but she discontinued all of those activities due to the pain.

Intervention

The obligation to manage pain and relieve a client's suffering is fundamental. A multi- or interdisciplinary team approach to chronic pain is common and includes the client as an active and educated participant. The occupational therapist typically works in collaboration with the client, a physician, a psychologist, a physical therapist, and a nurse. Occupational therapy interventions focus on increasing physical capacities, productive and satisfying performance of life tasks and roles, mastery of self and environment through activities, and education.[40] As the causes of pain are multifactorial, so are the approaches to treatment. Effective pain management addresses all dimensions of pain. Typical **pain interventions** are described here.

Interventions should be introduced in a systematic manner to assess the appropriateness of the selected intervention for the specific client. The effectiveness of pain interventions can be measured and documented in a variety of ways. Clinical improvement can be measured by occupational performance (eg, BPI or COPM), increased participation (eg, diary), lower pain intensity (eg, NRS), reduction in pain behaviors (eg, University of Alabama Pain Behavior Scale), improved mood (eg, Sickness Impact Profile[5]), and decreased drug and healthcare utilization.

Medication

Medications are generally the treatment of choice for individuals experiencing acute pain and are prescribed by the physician. Occupational therapists need to observe clients for possible drug reactions. To reduce possible discomfort from rehabilitative procedures, practitioners should check that clients are adequately medicated in advance. The World Health Organization[82] analgesic ladder is well established in adult pain management as a stepwise approach for choosing an analgesic. Aspirin and acetaminophen are frequently used to treat mild pain (eg, backache) because of their high level of effectiveness, low level of toxicity, and limited abuse potential. Nonsteroidal anti-inflammatory agents have been used in the treatment of arthritis and inflammation of a musculoskeletal origin. Codeine is often used for moderate-intensity pain that has not responded adequately to aspirin or acetaminophen. Morphine is the standard medication used to relieve severe pain. The use of opioid analgesics (narcotics) in chronic nonmalignant pain has been controversial because of concerns about addiction.[36] Clear and accurate communication among the client, occupational therapist, and physician regarding responses to medications is critical to maximize the effectiveness of the entire intervention program.

Activity Tolerance

Although a few days of rest may be indicated for acute pain, therapeutic activity is important for the treatment of any underlying impairment. Activity levels are increased on a gradual basis, with the client working to "tolerance" (ie, gradual increase in task demands such as mobility, strength, and endurance), as opposed to "pain," before a scheduled rest period. The client should not initiate rest when the pain begins or exacerbates because this may reinforce pain behaviors.[24] A gradual increase in activity also lessens the likelihood of an exacerbation of pain. Fordyce[24] provided guidelines for the use of quota programs for clients with chronic pain. Regular gentle exercise (eg, walking, swimming, water aerobics) is recommended. Modalities (eg, heat or cold) may be applied before activity as a means of enhancing functional performance. When an individual is engaged in interesting and purposeful activity, he or she may be more relaxed, less preoccupied with pain, and have more fluid movement. Task selection based on occupational roles, interests, and abilities is a unique contribution of occupational therapy in pain management.[71]

Body Mechanics and Posture Training

Instruction in and rehearsal of proper body mechanics and posture that will not increase the risk of low back injury or strain are essential for clients experiencing both acute and chronic LBP.[51] The intervention plan should include opportunities to practice using the body safely and to maximize performance during routine tasks in natural (ie, home, work, or leisure) environments.[68,71] The client should be taught to avoid tasks or positions that do not allow balanced posture. For detailed guidelines on proper posture and body mechanics principles, please refer to Chapter 41. For clients in wheelchairs, the information on positioning in Chapter 11 is also helpful.

Energy Conservation, Pacing, and Joint Protection

Instruction in energy conservation, pacing, and joint protection may help clients to obtain the recommended amounts of rest during task completion, recommended time spent physically active, and balance between rest and physical activity. Clients, especially those with rheumatoid arthritis, are taught to use these strategies before they experience pain and fatigue so that occupational performance can continue as long as possible.[27]

Splinting

Splinting of the upper extremity may be necessary if contractures or muscle imbalances occur. In CRPS, static resting splints may provide pain relief. Splint use is alternated with tasks that require joints to be taken through range of motion, because total immobilization could increase pain and dysfunction. Static resting splints maintain joint alignment, reducing inflammation and pain during flare-ups of rheumatoid arthritis. Splints that support the wrist in a functional position throughout the day and night may be necessary for 4 to 6 weeks.[6] Caution is necessary because orthoses may add to the stress on proximal joints when the wrist is confined.[8]

Adaptive Equipment

Clients with acute LBP may use a back support for stabilization of the lumbar area and increased abdominal pressure to improve postural alignment. This can decrease muscle spasm, reduce pain, and improve one's ability to engage in occupations.[6,75] Adaptive equipment is often used to increase function and comfort in persons with arthritis.[70]

Relaxation

Relaxation training can decrease muscle tension, which is believed to precipitate or exacerbate pain. Progressive muscle relaxation involves the systematic tensing of major musculoskeletal groups for several seconds, passive focusing of attention on how the tensed muscles feel, and release of the muscles and passive focusing on the sensations of relaxation. As the client learns to recognize muscle tension, he or she can direct attention to inducing relaxation.[62]

Autogenic training is another means to induce relaxation. This approach involves the silent repetition of self-directed positive statements that describe the psychophysiologic aspects of relaxation (eg, "My arms and legs are warm"). The client passively concentrates on these phrases while assuming a comfortable body posture, with eyes closed, in a quiet setting. Relaxation training has been used successfully to modify a variety of chronic pain complaints, including headache, LBP, myofascial pain, arthritis, and cancer pain.[29,62]

Biofeedback

Biofeedback is the use of instrumentation to provide visual or auditory signals that indicate some change in a biologic process, such as skin temperature, as it occurs. The signals increase the client's awareness of these changes so that the changes may come under voluntary control. Biofeedback is based on the assumption that a maladaptive psychophysiologic response results in pain. Despite the questionable validity of this assumption, data do exist to support the use of biofeedback for the treatment of headache disorders, LBP, arthritis, myofascial pain, and CRPS.[29] Biofeedback for pain control is typically used in conjunction with relaxation training.

Distraction

Distraction is often used to divert an individual's attention and concentration away from acute mild-to-moderate intensity pain and reduce distress, especially during medical and rehabilitative procedures. Distraction may have an internal focus (eg, daydreaming, guided imagery) or an external focus (eg, listening to music, watching television).[38]

Therapeutic Modalities

Occupational therapists may use physical agent modalities (PAMs) as adjuncts to or in preparation for purposeful activities. Appropriate postprofessional education is needed to ensure that the practitioner is competent in the use of these modalities (see Chapter 29). Both heat and ice can reduce pain and muscle spasm of musculoskeletal and neurologic pathologies. Superficial heat includes hot packs, heating pads, paraffin wax, fluidotherapy, hydrotherapy, whirlpool, and heat lamps. The application of heat increases local metabolism and circulation. Vasoconstriction occurs initially, followed by vasodilatation resulting in muscle relaxation. The use of heat is indicated in the treatment of subacute and chronic traumatic and inflammatory conditions such as muscle spasms, arthritis of the small joints of the hands and feet, tendonitis, and bursitis.[7,22,47]

The use of heat is contraindicated for clients who have acute inflammatory conditions, cardiac insufficiency, malignancies, or peripheral vascular disease. Preexisting edema may be aggravated with the application of heat. It should not be used for clients who are insensate. Heat may cause malignancies to spread.[52]

Cold can help a client to control pain by elevating the pain threshold (ie, the minimal level of noxious stimulation at which the client first reports pain). Local vasoconstriction occurs in direct response to cold therapy (cryotherapy). When the area is subsequently exposed to air, vasodilatation occurs. Cold applications also decrease local metabolism, slow nerve conduction velocity, diminish muscle spasm secondary to joint or skeletal pathologic conditions and spasticity, decrease edema, and lessen tissue damage. Cold can be applied via commercial packs, sprays, ice cups, or a massage stick.[7,47]

There are several contraindications to the use of cryotherapy. Clients who are extremely sensitive may not be able to tolerate cold. If a client has a history of frostbite in the area to be treated, another modality must be used. If a client has Raynaud's disease, severe pain may occur in the treated area. Cryotherapy is contraindicated in the very young and elderly because their thermoregulatory responses may not function sufficiently.[22]

Transcutaneous Electrical Nerve Stimulation

Transcutaneous electrical nerve stimulation (TENS) is a noninvasive pain relief measure that uses cutaneous stimulation. A TENS unit consists of a battery-powered generator that sends a mild electrical current through electrodes placed on the skin at or near the pain site, stimulating A fibers. Some success has been demonstrated when using TENS to relieve acute and chronic painful conditions caused by disease or injury of nervous system structures or the skeleton, muscle pain of ischemic origin in the extremities, and angina pectoris.[67]

Relapse Management

Clients with chronic pain frequently experience a flare-up or an exacerbation of pain. During the flare-up the client is typically encouraged to reduce aerobic conditioning exercises (eg, walking, stationary biking, swimming). As pain subsides, activity can be added incrementally.[25] The client should be encouraged to increase his or her use of pain coping and self-management strategies throughout the flare-up.[19]

Threaded Case Study

Cathy, Part 4

The occupational therapy intervention program for Cathy considered her active lifestyle prior to the injury and began with simple activities such as accompanying a friend to a local shopping mall and walking in the complex. The occupational therapist helped Cathy plan the outing by suggesting that the walk occur during a weekday evening instead of on busy weekends and that Cathy take frequent breaks during the initial walk to sit on one of the benches provided within the mall.

Cathy employed energy conservation and pacing throughout her daily life and was able to return to many previous occupations. For example, she was able to do her laundry by using a portable table to hold the laundry basket when putting the clothes in her top-loading washer. She also used the table when she transferred the clothes from the washer to the side-opening dryer.

Relaxation strategies allowed Cathy to regain a bit of her old self. When out shopping with friends she would often pause briefly and appear to be studying a clothing item while using the relaxation strategies rehearsed during her occupational therapy sessions. This allowed her to continue with the outing.

Summary

Pain is a complex phenomenon. Occupational therapists bring their understanding of anatomy, physiology, kinesiology, psychology, and function to the comprehensive evaluation and treatment of the client with pain. Interventions focus on relieving pain, improving occupational performance, and developing coping strategies. Data are needed to support the use of the OT interventions described in this chapter.

Review Questions

1. Contrast acute pain and chronic pain.
2. List and describe two different pain syndromes that may be present in persons referred for occupational therapy.
3. Identify the essential elements of a pain assessment.
4. Explain at least six interventions used in the treatment of pain.
5. Describe the role and define the scope of occupational therapy in the evaluation and treatment of pain.

PART V

The Occupational Therapy Process: Implementation of Intervention

OUTLINE

29

Therapeutic Occupations and Modalities

Jacqueline Reese Walter, Kristin Winston

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, the student or practitioner will be able to do the following:

1. Recognize and differentiate occupation, activity, preparatory methods, and preparatory tasks as they relate to intervention choices.
2. Discuss the role of occupational analysis and activity analysis in the selection of intervention strategies.
3. Understand the similarities and distinctions between therapeutic activity and therapeutic exercise as intervention strategies.
4. Describe how grading and adapting intervention choices heighten occupational performance.
5. Describe how occupation, activity, preparatory methods, and preparatory tasks are used in practice in different contexts through case study exploration.
6. Differentiate between the various types of therapeutic exercise as intervention strategies.
7. Describe how and why preparatory methods, such as PAMs, are used in occupational therapy practice.
8. Identify the role of physical agent modalities in occupational therapy practice.
9. Identify the requirements established by the American Occupational Therapy Association for the use of physical agent modalities in occupational therapy practice.

Therapeutic exercise

Case Study

Fareed

Fareed is a 66-year-old, semiretired (working part time) bookkeeper whose primary diagnosis is s/p right CVA. The stroke resulted in his hospitalization and subsequent admission to a subacute facility. He has a past medical history of hypertension and prostate cancer, and he has exhibited reactive depression since his recent hospitalization.

Prior to this recent hospitalization, Fareed lived with his wife in a private two-story home in a suburban neighborhood. One of his children lives in a nearby town and visits weekly. His other two children and their families live in cities within a day's drive and visit several times a year. Since his change to semiretirement and working part time as a bookkeeper, Fareed has developed or expanded several interests, including woodworking, gardening, cooking, and traveling. He also enjoyed communicating with his grandchildren through interactive computer sites. He and his wife have taken a yearly vacation, traveling to various locations in the United States for periods of 3 weeks since his semiretirement. Fareed had also been responsible for managing the family's finances. In all, Fareed had an active schedule and was engaged in varied occupations before his recent hospitalization.

The initial evaluation in the subacute facility revealed that Fareed is dependent in dressing and bathing. He requires set-up for mealtimes (eg, opening containers, positioning the tray, and cutting foods as needed). Once set up Fareed was independent to feed himself using a spoon and a fork; he requires assistance with cutting. He is also independent with drinking from a cup. He exhibits a mild left visual field cut.

He requires moderate assistance for bed mobility. Results of the Berg Balance Scale indicate that Fareed is able to move from sit to stand with minimal assistance to stand or stabilize, and one person minimum (min) assist to complete a stand pivot transfer. He is able to sit unsupported at the edge of the bed with arms folded for up to 30 seconds. When interacting with the environment, he requires min assist to maintain his balance. Fareed requires several attempts to maintain a standing position for 30 seconds unsupported. When engaging in occupations, he requires min assist from another person to maintain dynamic standing balance.

Evaluation of upper extremity function revealed residual shoulder and hand pain of his left upper extremity (LUE). Fareed's range of motion (ROM) and strength are within normal limits in his right upper extremity (RUE). In the LUE he has limited active and passive ROM of the shoulder, with pain on passive flexion of the left shoulder at the end of the range. Active ROM is limited in the LUE, but Fareed is able to use a gross grasp with assistance to open his fingers secondary to increased tone. He is able to pronate his forearm, flex the elbow, and internally rotate the shoulder with a gross manual muscle grade of 3/5. Although his prospects for recovery are positive, Fareed expresses feelings of grief over his loss of function and discouragement about regaining his ability to resume his independence, roles, and occupations.

The focus of occupational therapy (OT) intervention included the following:

- Prepare Fareed and family with skills needed for him to return home through client and family education
- Engage in meaningful occupations to reduce feelings of grief over his loss of function and discouragement
- Adapt and grade occupations and activities
- Reduce pain associated with movement to enable use of LUE in occupations through the use of preparatory methods and modalities
- Increase ROM and strength of LUE to facilitate occupational performance in activities of daily living (ADLs), leisure, and work
- Improve balance and mobility through participation in occupations and activities to facilitate occupational performance in ADLs, leisure, and work
- Prepare Fareed to resume occupations and social participation with family, friends, and coworkers

Critical Thinking Questions

1. Identify occupations Fareed engaged in before his stroke, those he engaged in during intervention, and those he assumed or resumed. Describe how his progress relied on evaluation of his occupational performance.
2. Explore the contextual factors that influence Fareed in resuming preferred activities. Describe roles he resumed because of these influences.
3. Describe how the occupations and activities in which Fareed engaged could be graded and/or adapted to provide an interface between activity demands and client factors.

Occupational Therapy Intervention

OTPF-3 as the Foundation for Intervention Planning and Implementation

In 2014 the American Occupational Therapy Association (AOTA) developed the third edition of the "Occupational Therapy Practice Framework: Domain and Process"[1] (OTPF-3), a document that describes OT practice. The Framework contains two sections, the first of which is the domain, describing the profession's purview and the areas in which OT practitioners have established knowledge and expertise. The second area of the Framework is the process, which describes "the actions practitioners take when providing services that are client centered and focused on engagement in occupations"[1] (OTPF-3, p. S3). This chapter will focus primarily on aspects of intervention related to the process of occupational therapy.

Occupation

Occupation is the foundation of OT practice. **Occupations** may include personal care, caregiving, leisure occupations (eg, reading, bowling, games, or crafting), schoolwork (including the use of technology such as computers and iPads), work, and vocational pursuits. In support of engagement in a variety of occupations, Wilcox[35] states that "a varied and full occupational lifestyle will coincidentally maintain and improve health and well-being if it allows people to be creative and adventurous physically, mentally, and socially."

When clients face a physical disability and occupational performance becomes impaired, the OT practitioner works with clients to regain skills, using occupation as both means and ends. Trombly[33] describes occupation as end as "not only purposeful but also meaningful because it is the performance of activities or tasks that a person sees as important." Gillen[11] refers to this as the use of occupations that are the end product of the intervention. For example, an intervention focused on improving a client's ability to complete a meal for his or her family would be considered an end product. Occupation as means "refers to occupation acting as the therapeutic change agent to remediate impaired abilities or capacities."[33] For example, cooking (mixing and stirring) may be used to improve shoulder ROM and strength for a client who enjoys cooking.

Ultimately the focus of OT intervention is to design intervention that enables clients to assume or resume their ability to engage in their desired life occupations. The needs and interests of clients guide the selection of occupations used as intervention in therapy. These needs are often governed by the roles clients play in their worlds. The clients' needs and interests are tied to the societies in which they live. In a society in which independence, leisure, and work are all valued, the interests of clients are variable and include self-care, hobbies, and work-related tasks. As such, OT practitioners must remember that clients have an inner drive to engage in occupations beyond self-care or self-maintenance, which Tubbs and Drake[34] point out is too often the starting and stopping point of most traditional rehab programs. As OT practitioners working with clients with physical dysfunction, it is important to have a broad focus with regard to the scope of intervention.

Relationships Among Person, Environment, and Occupation as They Relate to Intervention Choices

There are many factors that OT practitioners address as a part of the intervention planning process. Occupational therapists complete a thorough analysis of each client's interests and abilities and the contexts within which they engage in occupations. Intervention choices are based on this analysis and may target aspects of the person, the environment or context, and/or occupations themselves. Intervention decisions should be made in collaboration with the client, family, and other important people in the client's life as appropriate and as feasible.

Aspects of the person that may influence the OT process include the client's values, beliefs, and spirituality.[1] What a client values or believes about his or her health, sense of purpose or meaning, and roles in life, for example, will be important factors for the OT practitioner to understand in terms of how these factors will influence intervention choices. In addition, understanding how a diagnosis or disease process may influence the client's body functions and body structures will affect intervention decisions. For example, in the case study, given Fareed's limitations in ROM of his left upper extremity, it will be important to assess the structure of the shoulder girdle as it relates to joint ROM at the shoulder.

OT practitioners will also assess the client's performance skills within a variety of occupations, depending on the setting in which he or she practices. Occupations within an acute care setting may differ from those within a home health setting, based on the client's goals and his or her health status. The Framework describes performance skills as “goal directed actions that are observable as small units of engagement in daily life occupations”[1] (OTPF-3, p. S7). In the case study, Fareed demonstrates concerns in the area of motor performance skills, such as stabilizing and positioning, reaching and grasping, and moving about his environment. Performance skill deficits may exist in many different areas, including motor and process skills. It is also important in planning intervention to consider what performance skills may be assets for the client in regard to his or her recovery and participation in OT intervention. Performance skills that assist Fareed in his recovery include motor skills in his right upper extremity and social interaction skills.

Aspects of the environment that may influence intervention include the physical and the social environment.[1] In addition to environment, OT practitioners consider contextual factors, such as cultural, personal, temporal, and virtual contexts. Environmental influences to consider for Fareed include the accessibility of his home, given the two stories; his workplace environment; and the many facets of his social support. Examples of contextual factors to consider include Fareed's previous experience with computer use for communication, his age, and any spiritual considerations as a part of his culture.

How various factors come together to support or inhibit a client's participation in desired and meaningful occupations is at the center of OT practice. As such, OT practitioners need to develop a wide range of skills related to understanding and facilitating participation and engagement in a variety of occupations across the lifespan and across multiple contexts. For persons with disabilities, participation may require relearning skills, learning new skills, or learning to perform activities in new ways. Therefore, the OT practitioner must be prepared with a broad knowledge of occupations, activities, and techniques that may be used as intervention strategies in a client-centered approach.

Types of Occupational Therapy Intervention

1. Occupations are described as "client-directed daily life activities that match and support or address identified participation goals"[1] (OTPF-3, p. S29). An occupation focus for Fareed might include a focus on his prior independence with self-care, his bookkeeping work, and his leisure interests, including gardening, cooking, traveling, and woodworking.

2. Activities are described as "actions designed and selected to support the development of performance skills and performance patterns to enhance occupational engagement. Activities often are components of occupations and always hold meaning, relevance, and perceived utility for clients at their level of interest and motivation"[1] (OTPF-3, p. S29).

3. Preparatory tasks are described as "actions selected and provided to the client to target specific client factors or performance skills"[1] (OTPF-3, p. S30). In preparatory tasks the client is an active participant. These tasks may simulate aspects of occupation but on their own do not necessarily hold meaning or relevance to the client.[1]

4. Preparatory methods are described as "modalities, devices, and techniques to prepare the client for occupational performance"[1] (OTPF-3, p. S29). Preparatory methods typically do not require the client's active participation but are done by the therapist to support the client's participation or engagement in the intervention process. Application of hot or cold packs at the beginning of a treatment session is an example of a preparatory method as part of an intervention plan. As an example with Fareed, before beginning the activity, to reduce pain in his LUE and improve his tolerance for movement, the OT practitioner applied heat to his shoulder using hot packs as a preparatory method of intervention.

5. Education is described as "imparting of knowledge and information about occupation, health, well-being, and participation that enables the client to acquire helpful behaviors, habits, and routines that may or may not require application at the time of the intervention session"[1] (OTPF-3, p. S30).

6. Training is described as "facilitation of the acquisition of concrete skills for meeting specific goals in a real-life, applied situation"[1] (OTPF-3, p. S30).

7. Advocacy is described as "efforts directed toward promoting occupational justice and empowering clients to seek and obtain resources to fully participate in daily life occupations"[1] (OTPF-3, p. S30).

Occupational Analysis and Activity Analysis

Participation in everyday occupation is quite complex when one stops to consider all the aspects that must work smoothly together to be successful. Careful analysis is essential to the selection of appropriate intervention strategies. Analysis should yield information about various occupations and activities as potential intervention strategies for addressing physical dysfunction and facilitating health and wellness. As discussed previously, analysis as a part of intervention planning should be done at the person level, the environment level, and finally the occupation level.

Activity analysis and occupational analysis are important for many reasons. Baum and Christiansen[3] state that "people are naturally motivated to explore their world and demonstrate mastery within it." They go on to state that "situations in which people experience success help them feel good about themselves." Analysis of clients' desired occupations will allow practitioners to create intervention sessions that motivate their clients and help clients experience success. Having done the analysis, practitioners can anticipate and address potential barriers at the person level and the environment level to facilitate self-efficacy in their clients. When people perceive themselves as competent and capable, they are more likely to want to continue to participate in the therapy process.[3] A thorough analysis facilitates OT practitioners' abilities to design and implement intervention strategies that help clients engage or reengage in occupations, roles, and routines that are meaningful and valuable to everyday life.

Occupational and activity analyses facilitate the ability to understand the complex nature of the things we do on a daily basis. For example, understanding the interaction of multiple factors is needed for Fareed to return to his prior level of function in self-care or his computer skills to stay in touch with his family. In addition, this type of analysis allows practitioners to consider the potential meaning that occupations have for clients. As such, intervention choices cannot be chosen or designed without careful and thorough analysis, the process of looking at all the components and requirements of an activity/occupation, and synthesis, the process of combining all of those factors to facilitate performance.[14]

Activity Analysis

Activity analysis considers activities and tasks in the abstract, or how these things might be done within a certain culture or a given situation.[1,6] Through activity analysis, OT practitioners can begin to anticipate what may facilitate a client's performance and participation. OT practitioners can anticipate where barriers to performance and participation may exist and, through careful selection of intervention strategies, can increase the likelihood of a "just right challenge" for the client in intervention.[32] The just right challenge occurs when OT practitioners design interventions that challenge the client just enough so that he or she does not become bored or does not see the need for therapy, but the challenge does not result in the client feeling defeated or a loss of self-efficacy. Completing a general analysis of a variety of activities and tasks allows OT practitioners to prepare options and generate ideas/strategies that may or may not work for clients. Additionally, it provides practitioners with a starting point from which they can then individualize assessment, intervention, and discharge plans. Thomas[32] states that activity analysis can help us to:

- Determine what equipment, materials, space, and time are needed for the activity
- Consider how we might prepare for instructing another by having knowledge of the steps involved in the activity
- Think about how the activity might be therapeutic and for what type of client
- Consider grading and or adapting the activity for greater success
- Identify options for clear documentation
- Think about how context might influence performance
- Consider the just right challenge
- Consider where the client may need help or where he or she will most likely do well

Occupational analysis, in contrast to activity analysis, helps OT practitioners understand the specific situation of the client with whom they are working.[6] In occupational analysis the practitioner considers several questions: What the client wants or needs to do, how he or she did things before coming to occupational therapy, what he or she feels has changed, what environments are typical for the occupations, and where the client envisions occupations taking place in the future. Occupational analysis is about how the individual engages in his or her daily life. Once OT practitioners have completed the analysis, the next step in designing appropriate intervention is to determine how to structure the intervention strategies to facilitate improvement and participation. One way to do this is through grading and adapting of intervention strategies.

Grading and Adapting Occupations and Activities

Grading and adapting of occupations, activities, and preparatory tasks is the crossroad where client-centered practice and clinical reasoning meet. The overall goal of **grading** is to find the just right challenge for the client; that is, one that encourages progress without causing the person to become frustrated or lose self-efficacy, but at the same time creates enough challenge so that the client does not become bored, lose interest, or fail to see the value in participating in the OT session. The overall goal of **adapting** a client's participation in an occupation or activity is to increase the individual's performance within that occupation or activity.

Adapting (Compensating)

As stated previously, the overall goal of adapting, or compensating, an intervention strategy is to change the occupation or activity to enable a client to continue to participate in that valued occupation and/or activity. When practitioners adapt an activity or occupation, the intent is to allow for greater participation and independence within the chosen occupation.

The use of adaptation as an intervention strategy requires flexibility on the part of the clinician and the client. Some clients will not want to participate in an occupation if they cannot do so the way they have always participated, "their typical way." For some this means that they may continue to participate in a way that increases their symptoms; for others it may mean that they will give up valued occupations. One concern OT practitioners have is being aware of clients' safety if they choose to continue with previous patterns.

Adaptations to occupations must maintain the intrinsic value and meaning for the client. Many clients will find meaning in new occupations once they see what is possible. In the OTPF-3,[1] adapting is also seen as modifying or compensating.

It may be necessary to adapt activities to suit the special needs of the client or the environment. An occupation may have to be performed in a special way to accommodate the client's abilities; for example, eating using a special orthosis with a utensil holder fitted to the hand (Fig. 29.1). An occupation may have to be adapted to the positioning of the client or to the environment; for instance, by setting up a special reading stand and providing prism glasses to enable a client to read while supine in bed. The problem-solving ability, creativity, and ingenuity of OT practitioners in making adaptations are some of their unique skills.

FIG 29.1 Eating with a special orthosis using a utensil holder fitted to the hand.

Practitioners should remember that for adaptations to be effective, the OT practitioner should collaborate with the client to develop adaptations that will be most applicable to his or her situation. The client must understand the need and purpose of the activity and the adaptations and must be willing to perform the activity with the simple modifications. Complicated adaptations that require frequent adjustment and modification should be avoided.[27,30] In most cases simpler adaptations are more useful for the client compared to complicated adaptations. The complexity of the adaptation must be decided with the client, not for the client.

Grading (Remediating)

The overall goal of grading is to "increase or decrease the activity demands on the person while he or she is performing an activity."[32] Grading participation or engagement in an occupation or activity within your intervention allows for the just right challenge.[32] As such, OT practitioners grade the client's participation incrementally. Grading allows for the development of skills while at the same time assuring the client's success within individual sessions. In other words, grading refers to structuring an activity such that the challenge or demand will gradually facilitate improvement in the client's function and participation. It may be necessary to start by making an intervention strategy easier. There is no one correct way to grade an occupation or activity because multiple factors can be considered in terms of how participation is graded. The clients' goals, current level of function, and the occupational model or frame of reference a therapist uses will help determine how and what aspects of the occupation or activity are graded within intervention choices.

How does a practitioner begin to grade an intervention strategy? First, the practitioner needs to understand the strengths and needs of the client. Second, the practitioner needs to thoroughly understand the multiple demands of the chosen intervention. Finally, there is the need to determine what factors support the client's participation and what factors hinder his or her participation. In the OTPF-3, grading may also be seen as establishing, restoring, or remediating a skill.[1]

Grading Down

When choosing to "grade down," the OT practitioner seeks to make components or aspects of an intervention strategy easier for the client. For an adult experiencing difficulty with clothing fasteners secondary to muscle weakness or incoordination, the strategy may be to use pull-on clothing or clothing items with large fasteners (eg, large buttons), making it easier for the client to hold and manipulate the button through the buttonhole. For a client with muscle weakness due to a long-term hospitalization, the OT practitioner may begin morning ADLs at the bedside, as opposed to the bathroom, to conserve strength and energy. These are both examples of grading to make participation easier for a client the therapy practitioner believes has the potential to work up to a higher level of skill within these occupations.

Grading Up

When choosing to "grade up," the OT practitioner seeks to make components or aspects of an intervention more challenging for the client. A client recovering from a post-traumatic brain injury who demonstrates the ability to make decisions about meal choices in a quiet clinic environment from a set menu with limited choice needs to be able to do so in the community. To grade up, the intervention session moves from the clinic to working on making meal choices in the hospital cafeteria or a local restaurant, where choices are greater and the client must deal with multiple factors. This is a busier and more complex environment, thereby increasing the demands on the client. An additional example might be the case of a client with decreased activity tolerance who heretofore has been dressing at the bedside, with all items arranged for him or her. The OT practitioner now changes the intervention's focus to work on accessing clothing from the closet and carrying clothing items to a chair beside the bed to increase the demands on the client, with the expectation that he or she will be able to improve his or her level of function.

Caution!

When grading an intervention, be sure you don't grade down to the extent that the client is not engaged, challenged, or motivated. Conversely, be sure not to grade up such that the client experiences unnecessary struggles, resulting in frustration, a loss of self-efficacy, or loss of motivation. In addition, select only one or two aspects to grade within the occupation/activity at any one time. Grading or changing too many aspects of any intervention/occupation will make it difficult to know what is working or not working as the practitioner documents the client's progress. The example of the client working on meal choices first in the therapy setting and then in the hospital cafeteria or community may change too many parts of the task at one time. If the client is asked to work on making choices in a quiet, therapy setting while seated, the task demands are limited compared to maneuvering through a hospital cafeteria or restaurant and making choices for a meal. This client might be experiencing difficulties not only with meal choice, but also with mobility, following directions, balance, or sensory integration concerns. It then becomes difficult to determine which factor to grade for improved performance. The practitioner needs to know that he or she is confident the client can handle the other factors that have changed in the context. This is where the connection between activity/occupational analysis and grading and adapting becomes most apparent.

Examples of Grading

Strength

Strength may be graded by an increase or decrease in resistance. Methods to modify the resistance for strengthening can include changing the plane of movement from gravity eliminated to gravity minimized to against gravity; by adding weights to the equipment or to the client, or by using tools of increasing weights. For example, a weight attached to the wrist by a strap increases resistance to arm movements during needlework or leatherwork (Fig. 29.2) to improve muscle strength while engaged in occupation. When grasp strength is inadequate, grasp mitts may be used to fasten the hand to a tool or equipment handle to assist grip strength and allow arm motion.

FIG 29.2 Weight attached to the wrist increases resistance during needlework or crocheting.

Range of Motion

Activities for increasing or maintaining joint ROM may be graded by positioning materials and equipment to demand greater reach or excursion of joints. As the work progresses, the activity itself establishes increased demands on active range. Positioning objects, such as dominos used in a game, at increasing or decreasing distances from the client changes the range needed to reach the materials (Fig. 29.3). Tool handles, such as those used in eating or painting, may be increased in size by padding the handle with foam tubing to accommodate limited ROM or to facilitate grasp for clients the practitioner believes will gain ROM as they progress in therapy (Fig. 29.4). Reducing the amount of padding as range or grasp improves is an example of grading up, changing the participation to require increased range of motion as ROM becomes available to the client. Reaching for clothing items hung in a closet as opposed to items in a bureau drawer can be used to increase a client's shoulder ROM.

FIG 29.3 Placing objects at alternate distances changes the range needed to reach materials.

FIG 29.4 The size of tool handles may be increased by padding the handle with foam tubing.

Endurance and Tolerance

Endurance may be graded by moving from light to heavy work and increasing the duration of the work period. Standing and walking tolerance may be graded by an increase in the time spent standing to work, perhaps at first at a standing table (Fig. 29.5), and an increase in the time and distance spent in activities requiring walking, such as home management and gardening activities. Medical conditions that are progressively degenerative, such as muscular dystrophy, multiple sclerosis, or Parkinson's disease, require grading endurance task demands down to make aspects of participation easier for the client. The practitioner and client may decide to begin by discussing how to adapt participation instead of changing participation to an occupation or activity that requires less effort.

FIG 29.5 Midland Electric Stand-In Table. Four-point support system stabilizes clients at the feet, knees, buttocks, and chest. (Courtesy Performance Health, Warrenville, IL.)

Coordination

Coordination and muscle control may be graded by decreasing the gross resistive movements and increasing the fine controlled movements required. An example for a client with an interest in craftsmanship is progressing from sawing wood with a crosscut saw to using a jeweler's saw. Dexterity and speed of movement may be graded by practicing at increasing speeds once movement patterns have been mastered through coordination training and neuromuscular education. OTs may wish to consider aspects of motor control theory (see Chapter 19) as a way to grade the demands on motor coordination within participation.

Perceptual, Cognitive, and Social Skills

In grading cognitive skills, the practitioner can begin the treatment program with simple one- or two-step activities that require minimal judgment, decision making, or problem solving and progress to activities with several steps that require some judgment or problem-solving processes. A client in a lunch preparation group may butter bread that has already been placed on the work surface. This task could be graded to increase task demands by asking the client to position the bread, butter it, and place a slice of lunch meat on it, and, ultimately, to make several sandwiches.

For grading social interaction, the intervention plan may begin with an activity that demands interaction only with the OT practitioner. The client can progress to activities that require dyadic interaction with another client and, ultimately, to small group activities. The practitioner can facilitate the client's progression from the role of observer to that of participant and then to leader. At the same time, the practitioner decreases his or her supervision, guidance, and assistance to facilitate more independent functioning in the client.

There are a number of factors that influence the decision to adapt or grade intervention strategies to support a client's occupational performance. Knowing the client's desired outcomes and understanding the client's ability to change may determine whether the OT practitioner grades or adapts. If there is a belief that the client's condition can change for the better or the diagnosis is static in nature, the choice may be to grade participation with increasing demands. If it is determined that the client's condition will likely not improve, the decision may be to adapt participation. The OT practitioner, in collaboration with the client, will determine the client's interest in new ways of participating in previous occupations through adaptation. The OT practitioner may choose to adapt if the client's skill level is not likely to change or change in the near future or if the diagnosis is degenerative in nature. The choice to grade or adapt may also depend on the length of time established for the client's OT services. If there are multiple visits, the goal may be to grade participation as improvements occur. If there are limited visits, the decision may be made to adapt for safety or independence within an occupation.

The second half of this chapter will focus on the intervention strategies of preparatory tasks and preparatory methods, more specifically the topics of therapeutic exercise, therapeutic activity, and physical agent modalities. The concepts of analysis, grading, and adapting can be applied to all of these intervention strategies.

Preparatory Tasks and Preparatory Methods

Preparatory tasks and preparatory methods are used by the OT practitioner to prepare the client for occupational performance. **Preparatory tasks** are carefully selected to address or remediate client factors or performance skills that the OT practitioner and the client have identified as barriers to the client's desired occupational performance. Preparatory tasks typically include active client participation and occur in a clinical or simulated setting. Examples of preparatory tasks may include using resistive Thera-Bands to increase strength, performing active stretching to restore ROM, opening and closing various-sized jars to improve hand strength and dexterity, or folding and sorting towels on a linen cart.

Preparatory methods are also used to prepare the client for occupational performance. The main difference between preparatory tasks and preparatory methods is that the client is typically passive during the administration of preparatory methods. An example of a preparatory method is the application of heat to prepare soft tissue for movement or stretch. Other examples of preparatory methods may include the use of physical agent modalities, such as paraffin or ultrasound, to influence soft tissue extensibility and prepare muscles for stretch or movement; the application of a mechanical device, such as a continuous passive motion machine to restore ROM and improve flexibility; and the use of various manual techniques to prepare the client for occupational performance, such as manual edema mobilization or manual lymphatic drainage.

The following sections will further discuss the use of preparatory tasks such as therapeutic exercise and therapeutic activity. Additionally, preparatory methods, which include physical agent modalities, manual interventions, and the application of mechanical devices and orthoses, will be discussed.

Preparatory Tasks: Therapeutic Exercise and Therapeutic Activity

Therapeutic exercise and **therapeutic activity** are preparatory tasks that often complement one another in a single intervention plan. Therapeutic exercises and therapeutic activities are used to remediate sensory and motor dysfunction and augment purposeful activity. It is important to remember that preparatory tasks, such as exercise and simulated activities, are used to prepare the client for occupational engagement and should always be performed in connection with the restoration of the client's desired occupations.

In practice, therapeutic exercise and therapeutic activities are considered to be different therapeutic approaches and are coded and billed differently. Although both are preparatory tasks as defined by the OTPF-3, they take on slightly different meanings clinically. The term therapeutic exercise usually describes interventions that are used to develop strength and endurance, ROM, and flexibility. Therapeutic activity usually describes dynamic activities to improve functional performance. Therapeutic exercises tend to include rote exercises, such as resistive Thera-Band exercises or pinching Theraputty. Therapeutic activities tend to include simulated occupations or components of occupations. For example, pinching clothespins to improve finger strength or manipulating coins to improve dexterity. In both of these examples, the activities performed are possible components of large occupations, such as the instrumental daily activities (IADLs) of laundry and manipulating money while paying for items at a store.

The occupational therapist must have a comprehensive understanding of the principles of kinesiology and exercise physiology in order to develop and apply therapeutic exercise and therapeutic activity. Therapeutic exercise and therapeutic activities are carefully selected to target body movements and/or muscle actions in order to prevent or correct a physical impairment, improve musculoskeletal function, and maintain a state of well-being.[19] A wide variety of exercise options is available, and each should be tailored to meet the goals of the intervention plan and the specific capacities and precautions relative to the client's physical condition.

Purposes

The general purposes of therapeutic exercise and therapeutic activity are:

- To develop or restore normal movement patterns and improve voluntary, automatic movement responses
- To develop or restore strength and endurance in patterns of movement that are acceptable and necessary and do not produce deformity
- To improve, develop, or restore coordination
- To increase muscle power
- To increase muscle endurance
- To remediate ROM deficits
- To increase work tolerance and physical endurance through increased strength
- To prevent or eliminate contractures

Indications for Use

Therapeutic exercises and therapeutic activities can be implemented when the client is experiencing limitations in ROM, decreased strength, decreased coordination, and/or decreased endurance. These deficits may be observed in orthopedic disorders resulting in contractures and arthritis and in lower motor neuron disorders that produce weakness and flaccidity. Examples of the latter are peripheral nerve injuries and diseases, Guillain-Barré syndrome, infectious neuritis, and spinal cord injuries and diseases.

The candidate for therapeutic exercise must be medically able to participate in the exercise regimen, able to understand the directions and purposes, and interested and motivated to perform the exercise. The client must have available motor pathways and the potential for recovery or improvement of strength, ROM, coordination, or movement patterns, as applicable. Some sensory feedback must be available to the client; that is, sensation must be at least partially intact so that the client can perceive motion and the position of the exercised part and sense superficial and deep pain. Muscles and tendons must be intact, stable, and free to move. Joints must be able to move through an effective ROM for those types of exercise that use joint motion. The client should be relatively free of pain during motion and should be able to perform isolated, coordinated movement. The type of exercise selected depends on the client's muscle grade, muscle endurance, joint mobility, diagnosis and physical condition, treatment goals, position of the client, and desirable plane of movement.

Contraindications

Therapeutic exercise and therapeutic activity are contraindicated for clients who are in a fragile medical state. Other contraindications include, but are not limited to, recent joint surgery, recent tendon or nerve repair, inflamed joints, and certain cardiopulmonary diagnoses and surgical interventions. Therapeutic exercise and therapeutic activities may not be useful where joint ROM is severely limited, as in the case of a long-standing, permanent contracture. Careful consideration is required to determine the appropriateness of the use of therapeutic exercise and therapeutic activities with those who have severe spasticity and severe lack of controlled movement. If the motor control in such cases is severely impaired, the therapeutic exercise or therapeutic activity cannot be executed in a controlled fashion, and therefore benefit from engagement in the preparatory task will not be gained.

Exercise Programs

Progression of Exercise Programs

If a client lacks both ROM and strength, it is important that the therapeutic exercise program focus on restoration of the available joint ROM prior to emphasis on progressive strengthening. When therapeutic exercises and therapeutic activities are performed, the most effective strength benefit will be gained if the individual is able to exercise the muscle or muscles through the full range of motion. Therefore, the progression of therapeutic exercises and therapeutic activities begins with resolution of ROM deficits and then progresses to muscle strength and endurance. The emphasis on improving coordinated movement occurs last in this progression because the individual would have to be able to move freely (resolution of ROM deficits) and be able to tolerate movement (muscle strength and endurance) prior to achieving the ability to develop or improve coordinated movement.

Range of Motion and Joint Flexibility

There are three main types of movement the OT practitioner may use to improve or maintain joint ROM and flexibility. The three main types of movement include passive ROM, active-assistive ROM, and active ROM.

Passive range of motion (PROM) occurs when the client does not exert any effort to move independently, but rather an outside force, typically the OT practitioner, moves the client's body segment for him or her. The purpose of PROM is to improve or maintain joint ROM and to prevent joint contracture or capsular adhesion. During PROM no muscle contraction occurs within the body segment being moved, either because the client is unable to generate a muscle contraction independently (muscle grade 0 or 1) or because it is contraindicated for the client to produce muscle force and/or active movement because generation of muscle force could cause damage to intracapsular or extracapsular joint structures (as in the case of tendon repair or rotator cuff repair). Passive range of motion may be performed in several different ways. First, PROM may be performed when the therapist moves the client's body part through the range of motion. The joint proximal to the joint being exercised should be stabilized during the procedure (Fig. 29.6). Next, the client may perform self-initiated PROM. During self-initiated PROM, the client uses the unaffected extremity to move the affected extremity when no active movement of the affected extremity is available or permitted. Our case study client, Fareed, would be able to support his LUE with his RUE and gently perform PROM to his left shoulder. Last, PROM may be performed by an external mechanical force, such as a continuous passive motion (CPM) machine. A CPM machine is an electrically powered mechanical device that is attached to the client's affected extremity and moves the extremity through a preset ROM. A CPM machine is considered to be a preparatory method that is used when a client is unable to generate active muscle force independently or when it is contraindicated for the client to generate internal active muscle force. It is important to note that the use of such a mechanical device requires skillful application and careful monitoring, which are achieved through specialized training.

FIG 29.6 Passive exercise of the wrist with stabilization of the joint proximal to the one being exercised.

Active-assistive range of motion (AAROM) occurs when the client is able and permitted to move the affected extremity under his or her own muscle power but requires the assistance of an outside force to complete the range of motion. The outside force needed to complete the ROM may be provided by the therapist or by the client's unaffected extremity. As Fareed gains control over his LUE, the support provided by his RUE can be reduced. The outside force needed to complete the ROM may also be provided by a mechanical device or external force, such as pulleys.

Active range of motion (AROM) is performed when the client is able to generate enough muscle force to independently move the extremity through the range of motion without the assistance of an outside force. AROM is performed when the client is able to generate muscle force independently and when generating internal muscle force is not contraindicated. AROM can be used to maintain full joint ROM.

Active and Passive Stretch

If the OT practitioner determines that the client has limited joint ROM during the initial evaluation, the practitioner may opt to perform passive stretch or active stretching to restore the joint movement. Passive stretch, like PROM, may be performed in several different ways, including passive stretch performed by the practitioner, passive stretch performed by the client, or passive stretch performed by an external mechanical device. Passive stretch is performed by the practitioner when he or she moves the client's body segment through the available joint ROM and holds the segment at the end of the ROM while applying gentle but firm force or stretch. Passive stretch may also be performed by the client. This is performed when the client uses his or her unaffected extremity to move the affected extremity through the available range of motion and holds the stretch at the end of the ROM. Last, passive stretch may be performed through the use of an outside mechanical device, which may include CPM machines, pulleys, or static or dynamic orthotic devices.

It is important to note that passive stretch is meant to increase ROM and is not needed when full range of motion is available within the joint. It is used only when a loss of joint ROM is evidenced through comparison to the contralateral side and stretching is not contraindicated. Passive stretching requires a good understanding of joint anatomy and muscle function because incorrect stretching may cause damage to the joint and/or surrounding structures. Passive stretching should be carried out cautiously and is often specifically prescribed by the referring medical professional. The therapist should never force movement when pain is present unless ordered by the physician to work through pain. Slow, gentle, and firm stretching held at the end of the range of motion is required to elongate the soft tissue responsible for limiting the joint ROM and to increase the joint angle. The amount of time a stretch should be held at the end of the range of motion is somewhat controversial and largely depends on the velocity, force, and frequency of the stretch. Current evidence suggests that effective stretching can occur when the limb is held in the maximal end range position for as little as 15 seconds or for as long as 2 minutes.[18] It is important to stabilize the body parts around the joint being stretched in order to prevent extraneous or compensatory movements.

As with passive stretching, the OT practitioner may choose to initiate active stretching. The purpose of active stretching is also to increase joint ROM. In active stretching the client uses the force of the agonist muscle to increase the length of the antagonist muscle. This requires good to normal strength of the agonist muscle, relatively good coordination, and motivation of the client. For example, forceful contraction of the triceps could be used to stretch the bicep muscles. Another stretching technique is the proprioceptive neuromuscular facilitation (PNF) technique referred to as contract relax stretching (CR) or contract relax-agonist stretching. To perform this technique, the practitioner passively brings the muscle to the point of stretch, and the client is asked to contract and hold the muscle in an isometric contraction. This procedure is followed by relaxation of the isometric contraction and manual stretch toward the end of the range of motion.[15,16] Research has shown that the contract relax method is an effective technique that can be used to increase joint ROM; however, there is controversial evidence regarding the length of time the stretch and/or the isometric contraction should be held and the intensity of the isometric contraction and stretch performed.[7]

When performing passive or active stretching, the OT practitioner must take care not to overstretch joints. Thorough assessment of the joint mobility and end feel must be performed, with careful comparison to the contralateral side, prior to initiating stretching. A thorough evaluation will inform the OT practitioner of preexisting joint hypermobility or instability. Such conditions easily allow for overstretching with little force, resulting in injury and damage to the surrounding soft tissue.

It is important that the OT practitioner begin to include functional activities and meaningful occupations that use the target movement or movements in order to maintain joint ROM gains achieved through passive and active stretching. Such gains will not last unless the client continues to move through the full available range of motion, which is most effectively accomplished through engagement in meaningful occupations.

Muscle Strengthening

The OT practitioner may opt to use muscle strengthening exercises when the client's muscle strength has decreased due to inactivity or disuse secondary to injury or disease. The OT practitioner may also choose to perform strengthening exercises when joint instability is present. Strengthening the muscles on either side of an unstable joint can improve the stability of that joint. The OT practitioner is particularly concerned with muscle weakness when it prevents or inhibits the client's ability to engage in meaningful occupations. Three primary types of muscle actions may be used to improve muscle strength: isometric contractions, concentric contractions, and eccentric contractions.

During an isometric contraction the muscle fibers generate tension; however, no joint motion occurs, and the muscle length remains the same. The limb is set or held taut as agonist and antagonist muscles are contracted simultaneously such that the joint ROM remains constant. This action may be performed without resistance or against some outside resistance, such as the therapist's hand or a fixed object. Isometric exercises are appropriate to use under a variety of circumstances. First, isometric exercises are useful when AROM, which produces joint movement, is contraindicated, as in the case of tendon rehabilitation or an unhealed fracture. Performing isometric exercise under these circumstances, when prescribed by the referring medical professional, will improve muscle strength while producing controlled stress, which has the potential to facilitate tendon and bone growth and improved function in the early stages of recovery.[9,31] Isometric exercises are also useful when first initiating active movement and strengthening in the early stages of the rehabilitation process, particularly in clients in whom the bone may be fragile due to prolonged immobilization or when extremely gentle exercises are indicated in order to prevent reinjury. Isometric exercises may also be used when it is not possible to apply resistance to the targeted muscle or muscle groups, as in the case of Kegel exercises to strengthen the pelvic floor.

There are many ways to incorporate functional tasks while performing isometric exercises. For example, isometric strengthening of the bicep occurs when an individual is holding a grocery bag draped from the forearm while maintaining elbow flexion. Isometric strengthening of the shoulder can be achieved while an individual maintains shoulder flexion, external rotation, and abduction to perform hair care tasks. Isometric grip strengthening can be achieved while an individual maintains a static grasp on an object during a functional activity such as holding onto a spoon while stirring.

Isometric exercises may be graded as the individual's strength increases. This is done by altering the amount of external resistance needed to maintain the targeted static contraction and/or the amount of time the client is able to maintain the contraction. For example, to facilitate grip strength during cooking tasks, the therapist may opt to begin with using an isometric contraction on a spoon to stir soup and progress to an isometric contraction to maintain grasp on a mixing spoon to stir cookie batter. The amount of force needed to maintain the grasp on the spoon is greater when stirring cookie batter than it is to stir soup. It is important to note that isometric exercises may affect the cardiovascular system, which may be a contraindication for some clients.

Muscle strengthening may also be accomplished through the use of concentric contractions. Exercising muscles using concentric contractions is a very common method of strengthening and can be performed with or without resistance, depending on the client's muscle grade. During concentric contractions the muscle fibers generate force, which shortens the muscle and creates joint movement, provided the force generated by the muscle is strong enough to overcome the resistance provided by the outside force. If the client's strength allows movement through the full ROM against gravity (muscle grade 3/5), the therapist may use AROM to strengthen a particular muscle or muscle group. Depending on the muscle or muscles targeted for strengthening, the OT practitioner may need to position the client correctly in order to challenge the muscle or muscles to move the body segment against the force of gravity. For example, when aiming to strengthen the wrist flexors, the practitioner must position the forearm in supination so that the wrist flexors have to overcome the force of gravity in order to pull the wrist up into flexion. If the client can tolerate resistance during manual muscle testing (muscle grades 3+/5 or 4/5), resistance may be added to the movement against gravity. Outside resistance may be added by using dumbbells or resistive elastic bands. In a more occupation-based approach, resistance may be added by applying wrist weights while the client performs a functional task or meaningful occupation. In order to strengthen the targeted muscle or muscles, the contraction must be forceful enough to overcome the pull of gravity with the additional weight. It is important that the weight be heavy enough to challenge the muscle but not too heavy, such that the individual cannot complete the full movement. Optimal strengthening occurs when resistance is overcome throughout the entire range of motion.

If the client cannot move through the full ROM against gravity (muscle grade below 3/5), the OT practitioner may still opt to use concentric strengthening; however, rather than have the client move against gravity, the practitioner places the targeted muscle or muscles in a gravity-modified position. For example, if the aim is to strengthen the elbow flexors (the bicep muscles), the client could be given a task that would require AROM with the arm supported on the table in front of him or her. In this example, as the client performs elbow flexion and extension, the arm is supported by the table, and therefore the client does not need to overcome the force of gravity in order to complete elbow flexion. When the client is performing exercises in a gravity-modified position, the OT practitioner must monitor for and eliminate friction that may occur between the client's extremity and the table or mat surface he or she is working on. If the friction is significant, it will generate resistance and prohibit movement. Friction may be reduced by using a powder board, placing a cloth under the extremity, or resting the extremity on a skateboard.

In some instances the OT practitioner may opt to have the client perform exercises through the use of eccentric muscle contractions. During an eccentric muscle contraction, the muscle generates force that creates a change in the joint angle; however, during an eccentric contraction the muscle belly is actually elongating, rather than shortening (as happens in a concentric contraction). For example, if a client is lowering a can of soup from a shelf to the countertop and the elbow is extending, the bicep muscle is elongating as it controls the descent of the soup can toward the counter.

Although eccentric contractions are a typical component of normal movement patterns, the use of resistive eccentric exercises is somewhat controversial. There is some evidence that eccentric exercise programs generate superior results in muscle strength compared to concentric strengthening.[29] Additional evidence indicates that eccentric exercise may also be useful in the rehabilitation of tendon pathology and for strength training around arthritic joints.[7,13] Conversely, there are also studies that indicate that more research is needed to conclude that eccentric exercises are superior to concentric exercises in regard to strength training, the management of tendinopathies, and the prevention of injuries.[12,15] It is recommended that the OT practitioner stay abreast of the current evidence in regard to the use of concentric and eccentric resistive strength training to understand the proper application of each technique in order to prevent soft tissue damage and injury to the client.

When a client performs ROM or strengthening exercises, it is important that the OT practitioner watch for compensatory movements or substitution patterns of movement made by the client. For example, if the exercises are targeted to strengthen shoulder flexion, the therapist should watch that the client does not use shoulder elevation and/or protraction to complete the movement. Another example is using shoulder abduction to achieve a hand-to-mouth movement if elbow flexors cannot move through the ROM against gravity (Fig. 29.7). Such substitutions do not strengthen the targeted muscles and can perpetuate muscle imbalance or weakness, which may further inhibit functional performance. Typically, it is the practitioner's aim to prevent or correct compensatory movements; however, when muscle loss is permanent, some substitution patterns may be desirable. For example, the therapist may work on tenodesis as a compensatory measure to develop a functional grasp, which in turn will enable engagement in occupations such as self-feeding.

FIG 29.7 Using shoulder abduction as compensation to achieve hand-to-mouth movement.

It is important for the OT practitioner to remember that performing ROM and strengthening exercises is a preparatory task. Preparatory tasks are intended to prepare the client for occupational performance and should always be performed in connection to the restoration of the client's ability to perform functional tasks and meaningful occupations. Whenever possible, the OT practitioner should incorporate functional tasks and/or meaningful occupations into the treatment plan to improve client motivation, facilitate carryover of the exercises and, ultimately, enhance long-term functional gains.

Implementing Therapeutic Exercises and Therapeutic Activities

The OT practitioner may choose to use therapeutic exercises or therapeutic activities for several reasons. Therapeutic exercise and therapeutic activities may be used to increase muscle strength, increase muscle endurance, provide overall physical conditioning and improve cardiovascular endurance, or to improve coordination and neuromuscular control. Prior to initiating therapeutic exercises or therapeutic activities, the occupational therapist must thoroughly evaluate the client's muscle strength and occupational desires in order to determine the most appropriate therapeutic exercises or therapeutic activities to use.

Improving Muscle Strength

If the aim of the exercise is to increase muscle strength, the client is asked to perform exercises with a relatively high load over few repetitions. In order to correctly strengthen a muscle, the amount of resistance must allow the client to overcome the resistance force and perform exercise through the entire range of motion. The type of exercise must suit the muscle grade and the client's fatigue tolerance level. It is important to note that there are specific techniques used in strength training known as progressive resistive exercises. Progressive resistive exercises are specific protocols that are performed by incrementally increasing or decreasing the amount of resistance applied during the exercise. Progressive resistive exercises have been found to improve muscle strength in individuals with a wide variety of musculoskeletal injuries and disorders.[17]

Muscle strengthening exercises are graded by gradually increasing the amount of resistance as the client's strength improves. For example, if the client enjoys painting, the OT practitioner may opt to apply 3-pound wrist weights while the client participates in painting on a vertical surface using several large brush strokes. As the client's strength progresses and his or her strength improves, the wrist weight may be increased to 5 pounds with the same number of repetitions. When grading muscle strengthening exercises and activities, the occupational therapist gradually increases the amount of weight used but the number of repetitions remains the same.

Improving Muscle Endurance

Muscle endurance is the ability of the muscle to tolerate activity over time, work for prolonged periods, and resist fatigue. If the aim of the exercise is to increase muscle endurance, the exercises are performed in a relatively low-load, high-repetition regimen that is generally performed over an extended period of time.[17] It is important to differentiate muscle strength from muscle endurance because the two are not always correlated with one another.[17] For example, an individual who is able to lift a 25-pound bag of dog food one time to fill his or her dog's dish may not necessarily be able to carry several 5-pound grocery bags into the house, over two or three trips to and from the car, without experiencing extreme fatigue in the muscles of the upper extremities. In order to grade muscle endurance exercises and activities, the OT practitioner will increase the length of time the client performs an exercise or activity and/or the number of repetitions.

Physical Conditioning and Cardiovascular Fitness

Improving general physical endurance and cardiovascular fitness requires the use of large muscle groups in sustained, rhythmic aerobic exercise or activity. Examples are swimming, walking, bicycling, jogging, and some games and sports. This type of activity is often used in cardiac rehabilitation programs in which the parameters of the client's physical capacities and tolerance for exercise should be well defined and medically supervised. To improve cardiovascular fitness, exercise should be done 3 to 5 days per week at 60% to 90% of maximum heart rate or 50% to 85% of maximum oxygen uptake. Between 15 and 60 minutes of exercise or rhythmic activities using large muscle groups is desirable.[5] Grading of exercises and activities used to target overall physical conditioning and cardiovascular fitness involves gradually increasing the aerobic demands of the activity with careful monitoring of the client's response to activity, especially in the acute rehabilitation phases.

General Exercise and Activity Precautions

During therapeutic exercises and activities the OT practitioner must carefully monitor the client's response to the intervention. Excessive repetitions of strengthening exercises may result in muscle fatigue, pain, and temporary reduction of strength. If a muscle is overworked, it becomes fatigued and is unable to contract. Other signs of fatigue include slowed performance, distraction, perspiration, an increase in the rate of respiration, performance of an exercise pattern through a decreased ROM, and inability to complete the prescribed number of repetitions. It is important to realize that various disease states may significantly alter a person's endurance capacity and tolerance for activity. Many clients may not be sensitive to fatigue or may push themselves beyond tolerance in the belief that this approach hastens recovery. Therefore, the occupational therapist must carefully assess the client's muscle power, capacity for performance, and response to the therapeutic exercise or activity.

Neuromuscular Control and Coordination

Coordination is the combined activity of many muscles into smooth patterns and sequences of motion. Coordination is an automatic response monitored primarily through proprioceptive sensory feedback. Kottke[21] defined control as "the conscious activation of an individual muscle or the conscious initiation of a pre-programmed engram." Control involves conscious attention to and guidance of an activity.

A preprogrammed pattern of muscular activity represented in the central nervous system (CNS) has been described as an engram. An engram is formed only if many repetitions of a specific motion or activity occur. With repetition, conscious effort by the client is decreased and the motion becomes more and more automatic. Ultimately the motion can be carried out with little conscious attention. It has been hypothesized that when an engram is excited, the same pattern of movement is produced automatically.

Procedures for the development of neuromuscular control and neuromuscular coordination are briefly outlined in the following paragraphs. The reader is referred to original sources for a full discussion of the neurophysiologic mechanisms underlying these exercises. Neuromuscular education or control training involves teaching the client to control individual muscles or motions through conscious attention. Coordination training is used to develop preprogrammed multimuscular patterns or engrams.[20]

Neuromuscular Control

It may be desirable to teach control of individual muscles when the muscle is so weak that it cannot be used normally. The purpose is to improve muscle strength and muscle coordination to new patterns. To achieve these ends, the person must learn precise control of the muscle, an essential step in the development of optimal coordination for persons with neuromuscular disease.

To participate successfully the client must be able to learn and follow instructions, cooperate, and concentrate on the muscular retraining. Before beginning, the client should be comfortable and securely supported. The exercises should be carried out in a nondistracting environment. The client must be alert, calm, and rested. He or she should have an adequate, pain-free arc of motion of the joint on which the muscle acts, in addition to good proprioception. Visual and tactile sensory feedback may be used to compensate or substitute for limited proprioception, but the coordination achieved will never be as great as when proprioception is intact.[20]

Awareness of the desired motion and the muscles that produce it is first taught to the client using passive motion to stimulate the proprioceptive stretch reflex. This passive movement may be repeated several times. The client's awareness may be enhanced if the therapist also demonstrates the desired movement and if the movement is performed by the analogous unaffected part. The skin over the muscle belly and tendon insertion may be stimulated to enhance the effect of the stretch reflex. Stroking and tapping over the muscle belly may be used to facilitate muscle action.[20]

The occupational therapist should explain the location and function of the muscle, its origin and insertion, line of pull, and action on the joint. The therapist should then demonstrate the motion and instruct the client to think of the pull of the muscle from insertion to origin. The skin over muscle insertion can be stroked in the direction of pull while the client concentrates on the sensation of the motion during the passive movement performed by the therapist.

The exercise sequence begins with instructions to the client to think about the motion while the therapist carries it out passively and strokes the skin over the insertion in the direction of the motion. The client is then instructed to assist by contracting the muscle while the therapist performs passive motion and stimulates the skin as before. Next the client moves the part through ROM with assistance and cutaneous stimulation while the therapist emphasizes contraction of the prime mover only. Finally the client carries out the movement independently, using the prime mover.

The exercise must be initiated against minimal resistance if activity is to be isolated to prime movers. If the muscle is very weak (trace to poor muscle grade), the procedure may be carried out entirely in an active-assisted manner so that the muscle contracts against no resistance and can function without activating synergists. Progression from one step to the next depends on successful performance of the steps without substitutions. Each step is carried out 3 to 5 times per session for each muscle, depending on the client's tolerance.

Coordination Training

The goal of coordination training is to develop the ability to perform multimuscular motor patterns that are faster, more precise, and stronger than those performed when control of individual muscles is used. The development of coordination depends on repetition. Initially in training, the movement must be simple and slow so that the client can be conscious of the activity and its components. Good coordination does not develop until repeated practice results in a well-developed activity pattern that no longer requires conscious effort and attention.

Training should take place in an environment in which the client can concentrate. The exercise is divided into components that the client can perform correctly. Kottke[21] calls this approach desynthesis. The level of effort required should be kept low, by reducing speed and resistance, to prevent the spread of excitation to muscles that are not part of the desired movement pattern. Other theorists offer contrary advice, which emphasizes the integration of movements that customarily occur during activity. The therapist's experience and judgment are important in determining which method to use.

When the motor pattern is divided into units that the client can perform successfully, each unit is trained by practice under voluntary control, as described previously for training of control. The therapist instructs the client in the desired movement and uses sensory stimulation and passive movement. The client must observe and voluntarily modify the motion. Slow practice is imperative to make this monitoring possible. The therapist offers enough assistance to ensure precise movement while allowing the client to concentrate on the sensations produced by the movements. When the client concentrates on movement, fatigue occurs rapidly and the client should be given frequent, short rests. As the client masters the components of the pattern and performs them precisely and independently, the sequence is graded to subtasks or several components that are practiced repetitively. As the subtasks are perfected, they are linked progressively until the movement pattern can be performed.

The protocol can be graded for speed, force, or complexity, but the therapist must be aware that the increased effort put forth by the client may result in incoordinated movement. Therefore, the grading must remain within the client's capacity to perform the precise movement pattern. The motor pattern must be performed correctly to prevent the development of faulty patterns.

If CNS impulses are generated to muscles that should not be involved in the movement pattern, incoordinated motion results. Constant repetition of an incoordinated pattern reinforces the pattern, resulting in a persistent incoordination. Factors that increase incoordination are fear, poor balance, too much resistance, pain, fatigue, strong emotions, prolonged inactivity,[20] and excessively prolonged activity.

Physical Agent Modalities

According to the OTPF-3, **physical agent modalities (PAMs)** are preparatory methods that the OT practitioner may use to prepare the client for occupational engagement.[1] The AOTA recognizes and supports the use of PAMs by OT practitioners as outlined in its position paper on physical agent modalities.[2] If an OT practitioner chooses to implement a PAM in treatment, it must be connected to a preparatory task or occupation. The AOTA's position paper clearly states that "[the] exclusive use of PAMs as a therapeutic intervention without direct application to occupational performance is not considered occupational therapy."[2] Furthermore, the application of PAMs by an OT practitioner is not considered to be an entry-level skill and is only permitted after the practitioner has obtained foundational education and training through continuing education and has demonstrated competence in the use of PAMs.[2] Before an OT practitioner may use PAMs, it is mandatory that he or she comply with the guidelines outlined by the AOTA.

PAMs may be used before or during functional activities to enhance the effects of the OT intervention program in order to facilitate occupational engagement . PAMs are often used by OT practitioners working in orthopedic settings (eg, hand therapy) but may also be used in other settings, such as neurological rehabilitation and wound management. This section introduces the reader to basic techniques and when and why they may be applied. The following sections are divided into the four main areas outlined in the AOTA position paper on PAMs: superficial thermal agents, deep thermal agents, electrotherapeutic agents, and mechanical devices. Because modalities are commonly used by OT practitioners for treatment of hand injuries and diseases, the examples provided are focused on intervention to improve upper extremity function. The use of PAMs is not limited to the treatment of hands, however.

Thermal Agents

Thermal agents may be divided into two overarching categories: superficial thermal agents and deep thermal agents. The AOTA position paper states:

Superficial thermal agents include but are not limited to hydrotherapy/whirlpool, cryotherapy (cold packs, ice), Fluidotherapy, hot packs, paraffin, water, infrared, and other commercially available superficial heating and cooling technologies. Deep thermal agents include but are not limited to therapeutic ultrasound, phonophoresis, short-wave diathermy, and other commercially available technologies.[2]

The following sections will further discuss the various thermal agents, their properties, and their applications within the practice of occupational therapy.

Superficial Thermal Agents

There are two primary ways by which superficial thermal agents may alter the temperature of soft tissue. Superficial thermal agents may change soft tissue temperature through a process known as convection or through a process known as conduction. The process of convection and the process of conduction each have the ability to cool soft tissue, known as cryotherapy, or to heat soft tissue.

Convection

Convection includes superficial thermal modalities such as hydrotherapy and Fluidotherapy. Convection transfers heat or cold to the tissues by fluid motion around a body segment. The practitioner may choose to use convection techniques to cool the soft tissue (heat abstraction) or to heat the soft tissue (heat transmission), depending on the aim of the modality. The most common example of convection for cryotherapy (cold therapy) is cold whirlpool.[10] When a cold whirlpool is used, the client's extremity is submerged in a tub of cold water and turbine jets are used to circulate the cold water around the extremity. The OT practitioner may choose to use a cold whirlpool to decrease inflammation, decrease pain, and/or decrease edema. Cold whirlpools are typically used for cooling distal extremities, such as the wrist or elbow, particularly when the aim is to cool large portions of the extremity evenly.[10] The client's comfort with and tolerance to the cold temperatures will serve to guide the therapeutic use of this modality. Additional uses of cryotherapy will be discussed in the following section.

As previously stated, convection may also be used to heat soft tissue. The most common example of convection for heating soft tissue is Fluidotherapy. Fluidotherapy involves a machine that agitates finely ground cornhusk particles by blowing warm air through them. This modality feels similar to a water whirlpool, but corn particles are used instead of water. The temperature is thermostatically maintained, with the therapeutic range between 102° and 118°F.[29] Fluidotherapy units are available in various sizes to accommodate various body parts,[29] but heating the elbow or hand is the most common use of this heat modality. An additional benefit of Fluidotherapy is its effect on desensitization. The agitator can be adjusted to decrease or increase the flow of the corn particles, thus controlling the amount of stimulation to the skin. Because an extremity can be heated gradually, this technique is effective as a warm-up before exercises, dexterity tasks, functional activities, and work simulation tasks.

Conduction

Conduction includes superficial thermal modalities such as cold packs (cryotherapy), hot packs, and paraffin. Conduction transfers heat or cold from one object to another through direct contact.

Cryotherapy, the use of cold therapy, is often used in the treatment of edema, pain, and inflammation. The cold produces a vasoconstriction, which decreases the amount of blood flow into the injured tissue. Cold decreases muscle spasms by decreasing the amount of firing from the afferent muscle spindles. Cryotherapy is contraindicated for clients with cold intolerance or vascular repairs. The use of cryotherapy may be incorporated into intervention programs provided in the clinical setting; however, it is particularly useful in a home program.

Cold packs can be applied in a number of ways. Many commercial packs exist, which range in size and cost. An alternative to purchasing a cold pack is to use a bag of frozen vegetables or to combine crushed ice and alcohol in a plastic bag to make a reusable slush bag. Ice packs should be covered with a towel to prevent tissue injury. The benefit of commercial packs is that they are easy to use, especially if the client must use them frequently during the day. When clients are working, it is recommended that they keep cold packs at home and at work to increase the ease of use.

Other forms of cryotherapy include ice massage and cooling machines. Ice massage is used when the area to be cooled is small and very specific; for example, inflammation of a tendon specifically at its insertion or origin. The procedure entails using a large piece of ice (eg, water frozen in a paper cup) to massage the area with circular motions until the skin is numb, usually for 4 to 5 minutes. Care must be taken to keep the ice moving to prevent damage to tissues that are most superficial. Cooling devices, which circulate cold water through tubes in a pack, are available through vendors. These devices maintain their cold temperatures for a long time, but they are expensive to rent or purchase. They are effective in reducing edema immediately after surgery or injury, during the inflammatory phase of wound healing.

Contrast baths combine the use of heat and cold. The physical response is alternating vasoconstriction and vasodilation of the blood vessels. For example, the client is asked to submerge the arm, alternating between two tubs of water. One contains cold water (55° to 65°F), and the other contains warm water (100° to 110°F).[4] The purpose is to increase collateral circulation, which effectively reduces pain and edema. As with the use of cold packs, contrast baths are a beneficial addition to a home therapy program. This technique is contraindicated for clients with vascular disorders or injuries.

Alternatively, the OT practitioner may choose to use heat as a therapeutic modality. Hot packs and paraffin provide heat through conduction. Heat may be used to increase circulation and promote healing. The increase in blood flow will also increase elasticity of soft tissue and improve soft tissue extensibility before stretch. This will more easily allow for permanent soft tissue elongation, resulting in improved joint movement and decreased joint stiffness. Heat may also be used to relieve muscle spasms and decrease pain.[29] To obtain maximum benefits from heat, the tissue temperature must be raised to 104° to 113°F.[29] Precautions must be taken with temperatures above this range to prevent tissue destruction.

Contraindications to the use of heat include acute inflammatory conditions of the joints or skin, sensory losses, impaired vascular structures, malignancies, and application to the very young or very old. The use of heat may substantially enhance the effects of orthotic interventions and therapeutic activities that attempt to increase ROM and functional abilities.

Paraffin is another form of heat modality. Paraffin is stored in a tub that maintains a temperature between 113° and 129°F.[29] The client repeatedly dips his or her hand into the tub until a thick, insulating layer of paraffin has been applied to the extremity. The hand is then wrapped in a plastic bag and towel for 15 to 30 minutes.[28] This technique provides an excellent conforming characteristic, so it is ideal for use in hands and digits. Partial hand coverage is possible. The paraffin transfers its heat to the hand, and the bag and towel act as an insulator against dissipation of heat to the air. An additional benefit to the use of paraffin is that it provides moisturization to the skin, which is especially beneficial in scar management or for improving skin elasticity, as in the case of scleroderma.

Care must be taken to protect insensate parts from burns. To prevent excessive vasodilation, paraffin should not be applied when moderate to severe edema is present. It cannot be used if open wounds are present. Paraffin can be used in the clinic or incorporated into a home program. The tubs are small, and the technique is safe and easy to use in the home. It is an excellent adjunct to home programs that include dynamic splinting, exercises, or general ADLs. It may be used in the clinic before therapeutic exercises and functional activities.

Hot packs contain either a silicate gel or a bentonite clay wrapped in a cotton bag and submerged in a Hydrocollator, a water tank that maintains the temperature of the packs at 158° to 167°F.[29] Because tissue damage may occur at these temperatures, the packs are separated from the skin by layers of towels. As with paraffin, precautions should be taken in application of hot packs to insensate tissue that has sustained vascular damage. Hot packs are commonly used for myofascial pain, before soft tissue mobilization, and before any activities aimed at elongating contracted tissue. For a client with a hand injury the packs may be applied to the extrinsic musculature to decrease muscle tone caused by guarding, without also heating the hand. Unless contraindicated, hot packs can be used (with precautions) when open wounds are present.

Deep Thermal Agents

Deep thermal agents use conversion to apply heat deep into the tissues. Conversion occurs when energy is converted from one form to another. For example, in ultrasound therapy, acoustic energy (sound waves) are converted internally to heat. As the sound waves penetrate the tissue, they vibrate the tissue molecules, causing them to rub against one another and create fiction, which in turn generates heat.[24] The energy of sound waves is thus converted to heat energy. The sound waves are applied with a transducer, which glides across the skin in slow, continuous motions. Gel is used to improve the transmission of the sound waves to the tissues. Ultrasound is considered a deep heating agent. Most ultrasound machines are dual frequency units, allowing the therapist to choose between a 1-MHz or a 3-MHz sound head or transducer. The OT practitioner selects the frequency of the sound head based on the depth of the structures targeted for treatment. The 3-MHz transducer is selected when the target tissue is relatively superficial (1 to 3 cm below the skin), and the 1-MHz transducer is selected to heat tissues more than 2 cm below the skin.[31] Because of its ability to heat deeper tissues, ultrasound is excellent for treating problems associated with joint contractures, scarring and its associated adhesions, and muscle spasms. When ultrasound is used, the OT practitioner should apply a stretch to the tissues while they are being heated. The gains made through this type of stretching are best maintained when they are followed by activities, exercises, or the application of an orthosis to maintain the stretch.

Ultrasound may also be used in a nonthermal application. For example, ultrasound has been shown to increase circulation, promote healing, and reduce inflammation.[24] Evidence suggests that nonthermal ultrasound is effective to facilitate wound healing, peripheral nerve healing, and soft tissue repair after injury. Nonthermal ultrasound has also been shown to facilitate tendon and bone healing.[24] One additional use of ultrasound involves using the sound waves to drive antiinflammatory medications into the tissue. This process is called phonophoresis.

There are many useful and effective applications for ultrasound; however, the OT practitioner must have a good understanding of this modality and be well aware of the precautions and contraindications for its use. Ultrasound at frequencies higher than recommended standards or failure to continually move the applicator during treatment can generate too much heat and can destroy tissue. Ultrasound can be used to facilitate bone healing, but if it is used with the wrong parameters, it can vibrate the bone, cause pain, and delay the healing process. When ultrasound is used over bone in children, precautions must be taken to avoid the growth plates in the client's bones. Ultrasound should never be used over an unprotected spinal cord or freshly repaired structures such as tendons and nerves. If ultrasound is being used to facilitate wound healing, the wound should be free from infection because increasing circulation has the potential to spread the infection. Last, because ultrasound can facilitate cell proliferation, it should never be used over a malignancy.

Electrotherapeutic Agents

The AOTA has defined electrotherapeutic agents in this way:

Electrotherapeutic agents use electricity and the electromagnetic spectrum to facilitate tissue healing, improve muscle strength and endurance, decrease edema, modulate pain, decrease the inflammatory process, and modify the healing process. Electrotherapeutic agents include but are not limited to neuro-muscular electrical stimulation (NMES), functional electrical stimulation (FES), transcutaneous electrical nerve stimulation (TENS), high-voltage galvanic stimulation for tissue and wound repair (HVGS), high-voltage pulsed current (HVPC), direct current (DC), [and] iontophoresis …[2]

As with all physical agent modalities, the OT practitioner must use these interventions to improve the client's functional performance and facilitate engagement in occupation. Many techniques are available; those most commonly used are presented here. It is important to note that electrical modalities should never be used with clients with pacemakers or cardiac conditions.

Transcutaneous Electrical Nerve Stimulation

Transcutaneous electrical nerve stimulation (TENS) uses electrical current to decrease pain. Pain is a very complex phenomenon and can cause severe functional impairment. Pain is considered to be acute when it immediately follows trauma. Individuals may also experience chronic pain, which is longstanding. When trauma occurs, an individual responds to the initial pain by guarding the painful body part, often by restricting motion of the body part or assuming a posture that limits use of the painful body part. This guarding may result in muscle spasms and fatigue of the muscle fibers, especially after prolonged guarding. The supply of blood and oxygen to the affected area decreases, and resultant soft tissue and joint dysfunction may occur. These reactions magnify and compound the problems associated with the initial pain response. The therapist's goal after an acute injury is to prevent this cycle. In the case of chronic pain, the goal is to stop the cycle that has been established.

TENS is commonly used to decrease acute pain and to control chronic pain. It should be noted that there is inconclusive evidence regarding the use of TENS for pain control. The lack of such evidence is likely due to the fact that pain is a difficult construct to study because it is a subjective measure and manifests very differently, depending on a wide variety of individual factors.[26] Many individuals respond favorably to TENS and report effective pain relief without the side effects of medications. TENS units are portable, safe to use, and clients can be educated in independent home use.

TENS units provide constant electrical stimulation with a modulated current that is directed to the peripheral nerves through electrode placement. The therapist can control several attributes of the modulation waveform, such as the frequency, amplitude, and pulse width. When TENS is applied at a low-fire setting, it creates an "electroanalgesia" effect.[26] When this occurs, the brain releases endorphins, which in turn reduce the sensation of pain. The effects of high-frequency TENS are based on the gate control theory. This theory describes how the electrical current from the TENS unit, applied to the peripheral nerves, blocks the perception of pain in the brain. Nociceptors (pain receptors) transmit information to the CNS through the A-delta and C fibers. A-delta fibers transmit information about pressure and touch. It is thought that TENS stimulates the A fibers, effectively saturating the gate to pain perception, and the transmission of pain signals via the A-delta and C fibers is blocked at the level of the spinal cord.[23] TENS can be applied for acute or chronic pain. TENS is frequently used postsurgically for orthopedic conditions when it is mandatory that ROM be initiated within 72 hours following surgery, such as in tenolysis and capsulotomy surgeries, or when it is important to maintain tendon gliding through the injured area after fractures. In these cases TENS may be useful in controlling pain so that the client can tolerate immediate, postsurgical movement. TENS can be especially helpful for clients with a low threshold to pain by making exercising easier. TENS may also be useful when working with clients with complex regional pain syndrome.

TENS can be used to decrease pain from an inflammatory condition such as tendonitis or a nerve impingement; however, the client must be educated in tendon and nerve protection and rest, with a proper home program of symptom management, positioning, and ADL and work modification. Without the sensation of pain the client may overdo and stress the tissues; therefore, education regarding activity level is important.

Neuromuscular Electrical Stimulation

Neuromuscular electrical stimulation (NMES) is the use of electrical current to activate muscles. It is applied through an electrode to the motor point of innervated muscles to provide a muscle contraction. The current is interrupted to enable the muscle to relax between contractions, and the durations of the on and off times can be adjusted by the therapist. Adjustments can also be made to control the rate of the increase in current (ramp) and intensity of the contraction.

NMES is used to increase ROM, facilitate muscle contractions, and strengthen muscles.[16] It may be used postsurgically to provide a stronger contraction for improved tendon gliding, for example, after a tenolysis. It also may be used later in the tendon repair protocol, once the tendon has healed sufficiently to tolerate stress. NMES may be used to lengthen a muscle that has become weakened because of disuse. During the reinnervation phase after a nerve injury this technique may be used to help stimulate and strengthen a newly innervated muscle. Care must be taken not to overfatigue the muscle. NMES can be applied during a dexterity or functional activity, which allows the muscle to be retrained in the purpose of its contraction. NMES is particularly beneficial when it is used to facilitate movement during functional activities or meaningful occupations. As with TENS, there are portable NMES units that can be prescribed for home use.

Other techniques that use an electrical current include high-voltage galvanic stimulation (HVGS) and inferential electrical stimulation. These techniques are applied to treat pain and edema.[25] Iontophoresis is yet another electrotherapeutic agent. Iontophoresis uses electrical current to drive ionized medication into the tissue. The medications most often used are antiinflammatory drugs and agents to decrease scar tissue. The technique uses an electrode filled with the medication of choice. The medicine is transferred by applying an electric field that propels the ions into the tissues.

Mechanical Devices

The OT practitioner may also choose to use a mechanical device to increase ROM in order to facilitate functional movement and engagement in occupational performance. The most common device used by OT practitioners is the continuous passive motion (CPM) machine. A CPM machine is a mechanical device that is electrically powered and provides passive movement to the client's extremity. The machine can be programmed to move the extremity through a specific ROM according to the parameters the therapist sets. CPM machines are particularly useful when a joint must be moved immediately after surgery to prevent stiffness and soft tissue scarring or when the client has difficulty performing full ROM independently.

Summary

Engagement in occupation is the primary tool and objective of occupational therapy practice. OT practitioners use occupational analysis, activity analysis, adaptation, grading of activities, therapeutic exercise, and adjunctive modalities in the continuum of intervention, and they may use these methods simultaneously toward these ends. Through this breadth of practice skills, based on the client's personal and social needs, the OT practitioner helps the client apply newly gained strength, ROM, and coordination during the performance of occupation and activity to assume or reassume life roles. Appropriate intervention strategies are individualized and designed to be meaningful to the client while meeting therapeutic goals and objectives designed collaboratively by the client and the practitioner.

Intervention strategies may be adapted to meet the individual needs of the client or the environment. Strategies may be graded for a number of factors, including physical, perceptual, cognitive, and social factors, to keep the client functioning at maximal potential at any point in the intervention program. The uniqueness of occupational therapy lies in its extensive and intentional use of occupation and goal-directed strategies as treatment modalities.

In practice, OT therapists' roles may not be clearly defined because they are subject to variations in expectations that stem from regional differences, healthcare developments, legislation, institutional philosophy, and the roles and responsibilities assigned by the treatment facility. In all instances, OT practitioners must be well trained and well qualified to deliver all aspects of practice. They should not hesitate to refer clients to experts for treatment whenever appropriate.

Review Questions

1. Define modality.
2. Define occupation, activity, preparatory tasks, and preparatory methods.
3. Name two reasons occupation is valuable.
4. Compare and contrast activity analysis and occupational analysis.
5. What term best describes how activities and environments are modified to meet the individualized needs of clients?
6. What is used to create the "just right" challenge in performance?
7. When are adjunctive modalities appropriately used by occupational therapists?
8. For which types of disabilities would therapeutic exercise (as defined in this chapter) be inappropriate?
9. List and define three types of muscle contraction.
10. Identify an activity that can be used to provide resistive exercise, and describe how it could be done.
11. List four general categories of physical agent modalities.
12. What kinds of symptoms are treated with cryotherapy?

Orthotics

Donna Lashgari, Michal Atkins, Jane Baumgarten

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, the student or practitioner will be able to do the following:

1. Identify basic hand anatomy.
2. Describe the difference between single-axis and multi-axis joints, and explain how they relate to orthotic use.
3. Define torque, and describe how an orthosis produces torque.
4. Discuss the relationship of angle of approach to dynamic orthosis use.
5. Describe the three major purposes and goals of orthotics and when they should be employed.

6. Demonstrate an understanding of the principles of making an orthosis pattern.
7. Identify three characteristics of low-temperature thermoplastic material.
8. Discuss two ways in which orthotics may apply force.
9. Demonstrate how to determine the proper length of a forearm-based orthosis.
10. Identify clients who may benefit from dynamic arm supports.
11. Describe general physical principles of dynamic arm supports.
12. Describe three types of dynamic arm supports and how they differ.
13. List the challenges of using dynamic arm supports for ambulatory people and for individuals who use a wheelchair.
14. Describe the occupations that a client with very weak arms can engage in with a mobile arm support (MAS) that they otherwise could not do.
15. Identify the advantages of a freestanding MAS over a wheelchair-mounted MAS.
16. Identify the benefits of robot-assisted therapy.
17. List the client factors that must be considered prior to recommending a MAS for home use.

KEY TERMS

Axis of motion
Dynamic arm supports
Dynamic orthoses
Force
Freestanding dynamic arm supports
Friction
Immobilization orthoses
Mobile arm supports
Mobilization orthoses
Orthosis
Restriction orthoses
Robot-assisted therapy
Serial static orthosis
Static arm supports
Static orthosis
Static progressive orthoses
Suspension arm devices
Tenodesis
Torque
Translational forces

Section 1 Hand Orthotic Fabrication: Principles, Practice, and Decision Making

Donna Lashgari

According to *Mosby's Medical, Nursing, & Allied Health Dictionary*, orthotics is "the design and use of external appliances to support a paralyzed muscle, promote a specific motion, or correct musculoskeletal deformities"; an **orthosis** is "a force system designed to control, correct, or compensate for a bone deformity, deforming forces, or forces absent from the body … [and] often involves the use of special braces"; and a splint is "an orthopedic device for immobilization, restraint, or support of any part of the body."[3] Splints and suspension arm devices (see Section 2 of this chapter) can be considered orthoses. Occupational therapists (OTs) often design and construct orthoses. *Occupational Therapy Practice Framework: Domain & Process*, 3rd edition,[2] supports occupational therapy's role in this intervention, stating that "occupational therapy practitioners… design occupation based intervention plans that facilitate change or growth in the client factors (body functions, body structures…..) and skills (motor, process, and social interaction) needed for successful participation." According to the framework, the practice of orthotics falls into the category of preparatory methods: splints (more recently referred to as *orthotics*) are used "to enhance participation in occupation" as well as assist in recovering the client's ability to engage in desired occupations (pp. S29–S35). [2] Thus splints, or orthoses, can offer support to a weak upper extremity or protection of an injury in order to allow the client to participate more fully in occupations that are meaningful to him or her. An orthotist typically designs and constructs suspension arm devices, and OTs adjust them and train clients to use them. In practice, the term *orthosis* historically was used more frequently to refer to suspension arm devices than splints; however, now the term is used for any custom fabrication of a splint by a therapist. Hand splinting, or orthosis fabrication, is the topic of Section 1 of this chapter, and suspension arm devices are described in Section 2.

Threaded Case Study

Alexei, Part 1

Alexei is a delightful, witty gentleman of 78 years who resides in a retirement complex since the passing of his wife 5 years ago. The complex offers three levels of care: independent apartment living, assisted living, and nursing care. At the time of his injury, Alexei was living in the independent area, had his own self-furnished apartment, took the van transportation provided by the complex once a week for grocery shopping, and took public transportation to his weekly computer class at a nearby senior center. The complex offers extra services for a fee, and Alexei paid for monthly housekeeping. He does his own laundry, cooking, and light cleaning. He has diabetes and takes care of his own testing and insulin injections. His beloved parakeet recently died, and he was shopping for another. He had trained the parakeet to do several tricks, and it was his pride and joy.

It was outside a pet store that he fell and suffered a comminuted distal radius and ulna fracture of his right dominant wrist. After open reduction and internal fixation (ORIF), he was discharged to the nursing care level of his complex for 2 days, then to the assisted living level. Unless he could quickly become independent with managing his activities of daily living (ADLs) and medical needs, in his case diabetic testing and injections, he would lose his apartment and be transferred to the assisted living level permanently. This level would not allow him to keep a pet.

Alexei was 5 weeks post ORIF when he was referred to hand therapy for beginning active range of motion (ROM) and edema reduction. He was wearing a protective removable splint. Because of maximal edema in his hand, he had only 20% total active motion of his fingers and thumb and was assisted with most self-care and ADLs; was eating with his left, nondominant hand; and was dependent on nursing for his diabetic needs. Alexei's goal was to regain enough range of motion and dexterity in his right dominant hand to be independent with all ADLs and medical needs so he could return to his apartment, which would allow him to keep his own furniture, get another bird, and set his own schedule.

Although Alexei's insurance would cover any needed therapy, he was able to attend only once a week because of transportation issues. Because his therapy time would be limited, our focus in OT was to work toward his goals by using dynamic splinting to regain ROM for functional grip and pinch, and to collaborate with the nursing staff at his assisted living residence to help him meet his goal of managing his medical needs. Alexei attended therapy six times over the following 5 weeks. We worked closely by telephone with the nurse in assisted living, who carried out our recommended contrast baths and nightly Isotoner glove application to reduce edema. We fabricated a volar-based dynamic flexion orthosis for metacarpophalangeal (MP) and proximal interphalangeal (PIP) flexion and a dorsal-based finger extension orthosis, which he alternated during the day for approximately 2 to 3 hours. We adjusted his orthoses each visit for greater ROM and proper 90-degree angle of pull on each finger; he was quick to learn his exercise regimen and followed it religiously. By his third visit, Alexei was independent in all self-care and hygiene tasks using built-up utensil handles and a zipper pull. At this time, we were able to discontinue his extension splint and focus on flexion and dexterity.

At this point, Alexei became assertive with his wish to return to his own apartment and was allowed to move back, with his assurance that soon he would once again be independent in all areas. He partnered with the nurse to work toward independence with medical needs—a difficult task because insulin needles are small and smooth. As his ROM and dexterity improved through the use of his dynamic orthoses, he was able to test his sugar levels and walk to the assisted living area to receive insulin as needed. At 14 weeks postop, he was once again independent with his own injections using coban or rubber finger cots for traction on the needle, and he was once again shopping for a parakeet.

Critical Thinking Questions

1. What would have happened to Alexei if therapy had consisted of just the 45-minute ROM and edema reduction sessions once a week, without the addition of the dynamic orthoses for home use?

2. How critical was the team approach of the client, the therapist, and the nurse in achieving this client's ultimate goals?

3. What part did ascertaining the client's main goal during the initial interview play in using limited time and resources to achieve that goal?

4. What would have happened if weekly therapy were conducted without that goal as the primary focus?

A client-centered focus is vital for any type of therapy. The case of Alexei illustrates how the use of dynamic orthoses helped to achieve a good outcome in a difficult case.

The human hand is the brain's most important instrument for exploring and mastering the world. We read with our hands if we suffer loss of vision; we communicate with our hands in the absence of speech or hearing. Our hands give us expression and console us. We first explore our hands and explore with our hands as infants. The wonder of the human hand is the precision with which it functions and the extremes of abuse it tolerates. We can and do take our hands for granted as they complete a multitude of functional tasks such as dressing, cooking, or typing, because they seem to function effortlessly—that is, until we experience some level of impairment or dysfunction.

The hand does not function independently of the whole human organism. It is connected to the brain via a complex system of nerves and is dependent on precise synaptic connections. The hand does not function independently of the upper extremity (UE); stability and control of the shoulder, elbow, and wrist are needed to position the hand in space. Dysfunction anywhere from the brain to the fingertips may impair function of the hand.

Humans achieve mastery and independence over their environment because of the superiority of the human brain and the dexterity of the hand. Tying a knot, opening a necklace clasp, wielding a hammer, and throwing a ball are abilities unique to the human hand. That we can close a necklace with our vision occluded is testament to the sensibility of the hand. That we can wield a hammer to drive a nail is testament to the integrity of the skin and the strength of the muscles that power the hand. That we can speak volumes with a sweep of our hands or a caressing touch is testament to the aesthetics of the hand. It is a remarkable instrument indeed. As Mary Reilly, one of the profession's most recognized leaders, stated in her 1961 Slagle lecture, "Man, through the use of his hands as they are energized by mind and will, can influence the state of his own health."

OTs deal with the human being as a whole, not just as a hand, a toe, or a shoulder. With the human hand, even the smallest impairment may affect function. Loss of placement of the hand may mean an inability to achieve a hand-to-mouth pattern, which makes independent feeding impossible. Pain and fear can and do accompany injury, and when independence or livelihood is threatened by hand dysfunction, the outcomes are often dramatic, affecting that person and the family members who rely on him or her. The hand is perhaps most valued only when it ceases to function and we must give it attention.

An orthosis is one of the most important tools therapists use to minimize or correct impairment and to restore or augment function. Little else so readily calls attention to the hand as an orthosis. An individual may not receive comments on a new ring or a recent manicure, but put an orthosis on the hand and all will take notice. The decision to provide or fabricate an orthosis requires an in-depth understanding of the pathologic condition to be affected and of the many orthotic designs available.

Section 1 of this chapter introduces the anatomic and biomechanical principles necessary to understand the basic concepts and models of orthotic fabrication. This section briefly reviews the anatomy of the hand and the biomechanical principles involved in orthotic design and fabrication, and introduces an orthotic fabrication process involving pattern making, material choices, types of traction, and techniques of fabrication.

Role of the Occupational Therapist

The education an OT receives in analysis of activity and assessment of human occupation and function leads naturally to the use of orthoses as one therapeutic tool in the intervention regimen. OTs most commonly fabricate orthotics for the hand and UE, but they may be called on to design and fabricate orthoses for the lower extremity (LE) and even for the back or spine. The basic principles of orthotic design and fabrication apply, regardless of which body part is being addressed.

Involvement of the OT in all phases of orthotic fabrication is recommended from the initial assessment of need, through the design phase, the fabrication, and the training and follow-up necessary to ensure proper use and fit of the splint. This involvement requires an understanding of the anatomy and biomechanics of the normal, unimpaired hand and of the pathology of the impaired hand. Many excellent texts describe both hand anatomy and biomechanics in extensive detail and should be included in the library of any OT treating the hand. This chapter briefly reviews the anatomy and biomechanics of the hand most pertinent to orthotic fabrication. The list of references at the end of this chapter provide excellent selections for further study.

One reference of note that should be included in every therapist's library is *Clinical Mechanics of the Hand*,[9] 3rd edition, by Paul W. Brand and Anne Hollister. This text is an exceptional source for a straightforward explanation of the mechanics of muscles, joints, and skeletal structures and how they contribute to the remarkable dexterity and strength of the hand. Brand and Hollister discuss clinical approaches and how they affect the natural biomechanics of the hand.[18]

Anatomic Structures of the Hand

Wrist

The hand and wrist are a complex of 27 bones that contribute to the mobility and adaptability of the upper extremity; the 54 bones that make up both hands and wrists account for approximately one fourth of the total bones of the human body. The wrist is a complex that consists of the distal ulna and radius and the eight carpal bones arranged in two rows. The carpal bones form the concave transverse arch and, with the configuration of the distal radius, contribute substantially to the conformability of the hand.[32] The distal ulna does not articulate with any carpal bone, and its contribution to wrist stability is made through the attachments of the ulnar collateral ligament, which places a check on radial deviation (Fig. 30.1).

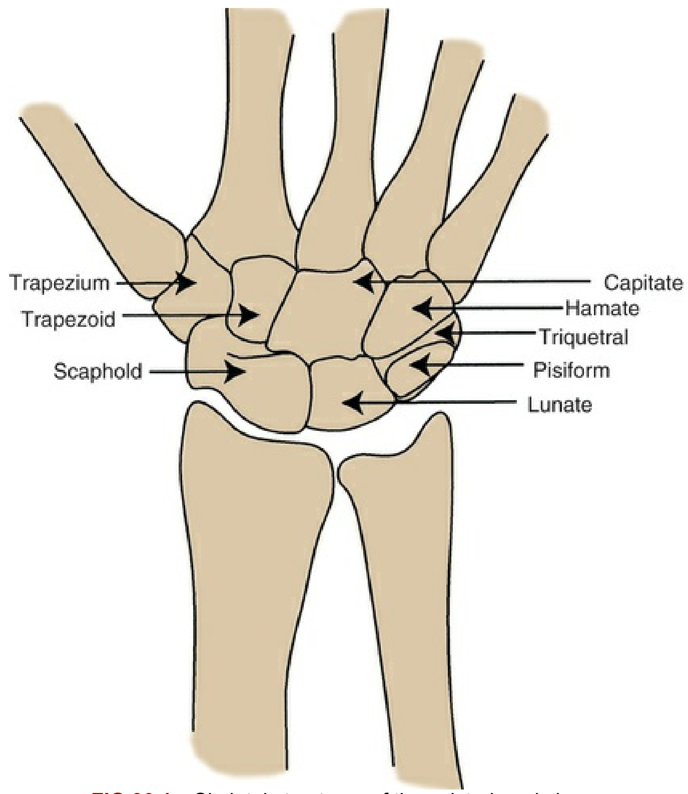

FIG 30.1 Skeletal structures of the wrist, dorsal view.

The wrist complex allows a greater arc of motion than any other joint complex except the ankle. This mobility is the result of a unique skeletal configuration and an involved ligamentous system. All motion at the wrist is component motion that occurs in more than one anatomic plane; no pure or isolated motions occur. This concept is key in any treatment directed at the wrist. Extension occurs with a degree of radial deviation and supination. Wrist flexion includes ulnar deviation and pronation. The wrist is contiguous and continuous with the hand. The distal carpal row (the trapezium, trapezoid, capitate, and hamate) articulates firmly with the metacarpals. Motion is produced across these articulations by muscles that cross the carpals and attach to the metacarpals. The proximal carpal row (the scaphoid, lunate, and triquetrum) articulates distally with the distal carpal row and proximally with the radius and the triangular cartilage. Gliding motions occur between the carpal rows during flexion, extension, and deviation, and the carpal ligaments check excessive motion.

Placement of the hand for functional tasks is reliant on the stability, mobility, and precision of placement permitted by the wrist complex. Any mechanism of injury or disease that alters this complex system, such as rheumatoid arthritis, translates into some level of dysfunction. Even the simplest splint that crosses the wrist alters in some way the functional abilities of the hand.

OT Practice Note

Splint designs that attempt to augment or substitute for wrist motion are likely to limit component motions or are too complex to fabricate or wear.

Wrist Tenodesis

Tenodesis is the reciprocal motion of the wrist and fingers that occurs during active or passive wrist flexion and extension. Tenodesis is the action of wrist extension producing finger flexion and wrist flexion producing finger extension. It is caused by a lack of change in length of the long finger muscles during wrist flexion or extension (Fig. 30.2). The extrinsic finger muscle tendon units have a fixed resting length; because they cross multiple joints before inserting onto the phalanges, they can affect the position of several joints with no contraction or length change required of the muscles. This concept is crucial for understanding how passive positioning of the wrist affects the resting position of the digits. In the nerve-injured hand, tenodesis is often harnessed by orthoses to provide function. The client with spinal cord injury with sparing of a wrist extensor (C6 or C7 functional level) gains considerable function from a tenodesis, or wrist-driven flexor hinge hand orthosis. In a dynamic orthosis, such as a tenodesis orthosis, the effect that tenodesis has on tendon length will dictate in part the wrist position that will optimize forces directed at the digits.

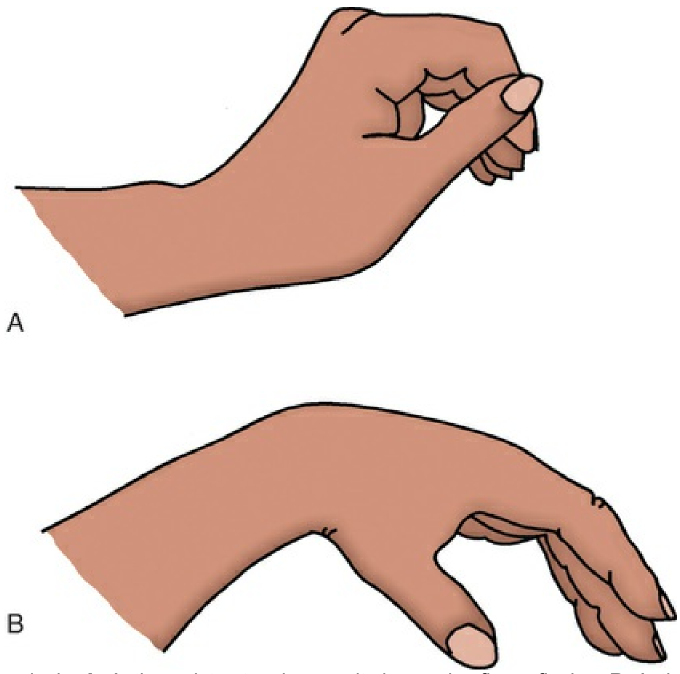

FIG 30.2 Tenodesis. **A,** Active wrist extension results in passive finger flexion. **B,** Active wrist flexion results in passive finger extension.

Metacarpal Joints

The metacarpals articulate with the carpal bones proximally and with the phalanges distally. The first metacarpal, the thumb, articulates with the saddle-shaped trapezium and is considered separately. The second metacarpal fits into the central ridge of the trapezoid, and the third articulates firmly with the facets of the capitate. These articulations form the immobile central segment of the hand around which the other metacarpals rotate. The fourth and fifth metacarpals articulate with the concave distal surface of the hamate. The shorter length of the ulnar two metacarpals and their greater mobility form the flexible arches of the hand; this allows it to conform and fold around objects of various shapes.

The distal transverse arch of the hand lies obliquely across the metacarpal heads. This obliquity is critical to the ability of the hand to adapt its shape to objects. The hand does not form a cylinder as it closes but instead assumes the position of a cone. In making a fist, the ulnar two digits of the hand contact the palm first, and the radial two digits follow. This cascade of the fingers is a direct result of the oblique angle formed at the metacarpal heads (sloping angle, not parallel to the wrist). This concept is most important when determining the distal trim lines for a wrist support when full MP flexion is desired. The orthosis in Fig. 30.3, A, is improperly trimmed distal to the MP creases. Distal trim lines should be established proximal to the MP creases, as in Fig. 30.3, B.

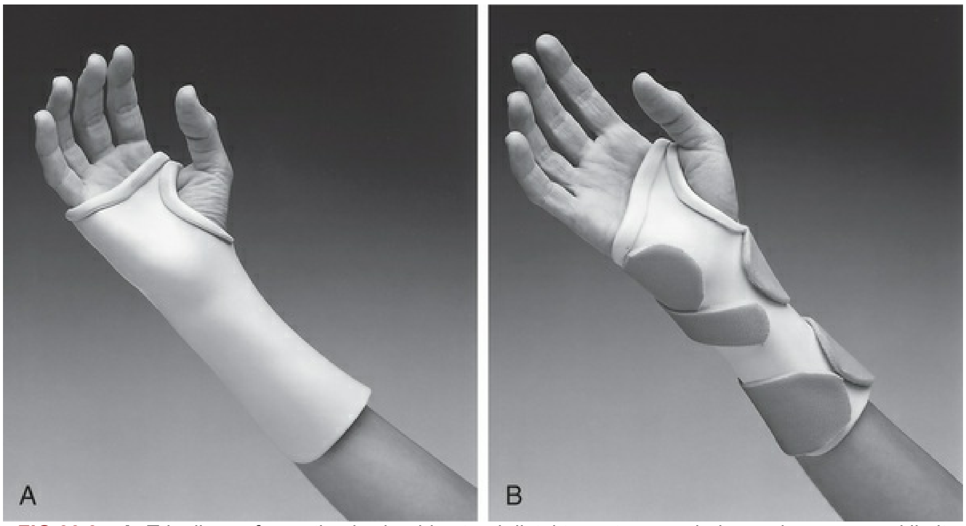

FIG 30.3 **A,** Trim lines of an orthosis should extend distal to metacarpophalangeal creases and limit finger flexion. **B,** The distal trim lines fall proximal to metacarpophalangeal creases (following the oblique angle of the metacarpal heads) and permit full finger flexion.

Metacarpophalangeal Joints

The distal heads of the metacarpals articulate with the proximal phalanges to form the MP joints. Active motion is possible along an axis of flexion and extension and along an axis of abduction and adduction. In addition, a small degree of rotation is present at the MP joints. These axes of motion allow for expansion or spreading of the hand and contribute to the ability of the hand to conform to different shapes and sizes of objects. An attempt to hold a softball without abduction of the fingers shows the importance of this motion. An orthosis with trim lines along the ulnar border of the hand that extend too far distally limits flexion and abduction of the fourth and fifth digits. As a result, the hand will have a limited ability to grasp large objects, and function will be restricted (Fig. 30.4, A). Distal trim lines that fall proximal to the MP creases will allow for full MP flexion (Fig. 30.4, B).

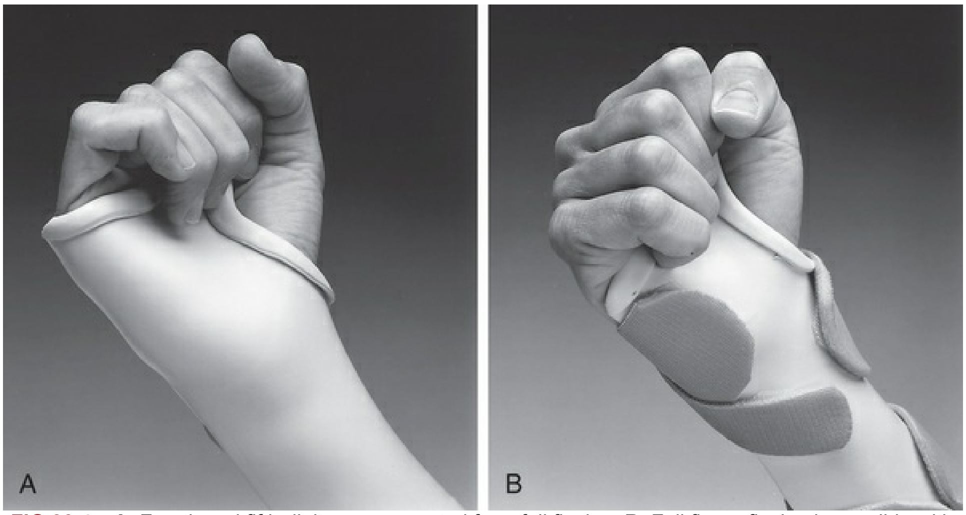

FIG 30.4 **A,** Fourth and fifth digits are prevented from full flexion. **B,** Full finger flexion is possible with proper trim lines.

Thumb

The base of the first metacarpal articulates with the trapezium to form a highly mobile joint that often is compared with the shape of a saddle. The base of the first metacarpal is concave in the anteroposterior plane and convex in the lateral plane. This surface is met by reciprocal surfaces on the trapezium. This configuration allows for a wide arc of motion, with the thumb able to rotate not only for pad-to-pad opposition but also for full extension and abduction to move away from the palm.[32] Both motions are important to function—that is, a thumb posted in permanent opposition may make grasp possible but release of objects impossible. This concept is crucial to an understanding of orthoses that augment the tenodesis action of the hand by posting the thumb in opposition to the index and long fingers. With such orthoses, the therapist must carefully consider the degree of abduction and opposition in which the thumb is posted to maximize both grasp and release.

Interphalangeal Joints

The proximal interphalangeal (PIP) and distal interphalangeal (DIP) joints are true hinge joints, with motion in only one plane. This limitation of motion ensures greater stability in these joints, which contributes to their ability to resist palmar and lateral stresses and so imparts strength and precision to functional tasks.

Forearm Rotation

Close consideration of forearm rotation (i.e., supination and pronation) is necessary because of the importance of these motions to function and to the fitting of splints. Forearm rotation occurs at the elbow and at the distal forearm, with axes of rotation through the center of the radial head and capitulum and along a line extending through the base of the ulnar styloid (Fig. 30.5). During pronation, the ulnar styloid moves laterally as the radial styloid travels medially. During supination, the opposite occurs, with the ulnar styloid moving medially. This movement displaces the styloids, which in turn alters the architecture of the forearm in supination as compared with pronation.

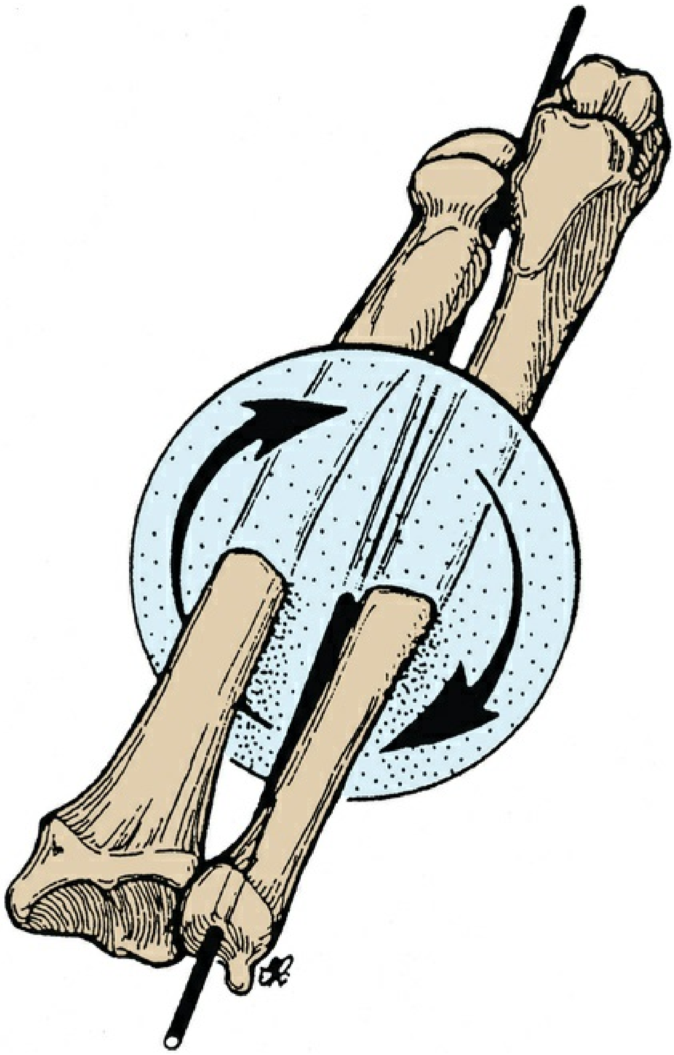

FIG 30.5 The axis of motion for supination and pronation extends the length of the forearm and is centered through the radial head and capitulum and the distal ulnar styloid. (From Hunter JM, Schneider LH, Mackin EJ, et al, editors: *Rehabilitation of the hand: surgery and therapy,* ed 3, St. Louis, 1990, Mosby.)

The way in which this change in dimensions affects orthosis trim lines is shown in Fig. 30.6. Lines drawn at midline along the supinated forearm shift dramatically upon pronation. Orthoses are generally used for function with the forearm in pronation, but they are easier to fabricate with the forearm in supination. Important to note is that if the forearm is not pronated before the orthotic material is set, the trim lines will be high on the radial border and low on the ulnar border.

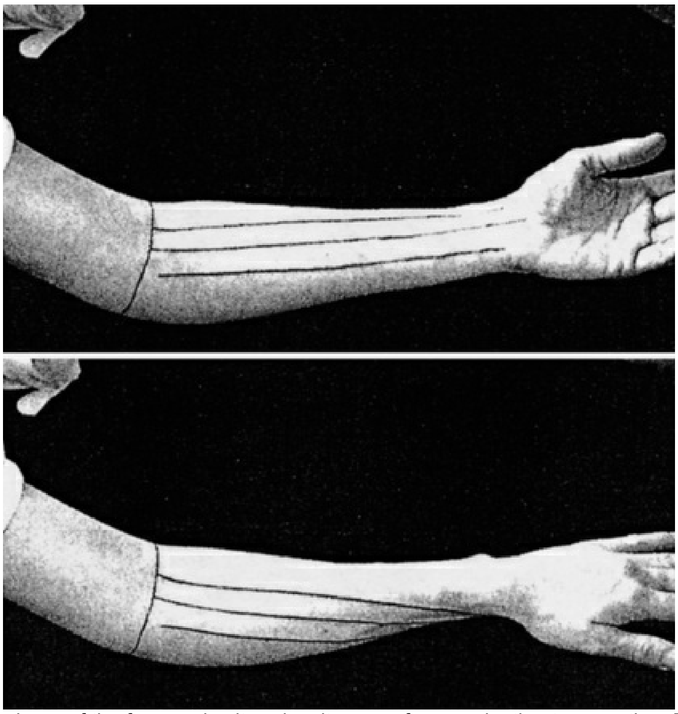

FIG 30.6 The shape of the forearm is altered as it moves from supination to pronation. Forearm-based orthoses must be repositioned to accommodate this if the forearm is rotated during the fabrication process. (From Wilton JC: *Hand splinting, principles of design and fabrication*, Philadelphia, 1997, Saunders.)

One final active demonstration highlights the importance of forearm position for hand function. Place a coin of any size on a tabletop, and while holding the forearm in neutral (thumb straight up), attempt to pick up the coin. It becomes rapidly apparent that the ability to position the hand for function relies in great part on the more proximal joints of the forearm.

Ligaments of the Wrist and Hand

The ligamentous structures of the hand act as checkreins for the hand and wrist; this limits extremes of motion and provides stability. The complex motions of the wrist depend in large part on the ligaments that restrain them, rather than on the contact surfaces between the carpals and metacarpals. Three groups of ligaments are discussed briefly to highlight their contribution to wrist stability and mobility.

The palmar ligaments include the radioscaphocapitate ligament, which contributes support to the scaphoid; the radiolunate ligament, which supports the lunate; and the radioscapholunate ligament, which connects the scapholunate articulation with the palmar surface of the distal radius. The stability and mobility of the thumb and radial carpus depend on the integrity of these ligaments. Disruption of the ligaments results in instability and pain at the wrist and in significant dysfunction of the thumb. Use of orthotics is frequently the treatment of choice to supply stability for pain reduction.

The radial and ulnar collateral ligaments provide dorsal stability. These capsular ligaments, along with the radiocarpal and dorsal carpal ligaments, provide carpal stability and permit ROM. Disruption of any of these ligaments may result in pain, loss of strength, and functional impairment.

The triangular fibrocartilage complex (TFCC) includes the ligaments and the cartilaginous structures that suspend the distal radius from the distal ulna and the proximal carpus. Tears or strains in this complex are evidenced by pain and weakness with resultant loss of function in resistive tasks. The advent of new imaging techniques has made the diagnosis of TFCC tears more common; splinting is often ordered for support and pain relief.

Metacarpophalangeal Joints

Soft tissue structures that surround the MP joints include the joint capsule, the collateral ligaments, and an anterior fibrocartilage or volar plate. The capsule covers the head of the metacarpal and is reinforced by the collateral ligaments. The collateral ligaments are configured to allow side-to-side motion when the MP is in extension and to tighten as the MP is flexed. The volar plate is attached to the base of the proximal phalanx and is loosely attached to the base of the neck of the metacarpal through the joint capsule. This configuration allows the plate to slide proximally during MP flexion. The plate returns to its lengthened state with the MP in extension and acts as a checkrein for volar displacement of the MP joint when it is extended.

When MPs are immobilized in extension, a strong tendency exists for secondary shortening of the lax collateral ligaments, in addition to contraction and adherence of the volar plate, which results in limited MP flexion and loss of functional grasp patterns. The commonly accepted resting position splint, which places the wrist in 25 degrees to 35 degrees of extension, the MP joints at 60 degrees to 70 degrees of flexion, and the PIP and DIP at 10 degrees to 35 degrees of flexion, is designed to prevent shortening and to maintain the joints in midrange for optimal function. An important consideration is to ensure that the mobile fourth and fifth digits are positioned in the orthosis to accommodate their additional degree of mobility by allowing somewhat greater flexion at their MP joints (Fig. 30.7).

FIG 30.7 Oblique angle of transverse arch at metacarpophalangeal joints must be accommodated to ensure maintenance of more mobile fourth and fifth digits.

Proximal Interphalangeal Joints

The PIP joint capsule and ligaments provide stability and allow mobility in one plane only. Collateral ligaments on each side of the joint run in a dorsal-to-palmar direction, inserting into the fibrocartilage plate of the PIP. These ligaments and the plate are lax with the PIP joint in flexion and taut with it in extension. The seemingly simple joint is made more complex by inclusion of the extensor mechanism passing through the capsule dorsally and contributing slips to the system of ligaments affecting this joint. The potential for disruption of the extensor mechanism is high. Many of the most commonly fabricated finger orthoses are used to correct PIP boutonniere (Fig. 30.8, A) and swan-neck (Fig. 30.8, B) deformities.

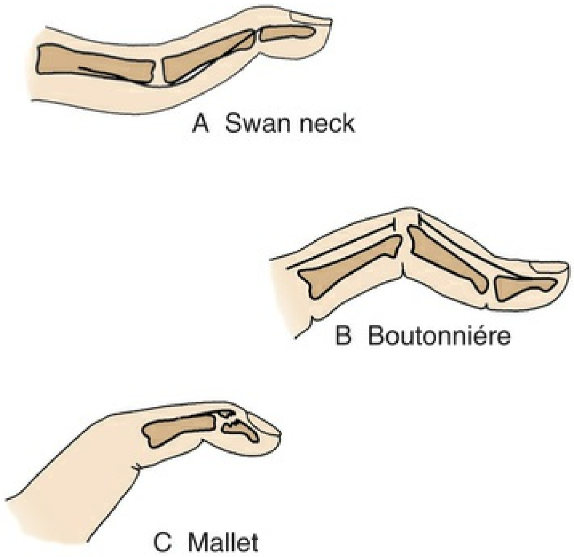

FIG 30.8 **A,** Swan-neck deformity, or joint change, with proximal interphalangeal joint hyperextension and distal interphalangeal joint flexion. **B,** Boutonnière deformity, or joint change, characterized by proximal interphalangeal joint flexion and distal interphalangeal joint hyperextension. **C,** Mallet finger with distal interphalangeal joint flexion and loss of active extension.

Distal Interphalangeal Joints

The DIP joint capsule and ligaments are similar to the PIP joint but have less structural strength to the terminal insertions of the palmar plate and collateral ligaments. As the structures become smaller, they lose integrity and strength. One of the most frequent injuries to the digits is disruption of the terminal end of the extensor tendon, which results in a mallet or "baseball" finger (Fig. 30.8, C).

Muscles and Tendons of the Forearm, Wrist, and Hand

Balance in the hand must be considered when the hand is assessed for an orthosis. Two groups of muscles act on the wrist and hand: (1) the extrinsic muscles that arise from the elbow and the proximal half of the midforearm and (2) the intrinsic muscles with origins and insertions entirely in the hand. The extrinsic muscles include both a flexor and an extensor group acting on the wrist and on the digits. The intrinsics include the lumbricals, the dorsal and palmar interossei, and the thenar and hypothenar groups. Smooth, coordinated motions of the hand in functional activities depend on a well-integrated balance between and within these two muscle groups. Many of the contractures that OTs attempt to correct with orthosis use are caused by neurologic dysfunction (central or peripheral), which results in an imbalance of muscle tone or innervation.

Nerve Supply

A discussion of the nerve supply to the hand should include mention of the continuity of the brachial plexus from its origins in the spinal cord to its terminal innervations in the hand. Injuries or compressions that occur anywhere along this continuum may result in motor or sensory dysfunction. When splinting the UE, the therapist must give attention to the pathways of the nerves that supply the UE and to potential sites for nerve entrapment. In the fabrication of any orthotic device, care must be taken to avoid applying pressure over sites where the nerves are superficial and prone to compression. These sites include the ulnar nerve at the elbow in the cubital tunnel and in Guyon's canal at the ulnar border of the wrist, the radial nerve at the elbow and in the thenar snuffbox, and the digital nerves along the medial and lateral borders of the digits (Fig. 30.9).

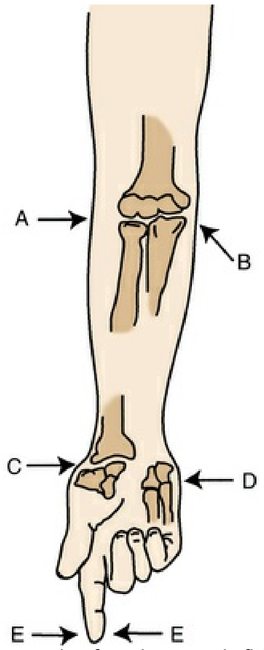

FIG 30.9 Potential sites for nerve compression from improperly fitted orthoses. **A,** Radial nerve. **B,** Ulnar nerve. **C,** Radial digital nerve in anatomical snuffbox. **D,** Ulnar nerve in Guyon's canal. **E,** Digital nerves.

Three peripheral nerves supply motor and sensory function to the hand (Fig. 30.10). The radial nerve is the primary motor supplier to the extensor and supinator muscles. The sensory fibers of the radial nerve supply the dorsum and the radial border of the hand. The median nerve provides motor supply to the flexor-pronator group, which includes most of the long flexors and the muscles of the thenar eminence. The sensory distribution of the median nerve is functionally the most important because it includes the palmar surface of the thumb, index, and long fingers and the radial half of the ring finger. The ulnar nerve supplies most of the intrinsic muscles, the hypothenar muscles, the ulnarmost profundi, and the adductor pollicis brevis. The sensory supply of the ulnar nerve includes the palmar surface of the ulnar half of the ring finger, the little finger, and the ulnar half of the palm.

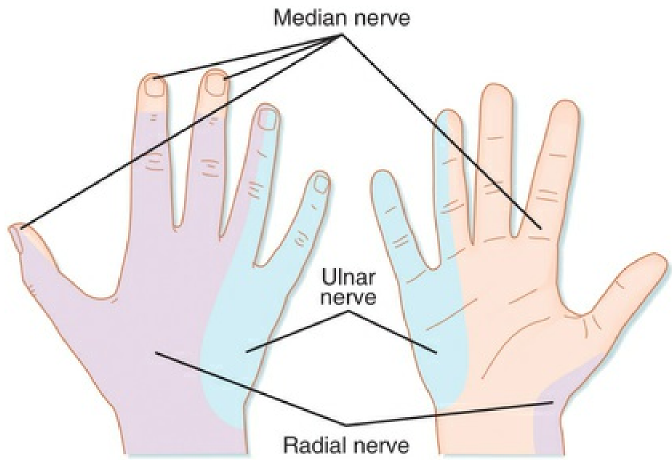

FIG 30.10 Sensory distribution in hand. Median nerve distribution includes most of the prehensile surface of the palm. (From Adams JG: *Emergency medicine: clinical essentials*, ed 2, Philadelphia, Saunders, 2013.)

Nerve dysfunction presents a challenge when fabricating an orthosis. Muscle imbalance leads to dysfunctional posturing of the hand, and muscle atrophy reduces the natural padding of the hand. Abrasions or ulcerations may occur in persons who do not remove their splints, because they do not feel pain caused by shearing forces or pressure areas inside the splint. Finally, skin with marked sensory impairment lacks natural oils and perspiration, leading to dry skin that abrades easily.

These factors must be assessed and considered carefully when orthotics are being fitted on persons with sensory impairment.

Fabrication of orthotics for the neurologically impaired hand is directed at preventing joint and soft tissue contractures and restoring functional positioning. Orthoses cannot restore sensibility, and care must be taken to prevent damage to sensory-impaired skin and to limit further reduction of sensory feedback by covering sensate surfaces (those surfaces that have sensation) and consequently reducing functional use of the hand in ADLs.

Little consensus has been reached on whether or not using orthoses for the neurologically impaired hand is best practice and should or should not be done, and for what long-term goals. Lohman and Coppard have provided an excellent summary of this debate in *Introduction to Splinting: A Clinical Reasoning and Problem-Solving Approach.*[23]

Blood Supply

Blood supply to the hand is contributed by the radial and ulnar arteries. The ulnar artery lies just lateral to the flexor carpi ulnaris tendon, where it divides into a large branch that forms the superficial arterial arch and a small branch that forms the lesser part of the deep palmar arch. The ulnar artery is vulnerable to trauma where it passes between the pisiform and the hamate (Guyon's canal). The radial artery divides at the proximal wrist crease into a small, superficial branch and a larger, deep radial branch. The superficial arterial arch further divides into common digital branches and then into proper digital branches.

Venous drainage of the hand is accomplished by two sets of veins: a superficial and a deep group. Therapists are more likely to be concerned with the superficial venous system because it lies superficially in the dorsum of the hand. Disruption of this superficial system may result in extensive fluid edema in the dorsum of the hand, which requires the therapist's intervention. Care must be taken not to strap orthotics too tightly over the dorsum of the hand; this traps fluids from draining.

Skin

The mobility of the hand is directly related to the type and condition of the skin. Anyone who has put on a ring that is slightly too small, only to be unable to remove it, has experienced the redundancy of the skin on the dorsum of the hand. The skin on the dorsum of the hand is loosely anchored to underlying structures and moves easily to allow flexion and extension of the digits. The ring problem occurs because of a greater degree of elasticity in the dorsal skin when it is pulled distally, as opposed to when it is pulled proximally. This fact should be considered when the use of finger splints is contemplated.

The palmar skin, by contrast, is thicker and relatively inelastic. It is firmly connected to the underlying palmar aponeurosis for stability and protection during prehension activities. Furthermore, the underlying fascia of the palmar skin is thicker and protects the nerve endings while it supplies adequate moisture and oils to the skin surface.

Superficial Anatomy and Landmarks

When fabricating an orthosis, therapists must consider where to apply force without causing further trauma. Despite its deftness and power, the hand's lack of protective fascia means that it tolerates external pressures poorly and shearing stresses not at all. The prominent ulnar styloid, the distal radial styloid, and the thumb carpometacarpal joint are common sites for pressure. A truism that will always hold in orthosis fabrication is that padding adds pressure. The softest padding added to a too-tight orthosis will only add more pressure. Pressure is relieved by the creation of a relief in the orthosis or by application of padding and material molded over the pad to make it an integral part of the orthosis (Fig. 30.11). Added padding to relieve pressure after the orthosis is formed should be avoided.

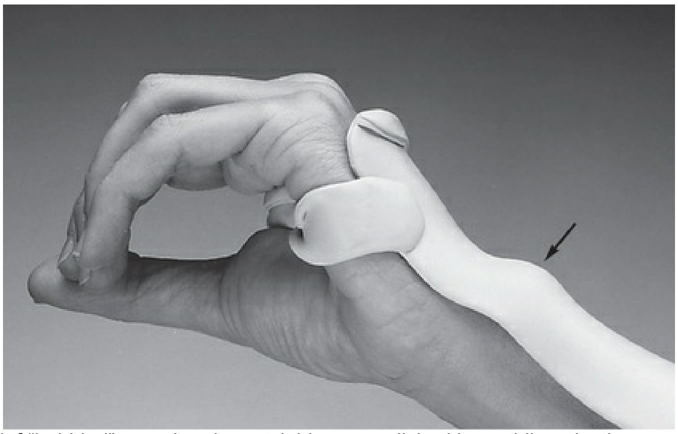

FIG 30.11 Relief "bubbled" over the ulnar styloid, accomplished by molding plastic over a pad placed on the styloid.

Prehension and Grasp Patterns

The ability of the human hand to assume myriad functional positions and to apply only the precise amount of pressure necessary to hold an object is a result of the mobility and stability supplied by the skeleton, the power of the muscles, and the remarkable degree of sensory feedback received from the nerves. This sensory feedback is used to assess the size, shape, texture, and weight of an object. The brain then determines which type of prehension to use to complete a functional task while using this object. The feedback used in grasping and lifting an object is dependent both on the brain interpreting correctly what is seen and on the hand responding appropriately. Once an object is in the hand, further adaptation in prehension will occur if the initial visual assessment was faulty.

Orthotics can maximize functional prehension. In achieving this goal, the therapist must be aware of what an orthosis can and cannot do: an orthosis can stabilize an unstable part, position a thumb in opposition, and even assist or substitute for lost motion. An orthotic with added dynamic components can even gradually revise tissue along its lines of pull by applying slow gentle stretch to gain increased functional range of motion. However, the therapist must be aware that an orthosis may negatively limit mobility at uninvolved joints, reduce sensory feedback, add bulk to the hand, and transfer stresses to the free joints proximal or distal to the part being addressed.

The prehension patterns the hand is able to achieve are as exhaustive as the objects that are available to grasp or pinch. Several authors have contributed to classifications of normal prehension, and the presentation by Flatt[14] is recommended for further study of the subject. It is possible to reduce the many patterns to two basic classifications—prehension and grasp—from which other patterns may be derived. *Prehension* is defined as "a position of the hand that allows finger and thumb contact and facilitates manipulation of objects." *Grasp* is defined as "a position of the hand that facilitates contact of an object against the palm and the palmar surface of partially flexed digits."

The thumb is involved in all but one type of grip, that of hook grasp. Carpometacarpal and MP rotation is crucial to prehension and cannot be overstressed in terms of its importance in splinting to achieve function. This rotation allows for full contact of the thumb in pad-to-pad prehension; this motion is used in a normally active person hundreds of times daily in performance of all areas of occupation, including ADLs, instrumental activities of daily living (IADLs), work, leisure, and social participation.

Lateral Prehension

In lateral prehension, the pad of the thumb is positioned to contact the radial side of the middle or distal phalanx of the index finger (Fig. 30.12, A). Most commonly, this pattern of prehension is used in holding a pen or eating utensil and in holding and turning a key. The short or long opponens splint is used to stabilize the thumb to achieve this prehension pattern.

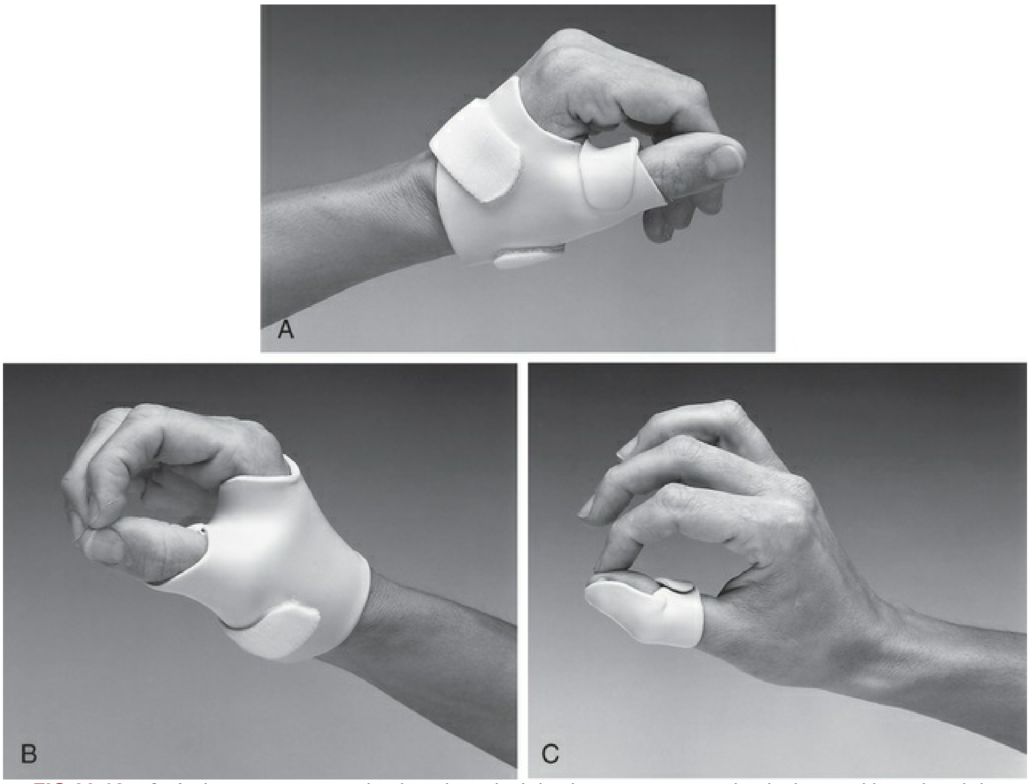

FIG 30.12 **A,** A short opponens orthosis or key pinch in short opponens orthosis that positions thumb in lateral opposition to index finger. **B,** Palmar prehension or three-jaw chuck pinch in short opponens that positions thumb in opposition to index and long fingers. **C,** Tip prehension with thumb and index finger in interphalangeal blocker that secures interphalangeal joint in slight flexion to assist tip prehension.

Palmar Prehension

Palmar prehension is also called *three-jaw chuck pinch.* The thumb is positioned in opposition to the index and long fingers (Fig. 30.12, B). The important component of motion in this pattern is thumb rotation, which allows for pad-to-pad opposition. This prehension pattern is used to lift objects from a flat surface, to hold small objects, and to tie a shoe or bow. The short and long opponens splints may be fabricated to position the thumb in palmar prehension.

Tip Prehension

In tip prehension, the interphalangeal (IP) joint of the thumb and the DIP and PIP joints of the finger are flexed to facilitate tip-to-tip prehension (Fig. 30.12, C). These motions are necessary for picking up a pin or a coin. It is difficult to substitute for tip prehension because it is rarely a static holding posture. Once a pin is in the hand, tip prehension will convert to palmar prehension to provide more skin surface area to retain a small object. A thumb IP hyperextension block is useful in limiting IP hyperextension and in facilitating the IP flexion required for tip prehension. In the case of Alexei, maximal edema and stiffness prevented him from achieving the tip or palmar prehension needed for his diabetes management, which included manipulation of small objects.

Cylindrical Grasp

Cylindrical grasp, the most common static grasp pattern, is used to stabilize objects against the palm and the fingers, with the thumb acting as an opposing force (Fig. 30.13, A). This pattern is assumed for grasping a hammer, a pot handle, a drinking glass, or the handhold on a walker or crutch. Static orthoses offer little to restore this grasp directly, although positioning the wrist in extension offers greater stability to the hand as it assumes this grasp pattern. However, a dynamic outrigger component can be added to a volar orthosis to gently gain increased MP and PIP flexion to enhance cylindrical grasping ability, as was found to be successful for Alexei. A dorsal wrist stabilizer alone offers stability while minimizing palm coverage.

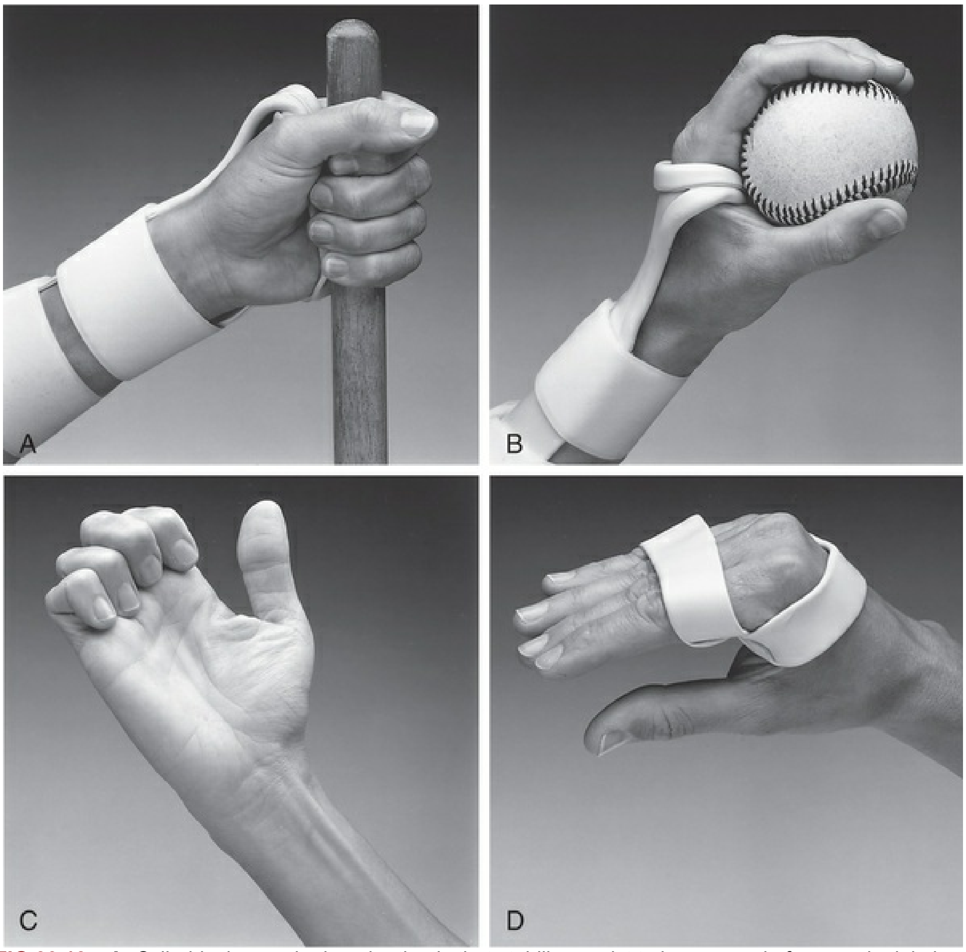

FIG 30.13 **A,** Cylindrical grasp in dorsal orthosis that stabilizes wrist to increase grip force and minimizes palm covering. **B,** Spherical grasp in dorsal orthosis. Orthosis stabilizes wrist to increase grip force and to permit metacarpal mobility required for spherical grasp. **C,** Hook grasp does not involve thumb. Grasp pattern is seen in median and ulnar neuropathy. Orthotics use is aimed at correcting rather than augmenting grasp. **D,** Figure-eight splint substitutes for loss of intrinsic function with median and ulnar neuropathy.

Spherical Grasp

Also called *ball grasp,* this pattern is assumed for holding a round object, such as a ball or an apple. It differs from cylindrical grasp primarily in positioning of the fourth and fifth digits. In cylindrical grasp, the two ulnar metacarpals are held in greater flexion. In spherical grasp, the two ulnar digits are supported in greater extension to allow a more open hand posture (Fig. 30.13, B). In orthosis fabrication, to facilitate or support this pattern of grasp, the wrist-stabilizing orthosis must be trimmed proximal to the distal palmar crease and contoured to allow for obliquity at the fourth and fifth metacarpal heads.

Hook Grasp

Hook grasp is the only prehension pattern that does not include the thumb to supply opposition. The MPs are held in extension, and the DIP and PIP joints are held in flexion (Fig. 30.13, C). This is the attitude the hand assumes when holding the handle of a shopping bag, a pail, or a briefcase. In the nerve-injured hand, splinting is directed more commonly at correcting this posture by flexing the MPs than at facilitating it.

Intrinsic Plus Grasp

Intrinsic plus grasp is characterized by positioning of all MPs of the fingers in flexion, the DIP and PIP joints in full extension, and the thumb in opposition to the third and fourth fingers (Fig. 30.13, D). This pattern is used to grasp and hold large, flat objects such as books or plates. Intrinsic plus grasp is often lost in the presence of median or ulnar nerve dysfunction, and a figure-eight or dynamic MP flexion orthosis is used for substitution.

Mechanics of the Hand and Principles of Orthotic Fabrication

McCollough and Sarrafian stated that the three basic motor functions of the upper limb are “prehension and release, transfer of objects in space, and manipulation of objects within the grasp.”[27] These functions depend on the structural integrity of the skeleton, the muscles that provide power, and the feedback to which the brain responds when enabling the limb to meet functional demands. The task of restoring any one of these basic functions through the application of an orthosis is complex and relies on an understanding of the biomechanics of the hand and the mechanics involved in orthotic design. It is beyond the scope of this chapter to present this topic in depth. However, here is an introduction to those tenets of clinical mechanics deemed necessary for the beginning orthotic fabricator.

Mechanics deals with the application of force, and biomechanics may be viewed as the body's response to those forces. In the hand, muscles supply the force required to produce motion. The force then is transmitted by the tendons to the bones and joints, with control supplied by the skin and pulp of the fingers and palm.[14] How the application of an orthotic affects the transmission of force to produce motion depends on the relationship between the axis of rotation of joints and anatomic planes and the forces imposed on the hand.

Axis of Motion

Hollister and Giurintano[18] define **axis of motion** as “a stable line that does not move when the bones of a joint move in relation to each other” (Fig. 30.14). This stable line is illustrated by Fig. 30.14, B, which shows a tire perfectly balanced around its axis of motion. When a tire is perfectly balanced, it does not wobble; it has pure motion around a single point.

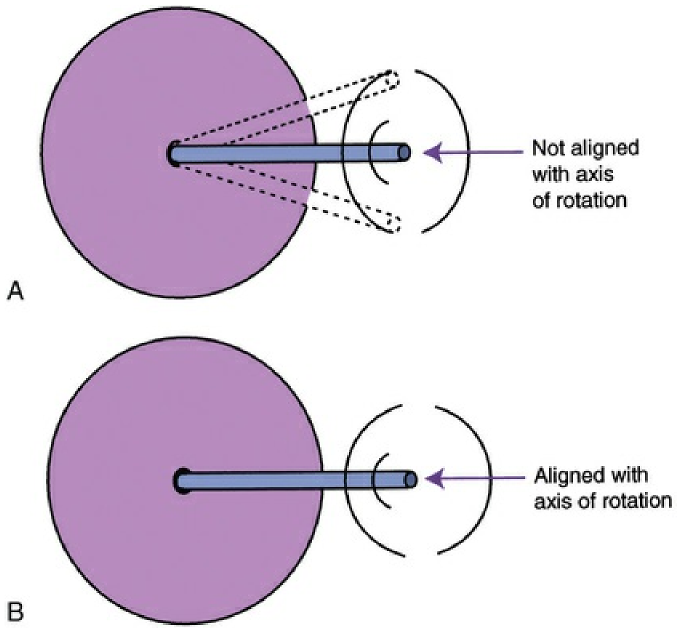

FIG 30.14 **A,** If a tire is not balanced around its axis, it wobbles. If an orthotic hinge is not aligned with the joint axis, wobble is seen as binding of the joint. **B,** Proper alignment of a tire or of a hinge with an anatomical joint results in smooth, unimpeded motion.

In a single-axis joint, motion occurs in only one plane. The PIP joint is an example of a single-axis joint in alignment with an anatomic plane. It moves only in the plane of flexion and extension.

Joints that have more than one axis of motion may move in more than one plane at a time. For example, the wrist complex has two axes of motion: flexion-extension and radial-ulnar deviation. A joint with multiple axes has conjoint motions that occur in addition to the primary motions described by the joint. Wrist flexion occurs with a moment of ulnar deviation and with a small degree of pronation. Wrist extension occurs with radial deviation and slight supination. These conjunct motions are what make circumduction of the wrist possible. They are also what make splinting the wrist with hinged joints a challenge.

An orthotic with a movable hinge or coil has a single axis. When used to splint a single-axis joint such as a PIP joint, a hinge can and should be properly aligned to avoid binding that will limit motion. If a single-axis hinge or coil is used to reproduce motion in a multiaxis joint, some binding or friction will always occur, no matter how well aligned, because the hinge or coil does not allow for, or reproduce, the conjunct motions available in the unsplinted joint.

Force

It is crucial to understand basic principles of **force** and apply them correctly in the fabrication of orthotics. An understanding of the forces applied by levers and the stresses that occur between opposing surfaces can help to explain what happens as forces are applied within the body by muscles and externally by splints.

Definitions

The term *force,* as it relates to splinting, describes the effects that materials and dynamic components have on bone and tissue. *Force* is a measure of stress, friction, or torque. *Stress* is resistance to any force that strains or deforms tissue. Shear stress occurs when force is applied to tissues at an angle or in opposing directions. Pinching skin between the surface of a splint and the underlying bony structures causes shear stress.

Friction occurs when one surface impedes or prevents gliding of a surface on another. Friction is produced in the stiff or contracted joint when soft tissue restriction prevents gliding of the bones. Orthotics may contribute to friction if they are misaligned in relation to a joint axis. For example, a hinged orthosis that is not properly aligned with the axis of rotation will limit motion by producing friction as the joint attempts to move.

Torque is a measure of the force that results in rotation of a lever around an axis. The torque created when a lever rotates depends on the force used and the length of the lever employed. In the body, muscles are the levers that create torque when they act to move a joint. Externally, orthoses may act as levers to apply the force necessary to move a bone around its axis. The measure of torque is given by the following formula:

$$\text{Torque} = (\text{amount of})\ \text{Force} \times (\text{length of})\ \text{Lever arm}$$

Internally, the length of the lever arm is measured as the perpendicular distance from the axis of the joint to the tendon. Externally, the length of the lever arm is measured as the estimated distance from the joint axis to the attachment of force. In orthotics, the attachment point of the force is usually a soft or molded cuff. If the orthosis includes an outrigger with a finger cuff, as shown in Fig. 30.15, the lever arm is the distance from the axis of the joint to the finger cuff, as indicated in line M.

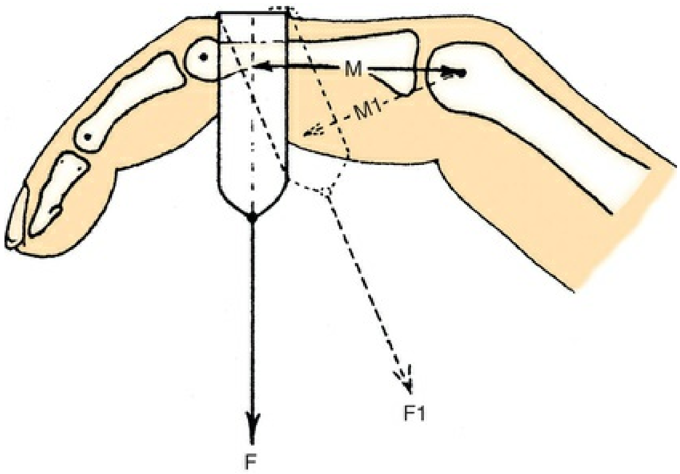

FIG 30.15 Tension F on the phalanx has a moment arm of M acting on the joint. Tension F1 has a smaller moment arm, M1 (with less resulting torque), when the angle of approach is not 90 degrees. (Adapted from Brand PW, Hollister A: *Clinical mechanics of the hand,* ed 3, St. Louis, 1999, Mosby.)

Fig. 30.15 demonstrates that the angle of approach of the force to the finger also affects the length of the lever arm and ultimately the torque applied. The angle of approach is the angle that the line of traction makes as it meets the part being splinted. When the approach is at a right angle (90 degrees) to the long axis of the phalanx, the lever arm is M. When the cuff is at less than 90 degrees to the long axis of the phalanx, the lever arm is shortened to M1. This shorter lever arm produces less torque and therefore less rotation unless greater force is applied.

Given an equal amount of resistance or load, a 2-foot lever will require half as much force to create motion around an axis as will a 1-foot lever. The important principle in orthotic fabrication is that as the distance between the attachment of the cuff or strap and the joint axis increases, less force is required to achieve motion.

Translational Forces

In addition to the angle of approach affecting the length of the lever arm, an approach of less than or greater than 90 degrees results in **translational forces**. The outrigger splint in Fig. 30.16, A, shows a 90-degree angle of approach between the nylon line and the phalanx, demonstrating the correct angle of pull.

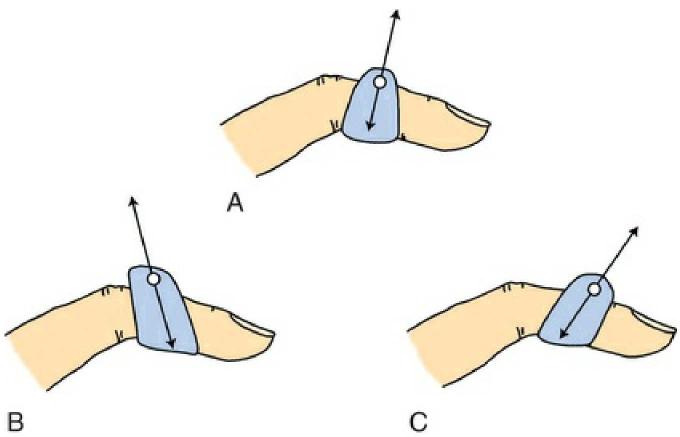

FIG 30.16 **A,** Angle of approach is 90 degrees to middle phalanx, ensuring that force pulling the proximal interphalangeal joint into extension is not causing distraction or compression. **B,** Angle of approach less than 90 degrees to middle phalanx causes joint compression. **C,** Angle of approach greater than 90 degrees distracts joint.

When force is applied at any angle other than 90 degrees, translational forces are created. This alteration of the angle of approach translates some of the rotational force away from producing joint extension and directs the force into joint compression or joint distraction (Fig. 30.16, B and C). The greater the deviation from 90 degrees, the greater is the translational force. Depending on the type of orthosis and the condition of the joint, joint compression or distraction may lead to mere discomfort or to actual joint damage. Translational force is also undesirable because it undermines the effectiveness of the orthosis by shortening the lever arm.[9]

The challenge in splinting with an outrigger is to position the splint so that a 90-degree angle of approach exists. In the outrigger in Fig. 30.17, as long as the finger does not move, the 90-degree angle will remain. As soon as the finger moves, however, the 90-degree angle changes. Because few outriggers allow for this automatic readjustment in position, the outrigger must be adjusted as the contracture lessens to maintain the 90-degree angle of approach.

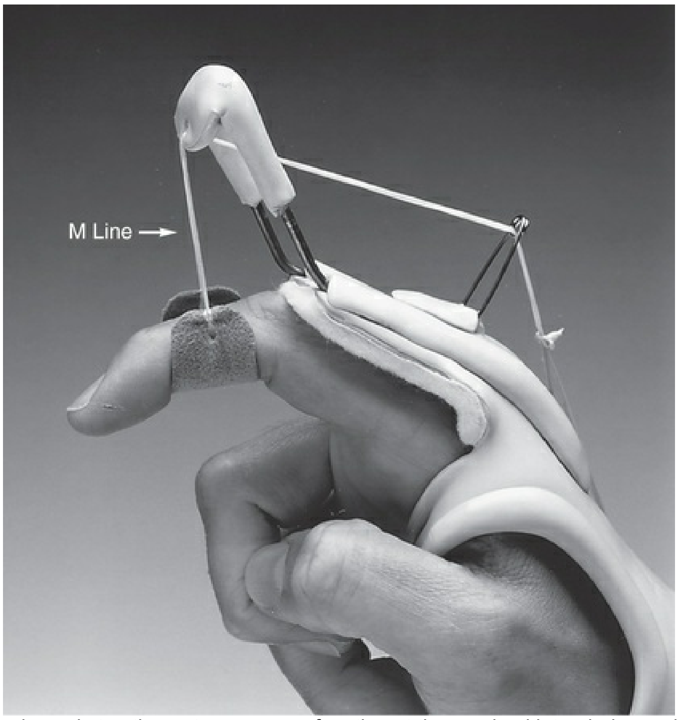

FIG 30.17 As dynamic traction acts on range of motion at the proximal interphalangeal joint, orthosis must be adjusted to maintain 90-degree angle of approach.

Alexei required weekly adjustments of his flexion outrigger to maintain the 90-degree angle of approach as his MP and PIP flexion increased. As his finger flexibility and functional hand motion improved, he was able to lessen time spent in the splint.

Orthosis Classifications

Orthoses may be described in various ways. Terminology varies, and it is useful to understand some of the ways that orthoses may be described. For purposes of clarity, orthoses classifications are described here according to type, purpose, and design.

Historically, one reference to be considered when classification is discussed is the Splint Classification System (SCS),[1] as published by the American Society of Hand Therapists (ASHT). An excellent summary of the Splint Classification System can be found in Jacobs and Austin's *Splinting the Hand and Upper Extremity, Principles and Process* (Chapter 1).[19]

However, the 2012 position statement of ASHT 2 describes the correct use of the term *splint* as a cast or strap and the use of the terms *orthosis, orthoses, orthotic,* and *orthotics* to describe custom-molded, custom-fitted, and prefabricated orthoses fabricated by therapists. The terms *splint* and *orthosis* can no longer be used interchangeably.

Orthoses Classified by Type

Dynamic orthoses include one or more resilient components (elastics, rubber bands, or springs) that produce motion. The force applied from the resilient component is constant even when tissues have reached end range. Dynamic orthoses are designed to increase passive motion, to augment active motion by assisting a joint through its range, or to substitute for lost motion. Dynamic splints generally include a static base on which movable, resilient components can be attached (Fig. 30.18). A common use of dynamic orthotics is to gain greater finger range of motion by adding dynamic MP extension or MP flexion components. Fig. 30.18 shows the type of dynamic orthotic fabricated for Alexei to gain finger extension. Fig. 30.19 shows the type of dynamic orthotic fabricated for Alexei to gain finger flexion.

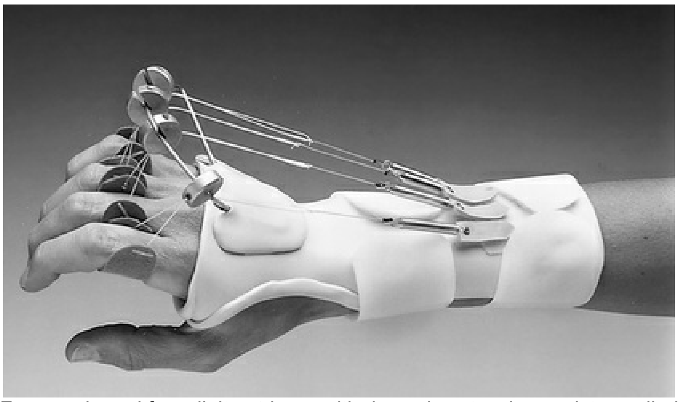

FIG 30.18 Forearm-based four-digit outrigger with dynamic extension assist supplied by springs.

FIG 30.19 Dynamic outrigger for finger flexion. (From Sahrmann S: *Movement system impairment syndromes of the extremities, cervical and thoracic spines,* St. Louis, 2011, Mosby. Used with permission from Ann Kammien, PT CHT, St. Louis, MO.)

A **static orthosis** has no movable components and immobilizes a joint or part. Static orthoses are fabricated to rest or protect, to reduce pain, or to prevent muscle shortening or contracture. An example of a static orthosis is a resting pan splint that maintains the hand in a functional or resting position (Fig. 30.20).

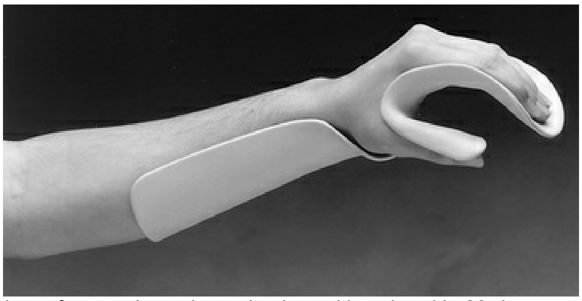

FIG 30.20 Single-surface static resting orthosis positions hand in 20-degree to 30-degree wrist extension, 45-degree to 60-degree metacarpophalangeal flexion, and 15-degree to 30-degree proximal interphalangeal and distal interphalangeal flexion.

A **serial static orthosis** achieves a slow, progressive increase in ROM by repeated remolding of the orthosis or cast. The serial static orthosis has no movable or resilient components but rather is a static orthosis whose design and material allow repeated remoldings. Each adjustment repositions the part at the end of the available range to progressively gain passive motion. A cylindrical cast designed to reduce a PIP joint flexion contracture through frequent removal and recasting is a classic example of a serial static orthosis (Fig. 30.21).

FIG 30.21 A series of cylindrical plaster casts is made to reduce flexion contracture at proximal interphalangeal joint.

Static progressive orthoses include a static mechanism that adjusts the amount or angle of traction acting on a part. This mechanism may be a turnbuckle, a cloth strap, nylon line, or a buckle. The static progressive orthosis is distinguished from the dynamic orthosis by its lack of a resilient force. It is distinguished from a serial static orthosis in having a built-in adjustment mechanism, so that the part can be repositioned at end range without the need to remold it. Generally, the client can adjust the static progressive mechanism as prescribed or as tolerated (Fig. 30.22).

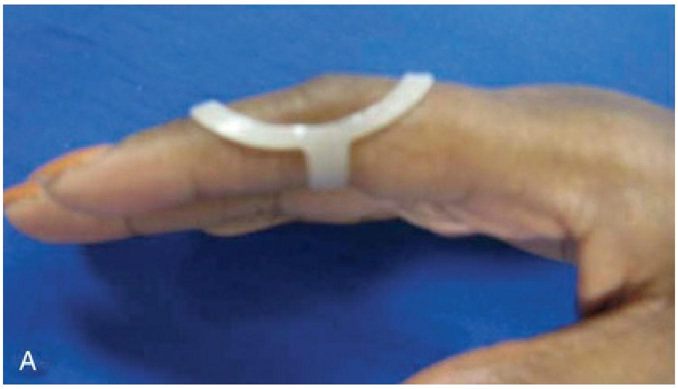
FIG 30.22 Static progressive web strap adjusts with hook closure. Client is taught to adjust strap as tolerance permits.

Orthoses Classified by Purpose

Although nomenclatures may vary, orthoses are usually described in functional terms.[1] They are broadly described first as articular or nonarticular, then by location and direction, and then divided into three overriding purposes: restriction, immobilization, and mobilization. The publication also lists many functions of orthotics, each of which is placed in one of three categories. Orthoses may fulfill more than one function or purpose, depending on the method of fabrication and the problems they address.

Restriction Orthoses

Restriction orthoses limit joint ROM but do not completely stop joint motion. One example is the orthosis in Fig. 30.23, which blocks PIP joint hyperextension while allowing unlimited PIP joint flexion. Semiflexible orthoses are available that limit motion at the extremes of range but allow motion in the middle of the range. Although the orthosis may be restrictive, the goal or function may vary.



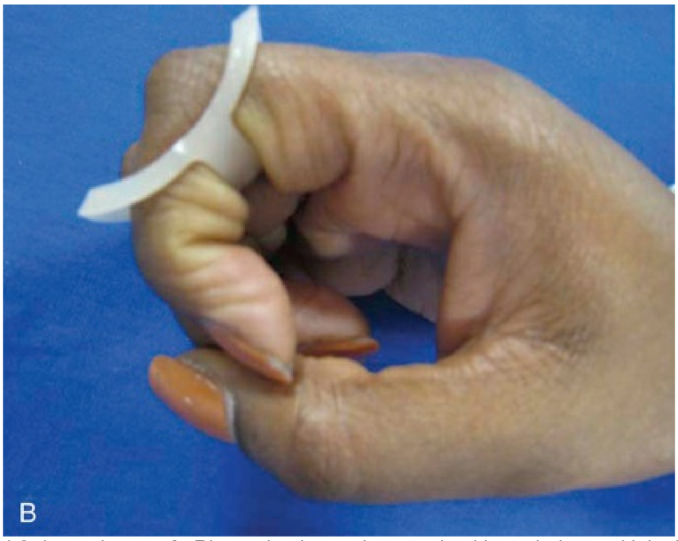


FIG 30.23 Oval-8 ring orthoses. **A,** Ring orthosis restricts proximal interphalangeal joint hyperextension. **B,** Ring orthosis allows full flexion. (From Skirven TM, et al, editors: *Rehabilitation of the hand and upper extremity,* ed 6, Philadelphia, 2011, Mosby.)

Immobilization Orthoses

Immobilization orthoses may be fabricated for protection to prevent injury, for rest to reduce inflammation or pain, or for positioning to facilitate proper healing after surgery. The classic example is the resting pan orthosis (see Fig. 30.20), which serves two of the three functions. A resting orthosis fabricated for a client after a cerebrovascular accident (CVA) positions the wrist and digits to maintain soft tissue length and can protect the insensate hand against damage.

Mobilization Orthoses

Mobilization orthoses are designed to increase limited ROM or to restore or augment function. A mobilizing orthosis may assist a weak muscle or substitute for motion lost because of nerve injury or muscle dysfunction (Fig. 30.24). The orthosis may attempt to balance the pull of unopposed spastic muscles to prevent deformity or joint changes and to assist function. An orthosis may provide resistance against which a weak muscle can exercise to improve its strength or to facilitate tendon gliding after tendon surgery. Frequently, mobilizing orthoses are used to increase the ROM of contracted joints, as in the case of Alexei, who experienced severe finger stiffness as a result of edema, which pooled in his hand after his forearm fracture.

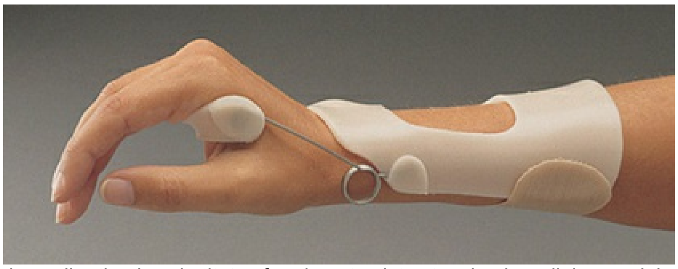

FIG 30.24 Spring coil orthosis substitutes for absent wrist extension in radial nerve injury. (Courtesy North Coast Medical, Inc., Gilroy, CA.)

Orthoses Classified by Design

After the purpose of the orthosis has been determined, the next decision relates to its design. Each of the types of orthoses described earlier (static, dynamic, serial static, and static progressive) may be fabricated as a single-surface design, a circumferential design, or a three-point design. A final category, the loop design, is generally limited to acting on finger IP joints by providing a loop of material that wraps around the joints to restore the final degrees of joint flexion.

All orthoses are designed to provide some degree of force. This force may be distributed as a continuous loop, with equal and opposing forces wrapping around two or more joints (Fig. 30.25, A). More commonly, the force is applied through three points of pressure (Fig. 30.25, B). Although the loop design generally is used only on finger IP joints, some variation of the three-point pressure design is used in all other splints.

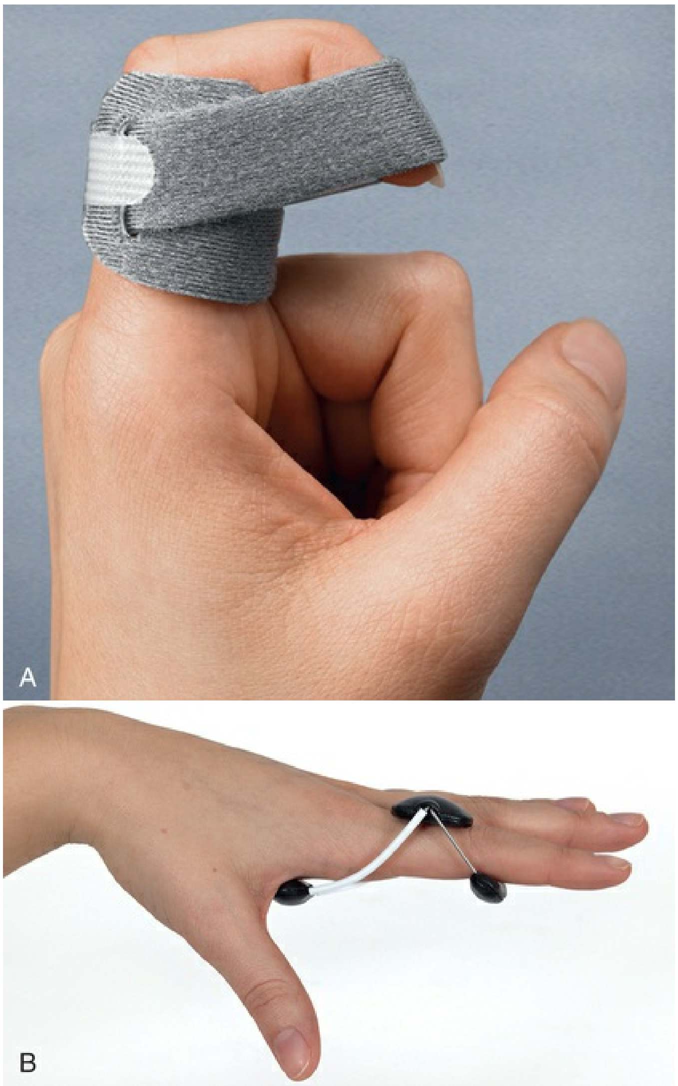

FIG 30.25 **A,** Final flexion strap designed to restore full interphalangeal joint flexion provides equal force on all surfaces of the digit. **B,** Three-point pressure orthosis with spring wire reduces proximal interphalangeal joint flexion contractures of 35 degrees or less. (*A,* Courtesy 3-Point Products, Inc., Stevensville, MD. *B,* Courtesy GettyImages.com.)

Three-point finger orthoses that incorporate springs, spring wire, or elastics are often used to correct DIP and PIP joint flexion contractures. A flexion contracture exists when a joint will not move passively out of a closed position into extension. These designs include two points of pressure—one proximal to the joint and one distal—and the third or central opposing force, acting directly over or close to the joint, as in Fig. 30.25, B. In a three-point finger orthosis, the force of the central point is equal to the sum of the two forces of the correcting points. This fact is clinically important because tissue tolerance under this central point may be insufficient and may react with pain and inflammation. This problem is seen frequently at the PIP joint, where limited surface area exists over which to distribute pressure. Pressure must be distributed with contoured surfaces that are as broad as possible, and the spring or elastic force and the wearing time must be adjusted to the client's tolerance. Proper padding incorporated into the orthosis can aid in distributing pressure.

The dynamic finger-based three-point orthosis just described is a unique design that does not adhere to the 90-degree rule—that is, when the splint is applied to a joint with a flexion contracture, the angle of approach of the line of traction is never 90 degrees. The more severe the contracture, the greater the translational force that is present; therefore it is less effective than a properly contoured outrigger orthosis that adheres to the 90-degree rule. This design should be fitted only in the presence of IP joint flexion contractures of 35 degrees or less. For finger contractures in excess of 35 degrees, a hand- or forearm-based outrigger orthosis is recommended because it can be positioned to apply force at a 90-degree angle of attack. Alternatively, a conforming, serial static orthosis can be used, as described in the section on traction.

Single-Surface or Circumferential Design

If a molded orthotic is to be fabricated, the next decision is whether to use a circumferential or single-surface design. Single-surface orthoses are fabricated to cover only one surface—the volar or dorsal surface of a limb or the ulnar or radial half of the hand or forearm. Straps are added to create the three points of pressure necessary to secure the orthosis (Fig. 30.26, A).

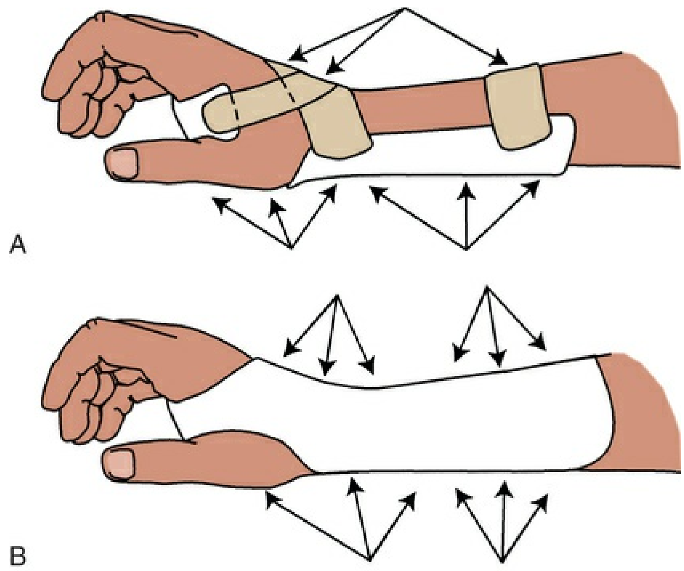

FIG 30.26 **A,** Single-surface orthosis requires properly placed straps to create three-point pressure systems to secure orthosis and ensure distribution of pressure. **B,** Circumferential orthoses create multiple three-point pressure systems to secure orthosis for immobilization.

Circumferential orthoses wrap around a part, covering all surfaces with equal amounts of pressure (Fig. 30.26, B). Straps are used solely to close the orthotic or to create an overlap. Thinner materials can be used in molding a circumferential orthosis, because increased contours in the material add to the rigidity. An example of added strength from contours is corrugated paper. Consequently, circumferential orthoses can be made lighter and out of highly perforated materials for air circulation without sacrifice of control.

Indications for Single-Surface Orthosis Fabrication

Single-surface orthoses are effective for supporting joints surrounded by weak or flaccid muscles, for instance, following a CVA or peripheral nerve injury. Because little or no active motion is available, the extra control given by circumferential orthotics is not needed, and donning and doffing the orthotic will be easier. A single-surface orthosis is also effective as the base for attaching outriggers in dynamic orthoses and for postoperative orthoses in which fabrication of a circumferential orthotic may damage repaired structures.

Indications for Circumferential Orthosis Fabrication

Circumferential orthoses are effective for immobilizing painful joints or for protecting soft tissue (see Fig. 30.25, B). Because the circumferential design gives comfortable, complete control, it is particularly helpful when the client will be wearing the orthosis during activity, when shear forces can be a problem. This comfortable, complete control also makes a circumferential design useful for serial static orthoses used to reduce contractures. The control that a circumferential design supplies makes it a good choice for stabilizing proximal joints when outriggers are applied to act on more distal joints.

When to Use and When Not to Use Orthotics

A first step in deciding which orthosis style and design to choose is to determine whether the client is a good candidate for wearing an orthosis. Several issues should be examined in this regard.

Compliance Issues

First, the therapist must consider whether or not the client is likely to comply with the orthosis wearing program. The orthosis may have a negative effect on the client's ability to be independent in self-care or to function at work. Some clients are sensitive about their appearance and may refuse to wear an orthosis if it offends their aesthetic sense or negatively affects their body image. Compliance with an orthosis wearing program may be poor if the client's general level of motivation to get better is low. On the other hand, some clients are so highly motivated that they will overdo the wearing program and cause themselves damage. Finally, the client's cognitive and perceptual ability to follow an orthosis wearing program should be considered, especially if no responsible care provider is available to supervise the orthosis-wearing precautions.

Ability to Don and Doff an Orthosis

Even if compliance is not an issue, the client may have problems donning and doffing (putting on and removing) the orthosis. For example, the client may have no one at home to assist in donning and doffing a difficult orthosis. The hospitalized client may not have adequate staff help to follow the wearing schedule or to apply the orthosis correctly.

Skin Tolerance and Hypersensitivity

The therapist must assess the client's skin condition before deciding to fit an orthosis. Clients who experience diaphoresis and produce excessive perspiration that may lead to skin maceration need to be evaluated more carefully for orthotic consideration and type, such as ventilated plastics and absorbent padding. Some clients are intolerant of any pressure because of extremely fragile skin or sensory dysfunction. If these issues arise and cannot be ameliorated, safe alternative therapeutic interventions must be substituted for the orthotic.

Wearing Schedule

If none of the preceding issues prevents the client from being a candidate for splinting, the therapist must decide on the optimum wearing schedule for the splint. Nighttime may be the best time for a client to wear a static splint designed to change ROM. It is also the time when clients need resting splints to prevent them from sleeping in positions that may damage the hand or allow nerve compression. During the daytime, the client may wear a dynamic splint or a splint designed to assist function. It is often best to minimize splinting during the day if possible, so that the client can use his or her hand as normally as possible. For some who must wear positioning hand splints at night, it may be advisable to alternate wearing splints on one hand at a time so that the individual is not left without the sensory input and function of a splint-free hand. Such a splint-wearing schedule, although not ideal for meeting therapeutic goals, may at least offer a compromise for better compliance.

Orthosis Fabrication Process

Step One: Creating a Pattern

Once the decision has been reached to fabricate an orthosis, arguably the most important step in the fabrication process is deciding on and creating a pattern. Although it may seem elementary even to the novice fabricator, this step can determine the success of the orthosis in terms of fit and function. Allowing the time to make a well-thought-out and properly fitted pattern gives the therapist the chance to deal with such issues as what he or she is trying to accomplish with the orthotic and how it is going to fit. Ultimately a properly fitted pattern makes the entire fabrication process easier and faster and increases the chance of success.

OT Practice Note

The process of making a pattern involves an understanding of the anatomy and biomechanics of the hand and the materials to be used, in addition to a bit of old-fashioned dressmaking. Understanding how positional changes alter length and how depth and width relate to the pattern is paramount to success.

The common technique of making a pattern starts with a tracing or outline of the hand. This generally is taken with the hand lying flat when possible, or by tracing the uninvolved hand if necessary. An amount is added to this outline to approximate the width and length needed for the orthotic. A common error in this technique is not taking into account the position in which the hand (or other body part) will ultimately be held in the finished orthotic.

Fig. 30.27, A and B, shows a pattern taken with the hand lying flat, with no length added to the pattern. In Fig. 30.27, C, when the pattern is fit on the volar surface of the hand with the hand in functional position (the wrist in 35 degrees of extension, the MP joints at 70 degrees of flexion, and the IP joints in 10 to 20 degrees of flexion), the pattern extends beyond the fingertips and in fact is too long. The same pattern on the dorsum of the hand (Fig. 30.27, D) with the wrist now in flexion illustrates that the pattern is now too short. Going from the volar surface of the hand to the dorsal surface is akin to driving around the inside of a curve as opposed to the outside of a curve. As any racecar driver knows, the inside of a curve is the shorter distance. Altering the position of the hand and the surface to which the orthotic will be fit alters the length of the pattern. The therapist must accommodate for this by checking the pattern on the hand in the position in which the hand will be held.

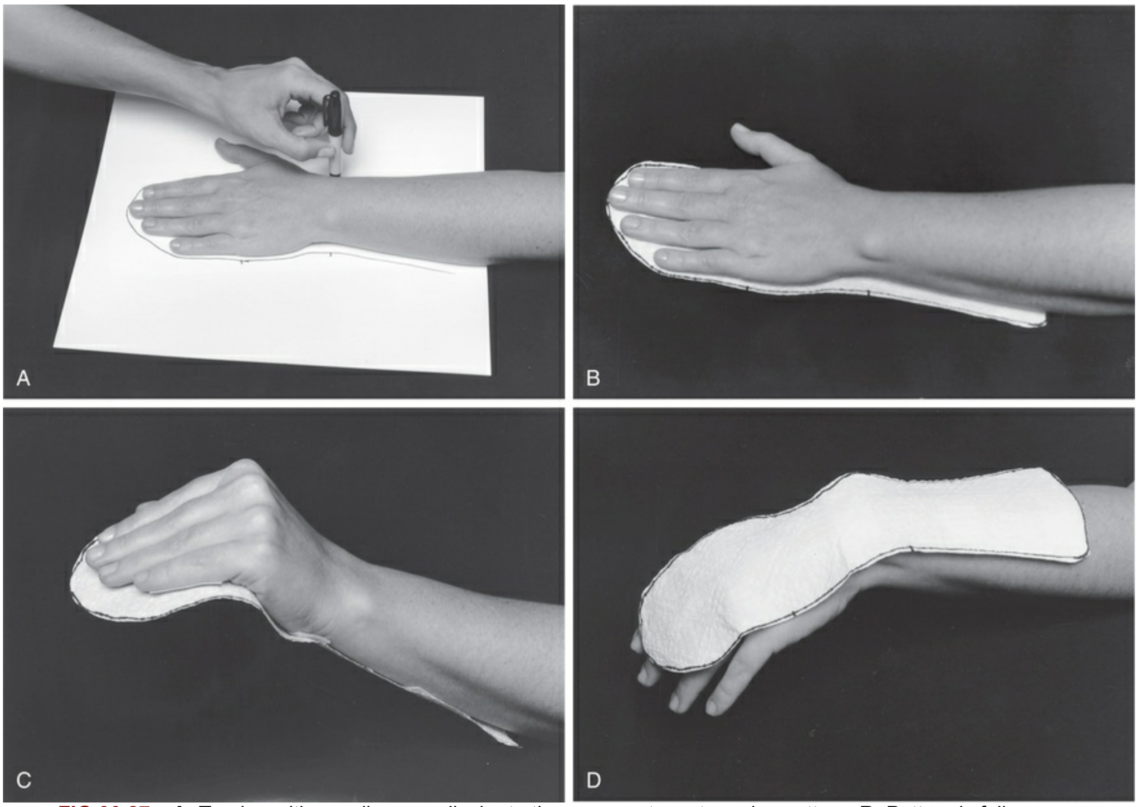

FIG 30.27 **A,** Tracing with pencil perpendicular to the arm creates a true size pattern. **B,** Pattern is full length with hand flat. **C,** Pattern is too long when fit on the volar surface with hand in resting position. **D,** Pattern is too short when fit on dorsum of hand with wrist and fingers in flexion.

Depth is the second dimension that must be considered when a pattern is made. The ideal trim lines of a single-surface orthotic fall at midline along the arm, hand, leg, or foot. An orthosis trimmed at midline provides optimal support and allows for proper strapping to help secure it in place (Fig. 30.28).

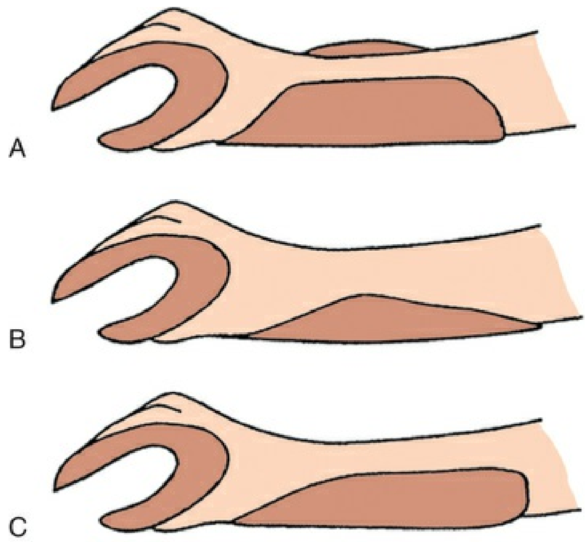

FIG 30.28 Forearm trim lines. **A,** Trim lines are too high, extending above forearm. Straps will bridge arm and will be ineffective. **B,** Trim lines are too low. Straps cannot substitute for too-low trim lines without applying excessive pressure. **C,** Midline trim lines ensure that straps properly secure splint on arm and hand.

To determine how much to add to the outline to achieve midline trim lines, the maker must observe the width and depth of the arm or hand. The forearm is cone shaped, not a straight cylinder, and it graduates in depth over the forearm muscle. Even the thinnest forearm graduates in width and depth proximally. Persons with significant muscle bulk may have graduation at quite an acute angle from the wrist to the proximal forearm. Determination of how much to add to a forearm trough must consider how much the orthosis must come out, around, and up the forearm to reach midline. The depth of the hand, particularly the depth of the hypothenar eminence, must be known to create the proper trim lines for a hand platform.

In the fit of any forearm-based orthosis, the proximal trim lines must take advantage of the soft muscle bellies that protect the radius and the ulna. The proximal borders of the orthosis should be flared so that the trim line remains at midline to help secure the orthosis in place on the arm (Fig. 30.29).

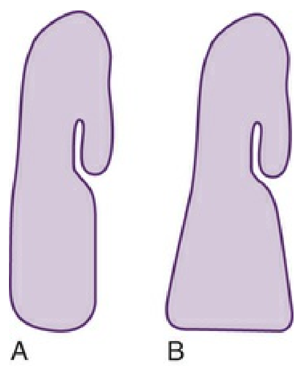

FIG 30.29 **A,** Narrowing the proximal pattern will cause trim lines to drop below midline. **B,** Flaring the proximal border of the splint maintains trim lines at midline.

A forearm-based orthosis should extend approximately two thirds of the length of the forearm, as measured from the wrist proximally. A good rule to remember is to bend the client's elbow fully and mark where the forearm and the biceps muscle meet. The orthosis should be trimmed one-quarter inch below this point to avoid limiting elbow flexion and to prevent the orthosis from being pushed distally when the elbow is flexed (Fig. 30.30).

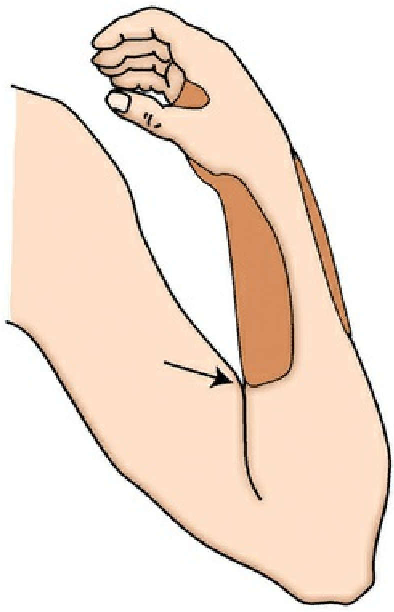

FIG 30.30 Length of forearm-based orthosis is checked by flexing elbow and noting where biceps meet forearm. Splint is trimmed 1/4 to 1/2 inch distal to point of contact.

Most low-temperature thermoplastics used to make orthotics will stretch to conform around angles and contours. When a pattern is created that will go around an acute angle, such as a 90-degree angle around a flexed elbow or wrist, the pattern should include a dart, where the material can be overlapped without causing undue bulk (Fig. 30.31). The pattern may be angled where necessary to accommodate acute angles. A well-fit and well-thought-out pattern translates to less material wasted, less expense, and shorter fabrication time.

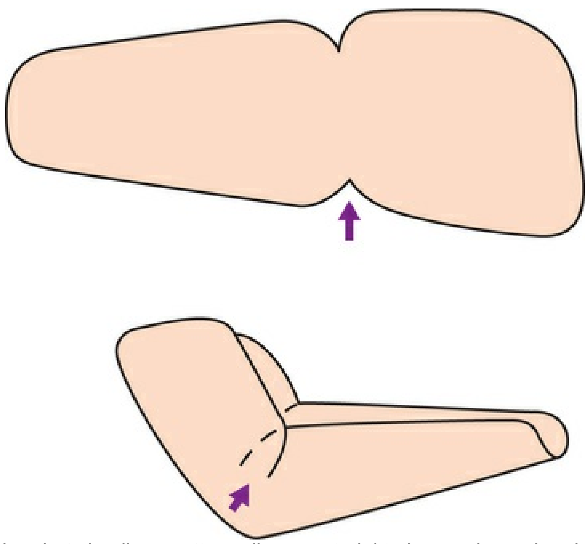

FIG 30.31 Drawing darts in elbow pattern allows material to be overlapped and contoured without excess material.

Step Two: Choosing Appropriate Material

The materials commonly used for custom-fabricated orthotics are those in a family of plastic polymers that become pliable at a temperature low enough for the material to be molded directly onto the skin. The low-temperature thermoplastics (LTTs) currently available have certain characteristics that can be defined according to how a material reacts or handles when warm and how it reacts once molded.

Choosing the optimal material for a given orthosis application can make the difference between a quick and easy fabrication process and one that requires extensive adjustments and reheating. It behooves every therapist, novice to advanced, to sample a variety of materials and test the handling characteristics so that no surprises occur when a material is heated and is ready to be cut and fitted to a client.

Characteristics of Orthotic Materials

Each LTT has some handling characteristics that apply when the materials are warm and pliable and others that apply when they are cold or molded. Following are the most common characteristics and a description of how each contributes to the choice of a material for a specific application.

Resistance to stretch.

Resistance to stretch describes the extent to which a material resists pulling or stretching. The greater the resistance, the greater is the degree of control that the fabricator will have over the material. Materials that resist stretch tend to hold their shape and thickness while warm and can be handled more aggressively without thinning. More resistant materials are recommended for large orthotics and for orthotics made for persons who are unable to cooperate in the fabrication process. In contrast, the less resistance to stretch a material has, the more the material is likely to thin during the fabrication process, and the more delicately it must be handled. The advantage of stretch is seen in the greater degree of conformability attained with less effort on the part of the fabricator.

Conformability or drape.

Resistance to stretch and conformability or drape describe nearly the same characteristic—that is, if a material stretches easily, it will have better drape and conformability. The great advantage of materials with a high degree of drape or conformability is that with a light, controlled touch or simply the pull of gravity, they readily conform around a part for a precise fit. The disadvantage of materials with a high degree of drape (and generally also low resistance to stretch) is that they tolerate only minimal handling, and care must be taken to prevent overstretching and fingerprints in the material. Materials with a high degree of drape are not recommended for large orthotics or for uncooperative clients. They are ideal, however, for use with postoperative clients when minimal pressure is desired, and for dynamic orthosis bases, in which conformability secures the orthosis against migration (movement distally) when components are attached. Materials with a low degree of drape must be handled continuously until the materials are fully cooled to achieve a contoured fit; often they will not conform intimately around small parts such as the fingers.

Memory.

Memory is the ability of a material, when reheated, to return to its original, flat shape after it has been stretched and molded. The advantage of high memory in a material is that the orthosis can be remolded repeatedly without thinning and weakening of the material. Materials with memory require handling throughout the fabrication process because until they are fully cooled and molded, they tend to return to a flat shape. This and the slightly longer cooling time of materials with high memory can be used to advantage with clients who require more aggressive handling to achieve the desired position. Disadvantages of materials with excellent memory are their tendency to return to a flat sheet state when an area is spot heated for adjustment and their need for longer handling to ensure that they maintain their molded shape until fully cooled.

Rigidity versus flexibility.

Rigidity and *flexibility* in orthotic splint material are terms that describe the amount of resistance a material gives when force is applied to it. A highly rigid material is very resistive to applied force and may, with enough force, break. A highly flexible material bends easily when even small force is applied to it, and it is not apt to break under high stress. Materials are available that fall all along this continuum.

Generally, the thicker a thermoplastic and the more plastic its formula contains, the more rigid the material will be. Thermoplastics come in thicknesses ranging from $\frac{1}{8}$ inch (3.2 mm) to as thin as $\frac{1}{16}$ inch (1.6 mm). Thinner materials and thermoplastics that contain rubber-like polymers in their formula tend to have greater flexibility in their molded state. Flexibility in a material allows for easier donning and doffing of orthotics and may be desirable for clients unable to tolerate the more unforgiving rigid materials. Rigidity is also a factor of the number and depth of contours included in the design. The same material may yield a semiflexible orthosis when used to make a single-surface orthosis with shallow contours or a rigid orthosis when used to make a tightly filled circumferential orthosis.

Bonding.

Bonding is the ability of a material to adhere to itself when warmed and pressed together. Many materials are coated to resist accidental bonding and require solvents or surface scraping to remove the coating to bond. Uncoated materials, which require no solvents or scraping, have strong bonding properties when two warm pieces are pressed together. Self-bonding is helpful when outriggers or overlapping corners are applied to form acute angles, but it can be a problem if two pieces adhere accidentally.

Self-sealing edges.

Self-sealing edges are edges that round and seal themselves when heated material is cut. This characteristic produces smooth edges that require no additional finishing, which adds time to the fabrication process. Materials with little or no memory and high conformability generally produce smooth, sealed edges when cut while warm. Materials with memory and those with high resistance to stretch resist sealing, requiring additional finishing.

Soft orthotic materials.

Soft, flexible materials such as cotton duck, neoprene, knit elastics, and plastic-impregnated materials may be used alone or in combination with metal or plastic stays to fabricate semiflexible orthotics. These materials allow fabrication of orthotics that permit partial motion around a joint yet limit or protect the part. Semiflexible orthoses are sometimes used during sporting activities and to assist clients with chronic pain in returning to functional activity. Semiflexible orthoses are also used for geriatric clients and for clients with arthritis, who often cannot tolerate rigid material.

Neoprene orthoses can be fabricated with the use of sealing glue or iron-on tapes. Careful attention must be given to the patterns for soft orthoses, because the support they offer relies primarily on achieving a secure fit without gapping or excess material. Most other soft materials require sewing, and the fully equipped OT department should include a sewing machine. A sewing machine is useful for adapting and adjusting prefabricated soft orthoses to ensure that each orthosis that leaves the clinic is indeed custom fit, if not custom fabricated.

Choosing the Best Category of Material for the Orthosis

Although an experienced therapist can make many types of orthoses from the same material, it is better to choose a material with appropriate handling characteristics for the type of orthosis being made. The following can be used as a guide from which to start choosing materials for different applications. The availability of materials and the experience level of the therapist assist in determining the most appropriate material.

Forearm-based and hand-based orthoses.

Orthoses need close conformability around a part when they serve as a base for a dynamic orthosis, stabilize a part of the body, reduce contractures, remodel scar tissue, or immobilize to facilitate healing of an acute condition. Such orthoses should be made from a material with a high degree of conformability to achieve a conforming fit. When conformability is not crucial, the orthosis can be made from a material with high resistance to stretch and low to moderate drape. Orthoses fabricated for burns and other acute trauma do not require as conforming a fit and can be made from low-drape materials. Materials that resist stretch and tolerate aggressive handling are recommended for positioning of a spastic body part, because such materials will not stretch and thin during the fabrication process. Experienced OTs who work without a formal pattern choose a material with a higher degree of drape and conformability and allow gravity to assist in the fabrication process.

Large upper and lower extremity orthoses.

Long orthoses fabricated for the elbow, shoulder, knee, or ankle generally should be made of materials that have high resistance to stretch, to provide the control necessary for dealing with large pieces of material. Such orthoses generally do not need to be highly conforming because they are molded over broad expanses of soft tissue. Care must be taken to provide relief for bony prominences or to provide padding to distribute pressure.

Circumferential orthoses.

An orthosis designed to wrap all the way around the part should be fabricated from materials that have a high degree of memory and that tolerate stretching without forming thin spots. The materials should be highly perforated, thin, and able to be stretched evenly. After being stretched, these materials will cinch in around the body part while still allowing sufficient flexibility for easy donning and doffing. These materials work well for fracture bracing and for circumferential orthoses that are used for contracture reduction and for stabilizing or immobilizing joints. Another choice for making less restrictive circumferential orthoses is the use of semiflexible materials, which facilitate easy donning and doffing and allow limited motion within the available arc of motion.

Serial orthoses.

Serial orthoses that require frequent remolding to accommodate increases in joint range of motion should be made from a material that has considerable memory or is highly resistant to stretch to avoid thinning with repeated remolding. The chosen material should have moderate to high rigidity when molded to resist forces from contracted joints or from spastic muscle tone.

Step Three: Choosing the Type of Traction

All orthoses provide some form of traction to move or stabilize a joint or joints. The traction mechanism may be dynamic, using a spring, hinge, or elastic. Traction may also be static, employing straps or turnbuckles or involving remolding of the splint base itself. If the mechanism moves or is resilient, the orthosis is called a *dynamic orthosis,* and if it does not move, it is called a *static orthosis.* The following section describes the various options for applying traction and discusses appropriate uses of each option.

Dynamic Traction

The purpose of dynamic orthoses is mobilization of a joint through the use of a resilient force attached to an outrigger or through the use of a spring coil. Each mechanism of force has advantages and disadvantages that make it suited for some uses and ill suited for others. Construction techniques differ substantially when spring coils are used versus outriggers with elastic components. Thus the indications for each style of orthosis will vary.

Spring coils are best suited to assist weak muscles or to substitute for paralyzed muscles (see Fig. 30.24). Clients with weak or paralyzed muscles will likely require the orthosis for a long time and will wear it while working or performing their ADLs. The low-profile, lightweight construction of a coil orthosis is recommended because it is less likely to interfere with hand function. Spring coils retain their force and alignment over time, rarely require adjustment, and are ideal for long-term conditions.

Orthoses with outriggers may be the optimal choice for splinting postoperative clients (Fig. 30.32). These splints allow frequent adjustments to maintain correct positioning and to accommodate changes in bandage thickness and edema as healing and rehabilitation progress. The postoperative client will likely use the orthosis for only a short time, generally 4 to 6 weeks. Such a client will not be returning to normal functional activities with the affected hand during that time. Thus the bulkiness and limited function associated with an outrigger orthosis are relatively unimportant, but it is vital that the orthosis be able to be self-donned, because it is usual for the client to remove it for periods of time or to alternate it with other orthoses. Alexei's dynamic extension outrigger (see Fig. 30.18) is an example. He alternated it with his dynamic flexion outrigger and discontinued it after 3 weeks, when his extension goal was met.

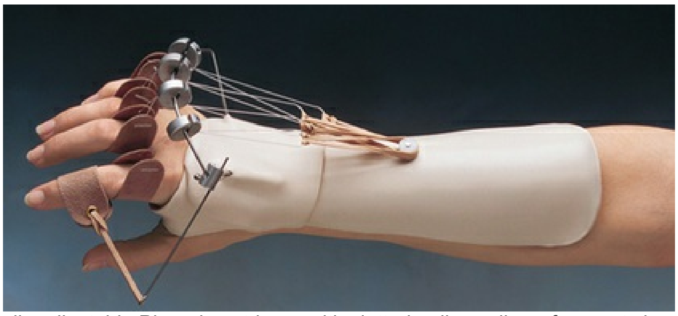

FIG 30.32 Easily adjustable Phoenix outrigger with slotted pulleys allows frequent changes in angle of approach. (Courtesy North Coast Medical, Inc., Gilroy, CA.)

Orthoses with outriggers are also used for contracture reduction. For this purpose, they are generally most effective when used during the early stages of healing, when the contracture feels soft and is easy to reduce.[6] Frequently, clients at this stage still have pain and inflammation. They cannot tolerate a rigid, static orthosis, but they will tolerate a light force provided by an outrigger.

Static Traction

The overall purpose of static traction orthosis is to apply traction to immobilize or restrict motion. When static orthoses immobilize, they are protecting, resting, or positioning. When they restrict, they are blocking motion, aligning joints, or limiting motion. When static orthoses are used to mobilize, they are used in a serial static or static progressive fashion to reduce contractures and remodel scars.

Serial Static Traction

A serial static orthosis is fabricated by repeated adjustments that position a joint at its end range of motion each time to achieve slow, progressive increases in ROM. For example, a cylindrical cast made for gaining PIP extension must be remade after a time (usually 1 to 3 days) to reposition the joint at the end of its range of motion (see Fig. 30.21).

Static Progressive Traction

A static progressive orthosis requires a built-in mechanism for adjusting the traction. Choosing which mechanism to use, be it a turnbuckle, a Velcro strap, or a buckle (see Figures 30-22 and 30-25, *A*), depends on availability, the therapist's experience, and the client's ability to manage the mechanism. A good rule to follow is to choose the simplest component that will achieve the desired goal.

Serial static orthoses and static progressive orthoses each have certain advantages and disadvantages. Serial static orthotics are useful for difficult clients who have high muscle tone or who are cognitively impaired and would have problems with the adjustment mechanisms. This orthotic choice also gives the therapist the control necessary for clients who are noncompliant or who would be overly zealous and would apply too much force. Disadvantages are that it requires more of the therapist's time because it must be remolded repeatedly, and if the client does not remove it for several days, some ROM may be lost in the direction opposite to that in which the orthosis is applying force.

Advantages of a static progressive orthosis are that the therapist has to make only one splint and that reliable clients with normal muscle tone may make more rapid progress because they can tailor the adjustment to their own pace and tolerance. The disadvantage of a static progressive orthosis is that it cannot be used on the client who has abnormal tone or who is unreliable.

Implications of application of force.

All orthoses, whether static or dynamic, apply force and to some degree stress on the structures they contact. The unimpaired hand tolerates a wide range of stresses by adaptation when possible and by avoidance when not. The client with sensory or cognitive impairment may lack the protective responses necessary to reposition the hand away from stresses applied by orthoses.

Pressure causes ischemia (localized anemia caused by obstruction of blood supply to tissues), and pressure increases when orthoses are contoured too sharply, when they do not conform uniformly, or when they do not cover a broad enough area of soft tissue. Orthoses that migrate or move on the hand because of insufficient strapping or contouring may actually apply pressure in areas that the orthosis was designed to relieve.

Amount of force to apply.

How much force can be applied safely? No absolute rules exist regarding the amount of force that can be applied for immobilization or to a restricted joint to produce motion. The therapist must apply sufficient force to create motion, but not so much as to cause ischemia. Much depends on the degree of the contracture, how long the restriction has existed, the age of the client, and the location of the restriction. This leaves the therapist with several options when choosing which force and how much force to apply.

For example, external force in dynamic orthoses generally is applied through the addition of rubber bands, elastic, or springs. No option is ideal, and all require careful selection, frequent adjustment, and client education on frequent skin checks. The amount of force supplied by rubber bands and springs depends on their thickness and their length. The thickness of the band or spring determines its potential force, whereas the length of the band or spring (or the number of coils in the spring) determines the ROM through which the force can be applied. When bands or springs are used, it is desirable to use the optimal force (i.e., the greatest tolerable force over the longest wearing time) that does not produce ischemia. To accomplish this goal, the midrange of the bands or springs should be used, rather than their end ranges, which may be too slack or too strong. A gauge is available for measuring the applied force of elastic, which generally should be between 100 and 300 g.

Techniques are available for avoiding pressure areas and shear forces in a dynamic orthosis, particularly when traction is applied to mobilize a finger joint. First, the joint(s) proximal to the finger joint being addressed must be stabilized. For instance, to mobilize a PIP joint with an outrigger and cuff, the MP joint must be held securely, so that no movement occurs to cause the orthosis to produce pressure points elsewhere on the hand or digits. Care must be taken in contouring the orthosis around the proximal phalanx, to distribute pressure and prevent motion that could cause shearing over the dorsum of the finger. In this case, padding may be necessary to help distribute pressure over the small and thinly padded phalanx (Fig. 30.33).

FIG 30.33 Felt padding distributes pressure over bony proximal phalanx.

Duration of traction.

Basic to answering the question "How long should traction be applied?" is an understanding of theories of tissue stretching versus tissue growth. Three key concepts aid in understanding these two different tissue responses. First, all materials, including human tissue, respond to applied stress. If stress is applied over time and then is relaxed, the tissue will no longer return to its original shape but will adapt to the new shape. This stretching phenomenon in skin is a result of its plastic behavior and is known as *creep.* The lengthening that occurs with creep is found to be the result of "a slippage of short collagen fibers on one another within the tissue. Some fibers may rupture, while others just slide on each other."[9]

The second concept is that of the elastic limit of tissue. Think of pulling on a rubber band. As the band is pulled, tension increases until the elastic limit is reached. If pulled beyond its elastic limit, the rubber band will break. In clinical terms, the end of the elastic limit is the point of tissue elongation at which pain will be felt and tissue damage may occur. Stretching tissue beyond its elastic limit does not lead to permanent lengthening, but it does cause unwanted tearing and probable further tissue contracture.[9] For creep to occur in living tissue, traction must hold the skin with sufficient force to exceed the elastic limit of the skin. This may cause tearing of small fibers, which leads to inflammation and additional scarring caused by fibrogen deposits.

The third concept is tissue growth. True growth occurs when "living cells will sense strain and collagen fibers will be actively and progressively absorbed and laid down again with modified bonding patterns with no creep and no inflammation."[9] This is the aim of splinting when the goal is contracture reduction or lengthening of restricted soft tissue.

Two approaches may be used to apply traction to lengthen soft tissue and reduce contractures. One approach is to position the tissue at the end range of its elastic limits and hold it statically for short periods, and then to relax and reposition it frequently. This approach is termed *stress relaxation*.[8] The second approach is to apply force within the elastic limits of the tissue, hold it for a long period, and then reposition it. Differences between these two approaches include time and ability to judge the elastic limits of tissue. The first approach relies on principles of stress relaxation, which theorize that tissues reach their elastic limit over a shorter period with frequent repositioning and will retain this newly set limit over time.[8] The second and more commonly used approach relies on the application of a low load over a long time to allow tissue growth to occur. Both approaches have merit, and it is up to the therapist, who develops this skill with experience over time, and the prescribing physician to determine the appropriate approach in each instance.

Step Four: Choosing an Orthosis Design for a Given Purpose

Mobilizing Orthoses to Remodel Scar Tissue and Reduce Contractures

Scar tissue is one of the major contributors to deformity or joint changes. Any time an insult to tissue occurs, as after an open injury or after surgery, the body to heal the wound produces scar tissue. The scar may be subcutaneous, superficial, or both. When it is subcutaneous, it often results in loss of motion, because scar tissue acts like glue, keeping tissue planes from gliding. Scar also contracts; when this contracture occurs over a joint, loss of joint motion results. To restore motion, scar tissue must be remodeled—that is, it must be softened and lengthened. If the contracture is caused by shortened soft tissue that is not scar, that soft tissue must also be lengthened. The process is the same for scar or soft tissue.

The effectiveness of using orthoses for remodeling scar and reducing contractures can be increased greatly by application of a deep heat modality, such as paraffin or moist heat, before application of the orthosis. When tissue is unheated, it is less elastic, meaning that it has a great deal of tension and is difficult to elongate. With the application of heat, tissue becomes temporarily more elastic, meaning that tension in the tissue is reduced and the tissue is much easier to elongate.

Many approaches are available for using orthoses for remodeling scar and reducing contractures. Three-point orthoses can be used for flexion contractures (extension ROM is decreased), loop splints for IP joint extension contractures (flexion ROM is decreased), and outriggers for metacarpophalangeal (MCP) extension contractures (lack full flexion ROM at the MCPs). Dynamic outriggers can be used to reduce early, soft tissue contractures, particularly when the client cannot tolerate a static orthosis. Static progressive orthoses or static orthoses can be used in a serial fashion.

Immobilizing and Restrictive Orthoses for Pain Reduction

Of the many uses of orthoses, perhaps the most common is to limit or reduce pain by providing rest and support. The most common orthotic prescriptions are written for orthoses to reduce the pain caused by the inflammatory processes of tendinitis or after sprain or strain injuries.

Several questions help determine which orthosis will best serve the client's needs. First, if the injury is caused by an acute sprain, the choice may be an immobilizing orthosis until pain and edema have subsided. If the pain is chronic in nature and is caused by the performance of a particular activity, a semiflexible orthosis may serve best. A semiflexible restrictive orthosis may sufficiently reduce pain by limiting ROM, yet still allow function without increasing stress on unaffected joints or tissue (Fig. 30.34).

FIG 30.34 Flexible thumb orthosis provides support yet allows midrange movement. (Courtesy GettyImages.com.)

A second question concerns the need for full-time orthosis wear versus intermittent wear. In the presence of an acute injury with orthopedic involvement or tissue damage, the orthosis may need to immobilize and to protect the part from further damage. Here, client tolerance and compliance will in part determine material and design choice. The therapist may also need to consider the integrity of the tissue and the need to accommodate bandages and bandage changes. If the orthosis is indicated only for intermittent wear, the design choice may depend more on the client's ability to readily don and doff the orthosis. The choice of materials may be dictated by the functional needs of the client. For intermittent orthoses used for vocational activities, lightweight, well-aerated materials may be indicated. For intermittent orthoses used for positioning, such as a resting orthosis designed to maintain functional position between exercise sessions, stronger materials may be indicated, and perforations may not be necessary.

A third important question in deciding on an orthotic design is, "What structures need to be immobilized or supported, and which should be left free?" When protective or pain-reducing orthoses are provided, care must be taken to immobilize only the involved structures without impeding motion elsewhere. If the purpose of the orthosis is to rest the tendons at the wrist to reduce inflammation, the orthosis must not limit carpometacarpal (CMC) or MP joint motion if these structures are not symptomatic. If used during the performance of ADLs, orthoses that fully immobilize a joint may transfer stress to joints proximal or distal to the immobilized joint. For this reason, semiflexible orthoses that restrict only end ranges of motion may be indicated during activity, whereas an immobilizing orthosis may be indicated for total rest at night.

Immobilizing Orthoses for Positioning

One of the orthoses most frequently fabricated by OTs is the resting pan (also known as the resting hand or functional position orthosis), which is used to maintain the hand in a functional position (see Fig. 30.20). The purpose of this positioning orthosis is to keep the soft tissues of the hand in midrange to maintain optimal mobility and to prevent shortening of the soft tissue structures around the joints. Occasionally, positioning orthoses are prescribed to position joints at end range to prevent contractures in the presence of severe tissue damage, as with burns. The important decision involves determining the optimal position for the most functional outcome.

Positioning orthoses may be fabricated for temporary use after surgery and may require frequent adjustment to accommodate changes in edema and bandages. The materials chosen for these orthoses should have memory to allow for remolding while keeping their thickness and strength. The choices of a dorsal versus a volar-based orthosis and a single-surface versus a circumferential orthosis depend on surgical and wound sites, the need for ease of donning and doffing, the client's available sensation, and the therapist's and physician's preferences and experience.

Step Five: Fabrication

The fabrication processes for single-surface and circumferential orthoses differ significantly. They do have a starting point in common: the pattern from which the orthosis will be made. Starting with a paper pattern is recommended, particularly for the novice therapist. One basic rule of orthotics fabrication is to get the pattern right before beginning to work with plastic. It is far less expensive to discard a few pieces of paper than even a small piece of LTT. Also, if one saves the paper pattern in the client's chart, it is easy to use to fabricate another should the orthosis be lost, or to enlarge it as a pediatric client grows. Pattern making, design principles, and principles of fit are important components of knowledge for orthosis fabrication; these concepts can be learned by going online to the Evolve website associated with this publication or by referring to a book such as *Hand and Upper Extremity Splinting: Principles and Methods.*[13]

Fabrication Techniques for Single-Surface Orthoses

Single-surface orthoses cover the volar surface, the dorsal surface, the ulnar half, or the radial half of the arm and hand. Generally, single-surface orthoses have gentle contours and cover as broad an area of tissue as is feasible to distribute pressure. The following steps should be used as a guide in the process of creating a single-surface orthosis. For the sake of demonstration, the single-surface and circumferential orthoses described and pictured are wrist extension (cock-up) orthoses (Fig. 30.35, A):

1. Except for the fingers, ⅛-inch–thick material is recommended to obtain sufficient rigidity to hold the joint firmly in position. The broad contours of single-surface orthoses require thicker materials to provide sufficient support.

2. Etch the pattern onto the cold thermoplastic material with a scratch awl or wax pencil before placing the material in a hot water bath. The water temperature required for most materials to soften properly is approximately 160°F. Temperature and time will vary, depending on the material and its thickness; this information is typically provided by the material's manufacturer in the accompanying literature. Most materials heat to the pliable stage in 1 to 2 minutes.

3. Carefully remove the material from the hot water bath and lay it flat on the table for cutting. To prevent stretching, avoid holding material unsupported while cutting (Fig. 30.35, B).

4. Starting at the neck of the scissors, cut with long, even strokes to prevent jagged edges.

5. Reheat the material if it has cooled too much to be formed. Place the material on the forearm and hand with the forearm in supination so that gravity can assist the initial molding. Some therapists prefer the elbow propped on a table with the hand in the air if the client is compliant. Check that the trim lines fall at the midline. If they do not, mark where excess material needs to be removed. Trim the material before it cools. Note areas that will need to be folded for clearance and for creation of smooth edges. Fold and secure the edges firmly in place (Fig. 30.35, C).

6. Reposition the orthosis on the forearm. Maintaining control on the wrist and forearm sections, carefully pronate the forearm. Maintain the wrist in extension at all times. The tendency for the wrist to drop into flexion when the forearm is pronated is universal. Controlling the wrist will ensure that the desired wrist position is maintained at all times (Fig. 30.35, D). If necessary, rotate the forearm section to ensure that the trim lines are at midline. Refer to Fig. 30.6 to review the importance of the changing shape of the forearm from a supinated to a pronated position.

7. Allow the material to cool until it holds its shape. It does not have to be held in place until completely cold. Remove, heat, and smooth any rough edges as needed, and apply the straps.

8. Strapping is critical to secure the part in the orthosis and to diminish shear forces and the possibility that pressure areas may develop. The orthosis may require several straps; wide or crossed straps are suggested to obtain the necessary control. Because the forearm is cone shaped, straps placed straight across the forearm will contact the skin effectively only on their proximal surface (Fig. 30.36). To have the forearm straps apply effective and well-distributed pressure, you may consider placing them at an angle.

9. Single-surface orthoses rely on strapping to hold them in place and to create one or more three-point pressure systems to securely hold the joint or joints being addressed (see Fig. 30.25, B). For straps to function properly, trim lines must fall midline along the arm and hand. If the trim lines are left too high, making the trough too deep for the part, the straps will bridge the part and sit up on the edge of the splint, where they are ineffective. The most effective way to secure an orthosis in place on the forearm is to apply pressure through the orthosis onto the soft tissue of the forearm muscle bellies. If the forearm trim lines angle below the muscle bellies, the orthosis will no longer be secured on the muscle bellies.

10. Instruct the wearer regarding the wearing schedule and proper care of the orthosis. To prevent ischemia and shear forces, check the fit of the orthosis regularly.

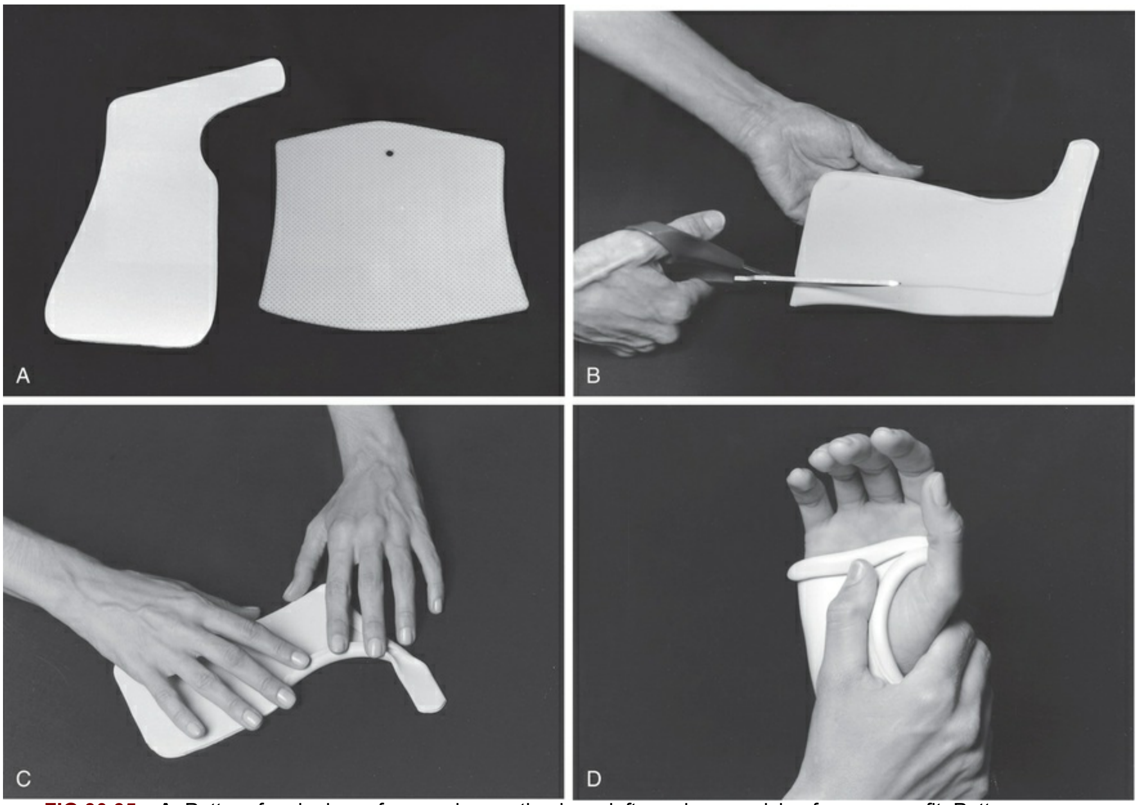

FIG 30.35 **A,** Pattern for single-surface cock-up orthosis on left requires precision for a proper fit. Pattern on right for circumferential orthosis does not need precise fit because material stretches and overlaps to achieve proper size. **B,** Support material on table to prevent stretching, and cut with long strokes of scissors. **C,** Fold edges of material and gently press flat to create thin, smooth edges that distribute pressure better. **D,** Gently support the wrist at all times to achieve proper fit.

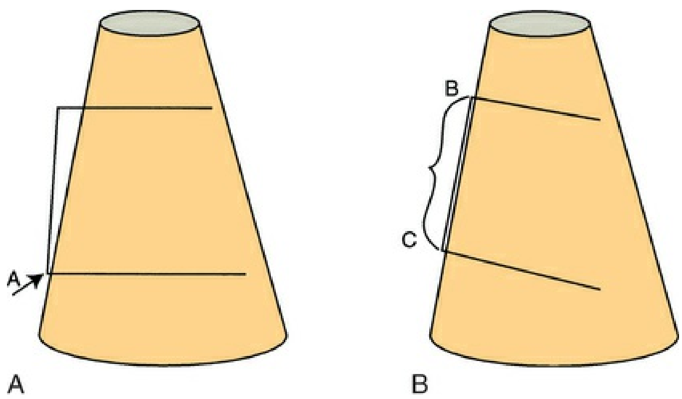

FIG 30.36 Forearm is cone shaped, gradually widening from wrist to elbow. **A,** Strap laced straight across broader proximal forearm contacts skin only at point *A* and does not secure orthosis. **B,** Strap placed at angle applies even pressure along line *BC* to secure orthosis.

Fabrication Techniques for Circumferential Orthoses

1. Use a thin or highly perforated elastic material or a flexible rubber material that has some memory. For hand- and forearm-based orthoses, thin elastic materials ($\frac{1}{16}$, $\frac{1}{12}$, or $\frac{3}{32}$ inch) provide sufficient strength because of the rigidity provided by the curves of the splint. For orthoses covering larger areas, a highly perforated $\frac{1}{8}$-inch material is recommended. Materials for circumferential orthotics should be coated to prevent permanent adherence when warm or should be able to be pulled apart once cooled.

2. Etch the pattern onto the material. Because the materials for circumferential orthoses are generally stretched to contour around the arm, the pattern does not need to be as precise as for a single-surface orthosis. It is important to know how much the material will be pulled and if it will be overlapped or finished edge to edge, so that a piece of sufficient size is cut (Fig. 30.37).

FIG 30.37 Circumferential orthosis trimmed to close edge to edge.

3. Wrap the material all the way around the part being addressed. Two techniques can be used to create closure for a circumferential orthosis. The first is to pull the material around the part and pinch the remaining material together to create a seam. Gently tug on the seam to conform the material. When the material is cool, open the seam and trim the orthosis. The second technique is to overlap the two ends to form a flap (Fig. 30.38). To prevent the flap from adhering (this may happen when the coating is thinned as the material is stretched), wait until it has cooled slightly before overlapping.

FIG 30.38 Circumferential orthosis made from flexible material with overlap for easy donning and doffing.

4. Smooth edges as necessary. The circumferential orthosis creates multiple three-point pressure systems by virtue of its design, and strapping is used only to hold the orthosis firmly closed.

Fabrication and Fitting of Semiflexible Orthoses and Prefabricated Orthoses

Materials used in the fabrication of semiflexible orthoses include neoprene, cotton duck, woven elastics, and thermoplastic-impregnated materials. Neoprene orthoses are generally fabricated with use of a special glue that adheres pieces together at the edges. The patterns for neoprene orthoses must be precise to achieve a conforming fit. Cotton duck and other woven materials require sewing and considerable skill in pattern creation and the addition of darts to ensure a good fit. Very thin thermoplastic materials can be used to create semiflexible orthoses, and certain patterns can be adapted to allow for partial range of motion within an orthosis.

Many commercially prefabricated orthoses are made from woven materials, because these materials present the broadest range of size adjustability and are less likely to require custom fabrication. It is highly recommended that even a prefabricated orthosis should be custom fit by a therapist to ensure proper fit and adherence to an appropriate wearing schedule. Remember that it is the therapist's responsibility to take the time to develop the skills needed to ensure that even prefabricated orthoses fit the client as if they were custom made.

Threaded Case Study

Alexei, Part 2

Using the Occupational Therapy Practice Framework, the evaluation of Alexei began with an occupational profile to establish his needs, priorities, and goals, which included the ability to administer his own medications and to be independent in his ADLs so he could return to his independent living apartment. Analysis of Alexei's occupational performance identified his inability to grasp small objects, such as insulin syringes and a glucose level tester, and to perform ADLs, such as grasping a normal eating utensil or toothbrush, zipping his pants, or taking money from his wallet. Alexei demonstrated problems within the performance skills category, including poor coordination of motion and difficulty manipulating objects. Under the category of client factors, problems with his right-dominant hand included lack of ROM and the mobility required to perform tasks successfully. The personal (or internal) contexts supporting Alexei that were identified during the evaluation revealed his flexibility and intelligence, his engaging and assertive communication style, his ability to learn an exercise regimen and how to use complex orthoses, his history of successfully managing health-related problems such as diabetes, his strong motivation to remain independent in his own apartment, and his psychological need to live in a place that would allow him to have a companion pet. His external contexts, including physical and social contexts, both supported and interfered with Alexei's achieving his goals. Positive aspects included his living in a full-service senior housing complex, a supportive nursing staff at his complex willing to help him regain independence, and an administrator at the complex who was willing to modify the rules slightly to support Alexei's goal of returning to his apartment in the independent living section of the complex. Negative aspects of these contexts included lack of adequate transportation to therapy and the living site's strict procedural rules that residents must stay in the least restrictive setting.

What would have happened to Alexei if OT intervention had consisted of just therapy sessions with no utilization of dynamic orthoses? ROM gains achieved during therapy probably would not have been maintained. The intervention plan of using dynamic orthoses was established on the basis of Alexei's limited ability to get to therapy appointments, coupled with his ability to carry out much of his rehabilitation on his own or with the assistance of nursing staff at the assisted living complex.

How critical was the team approach, and how important was ascertaining the client's main goal during the initial evaluation? The outcome was ultimately successful because (1) a collaborative relationship was formed between the very motivated client, the OT, and the nursing staff, with all participants focusing on and working toward the goal of retraining Alexei in independent medical management, and (2) the complex administrator agreed to bend the rules for a month until Alexei could achieve his goal of complete independence. Without a focused goal, much therapy time could have been lost working toward gains less important to the client, which may have ultimately robbed him of his independence.

Section 2 Arm Supports

Michal Atkins, Jane Baumgarten

Introduction and Clinical Reasoning

There is an increasing array of orthotic devices available in today's marketplace to support the weak upper extremity (UE). Like the orthoses described in the first part of this chapter, these devices are used to support, align, or prevent/decrease deformity of a specific body part; however, their primary function is to allow clients with significant UE weakness to move their arms and engage in meaningful occupation.

Commercially available products range from simple to complex and may be prescribed for temporary or permanent use. They may be home or clinic based in their application, and the indications for their use may be positional, therapeutic, occupation based, or any combination of these uses. Static positional devices provide support for weak UEs, prevent or reduce pain, and help to maintain range of motion (ROM). Dynamic orthoses may be utilized to decrease pain, increase strength or ROM, enable engagement in meaningful occupations, or any combination of these potential benefits. **Dynamic arm supports** maximize the potential for strengthening and UE function through a combination of supporting the weight of the arm and minimizing the effect of gravity.

The challenge to the occupational therapist is to combine a thorough occupational history with in-depth assessment and collaborative goal setting to establish the best choice of arm support for each client. Unfortunately, there is a paucity of evidence-based data that compares and contrasts different arm supports in order to assist the therapist in choosing the optimal device.[4] Garber and Gregorio[15] studied the prescription and use of upper limb devices in persons with tetraplegia. Although these authors did not provide specific information on mobile arm supports, they stated that "The devices retained in use most often were the more costly orthoses such as reciprocal orthoses and ball-bearing feeders."[15]

The following process is critical to the optimal selection of arm supports. The therapist must first give careful consideration to the nature of the trauma or the condition and its likely course. Will the client get stronger? Is the condition static? Or is it a degenerative condition where a decrease in function is expected? Are arm supports a short-term or long-term/permanent solution to decreased UE function and occupational engagement?

The first step is to clearly identify the goal of the intervention with respect to the use of an arm support. Is the goal of the treatment to provide comfortable positioning and pain reduction? Is it to provide a strengthening program in preparation for occupational engagement? Is it to achieve mastery of a specific task or tasks? Is it to combine both a meaningful occupation and exercise? Or is it a goal that is subject to repeated revision as the client's physical status changes?

Once the primary treatment goal for use of arm supports is defined, the acuity of the trauma or medical condition must be considered. Immediately following a traumatic injury, the first priority must be to manage pain and to prevent further complications. Static positioning devices provide support and stability but will limit mobility when the arms are very weak. Dynamic arm supports are necessary to increase function in the UEs and to increase strength and active movement of the arms, but their effect on pain must be carefully evaluated.

Expense and funding source can be significant factors in the prescription and use of arm supports, as is the setting in which the client is receiving treatment. Sample clinic equipment may be available for use in the inpatient rehabilitation setting, but not funded for long-term use. If the optimal arm supports are not available to a client, less expensive or homemade options will need to be considered.

It is crucial to evaluate where the arm device will be used and, if necessary, where it will be mounted. Will the client always be in a wheelchair when out of bed, or will he or she be independent in household or community ambulation and require an alternative mounting location?

A thorough assessment of client factors, including muscle strength, ROM, motor control, muscle tone, and sensation, will round out the evaluation process for determining the appropriate arm support. The therapist must ascertain if the client has adequate motor control and muscle strength to benefit from a particular dynamic arm support, as well as the space to use it, an adequate mounting surface, and the motivation to engage in the training necessary to maximize the benefits of an arm support.

Careful consideration of each of these factors will result in optimal prescription of static or dynamic arm supports, maximizing both therapeutic and functional benefits for the client.

Threaded Case Study

Matt, Part 1

Matt is 39 years old. He has been married for 8 years and has a 7-year-old daughter. He had been working for 10 years at a law firm with 20 attorneys when he sustained a C4 complete (American Spinal Injury Association [ASIA] Impairment Scale A) spinal cord injury in a motor vehicle accident. He was admitted to an acute hospital for 3 weeks and was just transferred to an inpatient rehabilitation facility near his family and friends. In an OT assessment in which the Canadian Occupational Performance Measure (COPM) was used, Matt was asked to identify the most important occupations in which he would like to participate upon his return home. The occupation of greatest importance to Matt was to resume his law practice, so that he could support his family financially and be active in the community. This meant that he would have to be able to write, use the computer and telephone, and manage some essential activities of daily living (ADLs) while at work (i.e., feeding, pressure relief, bladder management, and independent mobility). Matt also placed high importance on doing as much as possible with his daughter, including playing with her and being involved in her school activities. In addition, he wanted to be able to participate in social activities with his wife, such as going out to dinner. Upon admission to the acute rehabilitation unit, Matt was unable to participate in any of these activities.

Evaluation of client factors revealed that Matt's ROM was within normal limits (WNL) throughout his UEs except for 15- to 25-degree limitations in shoulder flexion, abduction, and external rotation bilaterally. Muscle tone was WNL. Bilateral UE strength was 2/5 (poor) in the anterior, middle, and posterior deltoids; 2/5 (poor) in the biceps and brachioradialis; 2−/5 (poor minus) in the supinators; 0/5 in the triceps; and 0/5 in all wrist and hand musculature. Matt's sensation with regard to light touch and superficial pain was intact through C4 bilaterally, impaired bilaterally at C5, and absent bilaterally at C6 and below. Proprioception was intact at the shoulders, impaired in the elbows, and absent in the wrists, fingers, and thumbs.

Critical Thinking Questions

1. Given Matt's status upon initial evaluation, are there any devices that would enable him to resume his most important occupation of practicing law? What are they?

2. What equipment and setup would allow Matt to play with his daughter at home and to continue to strengthen his arms?

3. What series of interventions would you provide to enable Matt to return to his law firm, where the partners are concerned about his ability to manage the many aspects of the job of an attorney?

Static Arm Supports

Optimal early static positioning is critical to maximizing later functional use of the UEs. **Static arm supports** are most commonly used to support the UEs in a comfortable, protected position in order minimize pain and subluxation.[7] At times, static supports are also used to stretch the shoulder(s) or elbow(s) to maintain or increase ROM.

Pillows are often the first and most readily available solution for providing static support to the upper limbs. While in bed, clients tend to rest their arms close to their body with the shoulder positioned in adduction and internal rotation. To prevent a functionally significant loss of ROM, the arms may need to be positioned in abduction and external rotation for part of the day (Fig. 30.39).

FIG 30.39 Static arm support with carefully placed pillows. (Courtesy of Department of Occupational and Recreational Therapy; Rancho Los Amigos National Rehabilitation Center, Downey, CA.)

Static arm supports must also be considered when the client is first seated either in a hospital bed, in a chair, or in a wheelchair, as the weight of the arm in an upright position may cause increased pain or shoulder subluxation.[7] The first priority must be to reduce pain and prevent further complications, as this may lead to decreased functional capabilities in the future. Static positioning while in a wheelchair may be achieved with lap trays or armrests (Fig. 30.40). Half lap trays are available for clients who need unilateral support such as survivors of stroke. Full lap trays are used when support for both arms is required, as with individuals with spinal cord injury (SCI) and resulting tetraplegia (also known as quadriplegia) or Guillain-Barré syndrome.[5] Static positioning devices provide support and stability, but they do not enhance mobility when the arms are very weak. Dynamic arm supports are necessary to allow clients to engage in functional and therapeutic activities.

FIG 30.40 Correct static arm support positioning in the wheelchair. (Courtesy of Department of Occupational and Recreational Therapy; Rancho Los Amigos National Rehabilitation Center, Downey, CA.)

Dynamic Arm Supports

Dynamic arm supports are devices that support the weight of the arm and minimize the negative effect of gravity on the functional use of weak UEs. They enable clients to move their arms despite significant weakness, exercise, and engage in ADL. Although these devices vary in design, complexity, and cost, they all assist the upper limb in moving as freely as possible. The use of robotic devices (computerized dynamic arm supports) has been introduced in an increasing number of therapy clinics to further enhance the benefits of therapy. Terminology associated with dynamic arm supports is inconsistent and confusing as the field continues to develop.[32] This is due in part to the different "languages" spoken by the engineers who develop the devices and the therapists and their clients who use them. It is the responsibility of the purchasing institution and the therapists to educate themselves regarding the capabilities of any device they are considering for use in treatment. Video demonstrations of various devices in use can be helpful in this process. In an attempt to identify and categorize the currently existing dynamic arm supports, Van der Heide, Gelderblom, and de Witte identified commercially available devices to support weak UEs.[32] The article classifies dynamic arm supports in three categories: (1) nonactuated devices, which provide no external power; (2) passively actuated devices, which assist the UE with rubber bands, springs, or weights; and (3) actively actuated devices that use electrical power, such as robotic arms.[32] This chapter discusses only the most commonly used devices and those that are available for purchase in the United States.

Suspension Arm Devices

Suspension arm devices are orthoses that hang from a bed frame or an overhead suspension rod attached to a wheelchair and support the arm. They are reasonably priced, easily adjustable, and offer a myriad of potential therapeutic and functional benefits for clients with significant UE weakness or motor control impairment. These devices support the shoulder, elbow, and forearm and may allow motion in weak proximal muscles, prevent disuse atrophy, maintain ROM, and relieve pain. They provide proximal support to allow for distal function, enabling occupational performance for individuals who otherwise would be unable to move their arms against gravity. With minimal training, suspension arm devices allow clients with very weak UEs to recognize early in rehabilitation that they can successfully engage in an occupation of choice, decreasing feelings of helplessness and hopelessness. Because of the mechanical principles on which they operate, suspension arm devices are generally more effective for positioning and exercise than for occupational performance. The upper limb swings as a pendulum from straps or springs attached to the suspension rod, which makes it difficult to make fine adjustments in movement.[24]

Suspension Arm Slings

The JAECO suspension sling (Fig. 30.41) has a single strap suspended from a suspension rod or over-the-bed frame. An adjustable balance bar supports the two leather suspension slings. These slings provide separate support for the wrist and elbow. The adjustable suspension mount is attached to the wheelchair and holds the suspension rod.

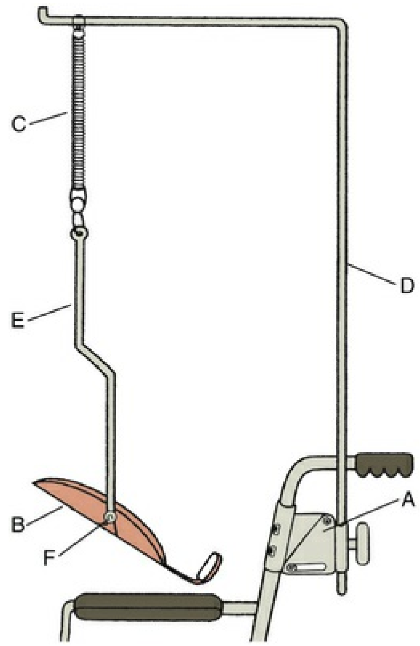

FIG 30.41 Suspension arm support. **A,** Adjustable suspension mount. **B,** Forearm support. **C,** Springs. **D,** Suspension rod. **E,** Suspension bar. **F,** Rocker arm (offset swivel). (Adapted with permission from Department of Occupational and Recreational Therapy; Rancho Los Amigos National Rehabilitation Center, Downey, CA.)

Suspension Arm Supports

The JAECO suspension arm support (Fig. 30.42) has a forearm support with an adjustable fulcrum instead of the two slings, which allows for greater customized adjustment in elbow flexion and extension. It is suspended from a single point on the suspension rod or over-the-bed frame, and allows the client to perform simple tabletop activities and occupations such as feeding or grooming.

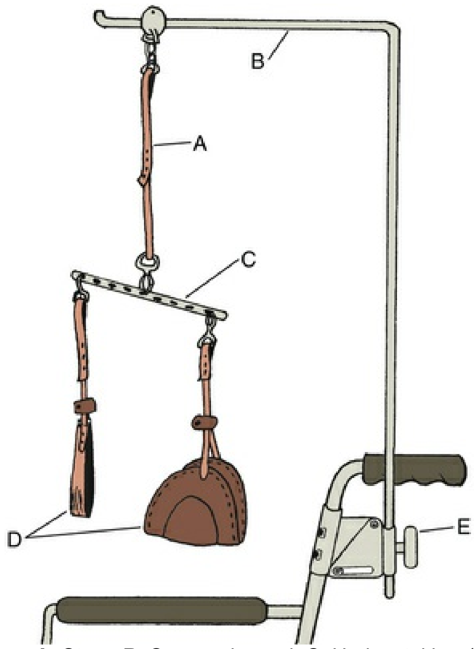

FIG 30.42 Suspension sling. **A,** Strap. **B,** Suspension rod. **C,** Horizontal bar (adjustable balance bar). **D,** Wrist and elbow suspension slings. **E,** Adjustable suspension mount. (Adapted with permission from Department of Occupational and Recreational Therapy; Rancho Los Amigos National Rehabilitation Center, Downey, CA.)

Adjustment of Suspension Arm Devices

Suspension arm devices are simple to adjust. The overall height of the device is adjusted at the interface between the suspension rod and the wheelchair mount. The higher the suspension rod, the flatter the arc of pendulum swing when the arm is in motion, enhancing the capability for occupational performance. The straps that connect the suspension rod to the limb can be adjusted to allow for use at various work surfaces and for specific activities. The placement of the straps along the horizontal balance bar will position the elbow in greater or lesser degrees of flexion, and if edema is present, the hand is held higher than the elbow. The forearm support used with the suspension arm support is the same as that used with a mobile arm support, which will be discussed in detail later in this chapter. The attached rocker arm can be adjusted lengthwise on the forearm support, which permits greater directional assistance for vertical motion.

Threaded Case Study

Matt, Part 2

When Matt was first cleared to sit in bed, he was frustrated that he could feel his muscles contracting, but he was unable to move his arms. When Matt's arms were placed in the suspension slings mounted to an over-the-bed frame, he was immediately able to move them. He was excited to be able to "exercise my arms." When asked what he would like to do with his arms in the slings, Matt decided that he would like to try to use his iPad. The iPad was positioned on an over-the-bed table, and with his arms in the suspension slings and a short training session, Matt was able to begin to use it. With practice he was able to listen to music and connect with friends on Facebook by moving his shoulders and activating the screen with the dorsum of his fingers or his thumb. This successful experience helped Matt realize that he could use his arms, despite the significant weakness and remaining paralysis.

Mobile Arm Supports

A **mobile arm support** (MAS) is a passively or actively actuated mechanical device that supports the weight of the arm and provides assistance to shoulder and elbow motions through a linkage of low-friction joints (Fig. 30.43). MASs are used for persons with weakness of the shoulder and elbow that limits their ability to position the hand in space. They were developed early in the 1950s and have been known by other names, including ball-bearing feeder, ball-bearing arm support, and balanced forearm orthosis (BFO).

FIG 30.43 The JAECO/Rancho MultiLink MAS mounted on a wheelchair. (1) MultiLink arm; (2) offset swivel with forearm support slide; (3) forearm support. (Courtesy North Coast Medical, Inc., Gilroy, CA.)

A MAS can increase UE function for persons with severe arm weakness caused by conditions such as cervical spinal cord injury, muscular dystrophy, Guillain-Barré syndrome, amyotrophic lateral sclerosis, poliomyelitis, and polymyositis.[16,17,34] The MAS has also been used for pain relief in the shoulder and elbow during occupational performance for clients with arthritis and other painful conditions. Motor control problems such as ataxia, the inability to generate coordinated motor activity during voluntary movement, can significantly interfere with successful occupational performance. There are also commercially available arm supports that provide dampening of extraneous motion, although results with these devices have been mixed.

How Mobile Arm Supports Work

MASs compensate for proximal weakness in the UEs in three ways: (1) they allow for a significant increase in active movement in the shoulder and elbow, (2) they enable hand placement in a variety of positions, and (3) they allow persons with significant weakness to engage in functional tasks. MASs can be used for occupational performance (allowing engagement in desktop tasks and ADLs such as feeding, hygiene, and grooming) or for therapeutic exercises (improving ROM, strength, and endurance). Their use may be temporary or permanent.[4,6,34] The mechanical principles on which the MAS functions are threefold. The devices (1) use gravity to assist weak muscles, (2) support the weight of the arm to reduce the load on weak muscles, and (3) use friction-reduced bushings in the arm support joints to increase the ease of movement.

Criteria for Use[33,34]

A person must meet several criteria to be considered for MAS use. Many of these criteria apply to use of other devices to assist weak arms, but they were initially developed for MAS use. These include the following conditions.

Goals, occupational performance, and client motivation.

The person must have a goal or need to perform specific occupations and motions of the arm that cannot otherwise be accomplished because of weak shoulder and elbow musculature. To optimize chances for successful use of a MAS, the client must *want* to use the device and must have sufficient motivation for training to use it proficiently.[4] Atkins and colleagues[4] surveyed therapists who specialize in treating clients with spinal cord injury, and the most frequently identified activities in which MAS users engaged were (in descending frequency) exercise, eating, page turning, power wheelchair propulsion, brushing teeth, and keyboarding.[4]

Adequate motor control.

The person must possess selective volitional control of the existing muscles that will power the MAS. People with conditions such as cerebral palsy, stroke, or traumatic brain injury who do not possess isolated selective motor control are typically not good candidates for use of an MAS.

Adequate source of power.

The potential MAS user must have adequate strength to move the MAS with the arm secured in it. Movement is typically generated by the shoulder and elbow muscles, although power can also come from a combination of functioning muscles in the neck, trunk, and shoulder girdle. Neck or trunk musculature alone is seldom adequate for performance of ADLs using a MAS but can enhance function in combination with other muscles. Muscle strength of 2−/5 (poor minus) in the available scapular, shoulder, and elbow muscles is typically the minimum for successful use of the MAS.

Sufficient passive range of motion.

To use an MAS, the potential user must have available passive range of motion (PROM) in shoulder flexion, abduction, internal and external rotation, elbow flexion and extension, and forearm pronation. The ideal available PROM for functional use of the MAS includes at least 0 to 90 degrees of shoulder flexion and abduction, external rotation of 0 to 30 degrees or more, normal shoulder internal rotation and elbow flexion, and 0 to 80 degrees of forearm pronation. PROM of 0 to 90 degrees in hip flexion allows for an upright sitting position and provides an optimal base of support for UE function.

Stable trunk positioning.

An upright sitting posture is ideal, but initially clients may have difficulty tolerating this position. Using the MAS in a semireclined (5–20 degrees) sitting position is possible, but more challenging. In addition to presenting with weakness in the UEs, clients may present with trunk weakness as well, as in the case of those with complete tetraplegia. Clients with significant trunk weakness will require lateral trunk supports for optimal use of the MAS.

Freedom from interfering pain.

A careful evaluation of pain level, pain triggers, and pain buffers assists the therapist in deciding whether a client is a candidate for MAS use. Using MASs may decrease chronic pain, as these devices support the weight of the arm and allow the person to move freely. However, freer movement may also have the opposite effect, increasing pain from overuse of weak muscles, as the MAS allows the person to engage in repetitive motion despite severe weakness. The occupational therapist should carefully monitor pain level when introducing and initially using the MAS.

Adequate cognition.

A basic understanding of the device, how it works, and its basic adjustments is crucial for clients who use the device at home. With young children or adults with cognitive impairment, a family member or a caregiver may receive training to assist with setting up and adjusting the MAS.

Threaded Case Study

Matt, Part 3

Matt meets all of the criteria listed here. He has occupations of interest that can be accomplished through the use of an MAS. Client factors, including motor control, strength, ROM, and stable trunk positioning, are sufficient to allow him to use an MAS. He has minimal pain in his arms, and his cognition is intact. He is highly motivated to return to his law practice and has a very supportive wife.

Mobile Arm Support Parts and Their Function: The JAECO/Rancho MultiLink Mobile Arm Support

The most commonly used MAS throughout the United States since the 1950s has been the JAECO MAS, manufactured by JAECO Orthopedics. In 1995, the Rehabilitation Engineering Program at Rancho Los Amigos National Medical Center received a series of National Institute on Disability and Rehabilitation Research (NIDRR) grants (NIDRR# H133E003001, #H133E020732) to design, develop, and test a new MAS.[22] The resultant JAECO/Rancho MultiLink MAS improved on the original MAS design and successfully addressed several concerns identified by long-term users and experienced therapists. It is the most commonly purchased MAS on the market, and few of the traditional JAECO MASs are being ordered.[12] Therefore our discussion of MAS parts, functions, and adjustment will focus on the JAECO/Rancho MultiLink MAS (Fig. 30.44; see also Fig. 30.43). The JAECO/Rancho MultiLink MAS is far easier to adjust than its predecessor and comes with a clear manual detailing its setup and basic adjustments. All parts of this MAS are interchangeable for application between the right and left side of the mounting surface (i.e., wheelchair or table). The MultiLink mount (see Fig. 30.44, B) is attached to the wheelchair or a standard chair and is the interface between the chair and the MAS arm. The MultiLink arm (see Fig. 30.44, A [3]) is then connected to the mount (see Fig. 30.44, A [1]) using the proximal shaft (see Fig. 30.44, A [2]) and allows for friction-reduced movement. The adjustable forearm support is connected to an adjustable offset swivel (see Fig. 30.44, C), which is inserted into the distal end of the MultiLink arm. The MAS user's arm is placed in the forearm support.

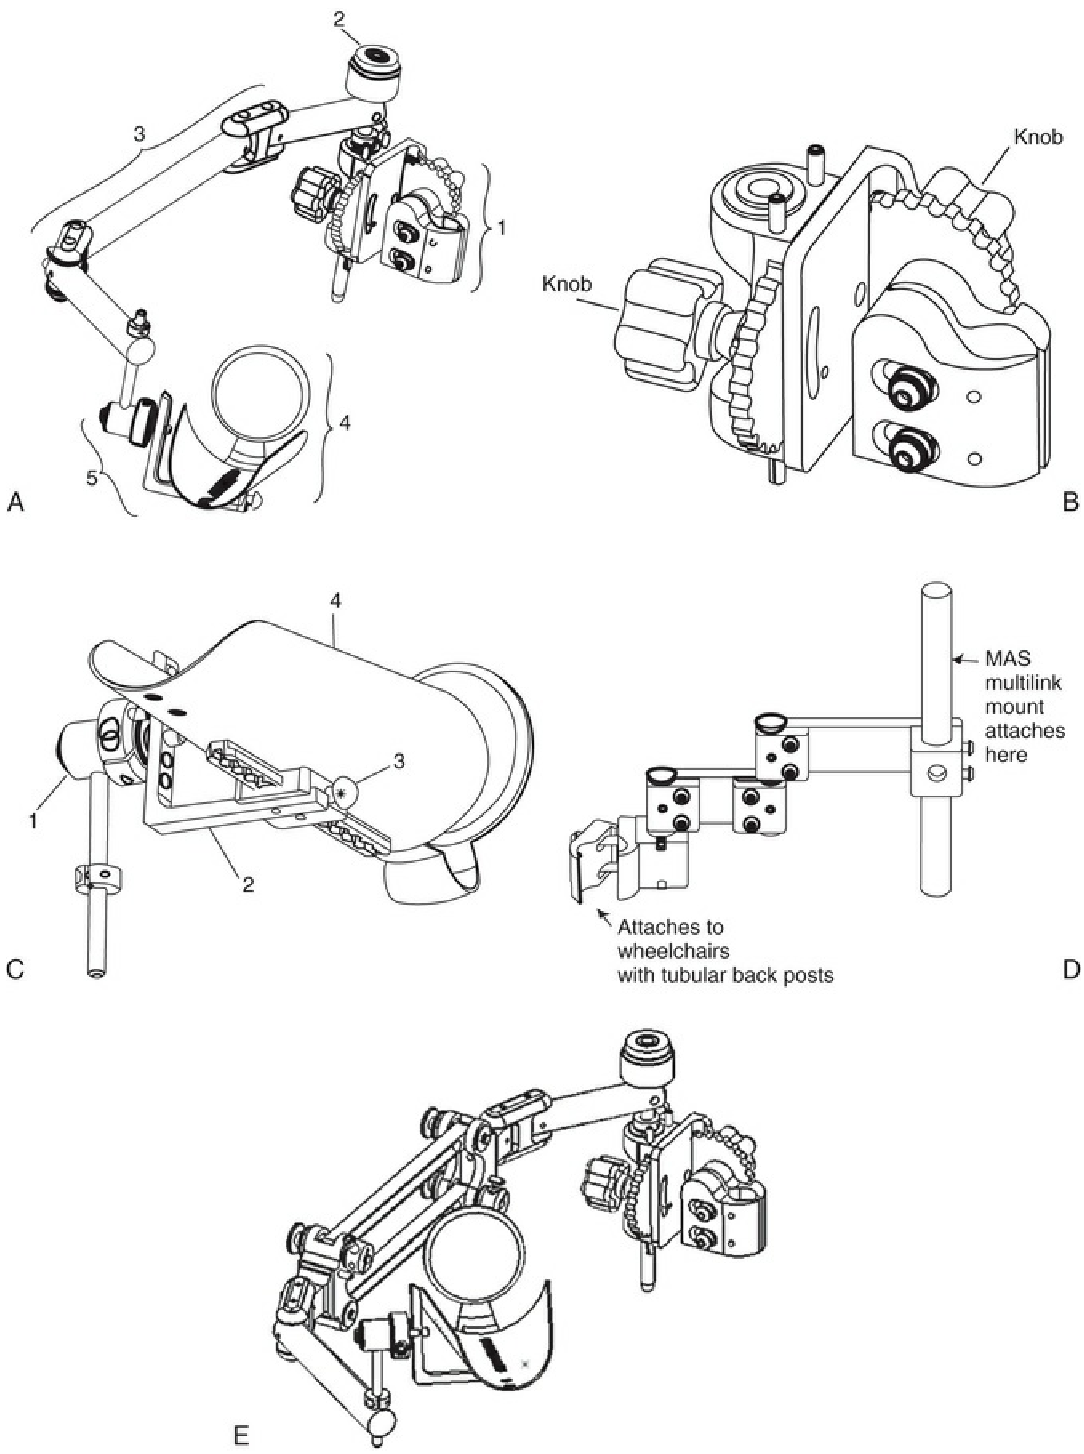

FIG 30.44 **A,** JAECO/Rancho Multilink Mobile Arm Support. (1) MAS mount. (2) Proximal shaft with bubble level. (3) MultiLink. (4) Forearm support with elbow dial. (Courtesy JAECO Orthopedic, Inc., Hot Springs, Ark.)

It is of greatest importance that the therapist understands the adjustment capabilities of each component of the MAS, as it is these adjustments that customize the MAS to meet the needs and goals of each individual MAS user and augment his or her available internal source of power (muscle strength).

Adjustment capabilities of individual parts.[20]

MultiLink mount.

The mount comes with two adjustable scroll wheels, which tilt the MAS to assist the user to move in the direction in which he or she is weaker (see Fig. 30.44, B). The user must have adequate strength to move against the assisted motion. These adjustments allow for optimal (1) forward reach and return movements and (2) side-to-side movements. Once the overall functional range of the MAS is maximized, the scroll wheels are tightened (locked) in place.

Forearm support and offset swivel.

Optimal vertical (hand-to-mouth) movements are achieved by adjusting the offset swivel along the slide, which is affixed to the bottom of the forearm support (see Fig. 30.44, C [2]). Moving the rocker arm along the slide toward the wrist aids in upward motion, and moving it toward the elbow aids in downward motion. As with the above-mentioned adjustments, the MAS user must have sufficient strength to move against the assisted motion. Each of these basic adjustments is made with the person's arm secured in the MAS.

MultiLink arms.

The therapist will choose between two types of MultiLink arms. The standard MultiLink arm (see Fig. 30.4, A [3]) provides horizontal movement, however, vertical motion is limited to that which is generated by elbow flexion and extension. The MultiLink arm with elevation assist (see Fig. 30.44) attaches to the mount in the same manner as the standard MultiLink arm but allows for elevation of the arm at the shoulder. According to 2014 data, this is the most frequently ordered type of MultiLink arm (M. Conry, personal communication).[11] The MultiLink arm with elevation assist is useful for the person who has deltoid strength between 2/5 (poor) and 3/5 (fair). This type of MultiLink arm allows for significantly greater freedom of movement and thus expanded functional use (Fig. 30.45). The client initiates the elevating motion (shoulder flexion or abduction), and the rubber bands attached to the middle section of the MultiLink arm help the client to flex or abduct the humerus to a higher level. The MultiLink arm with elevation assist has stops that can be adjusted to limit the amount of upward and downward motion. However, the client must have sufficient muscle power combined with the weight of the arm to return to the resting position. For this reason, not all persons with 2/5 to 3/5 deltoid strength are good candidates for this MAS component.

FIG 30.45 Sewing using the JAECO/Rancho MultiLink Arm with Elevation Assist.

Mobile arm support mount relocators.

Mounting the MAS to a wheelchair is frequently a challenge, as wheelchair backs and back posts vary in design and because other equipment such as lateral trunk supports must also be attached in the same area. To ensure that the MAS mount is placed in a position that will maximize function, JAECO developed a variety of MAS mount relocators (Figure 30-44, D). There are mount relocators that are designed specifically for use with wheelchairs with tubular back posts, for those with molded backrests, and for those with keyed back posts. Prior to ordering the MAS, the therapist must be familiar with the backrest design of the client's wheelchair.

Arm height adjustor.

The arm height adjustor allows for rapid adjustment of the height of the MultiLink arm for different activities and work surfaces.

Other mobile arm supports.

There are other MASs on the market that vary in design and may offer alternative and sometimes better solutions for certain clients than the JAECO/Rancho MultiLink MAS. One such device is the Wilmington Robotic Exoskeleton (WREX) (Fig. 30.46, A), which because of its design allows the arm to float. The mount is attached above the shoulder, which allows the arm to move more freely in a nonlinear fashion.[30] The Mobility Arm (Fig. 30.46, B) is a simpler wheelchair mounted arm support. Like the freestanding Swedish HelpArm (Fig. 30.46, C) described later in this chapter, it utilizes a weight to counterbalance the weight of the arm, allowing greater vertical movement from weak shoulder musculature. However, it lacks the fine adjustment of the JAECO/Rancho MultiLink MAS.

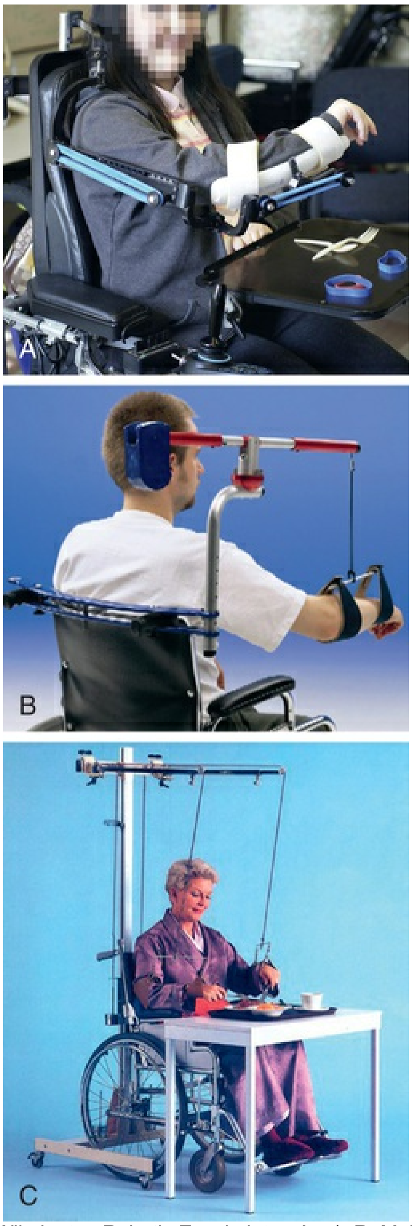

FIG 30.46 **A,** The WREX (Wilmington Robotic Exoskeleton Arm). **B,** Mobility arm sling mounted on a wheelchair. **C,** The Swedish HelpArm is similar in design to a traditional deltoid aid. (*A,* From Rahman T, Basante J, Alexander M: Robotics, assistive technology, and occupational therapy management to improve upper limb function in pediatric neuromuscular diseases, *Phys Med Rehabil Clin N Am* 23:701–717, 2012. *B* and *C,* Courtesy Performance Health, Warrenville, IL.)

Training

Training includes practice in all activities that interest the client and that need to be performed.[6,34] Any of these occupations may require fine adjustments to the MAS until the optimal settings are achieved. If strength or ROM increases during the training period, further adjustments will be needed. A wrist-hand orthosis or occupation-specific adaptive equipment may be necessary for use with the MAS.[6,34] When using a MAS to drive a power wheelchair, the client must practice in a variety of contexts to ensure that he or she can successfully negotiate hills and rough terrain. Because MASs rely on gravity to assist weak muscles, inclined terrain may pose significant challenges to the very weak client. Follow-up assessment and training with clients is indicated, especially for a growing child or for any client whose physical status may change.

Threaded Case Study

Matt Part 4

After 2 weeks in rehabilitation, Matt was able to sit upright in a wheelchair for 5 hours a day. He was given a power wheelchair, which he operated with a chin control for mobility and for reclining the wheelchair for pressure relief. He was still unable to participate in any of the most important occupations needed to return to work.

A JAECO/Rancho MultiLink MAS was mounted on his wheelchair, and he was given a lapboard for his wheelchair as well. With the MAS and his wrist-hand orthosis, he was able to use his iPad more easily and for an increasing variety of applications. His wife brought his laptop computer to the hospital, and he was able to send emails to his wife, coworkers, and friends. Activities that require hand-to-mouth skills are more complex than tabletop activities, so these occupations were introduced more gradually as Matt worked on reaching higher and higher. Once Matt could reach his mouth with his hand, eating activities were introduced. After training, Matt was able to feed himself using a wrist-hand orthosis and a universal cuff to hold a spoon or a fork. When Matt's daughter came to visit, the OT planned some treatment sessions to encourage Matt to use his MAS to play board games with her. Matt was encouraged by being able to play with his daughter, affirming the resumption of his role as a father.

Another of Matt's goals was to drive his power wheelchair using a hand control. He did not like the feeling of the chin switch in front of his face, and it made him self-conscious during social interactions. He practiced using the MAS to drive his wheelchair until he accomplished this task. With practice, Matt was able to use his iPad and his laptop computer, turn pages, manage a speakerphone, feed himself simple meals, and drive his power wheelchair.

Freestanding Dynamic Arm Supports

Freestanding dynamic arm supports that do not attach to the wheelchair allow the therapist to initiate treatment earlier in the rehabilitation process. These devices are more common in larger rehabilitation units and typically allow for quicker setup than a wheelchair-mounted MAS, maximizing inpatient therapy time. The rapid setup allows a client who is easily fatigued or in pain to begin engaging in self-care and tabletop activities and exercise as soon as minimal wheelchair sitting tolerance is established.

Because not all types of equipment are available in every facility, therapists must familiarize themselves with the devices available in their clinic to maximize their potential use. To achieve the optimal desired therapeutic outcome, the therapist must combine a clear understanding of the equipment at hand with the desired therapeutic goals.

Freestanding devices vary in complexity and ease of adjustment. All support the arm, allowing the client to engage in activities. These devices use rubber bands, springs, ball bearings, and other mechanical elements to negate the effects of gravity on weak proximal UE musculature.

The SaeboMAS has an adjustable parallelogram design offering various levels of assistance (Fig. 30.47). The mechanism is spring based, allowing for multidirectional activities. This device features a mechanical tension scale, which allows the therapist to grade the activity and to track and document progress. Height adjustment allows the client to practice skills in either a sitting or standing position.

FIG 30.47 The SaeboMAS floor model allows for a quick setup supporting the arm.

The JAECO/Rancho MultiLink MAS can be mounted to a lightweight, portable, and height-adjustable floor stand, which is placed next to the wheelchair (Fig. 30.48). This allows the seated client to engage in activities immediately and to evaluate whether a wheelchair or table-mounted MAS would be most beneficial.

FIG 30.48 The JAECO/Rancho MultiLink mounted to a stand allowing for a quick setup in the clinic.

The Swedish HelpArm (similar to what was once called a Deltoid Aid) utilizes weights to assist with upward movement of the arm. Increasing or decreasing the weights provides the optimal amount of assistance to the arm. This device can be used while the person is sitting in bed or in a chair. The therapist can limit the available motion, allowing clients with weak muscles to exercise and engage in self-care and tabletop activities.

Some devices, such as the ArmeoSpring, add interactive computerized elements to provide valuable feedback and monitoring of client performance (Fig. 30.49). Electrical sensors in the mechanical arm that are connected to a computer allow the client to focus on a clear goal and the therapist to monitor and record progress, optimizing the therapeutic session.

FIG 30.49 The ArmeoSpring mobile arm support by Hocoma.

Dynamic Arm Supports for the Ambulatory Client

Ambulatory clients with weak proximal UE musculature are unable to reach their upper torso and head, engage in tabletop activities, and reach for objects that are above waist height. When one arm is primarily affected, the person can easily use the less affected side. However, when both shoulders are weak, the hands may have functional strength, but the arms rest by the side of the body in a dependent position, making reaching for objects and lifting them impossible. Clients with bilateral proximal weakness may use table-mounted arm supports to allow them to position the hand in space for function. The JAECO/Rancho MultiLink MAS can be attached to a special table mount to allow the person to sit at a table and engage in activities. A similar mechanism is the SaeboMAS Mini, which is a lightweight, portable, table-mounted device (Fig. 30.50). Like the freestanding Saebo, it has an adjustable spring-based parallelogram design, offering graded levels of assistance in multiple planes of movement.

FIG 30.50 The SaeboMAS Mini mounted on a table. (Courtesy Saebo, Inc., Charlotte, NC.)

When using a table-mounted dynamic arm device, the ambulatory client must dedicate one location to engage in all desired activities. An activity center or desk with the dynamic arm support attached is a good solution for a person who spends hours in one area, such as at work. However, how do ambulatory clients with severe proximal weakness use their arms to brush their teeth at the sink, use an ATM, or reach for a cereal box at the supermarket?

Equipment solutions for those individuals who must use their arms while standing or walking exist but are seldom used. Dynamic arm supports can be attached to the trunk by a custom-made body orthosis, but they are cumbersome. These devices have been primarily studied and developed for children. A commercially available example is the Wilmington Robotic Exoskeleton (WREX). It is typically attached to a wheelchair but can be attached to a custom body jacket for ambulatory clients. The WREX has been fitted on children as young as 6 years old, allowing them to engage in activities while sitting, standing, or walking.[31] Since the 1990s, Tariq Rahman, PhD, and his team at the Alfred I. DuPont Hospital for Children have been improving the WREX to allow children with arthrogryposis to eat, play, and study using the device. This device is large and visible, and potential users have to weigh the benefits versus the negative social impact in deciding whether to use it.[31]

With the ongoing development of new materials and technologies, it is the hope of these authors that better equipment solutions for ambulatory, actively engaged adults with weak proximal UE musculature will be developed and marketed in the near future.

Robot-Assisted Therapy

Robot-assisted therapy for the upper limb includes a variety of complex and expensive devices (Fig. 30.51). These devices provide automated, goal-directed, repetitive movements with highly adjustable levels of assistance or resistance.[29] Robot-assisted therapy allows for the systematic adjustment of treatment parameters and provides the client with feedback and thus motivation to reach a goal.[26,29] In addition, it provides kinetic measurements that can assist the therapist in grading the therapy program and monitoring and recording progress. The interest in robot-assisted therapy began in the 1990s with the emergence of new evidence indicating that brain neuroplasticity can occur in adults, not only in children as was previously thought. Research showed that rote, repetitive exercise of an affected limb, shortly after trauma, leads to increased brain activity and improved function. Initial studies focused on gait training after neurologic injuries such as stroke and incomplete tetraplegia. The use of robot-assisted therapy for the upper limbs began with stroke survivors after initial evidence showed that (as with lower extremities) it reduced motor impairments in the upper limbs when administered shortly after onset of a cerebral vascular accident (CVA).

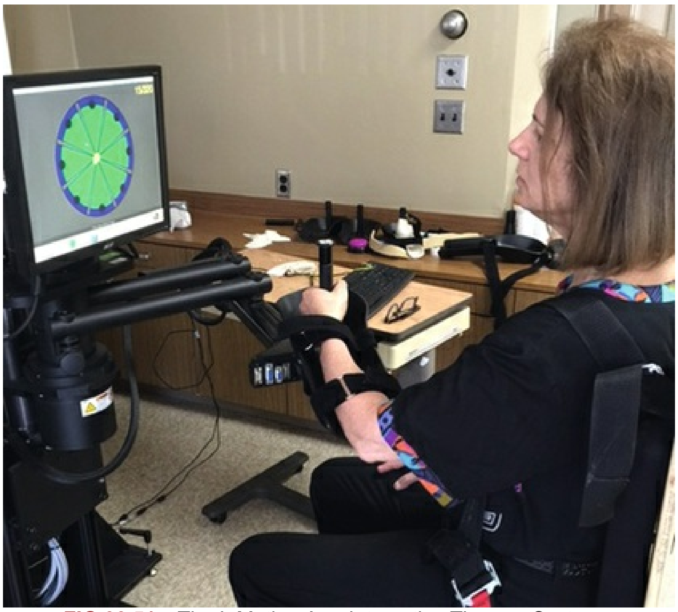

FIG 30.51 The InMotion Arm Interactive Therapy System.

It is important to note that robot-assisted therapies are not meant to replace the therapist but to augment traditional therapies and enable the therapist to provide more intensive therapy than was possible before. Robot-assisted therapy is frequently combined with neuromuscular electrical stimulation to facilitate and strengthen movement and to provide greater feedback to the client.

A robot-assisted therapy session may involve the therapist and client collaborating on a specific goal such as reaching a target on a screen by moving the arm in a prescribed direction. When the arm is weak, the robotic device can provide adequate assistance to allow the motion to be completed repeatedly. If the person is stronger, the device can provide resistance to the motion, with the goal of increasing strength. As stated previously, motor control problems such as ataxia pose a continual challenge to both therapist and client. Some robotic devices can be adjusted to dampen extraneous movements, allowing for greater function in certain clients. Suggested protocols for the frequency and duration of treatment have been developed for individuals recovering from CVAs[10,26]; however, at this time, there is no conclusive evidence to guide the therapist in determining what specific regimen is optimal for each client.[10,26] With the successful outcomes of robot-assisted therapy for stroke survivors, research being conducted on individuals with traumatic brain injury, spinal cord injury,[12] and cerebral palsy[21] is showing promise.

More and more companies are developing and marketing robot-assisted therapy devices. These devices are expensive (approximately $80,000 to $200,000) and are usually purchased by large rehabilitation hospitals and research institutions. Two of the advantages of robot-assisted therapy are the provision of ongoing feedback to the client and the ability to produce high-intensity, goal-directed repetition without boredom, due to the interactive component of the treatment.

Threaded Case Study

Matt, Part 5

Matt's OT utilized a robotic device several times a week for part of his treatment session. The goal of the sessions was to help Matt isolate shoulder and elbow movements and strengthen specific muscles. The settings of the robot were frequently adjusted in response to Matt's changing status, continually challenging him as his strength and endurance increased. He initially required active-assistive exercise, moving his arm through part of a predetermined pathway for reaching and returning his arm to his side with assistance provided by the robot at the end of his available active ROM. Next, Matt was able to complete the entire motion independently, and lastly the therapist changed the parameters by introducing light resistance to his movement. Matt was highly motivated to train on the robot, and he liked the visual and auditory feedback he received when he reached his daily goals. Interacting with the robot provided Matt with just the right challenge.

Cost

Recommending the optimal equipment for home use is critical for maximizing both UE strength and occupational performance. Cost and funding sources must always be considered. The therapist must establish whether equipment will be covered by insurance, and if the first attempt to procure equipment through insurance fails, the therapist may resubmit the request with a stronger justification. When insurance does not cover arm supports and additional adaptive equipment and the client has no means to pay for the orthosis, alternative funding sources such as community fundraising and nonprofit grant assistance should be explored. Another alternative to purchasing expensive devices is the use of cheaper, homemade equipment. Despite not meeting all of the capabilities of a well-designed orthosis, homemade solutions may provide an adequate substitute to an expensive device. For a home exercise program, the family may be instructed in the fabrication of a tabletop skateboard that allows the person to exercise his or her arm at home, in preparation for ADLs.

Threaded Case Study

Matt, Part 6

Matt was first able to benefit from using suspension arm supports in bed and using adapted equipment to access his iPad. Once he established adequate sitting tolerance in a power wheelchair, he was fitted for an MAS. Additional adaptive equipment and adequate training and practice allowed him to engage in many of his desired occupations, including feeding, hygiene/grooming activities, computer use, and controlling aspects of his home and office environments including operating light switches and using electronic devices. His daughter's visits always included special playtime using the MAS. Robot-assisted therapy sessions were used to strengthen weak muscles and to provide precise feedback that quantified gains in both strength and endurance. Following discharge, Matt was referred to the assistive technology service, where a plan was formulated for Matt and the occupational therapist to visit his home and law office to determine how he could manage his required work functions. In addition to the equipment he obtained as an inpatient, it was recommended that Matt would benefit from an adjustable desk, which would allow him to independently access his phone, computer, and files. He was also instructed in the procedure to obtain free specialized adaptive equipment from his telephone company, for both work and home. This visit and the implementation of equipment recommendations resulted in Matt's return to his law practice 2 months after discharge.

Summary

Clients with weak UEs benefit greatly from the use of carefully prescribed arm supports. Static arm positioning provides support for weak musculature, helps to prevent shoulder subluxation, and assists with the management of pain in the UEs. Dynamic arm supports allow the client with weak upper limbs to engage in meaningful occupations and may also be used for strengthening. Suspension arm supports are inexpensive and easy to adjust, but they do not allow for the discrete adjustments required for clients with severe weakness. Mobile arm supports are highly adjustable devices that support the weight of the arm and minimize the effects of gravity on weak proximal UE muscles. Depending on the client's diagnosis and prognosis, the use of MASs may be temporary or permanent. Clients must have a functional need and strong motivation to successfully use MASs. It is the role of the occupational therapist to select the arm support that best meets the needs of each client, and this is established through careful evaluation and the assurance that the client meets the minimum criteria for optimal use. Clients' concerns about MASs include increased overall wheelchair dimensions and a heightened appearance of disability.

With adequate training, however, clients who experience occupational benefits accept and use the device. Freestanding dynamic arm supports are used in therapy clinics and allow quick setup and early therapeutic intervention. Robot-assisted therapy is a rapidly growing field with mounting evidence to support its efficacy as an adjunct to traditional therapy. However, these devices are expensive and not readily available to all therapists and clients.

Acknowledgments for Section 2

We would like to thank Y. Lynn Yasuda, MA, OTR/L, FAOTA, and the staff and clients at Rancho Los Amigos National Rehabilitation Center, who have taught us so much. We would also like to thank Mark Conry and his family for their commitment to improving the JAECO MAS throughout the years and, by so doing, improving the lives of many individuals. Lastly, we would like to thank Lydia Cabico and Kim Hasday, MA, OTR/L, for their valuable assistance.

Review Questions

1. Describe the role of the OT in the orthoses-making process.
2. What is wrist tenodesis, and how can it be used functionally?
3. Describe the axis of motion of forearm rotation, and discuss how it affects the fit of an orthosis.
4. Name the three major nerves that supply the hand, and describe their sensory innervation patterns.
5. Why is tip prehension considered to be a dynamic rather than static prehension pattern?
6. What is the one grasp pattern that does not include the thumb?
7. Define the terms *friction*, *torque*, and *stress*.
8. How is shear stress created and how can it best be avoided?
9. Why do translational forces minimize the effectiveness of an orthosis?
10. Describe the difference between a dynamic and a static orthosis.
11. How may an orthotic pattern vary if it is to be fitted on the dorsum of the hand, as compared with the volar surface?
12. How does the amount of drape in a low-temperature thermoplastic material affect the making of an orthosis?
13. What is the recommended type of material for small finger orthoses? Why?
14. What is the recommended type of material for large elbow and lower extremity orthoses? Why?
15. What is the importance of straps on a single-surface orthosis?
16. Why is optimal early static positioning important?
17. What are the main purposes of dynamic arm supports?
18. Where can suspension arm devices be attached?
19. What are the benefits of an MAS?
20. How does a mobile arm support work?
21. What are the criteria for successful MAS use?
22. What occupations can be achieved with the use of an MAS?
23. What are the parts of the JAECO/Rancho MultiLink MAS?
24. What are the benefits and limitations of freestanding dynamic arm supports?
25. What dynamic arm supports are available for the ambulatory client? What are their benefits and limitations?
26. What are the benefits and limitations of robot-assisted therapy?
27. What strategies can the therapist employ to encourage a reluctant client to try using an MAS?

Traditional Sensorimotor Approaches to Intervention*

Winifred Schultz-Krohn, Julie Mclaughlin-Gray

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, the student or practitioner will be able to do the following:

1. Describe the four general processes of information flow related to control of movement.
2. Define motivational urge, and name the locus of this function in the brain.
3. Trace the flow of information in the central and peripheral nervous systems that leads to purposeful movement.
4. Define the sensorimotor system, its locus in the brain, and its function during motor performance.
5. List the structures that constitute the higher, middle, and lower levels of the central nervous system components for movement.
6. Name the four traditional sensorimotor approaches to intervention and the theorist responsible for each.
7. Name the two models of motor control that form the basis for the sensorimotor approaches to treatment.
8. Briefly describe each of the four traditional sensorimotor approaches to intervention; compare and contrast their similarities and their differences.
9. Understand and apply proprioceptive neuromuscular facilitation (PNF) as a preparatory method to facilitate client participation in desired occupations.
10. Define PNF and how this approach facilitates adaptive responses that are performed in daily occupations.
11. Understand the principles of PNF and how to apply them to enhance client performance.
12. Describe the influence of sensory input on motor learning.
13. Use the PNF evaluation to determine factors limiting clients' participation in their occupation.
14. Recognize upper and lower extremity diagonal patterns in daily performance skills.
15. Name the theorists who developed the PNF approach.
16. Discuss the historical background and current use of neurodevelopmental treatment (NDT) within occupational therapy.

7. Identify theoretical foundations of NDT as well as current principles of evaluation and intervention.
8. Identify management strategies associated with NDT intervention and treatment techniques.
9. Integrate NDT within an occupation-centered and client-centered approach to evaluation and intervention.
10. Discuss the relationship between evidence-based practice and NDT, and discuss the types of evidence available to support the use of NDT in occupational therapy.

KEY TERMS

Approximation
Asymmetric patterns
Bilateral patterns
Co-contraction
Combined movements
Conation
Contract-relax
Diagonal patterns
Generalizability
Hold-relax
Inhibitory techniques
Lower motor neurons
Manual contacts
Mass movement patterns
Maximal resistance
Motivational urge
Motor program
Movement strategy
Part-task practice
Proprioceptive neuromuscular facilitation
Proprioceptive stimulation
Reciprocal inhibition
Reciprocal patterns
Reflex and hierarchical models
Repeated contractions
Rhythmic initiation
Rhythmic rotation
Rhythmic stabilization
Sensorimotor system
Sensory stimulation

Slow reversal
Slow reversal-hold-relax
Stabilizing reversals
Stepwise procedures
Stretch
Symmetric patterns
Traction
Unilateral patterns
Upper motor neurons
Verbal commands
Verbal mediation
Whole-task practice

Overview*

Case Study

Carlos

Carlos, a 59-year-old construction foreman, suffered a right cerebrovascular accident 3 days earlier and currently requires maximum assistance for most self-care tasks. He is able to speak and recognizes his wife and two adult children, but he appears easily confused when expected to participate in self-care activities. He has no functional motor control of his left arm or hand, and sensation is markedly impaired on his left extremities. He exhibits a decorticate posture in both left extremities, with flexion tone dominating his arm and extensor tone dominating his leg. He is able to partially roll to the right side of the hospital bed and push up on his right arm to a sitting position, but at home he sleeps on the opposite side of the bed. He is able to stand by using a quad cane in his right hand but is unable to safely walk from the bed to the bathroom in his hospital room.

As Carlos's occupational therapist, you are expected to design and implement an intervention plan based on the best evidence available. Occupational therapists working with clients who have sustained damage to the central nervous system are often concerned with enhancing functional movement as a means of promoting independence in occupational performance.[16] To achieve this objective, a variety of intervention approaches are available from which the therapist may choose. This chapter reviews the traditional sensorimotor approaches and presents a brief description of each.

Critical Thinking Questions

1. How can a traditional intervention approach improve Carlos's occupational performance?
2. What potential difficulties should be anticipated when using a traditional intervention approach?
3. What current knowledge of central nervous system function could be used to support the selection and implementation of traditional sensorimotor intervention methods?

Occupation performance frequently requires precise voluntary movement that is controlled and monitored by the nervous system. Various structures within the nervous system are coordinated to selectively activate specific muscles to initiate, perform, and complete a desired task or activity. If a movement is poorly performed and thereby compromises task performance, feedback occurs through knowledge of the results of the action, and the neurologic commands to the muscles are modified so that accuracy of movement is achieved. Knowledge of the intricate working of the nervous system is of special importance to the occupational therapist concerned with refinement and improvement of the motor performance of clients with neurologic conditions.[3] A brief overview of the flow of information associated with the control of movement is described in the following sections.

Central Nervous System Control of Movement

The firing of motor neurons located in the anterior horn of the spinal cord produces all movements.[84] These neurons directly innervate the skeletal muscles. The activity of the spinal or lower motor neurons can be modulated by segmental spinal circuitry and by the descending influence of the upper motor neurons located in the motor cortex and brainstem.[52,54] Two other structures, the basal ganglia and the cerebellum, and their associated pathways, are also intimately involved with motor control. Lesions in these structures are associated with characteristic movement disorders.

Movement production does not begin and end with the **upper motor neurons** or **lower motor neurons**. Many central nervous system (CNS) structures contribute to the development of the signals that activate muscles. Although much about the control of movement is still unknown, animal and human research suggests that four general processes are related to the flow of information needed to control movement. The four general processes of information flow are motivation, ideation, programming, and execution.[10,18] A schematic diagram that indicates the main direction of information flow and connecting the various motor centers appears in Fig. 31.1.

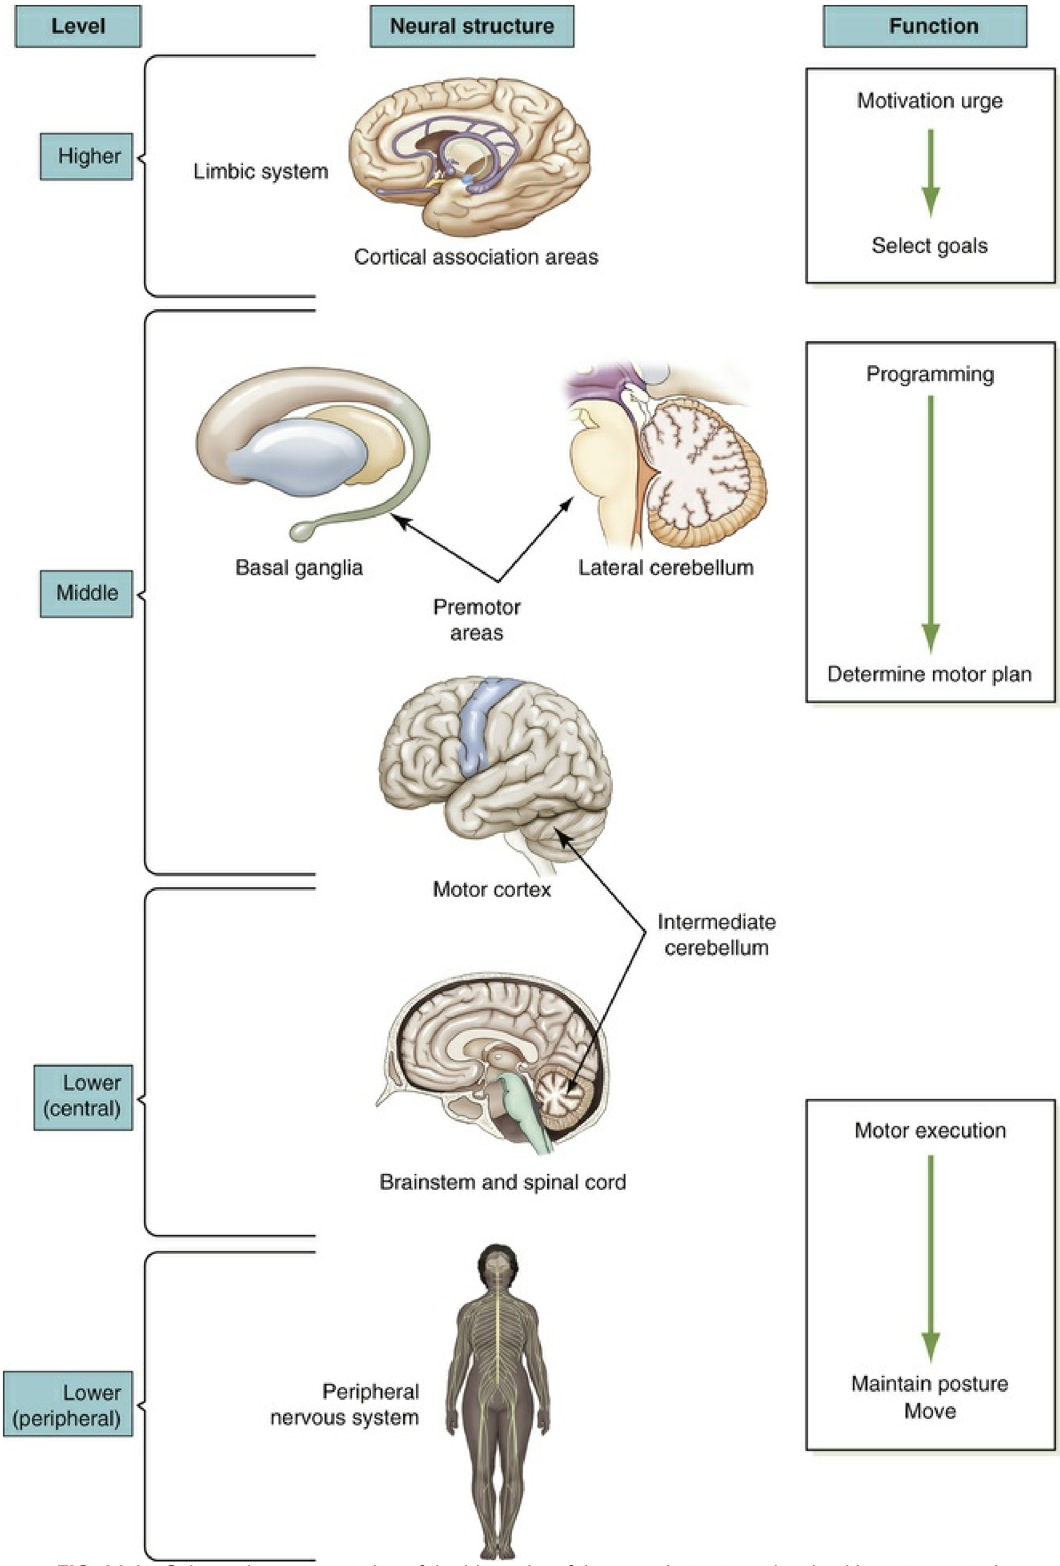

FIG. 31.1 Schematic representation of the hierarchy of the neural structures involved in motor control. The *left column* indicates the hierarchical level and the *right column* the major function of the neural structures shown in the center column during motor performance. (Adapted from Cheney PD: Role of cerebral cortex

in voluntary movements: a review, *Phys Ther* 65:624, 1985.)

The motivation or emotive component of the movement is a function of the limbic system.[10,77] The **motivational urge** or impulse to act associated with the limbic system is transformed to ideas by the cortical association areas. This connection of knowledge and affective behavior is also referred to as **conation**.[39] Conation represents the intentional, deliberate, and goal-directed aspect of behavior and is related to the individual's reason for the motor performance. The association areas of the frontal, parietal, temporal, and occipital lobes are concerned with ideation, or the goal of the movement, and the programming or **movement strategy** (plan) that best achieves the goal. Programming of a movement strategy also involves the premotor areas, the basal ganglia, and the cerebellum. The **motor program** is the procedure or the spatiotemporal order of muscle activation that is needed for smooth and accurate motor performance. The execution level, represented by the motor cortex, the cerebellum, and the spinal cord, is concerned with the activation of the spinal motor neurons and interneurons that generate the goal-directed movement and the necessary postural adjustments.

To appreciate the flow of information leading to purposeful movement, consider the actions of your client Carlos, who sustained a right cerebrovascular accident (RCVA) with resultant left hemiplegia, is thirsty, and is reaching out for a glass of water while seated at a table for support (Fig. 31.2). The limbic system, which connects with the areas of the midbrain and brainstem that control vital functions such as hunger and thirst, has registered the need for water.[37] This need for drinking water has been conveyed to the cortical association areas, which also received visual, auditory, somatosensory, and proprioceptive information about precisely where the body is in space and where the glass of water is relative to the body.[41] This sensory information is needed before the movement is initiated. Strategies or motor plans are formulated to move the arm and hand from their immediate location in space to one in which the glass of water is picked up and moved to the mouth. Motor programs are generated by the association cortex in conjunction with the basal ganglia, lateral cerebellum, and premotor cortex. Once a strategy is selected, the motor cortex is activated. The motor cortex, in turn, conveys the action plan to the brainstem and spinal cord. Activation of the cervical spinal neurons generates a coordinated and precise movement of the shoulder, elbow, wrist, and fingers. Input from the brainstem and cerebellum ensures that the axial musculature makes the necessary postural adjustments. Sensory information during the movement is necessary to ensure the smooth performance of the ongoing movement and to improve subsequent similar movements. Because the motor areas rely heavily on sensory feedback provided by exteroceptors and proprioceptors regarding the accuracy of movement, the structures of the brain that control movement are often referred to as the **sensorimotor system**. Carlos is able to use his right hand to pick up the glass of water but has compromised postural control. When he is supported, sitting at the table, he is able to complete this task, but when standing and holding his cane in his right hand he is unable to use his left arm and hand to reach and pick up the glass of water. The resultant motor problems from the RCVA further compromise his ability to perform a bimanual task such as pouring liquid into a glass even when he has the necessary motivational urge or intention for movement.

FIG. 31.2 A person reaching for a glass of water.

Given the motivation-ideation-programming-execution scheme of how information is organized through the nervous system, it is obvious that control of voluntary movement involves almost all of the neocortex. Voluntary movement depends on knowledge of where the body is in space, where the body intends to go with respect to this external space, the internal and external loads that must be overcome, and formulation of a strategy or plan to perform the movement. Once a strategy or plan has been formulated, it must be held in memory until execution, at which point appropriate instructions are sent to the spinal motor neurons. The primary functional aspects of the sensorimotor areas involved in motor control are examined next.[10,46,77]

Sensorimotor Cortex

The sensorimotor cortex is the major integrating center of sensory input and motor output. It is composed of cortical areas located immediately anterior and posterior to the central sulcus (Fig. 31.3). The three principal motor regions located in the frontal lobe are the primary motor area, the supplementary motor area, and the premotor area. The two principal sensory regions located in the parietal lobe are the primary somatosensory cortex and the posterior parietal cortex. Each area of the sensorimotor cortex (primary motor cortex, primary somatosensory cortex, posterior parietal cortex, supplementary motor area, and premotor cortex) is arranged in a manner that provides a topographical representation of the contralateral body segments.[46,70] Each of these areas is responsible for certain aspects of movement generation. In the previous example of reaching out for the glass of water, Carlos had a mental image of his body and its relation to the surrounding space by integrating the information supplied through somatosensory, proprioceptive, and visual inputs to the posterior parietal cortex. Clients with a lesion in this area demonstrate impairment of body image and its relation to extrapersonal space, and, in the extreme situation, neglect of the contralateral body segments.

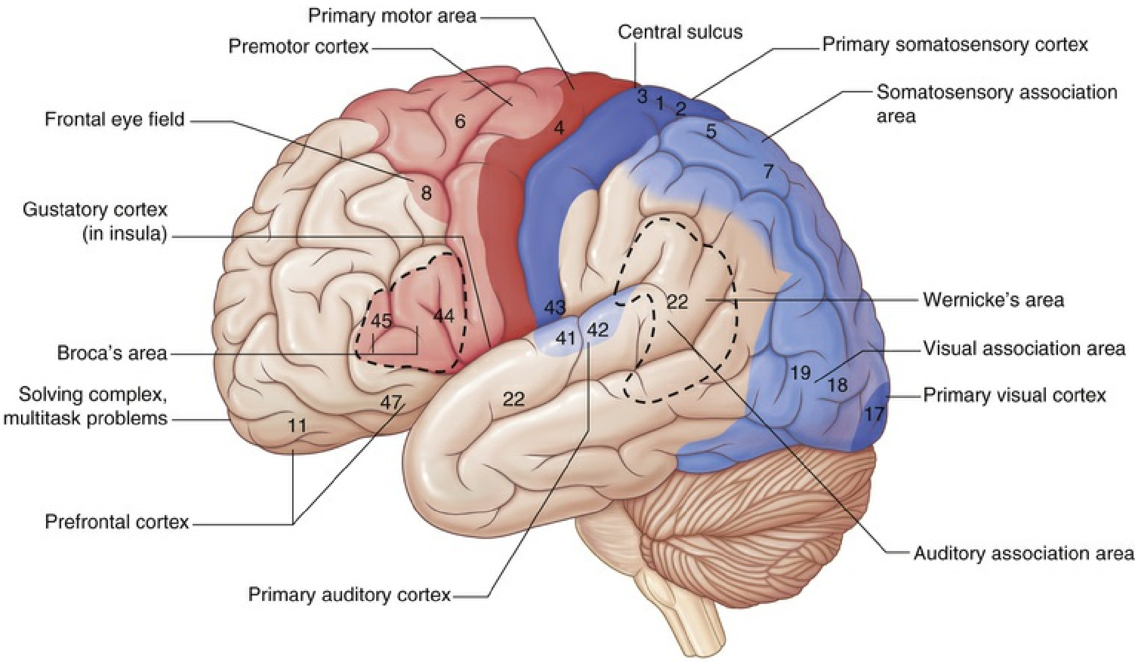

FIG. 31.3 Areas of the neocortex intimately involved in planning of and instruction for voluntary movement. Areas 4 and 6 constitute the motor cortex. (Red: motor cortex; blue: sensory cortex; pale blue and pale red: association cortex.) (From Naish J, Syndercombe D, editors: *Medical sciences*, ed 2, Edinburgh, 2015, Saunders.)

The posterior parietal cortex integrates and translates sensory information so that the ensuing movements are directed appropriately in extrapersonal space. It is extensively interconnected with the association areas of the frontal lobe that are considered to be involved in determining the consequences of movement strategies such as moving the arm forward, curling the fingers around the glass, and lifting the glass to the mouth. The fingers begin to curl appropriately before any contact occurs with the glass; therefore the size and shape of the glass must be recognized before grasping. The prefrontal association areas and the posterior parietal cortex project to the premotor area, which is thought to be concerned with the orientation of body segments before the initiation of movement. The input of the posterior parietal cortex to the premotor area may be important in the somatosensory guidance of movement.[18] Lesions of the premotor area or posterior parietal cortex have been demonstrated to generate an inappropriate movement strategy.[43]

Planning of movement is considered to be the function of the supplementary motor area. In animal studies, the electrophysiologic recordings of cells in this area indicate that the cells typically increase discharge rates about a second before the observable execution of movement of either hand.[89] The same findings have been corroborated in humans with the use of imaging techniques to study patterns of cortical activation. Imaging studies using positron emission tomography (PET) monitor changes in local blood flow, because an increase in the local cerebral blood flow is associated with increased neuronal activity. Under these conditions, when subjects were asked to imagine a movement without actually moving the finger, the blood flow to the supplementary motor cortex increased and no comparable increase in blood flow was seen in the primary motor area.[73] When subjects were asked to perform a series of finger movements from memory, blood flow to the supplementary motor cortex increased in advance of the movement but not during the performance of the movement. Unilateral lesions of the supplementary motor area result in apraxia (the loss of the ability to perform movement in the absence of motor or sensory impairments). Another effect of such lesions is the inability to produce the correct sequence of muscle activation for complex motor activities such as speaking, writing, buttoning, typing, sewing, and playing the piano.

The primary somatosensory cortex projection to the primary motor cortex and association areas provides the sensory input needed for motor planning, movement initiation, and regulation of ongoing movement.[29] The primary motor cortex integrates the information it receives from other areas of the brain and generates the descending command for the execution of movement. Not only is this descending command sent to the brainstem and spinal cord, but a copy of it is also sent to the basal ganglia and cerebellum. The descending command specifies the muscles to be activated and the direction, speed, and required force.[18] Lesions of the primary somatosensory cortex typically result in contralateral sensory loss. Movements are uncoordinated because the ability to register sensory feedback during and after the movement is compromised. Damage to the primary motor area results in motor execution deficits. The client presents the classic picture of contralateral muscle weakness, spasticity, and poor isolation of movement with corresponding loss of function.

Relation to Sensorimotor Intervention Approaches

The CNS structures involved with movement can be grouped functionally into higher, middle, and lower levels. The higher level consists of the limbic system and association areas, where the motivation for action is generated. The sensorimotor areas, along with the basal ganglia and cerebellum, form the middle level, and the lower level consists of the nuclei in the brainstem and spinal cord. Under normal circumstances, an individual's repertoire of motor activity is varied and complex, meeting the unique task and environmental demands. After damage to the CNS regions involved with movement, the coordinated efforts between the various levels of motor control are disrupted, and the motor response may be limited or stereotyped. Traditional sensorimotor approaches to intervention can be viewed as targeting the middle sensorimotor level, the motor planning–strategy formulation process, and the lower level–execution process, with the aim of reintegrating, as far as possible, a complete motor control hierarchy. A motor relearning program (discussed in Chapter 32) should also be cognitively oriented and targeted toward achieving a goal or "occupational" task and include all three levels of CNS function related to motor control. This represents the inherent limitation of the traditional sensorimotor approaches. These approaches do not actively engage the client's volitional intent or motivation to perform a motor act. The limitations of traditional sensorimotor approaches must be carefully considered prior to selecting this form of intervention for the client. The OT practitioner must include activities to foster the **generalizability** of movement patterns to functional and meaningful tasks for clients.

The foundational premise of these traditional sensorimotor approaches posits that clients need to be taught motor strategies or compensatory mechanisms to adapt to the deficits produced by a lesion. Compensatory mechanisms and the shaping of motor programs are brought about by the use of sensory inputs. The sensorimotor approaches use **sensory stimulation** to elicit specific movement patterns. Early in the intervention phase, the emphasis is on the use of external sensory stimuli. Once a movement response is obtained, to reinforce and strengthen the response, the focus shifts to the use of intrinsic sensory information, which thereby encourages voluntary motor control.

The four traditional sensorimotor intervention approaches historically used by occupational therapists (OTs) are the Rood approach, the Brunnstrom (movement therapy) approach, the **proprioceptive neuromuscular facilitation** (PNF) approach, and the Bobath or neurodevelopmental treatment approach. These approaches, developed in the 1950s and 1960s, have their theoretical basis in the reflex and hierarchical models of motor control. Although more contemporary models are currently being used to guide intervention with clients who demonstrate CNS dysfunction, an understanding of these traditional approaches is warranted to appreciate their contributions to clinical practice and to recognize the appropriate application of these approaches in selected populations.

Reflex and Hierarchical Models of Motor Control

Reflex and hierarchical models of motor control view movement strategies along a developmental continuum. Two major fundamental assumptions underlie the reflex and hierarchical models.

The basic units of motor control are reflexes. Reflexes are motor responses that occur in response to specific sensory stimuli. Reflexes are automatic, predictable, and stereotypical; they are normal responses seen from early infancy. As the CNS matures, reflexes become integrated and are believed to form the foundation for volitional motor control. Volitional (purposeful) movement is the summation and integration of reflexive movement. When damage to the CNS occurs, a resurgence of reflexive motor activity occurs in addition to an inability to modulate these reflexive movements.

Motor control is hierarchically arranged. In a hierarchical model of motor control, the CNS is believed to have a specific organizational structure, and motor development and function depend on that structure. This hierarchical organization refers to a system in which the higher centers of the brain regulate and exert control over lower centers of the CNS. The higher centers, specifically the cortical and subcortical areas, are responsible for regulation and control of volitional, conscious movement. The lower levels regulate and control reflexive, automatic, and responsive movement. Based on this conceptualization, when damage occurs to the CNS, it is believed that the damaged area can no longer regulate and exert control over the underlying areas. Motor control, according to this belief, becomes a function of the next lower functioning level of the CNS. Typically this means a return to more reflexive and primitive movement patterns.

The four traditional sensorimotor intervention strategies rely heavily on these basic assumptions about motor development and motor control. Consequently, intervention strategies used in these approaches frequently involve the application of sensory stimulation to muscles and joints to evoke specific motor responses, handling and positioning techniques to effect changes in muscle tone, and the use of developmental postures to enhance the ability to initiate and carry out movements. Table 31.1 presents a comparison and summary of key treatment strategies used in each of the four traditional sensorimotor approaches.

TABLE 31.1

Comparison of Key Treatment Strategies Used in the Traditional Sensorimotor Approaches

Key Treatment Strategies	Rood Approach	Brunnstrom Approach (Movement Therapy)	Proprioceptive Neuromuscular Approach	Neurodevelopmental Treatment
Sensory stimulation used to evoke a motor response	YES (uses direct application of sensory stimuli to muscles and joints)	YES (movement occurs in response to sensory stimuli)	YES (tactile, auditory, and visual sensory stimuli promote motor responses)	YES (abnormal muscle tone occurs, in part because of abnormal sensory experiences)
Reflexive movement used as a precursor for volitional movement	YES (reflexive movement achieved initially through the application of sensory stimuli)	YES (move the patient along a continuum of reflexive to volitional movement patterns)	YES (volitional movements can be assisted by reflexive supported postures)	NO
Treatment directed toward influencing muscle tone	YES (sensory stimuli used to inhibit or facilitate tone)	YES (postures, sensory stimuli used to inhibit or facilitate tone)	YES (movement patterns used to normalize tone)	YES (handling techniques and postures can inhibit or facilitate muscle tone)
Developmental patterns/sequences used for the development of motor skills	YES (ontogenic motor patterns used to develop motor skills)	YES (flexion and extension synergies; proximal to distal return)	YES (patterns used to facilitate proximal to distal motor control)	YES
Conscious attention is directed toward movement	NO	YES	YES	YES
Treatment directly emphasizes the development of skilled movements for task performance	NO	NO	NO	YES

Section 1 Traditional Sensorimotor Intervention Approaches*

Rood Approach

Margaret Rood drew heavily from both the reflex and the hierarchical models in designing her intervention approach.[74-76] Key components of the Rood approach are the use of sensory stimulation to evoke a motor response and the use of developmental postures to promote changes in muscle tone. Sensory stimulation is applied to muscles and joints to elicit a specific motor response. Stimulation has the potential to have either an inhibitory or a facilitatory effect on muscle tone. Rood described various types of sensory stimulation including the use of slow rolling, neutral warmth, deep pressure, tapping, and prolonged **stretch**. Examples of how this stimulation may be applied include tapping over a muscle belly to facilitate (increase) muscle tone and applying deep pressure to a muscle's tendinous insertion to elicit an inhibitory (decreased) effect. Rood also described the use of specific developmental sequences believed to promote motor responses.[75] These sequences were proximal to distal and cephalocaudal. Treatment strategies move clients through these developmental sequences.

In current clinical practice, practitioners may use selected principles from Rood's work as adjunctive or preliminary interventions to prepare an individual to engage in a purposeful activity—for example, the application of quick stretch over the triceps before instructing a client to reach for a cup or glass to improve elbow extension.[86] A client may be instructed in ways to apply his or her own sensory stimulation to enhance activities of daily living (ADLs) performance. For example, during upper extremity dressing, the occupational therapist may ask Carlos to perform a prolonged stretch to the left biceps, which reduces muscle tone, which may, in turn, increase the ease with which the arm is moved through the sleeve of his shirt.

Limitations in the use of Rood's approach are numerous and include the passive nature of the sensory stimulation (it is applied *to* an individual) and the short-lasting and unpredictable effect of some of the sensory stimulation. Please refer to the discussion later in this chapter for additional details regarding the Rood approach to intervention.

Brunnstrom (Movement Therapy) Approach

Signe Brunnstrom, a physical therapist (PT), developed an intervention approach specifically for individuals who had sustained a cerebrovascular accident (CVA).[12,13] The approach she designed draws strongly from both the reflex and hierarchical models of motor control. Brunnstrom conceptualized clients who had sustained a CVA as going through an "evolution in reverse." Spastic or flaccid muscle tone and the presence of reflexive movements that may be evident after a client sustains a CVA are considered part of the normal process of recovery and are viewed as necessary intermediate steps in regaining volitional movement.[80] Brunnstrom clearly detailed stages of motor recovery after a CVA (Table 31.2). These stages include the description of flexor synergy patterns and extensor synergy patterns for the upper and lower limbs and are used as descriptors of change following a CVA.[33] Carlos currently displays flexor tone dominating his left arm and extensor tone dominating his left leg. This dominating tone interferes with isolated control of his left extremities.

TABLE 31.2

Brunnstrom Recovery Stage of Hand Function

Stage	Arm Function (Naghdi et al, 2010, 1373)[68a]	Hand Function (Pandian et al, 2012, 331-332)[69a]
1	Flaccidity is present and no movements of the limbs can be initiated.	Flaccidity.
2	The basic limb synergies or some of their components may appear as associated reactions or minimal voluntary movement responses may be present. Spasticity begins to develop.	Little or no active finger flexion.
3	The patient gains voluntary control of the movement synergies, although full range of all synergy components does not necessarily develop. Spasticity is severe.	Mass grasp; use of hook grasp but no release; no voluntary finger extension; possible reflex extension of digits.
4	Some movement combinations that do not follow the synergies are mastered, and spasticity begins to decline.	Lateral prehension, release by thumb movement; semi-voluntary finger extension of digits, variable range.
5	More difficult movement combinations are possible as the basic limb synergies lose their dominance over motor acts."	Palmar prehension; possibly cylindrical and spherical grasp, awkwardly performed and with a limited functional use; voluntary mass extension of the digits, variable range.
6	"Spasticity disappears and individual joint movements become possible."	All prehensile types under control; skills improving; full range voluntary extension of the digits; individual finger movements present, less accurate than on the opposite side.

Pandian S, Arya KN, Davidson EW: Comparison of Brunnstrom movement therapy and motor relearning program in rehabilitation of post-stroke hemiparetic hand: A randomized trial, *J Bodywork Movement Ther* 16:330–337, 2012.

In the Brunnstrom approach emphasis is placed on facilitating the progress of the individual by promotion of movement, from reflexive to volitional. In the early stages of recovery this may include the incorporation of reflexes and associated reactions to change tone and achieve movement. For example, to generate reflexive movement in the arm, resistance may be applied to one side of the body to increase muscle tone on the opposite side. This technique is applied until the client demonstrates volitional control over the movement pattern.

Proprioceptive Neuromuscular Facilitation Approach

The PNF approach is grounded in the reflex and hierarchical models of motor control. Developed through the collaborative efforts of a physician, Dr. Herman Kabat, and two PTs, Margaret Knott and Dorothy Voss, in the 1950s, this intervention approach continues to be used but has not been revised since its origins. Major emphasis in this approach is on the developmental sequencing of movement and the balanced interplay between agonist and antagonist in producing volitional movement.[97] PNF describes **mass movement patterns**, which are diagonal in nature, for the limbs and trunk. Intervention strategies use these patterns to promote movement. The use of sensory stimulation, including tactile, auditory, and visual inputs, is also actively incorporated into treatment to promote a motor response.

In OT clinical practice the inclusion of PNF patterns often can be seen in the way functional activities are designed, especially in the placement of objects during purposeful activities. For example, a client is asked to reach into a shopping bag placed on his left side to retrieve objects that will then be placed into a cabinet on the right side. Specific information regarding the application of PNF is discussed later in Section 2. This approach has been successfully used to increase range of motion and to stretch tightened muscles.[82] The application of PNF has also been demonstrated to reduce falls in older adults.[85]

Neurodevelopmental Treatment Approach

Neurodevelopmental treatment (NDT), also known as the Bobath treatment approach, is based on normal development and movement. Berta Bobath, a gymnast who later became a PT, and her husband, Karel Bobath, a physician, provided the initial theoretical foundations of NDT in the 1950s.[38] At that time they drew from the hierarchical model of motor control. The primary objectives of neurodevelopmental treatment are to normalize muscle tone, inhibit primitive reflexes, and facilitate normal postural reactions.[8] Improving the quality of movement and helping clients relearn normal movement patterns are key objectives of this approach. To achieve these objectives, therapists employ numerous techniques, including handling techniques, use of **inhibitory techniques** to diminish the negative impact of spasticity on normal movement, weight bearing over the affected limb, the use of positions that encourage the use of both sides of the body, and the avoidance of any sensory input that may adversely affect muscle tone.[25] In clinical practice today, many of these techniques and strategies are used within the context of purposeful activities.

NDT continues to revise its theoretical framework in response to new evidence on the function of the CNS.[38] Discussions on the rationale for NDT include the current understanding of motor systems and motor learning. See Section 3 for further descriptions.

Section 1 Summary

Movement takes place within an occupational context. Emotional needs influence motor strategies. The spinal cord or brainstem can mediate reflexive responses, but interpretation and transformation of sensory signals by all areas of the sensorimotor system are essential for voluntary movement to occur with precision. The primary somatosensory cortex and posterior parietal cortex are primarily responsible for processing sensory information. The premotor area uses sensory information for the planning of movements, the supplementary motor area is important for bimanual coordination, and the motor cortex is important for execution.

The traditional sensorimotor intervention approaches have their theoretical basis in reflex and hierarchical models of motor control. These approaches offer a valuable link between neurophysiologic principles and the rehabilitation treatment of clients with CNS dysfunction. In contemporary practice many of the techniques described in these approaches are used as adjunctive or preliminary techniques or are incorporated into more task-directed treatment activities.

Section 2 Proprioceptive Neuromuscular Facilitation Approach

Winifred Schultz-Krohn

Threaded Case Study

Leticia, Part 1

Leticia, a 34-year-old married mother of two, was involved in an automobile accident in which she sustained a brain injury and fractures of her left wrist and several ribs. Leticia's injuries left her with diplopia, a rigid posture, and lack of motor control as a result of the ataxia. As a mother, Leticia had always been involved with her children and was a teacher's aide at their grade school. It is important to Leticia that she resume her parenting role, including caring for their home, driving a car, and resuming her work in the classroom. Unfortunately, she fatigues quickly and struggles to engage in the routine daily activities that she used to enjoy with her family. She specifically references her desire to be able to play games with her children, prepare family meals, and tutor children in the third grade class in which she assisted before her accident.

Critical Thinking Questions

1. How do you know which movement patterns to select to help Leticia regain the ability to perform these family- and work-related occupations or tasks?

2. Which PNF techniques will most effectively address Leticia's impairments, and how do you select a PNF technique to facilitate the desired performance of a task?

3. How do you determine the progression of intervention from a PNF perspective?

Based on normal movement and motor development, proprioceptive neuromuscular facilitation is more than a technique; it is a philosophy of intervention. Through the case study of Leticia we will discuss the application of PNF to the evaluation and intervention of occupational therapy. Basic principles, diagonal patterns, and more commonly used techniques will be introduced, and their application and presence in routine daily life skills will be demonstrated. PNF addresses the client factors of posture, mobility, strength, effort, and coordination. To use PNF effectively, it is necessary to understand normal development, learn the motor skills to use the techniques, and apply the concepts and techniques to OT activities.[4] This section should form the basis for further reading and training under the supervision of a therapist experienced in PNF.

PNF is based on normal movement and motor development. In normal motor activity the brain registers total movement and not individual muscle action.[42] Encompassed in the PNF approach are mass movement patterns that are spiral and diagonal in nature and that resemble movement seen in functional activities. In this multisensory approach, facilitation techniques are superimposed on movement patterns and postures through the therapist's **manual contacts**, **verbal commands**, and visual cues. These facilitation techniques and movement patterns can be preparatory methods that prepare clients to participate more effectively in their daily occupations or they can be applied within the performance of a task.

PNF is used as an intervention technique for numerous conditions, including Parkinson's disease, spinal cord injuries, arthritis, stroke, head injuries, and hand injuries. It has been effectively combined with neuromobilization techniques to reduce sensory deficits in individuals who sustained a CVA.[103]

History

PNF originated in the 1940s with Dr. Herman Kabat, a physician and neurophysiologist. He applied neurophysiologic principles, based on the work of Sherrington, to the intervention of paralysis secondary to poliomyelitis and multiple sclerosis. In 1948 Kabat and Henry Kaiser founded the

Kabat-Kaiser Institute in Vallejo, California. Here Kabat worked with PT Margaret Knott to develop the PNF method of intervention. By 1951 the diagonal patterns and core techniques were established. PNF is now used to treat numerous neurologic, musculoskeletal, and general medical conditions.

In 1952 Dorothy Voss, a PT, joined the staff at the Kaiser-Kabat Institute. She and Knott undertook the teaching and supervision of staff therapists. In 1954 Knott and Voss presented the first 2-week course in Vallejo. Two years later, the first edition of *Proprioceptive Neuromuscular Facilitation* by Margaret Knott and Dorothy Voss was published.

During this same period several reports in the *American Journal of Occupational Therapy* described PNF and its application to OT intervention.[4,17,20,45,94,101] It was not until 1974 that the first PNF course for OT practitioners, taught by Dorothy Voss, was offered. Since then, Beverly Myers, an occupational therapist, and others have offered courses for OT practitioners throughout the United States. In 1984 PNF was first taught concurrently to both PTs and OT practitioners at the Rehabilitation Institute in Chicago.[68,97] Today courses are offered throughout the United States as well as Europe, Asia, and South America. Currently, four main theoretical models are used to explain the beneficial effects of PNF to improve motor performance: autogenic inhibition, **reciprocal inhibition**, stress relaxation, and the gate control theory.[36]

Principles of Intervention

Voss presented 11 principles of intervention at the Northwestern University Special Therapeutic Exercise Project in 1966. These principles were developed from concepts in the fields of neurophysiology, motor learning, and motor behavior and are still essential to the practice of PNF today.[95]

All human beings have potentials that have not been fully developed. This philosophy is the underlying basis of PNF. Therefore in evaluation and intervention planning, the client's abilities and potentials are emphasized. For example, the client who has weakness on one side of the body can use the intact side to assist the weaker part. Likewise, the client who has hemiplegia with a flaccid arm can use the intact head, neck, and trunk musculature to begin reinforcement of the weak arm in weight-bearing activities.

Normal motor development proceeds in a cervicocaudal and proximodistal direction. The cervicocaudal and proximodistal direction is followed in evaluation and intervention. When severe disability is present, attention is first given to the head and neck region, with its visual, auditory, and vestibular receptors, and then to the upper trunk and extremities. If the superior region is intact, an effective source of reinforcement for the inferior region is available.[97] The proximodistal direction is followed by developing adequate function in the head, neck, and trunk before developing function in the extremities. This approach is of particular importance in intervention that facilitates fine motor coordination in the upper extremities. Unless adequate control exists in the head, neck, and trunk region, fine motor skills cannot be developed effectively. For example, Leticia needs to strengthen her head, neck, and trunk muscles to regain adequate postural control before she can adequately perform fine motor tasks required in her job such as cutting with scissors. This illustrates how addressing a specific client factor of postural control can influence occupational performance.

Early motor behavior is dominated by reflex activity. Mature motor behavior is supported or reinforced by postural reflexes. As the human being matures, primitive reflexes are integrated and available for reinforcement to allow for progressive development such as that of rolling, crawling, and sitting. Reflexes also have been noted to have an effect on tone changes in the extremities. Hellebrandt, Schade, and Carns[35] studied the effect of the tonic neck reflex (TNR) and the asymmetric tonic neck reflex (ATNR) on changes in tone and movement in the extremities of normal adults. They found that head and neck movement significantly affected arm and leg movement. In applying this finding to intervention, for example, weak elbow extensors can be reinforced with the ATNR by having the client look toward the side of weakness. Likewise, the client can be assisted in assuming postures with the influence of reflex support. For example, Leticia can use the body-on-body righting reflex to support her ability to assume sitting upright on the edge of the bed from a side-lying position when she gets up in the morning.

Early motor behavior is characterized by spontaneous movement, which oscillates between extremes of flexion and extension. These movements are rhythmic and reversing in character. In intervention it is important to attend to both directions of movement. When the OT practitioner is working with the client on getting up from a chair, attention also must be given to sitting back down. Often with an injury, the eccentric contraction (eg, sitting down) is lost and becomes very difficult for the client to regain. If not properly treated, the client may be left with inadequate motor control to sit down smoothly and thus may "drop" into a chair. This eccentric control would be particularly important for Leticia because she is required to sit in low chairs at her children's school. Similarly, in training for ADLs the client must learn how to get undressed and dressed.

Developing motor behavior is expressed in an orderly sequence of total patterns of movement and posture. In the normal infant the sequence of total patterns is demonstrated through the progression of locomotion. The infant learns to roll, to crawl, to creep, and finally to stand and walk. Throughout these stages of locomotion the infant also learns to use the extremities in different patterns and within different postures. Initially the hands are used for reaching and grasping within the most supported postures, such as supine and prone. As postural control develops, the infant begins to use the hands in side-lying, sitting, and standing positions. In intervention, to maximize motor performance, clients should be given opportunities to work in a variety of developmental postures. The use of extremities in total patterns requires interaction with component patterns of the head, neck, and trunk. For example, in swinging a tennis racquet in a forehand stroke, the arm and the head, neck, and trunk move in the direction of the swing. Without the interaction of the distal and proximal components, movement becomes less powerful and less coordinated.

The growth of motor behavior has cyclic trends, as evidenced by shifts between flexor and extensor dominance. The shifts between antagonists help to develop muscle balance and control. One of the main goals of the PNF intervention approach is to establish a balance between antagonists. Developmentally the infant establishes this balance before creeping (ie, when rocking forward [extensor dominant] and backward [flexor dominant] on hands and knees). Postural control and balance must be achieved before movement can begin in this position. In intervention it is important to establish a balance between antagonistic muscles by first observing where imbalance exists and then facilitating the weaker component. For example, if the client who has a stroke demonstrates a flexor synergy (flexor dominant), extension should be facilitated.

Normal motor development has an orderly sequence but lacks a step-by-step quality. Overlapping of skills occurs. The child does not perfect performance of one activity before beginning another, more advanced activity. In trying to ascertain in which total pattern to position the client, normal motor development should be heeded. If one technique or developmental posture is not effective in obtaining the desired result, it may be necessary to try the activity in another developmental posture. For example, if a client who has ataxia, such as Leticia, is unable to perform a fine motor task while sitting, it may be necessary to practice skills in a more supported posture, such as prone on the elbows or with her elbows supported on a surface such as a table. Just as the infant reverts to a more secure posture when attempting a complex fine motor task, the client also needs a secure posture when attempting more challenging tasks. On the other hand, if the client has not perfected a motor activity such as walking on level surfaces, he or she may benefit from attempting a higher-level activity such as walking up or down stairs, which in turn can improve ambulation on level surfaces. It is natural for the client to move up and down the developmental sequence, and this allows multiple and varied opportunities for practicing motor activities. The cognitive demands of the task in relation to the developmental posture also must be considered. When the client's position is varied, either by changing the base of support or by shifting weight on different extremities, the quality of visual and cognitive processing is influenced.[1]

Locomotion depends on reciprocal contraction of flexors and extensors, and the maintenance of posture requires continual adjustment for nuances of imbalance. Antagonistic pairs of movements, reflexes, and muscles and joint motion interact as necessary with the movement or posture. This principle restates one of the main objectives of PNF—to achieve a balance between antagonists. An example of imbalance is the client with a head injury who is unable to maintain adequate sitting balance for a tabletop cognitive activity because of a dominance of trunk extensor tone. Another example is the client who has hemiplegia with tight finger flexors secondary to flexor-dominant tone in the hand. In intervention, emphasis is placed on correcting the imbalances. In the presence of spasticity, first the spasticity is inhibited and then the antagonistic muscles, reflexes, and postures are facilitated.

Improvement in motor ability is dependent on motor learning. Multisensory input from the therapist facilitates the client's motor learning and is an integral part of the PNF approach. For example, the therapist may work with a client on a shoulder flexion activity such as reaching into the cabinet for a cup. The therapist may say, "Reach for the cup," to add verbal input. This approach also encourages the client to look in the direction of the movement to allow vision to enhance the motor response. Thus tactile, auditory, and visual inputs are used. Motor learning has occurred when these external cues are no longer needed for adequate performance.

Frequency of stimulation and repetitive activity are used to promote and retain motor learning and to develop strength and endurance. Just as the therapist who is learning PNF needs the opportunity to practice the techniques, the client needs the opportunity to practice new motor skills. With practice, habits will be formed that support motor performance in occupation. In the process of development, the infant constantly repeats a motor skill in many settings and developmental postures until it is mastered, as becomes apparent to anyone who watches a child learning to walk. Numerous attempts fail, but the child repeats the efforts until the skill is mastered. After the activity is learned, it becomes part of the child. He or she is able to use the activity automatically and deliberately as the occasion demands.[97] The same is true for the person learning to play the piano or to play tennis. Without the opportunity to practice, motor learning cannot successfully occur. Just as Leticia's students may be given homework to help them practice the material they learn in school, Leticia will also need to be given a home program that encourages her to practice the postures and movements facilitated in therapy.

Goal-directed activities coupled with techniques of facilitation are used to hasten learning of total patterns of walking and self-care activities. When facilitation techniques are applied to self-care, the objective is improved functional ability, but improvement is obtained by more than instruction and practice. Deficiencies are corrected by the direct application of manual contacts and techniques to facilitate a desired response.[40] During an intervention session, this approach may mean applying stretch to finger extensors to facilitate the release of an object or providing joint approximation through the shoulders and pelvis of a client who has ataxia to provide stability while the client is standing to wash dishes. With repetition of appropriate facilitation techniques, Leticia will have the opportunity to feel more normal movement and need to rely less on the therapist's external input.

Motor Learning

Motor learning requires a multisensory approach. Auditory, visual, and tactile systems are all used to achieve the desired response. The correct combination of sensory input with each client should be ascertained, implemented, and altered as the client progresses. The developmental level of the client and the ability to cooperate also should be taken into consideration.[97] The approach used with a client who has aphasia differs from the approach used with a client who has a hand injury. For example, the client with a hand injury would better understand verbal instructions than would the client with aphasia. Fewer verbal and more tactile and gestural cues would be appropriate with the client who has aphasia. Similarly, the approach used with a child varies greatly from that used with an adult. Interventions with Leticia must take into consideration her visual deficits in addition to any cognitive impairment that remains as a result of her head injury.

Auditory System

Verbal commands should be brief and clear. It is important to time the command so that it does not come too early or too late in relation to the motor act. Tone of voice may influence the quality of the client's response. Buchwald[14] stated that tones of moderate intensity evoke gamma motor neuron activity and that louder tones can alter alpha motor neuron activity. Strong, sharp commands simulate a stress situation and are used when maximal stimulation of motor response is desired. A soft tone of voice is used to offer reassurance and to encourage a smooth movement, as in the presence of pain (eg, when techniques are used to increase the mobility in Leticia's left wrist). When a client is giving the best effort, a moderate tone can be used.[97]

Another effect of auditory feedback on motor performance was studied by Loomis and Boersma.[54] They used a **verbal mediation** strategy to teach wheelchair safety before transferring out of the chair to clients with right CVA. Loomis and Boersma taught clients to say aloud the steps required to leave the wheelchair safely and independently. They found that only clients who used verbal mediation learned the wheelchair drill sufficiently to perform safe and independent transfers. These clients also had better retention of the sequence of steps, which suggests that verbal mediation is beneficial in reaching independence with better sequencing and fewer errors.

When Leticia first arrived in therapy, she suffered considerable pain at the site of her wrist fracture. Early PNF intervention should use soft verbal commands when activities that involve wrist mobility are performed. In contrast, when facilitating Leticia's ability to assume postures (ie, moving from side-lying to tall kneeling), more forceful, sharp commands may be needed.

Visual System

Visual stimuli assist in initiation and coordination of movement. Visual input should be monitored to ensure that the client is tracking in the direction of movement. For example, the therapist's position is important because the client often uses the therapist's movement or position as a visual cue. If the therapist desires Leticia to move in a forward direction, he or she should be positioned diagonally in front of the client. In addition to the therapist's position, placement of the OT activity also should be considered. Using one of her children's favorite board games, the therapist could place it in front and to the left of Leticia to increase head, neck, and trunk rotation. Because OT is activity oriented, an abundance of visual stimuli is offered to the client.

Special consideration will need to be given to the use of vision when working with Leticia. Her stronger head and neck musculature can be used to reinforce oculomotor control. Total body and extremity diagonal patterns can be used to reinforce eye teaming.

Tactile System

Developmentally the tactile system matures before the auditory and visual systems.[26] Furthermore, the tactile system is more efficient. This is because it has temporal and spatial discrimination abilities, as opposed to the visual system, which can make only spatial discriminations, and the auditory system, which can make only temporal discriminations.[32] Affolter[2] stated that during development, processing of tactile-kinesthetic information can be considered fundamental for building cognitive and emotional experience. Looking at and listening to the world do not result in change; however, the world cannot be touched without some change taking place. A Chinese proverb often cited at PNF courses reinforces this viewpoint: “I listen and I forget, I see and I remember, I do and I understand.”

It is important for the client to feel movement patterns that are coordinated and balanced. This is particularly important for clients with ataxia, such as Leticia. With the PNF approach, tactile input is supplied through the therapist's manual contacts to guide and reinforce the desired response. This approach may involve gently touching the client to guide movement, using stretch to initiate movement, and providing resistance to strengthen movement. The type and extent of manual contacts depend on the client's clinical status, which is determined through evaluation and reevaluation. For example, the use of stretch or resistance in the presence of musculoskeletal instability may be contraindicated, as in the early healing phases of Leticia's fractures. Likewise, stretch or resistance should not be used if they cause increased pain or tone imbalance.

To increase speed and accuracy in motor performance, the client needs the opportunity to practice. Through repetition, habit patterns that occur automatically without voluntary effort are established. The PNF approach uses the concepts of **part-task practice** and **whole-task practice**. In other words, to learn the whole task, emphasis is placed on the parts of the task that the client is unable to perform independently. The term **stepwise procedures** describes the emphasis on a part of the task during performance of the whole.[97] Performance of each part of the task is improved by combining practice with appropriate sensory cues and techniques of facilitation. For example, the client learning to transfer from a wheelchair to a tub bench may have difficulty lifting the leg over the tub rim. This part of the task should be practiced, with repetition and facilitation techniques to the hip flexors, during performance of the transfer. When the transfer becomes smooth and coordinated, it is no longer necessary to practice each part individually. It is also unnecessary for the therapist to facilitate.

Leticia has difficulty getting down on the floor to play games with her children. In intervention, she should be provided with facilitation and practice of moving from sitting on a chair to tall kneeling to side-sitting on the floor. She will initially require considerable manual facilitation by the therapist to move through and achieve these various movement patterns. As she develops more skill, the therapist will reduce and adjust the intensity of the tactile input.

In summation, several components are necessary for motor learning to occur. In the PNF intervention approach, these components include multisensory input from the therapist's verbal commands, visual cues, and manual contacts. Touch is the most efficient form of stimulation and provides the opportunity for the client to feel normal movement. Current motor-learning theory argues that for motor learning to occur, the client cannot be a passive recipient of intervention.

Therefore the client needs opportunities to practice motor skills in the context of functional life situations. Initially the therapist's manual contacts and sensory input are needed. These should be decreased, however, as the client demonstrates and learns skilled movement. The amount of feedback from the therapist should also be decreased as the client learns to rely on his or her own internal feedback system for error detection and correction.

Assessment

Assessment requires astute observational skills and knowledge of normal movement. An initial assessment is completed to determine the client's abilities, deficiencies, and potential. After the intervention plan is established, ongoing assessment is necessary to ascertain the effectiveness of intervention and to make modifications as the client changes.

The PNF assessment follows a sequence from proximal to distal. First, vital and related functions are considered, such as breathing, swallowing, voice production, facial and oral musculature, and visual-ocular control. Any impairment or weakness in these functions is noted. Because Leticia fatigues quickly, breathing patterns and efficiency need to be closely evaluated as she engages in her daily activities.

The head and neck region is observed after vital functions. Deficiencies in this area directly affect the upper trunk and extremities. Head and neck positions are observed in varying postures and total patterns during functional activities. It is important to note (1) dominance of tone (flexor or extensor), (2) alignment (midline or shift to one side), and (3) stability and mobility (more or less needed).[68]

After observation of the head and neck region, the assessment proceeds to the following parts of the body: upper trunk, upper extremities, lower trunk, and lower extremities. Each segment is assessed individually in specific movement patterns, in addition to in developmental activities in which the body segments interact. For example, shoulder flexion can be observed in an individual upper-extremity movement pattern, in addition to during a total developmental pattern such as rolling.

During assessment of developmental activities and postures, the following issues should be addressed:

- Is there a need for more stability or mobility?
- Is there a balance between flexors and extensors, or is one more dominant?
- Is the client able to move in all directions?
- What are the major limitations (eg, weakness, incoordination, spasticity, and contractures)?
- Is the client able to assume a posture and to maintain it? If not, which total pattern or postures are inadequate?
- Are the inadequacies more proximal or distal?
- Which sensory input does the client respond to most effectively: auditory, visual, or tactile?
- Which techniques of facilitation does the client respond to best?

When applying these questions to Leticia's evaluation, the following observations can be made. First, Leticia will need to develop stability to diminish the effects of her ataxia. She is not dominated by either flexor or extensor tone, but when fatigued she has more difficulty maintaining upright posture. She will therefore need to have facilitation of head, neck, and trunk extensors when fatigued. She can move in all directions but has less stability when walking backward. Her major limitations are poor motor control and rigidity, but prevention of a wrist contracture is also a concern. Leticia is having difficulty assuming kneeling, sitting, and standing postures because of her instability. Once in an upright posture, she can maintain it for a few minutes, but then fatigue sets in. She will therefore need to build endurance in more supported lower developmental postures. When moving into more upright postures, she will need PNF techniques to build strength and endurance. Her inadequate proximal control and trunk rigidity impact her ability to effectively use her extremities, especially in higher developmental positions. Visual sensory input may not be the best to start with because of her diplopia; however, facilitation of oculomotor control using PNF techniques will be of benefit as she progresses. Facilitation techniques that Leticia responds to best are rhythmic stabilization, stabilizing reversals, and approximation.

Finally the client is observed during self-care and other ADLs to determine whether performance of individual and total patterns is adequate within the context of a functional activity. The client's performance may vary from one setting to another. After the client leaves the structured setting of the OT or PT clinic for the less structured home or community environment, deterioration of motor performance is not unusual. Thus the intervention plan must accommodate the practice of motor performance in a variety of settings in locations appropriate to the specific activity.

Intervention Implementation

After assessment, an intervention plan is developed that includes goals the client hopes to accomplish. The techniques and procedures that have the most favorable influence on movement and posture are used. Similarly, appropriate total patterns (developmental postures) and patterns of facilitation are selected to enhance performance.

Diagonal Patterns

The **diagonal patterns** used in the PNF approach are mass movement patterns observed in most functional activities. Part of the challenge in OT assessment and intervention is recognizing the diagonal patterns in ADLs. Knowledge of the diagonals is necessary for identifying areas of deficiency. Two diagonal motions are present for each major part of the body: head and neck, upper and lower trunk, and extremities. Each diagonal pattern has a flexion and extension component, together with rotation and movement away from or toward the midline.

The head, neck, and trunk patterns are referred to as (1) flexion with rotation to the right or left and (2) extension with rotation to the right or left. These proximal patterns combine with the extremity diagonals. The upper and lower extremity diagonals are described according to the three movement components at the shoulder and hip: (1) flexion and extension, (2) abduction and adduction, and (3) external and internal rotation. Voss[95] introduced shorter descriptions for the extremity patterns in 1967 and referred to them as diagonal 1 (D_1) flexion/extension and diagonal 2 (D_2) flexion/extension. The reference points for flexion and extension are the shoulder and hip joints of the upper and lower extremities, respectively.

The movements associated with each diagonal and examples of these patterns seen in self-care and other ADLs are presented in the following sections. Note that in functional activities, not all components of the pattern or full range of motion (ROM) are necessarily seen. Furthermore, the diagonals interact during functional movement, changing from one pattern or combination to another, when they cross the transverse and sagittal planes of the body.[67]

Unilateral Patterns

Various **unilateral patterns** can be applied:

1. Upper extremity (UE) D_1 flexion (shoulder flexion-adduction-external rotation): scapula elevation, abduction, and rotation; shoulder flexion, adduction, and external rotation; elbow in flexion or extension; forearm supination; wrist flexion to the radial side; finger flexion and adduction; thumb adduction (Fig. 31.4, A). Examples in functional activity: hand-to-mouth motion in feeding, tennis forehand, combing hair on the left side of the head with right hand (Fig. 31.5, A), rolling from supine to prone.

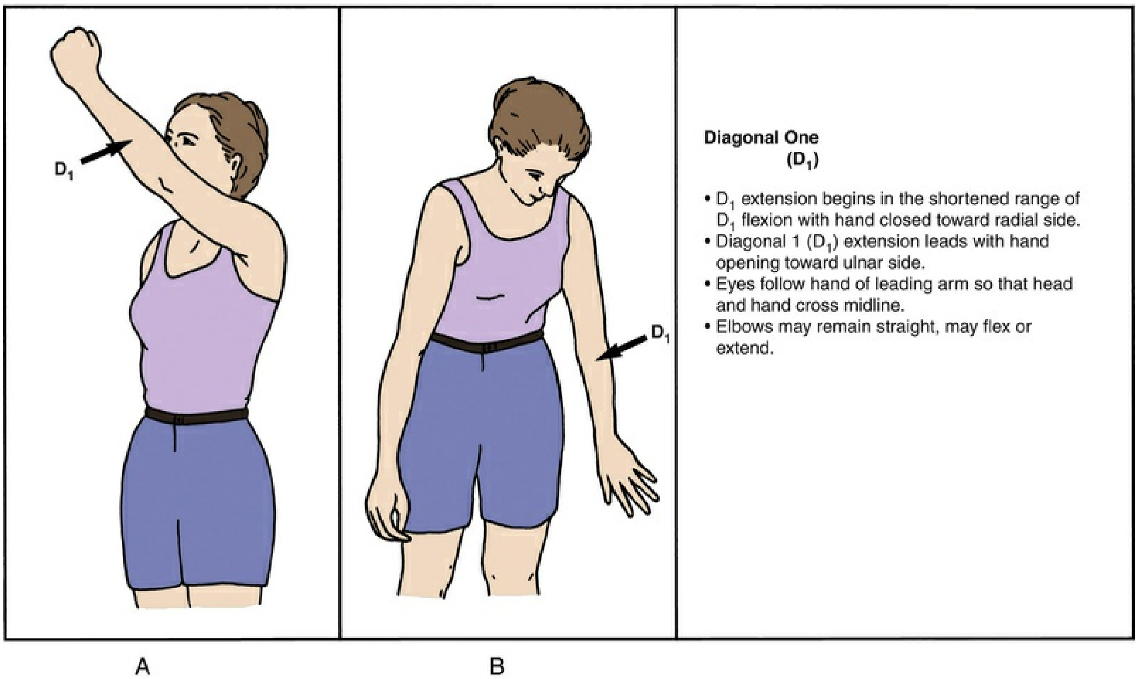

FIG. 31.4 **A,** Upper extremity D_1 flexion pattern. **B,** Upper extremity D_1 extension pattern. (From Myers BJ: Unit I: *PNF diagonal patterns and their application to functional activities, videotape study guide,* Chicago, 1982, Rehabilitation Institute of Chicago.)

FIG. 31.5 **A,** Upper extremity D_1 flexion pattern used to comb the hair, opposite side. **B,** Upper extremity D_1 extension pattern used to push a car door open. (*A,* From iStock.com.)

2. UE D_1 extension (shoulder extension-abduction-internal rotation): scapula depression, adduction, and rotation; shoulder extension, abduction, and internal rotation; elbow in flexion or extension; forearm pronation; wrist extension to the ulnar side; finger extension and abduction; thumb in palmar abduction (Fig. 31.4, B). Examples in functional activity: pushing a car door open from the inside (Fig. 31.5, B), tennis backhand stroke, rolling from prone to supine.

3. UE D_2 flexion (shoulder flexion-abduction-external rotation): scapula elevation, adduction, and rotation; shoulder flexion, abduction, and external rotation; elbow in flexion or extension; forearm supination; wrist extension to the radial side; finger extension and abduction; thumb extension (Fig. 31.6, A). Examples in functional activity: combing hair on the right side of the head with the right hand (Fig. 31.7, A), lifting a racquet in tennis serve, backstroke in swimming. The D_2 flexion pattern would be emphasized with Leticia in her left upper extremity to facilitate supination and wrist extension, which are weak secondary to her wrist fracture.

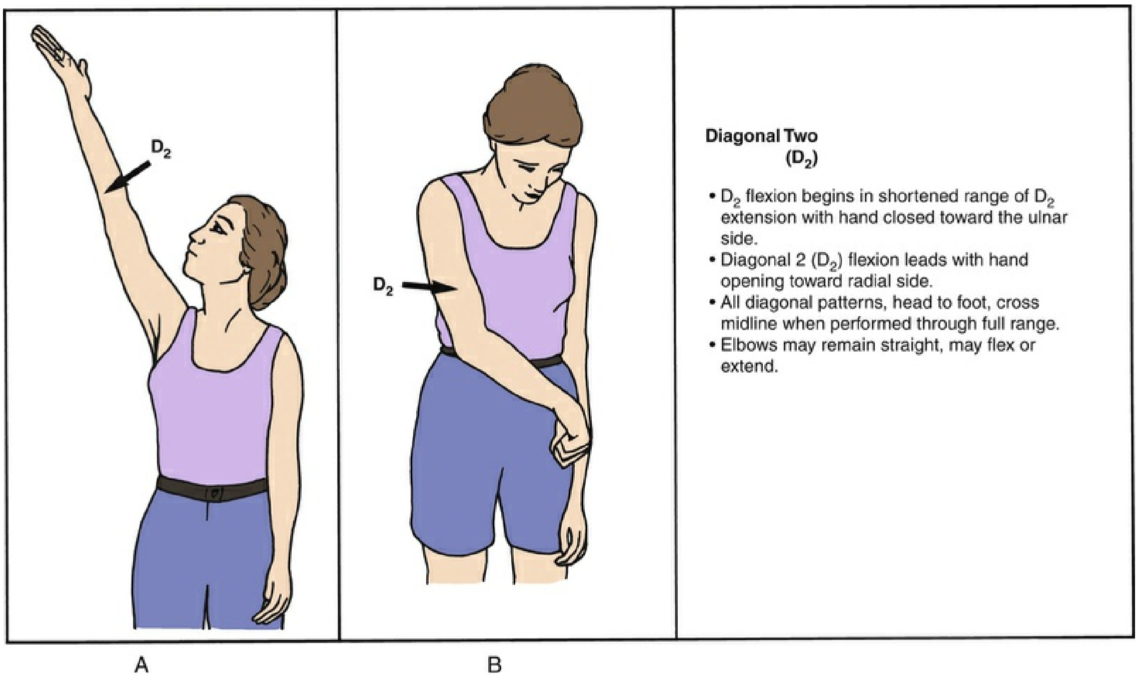

FIG. 31.6 **A,** Upper extremity D_2 flexion pattern. **B,** Upper extremity D_2 extension pattern. (From Myers BJ: Unit I: *PNF diagonal patterns and their application to functional activities, videotape study guide,* Chicago, 1982, Rehabilitation Institute of Chicago.)

FIG. 31.7 **A** and **B,** Upper extremity D_2 flexion pattern used to comb the hair, same side. **C,** Upper extremity D_2 extension pattern used to button trousers, opposite side. (*A*, From iStock.com. *B*, From Shutterstock.com.)

4. UE D_2 extension (shoulder extension-adduction-internal rotation): scapula depression, abduction, and rotation; shoulder extension, adduction, and internal rotation; elbow in flexion or extension; forearm pronation; wrist flexion to the ulnar side; finger flexion and adduction; thumb opposition (Fig. 31.6, B). Examples in functional activity: pitching a baseball, hitting a ball in tennis serve, buttoning pants on the left side with the right hand (Fig. 31.7, C). The rotational component in lower extremity (LE) D_1 flexion and extension parallels the UE patterns.

5. LE D_1 flexion (hip flexion-adduction-external rotation): hip flexion, adduction, and external rotation; knee in flexion or extension; ankle and foot dorsiflexion with inversion and toe extension. Examples in functional activity: kicking a soccer ball, rolling from supine to prone, putting on a sock with legs crossed (Fig. 31.8, A).

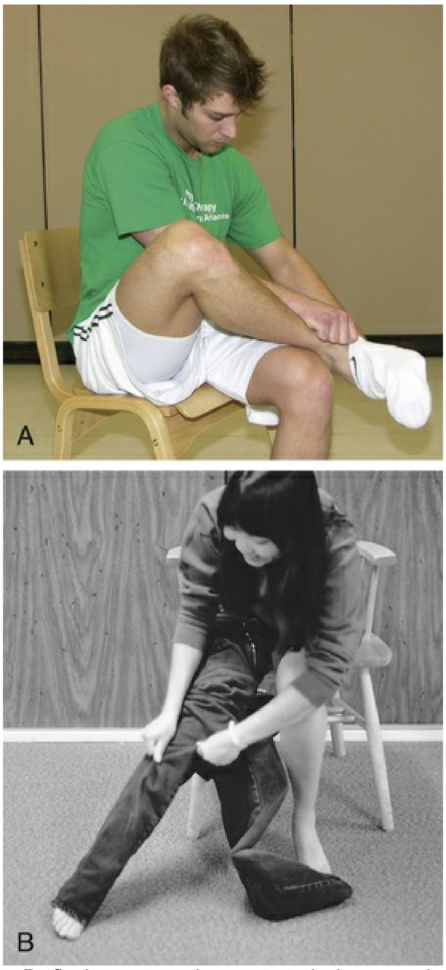

FIG. 31.8 **A,** Lower extremity D_1 flexion pattern demonstrated when crossing the leg to put on a sock. **B,** Lower extremity D_1 extension pattern used when pulling on trousers. (*A,* From Reese NB, Bandy WD: *Joint range of motion and muscle length testing,* ed 3, St. Louis, 2017, Elsevier.)

6. LE D_1 extension (hip extension-abduction-internal rotation): hip extension, abduction, and internal rotation; knee in flexion or extension; ankle and foot plantar flexion with eversion and toe flexion. Examples in functional activity: putting leg into pants (Fig. 31.8, B), rolling from prone to supine. The rotational component of LE D_2 flexion and extension is opposite to the UE patterns.

7. LE D_2 flexion (hip flexion-abduction-internal rotation): hip flexion, abduction, and internal rotation; knee in flexion or extension; ankle and foot dorsiflexion with eversion and toe extension. Examples in functional activity: karate kick (Fig. 31.9, A), drawing the heels up during the breaststroke in swimming.

FIG. 31.9 **A,** Lower extremity D_2 flexion pattern shown in a karate kick. **B,** Lower extremity D_2 extension pattern used in long sitting with the legs crossed. (*A,* From Shutterstock.com. *B,* From DAJ [via Thinkstock.com].)

8. LE D_2 extension (hip extension-adduction-external rotation): hip extension, adduction and external rotation: knee in flexion or extension; ankle and foot in plantar flexion with inversion and toe flexion. Examples of functional activity: push-off in gait, the kick during the breaststroke in swimming, long sitting with legs crossed (Fig. 31.9, B).

Bilateral Patterns

Movements in the extremities may be reinforced by combining diagonals in **bilateral patterns** as follows:

1. **Symmetric patterns**: Paired extremities perform similar movements at the same time (Fig. 31.10, A). Examples: bilateral symmetric D_1 extension, such as pushing off a chair to stand (Fig. 31.11, A); bilateral symmetric D_2 extension, such as starting to take off a pullover sweater (Fig. 31.11, B); bilateral symmetric D_2 flexion, such as reaching to lift a large item off a high shelf (Fig. 31.11, C). Bilateral symmetric UE patterns facilitate trunk flexion and extension.

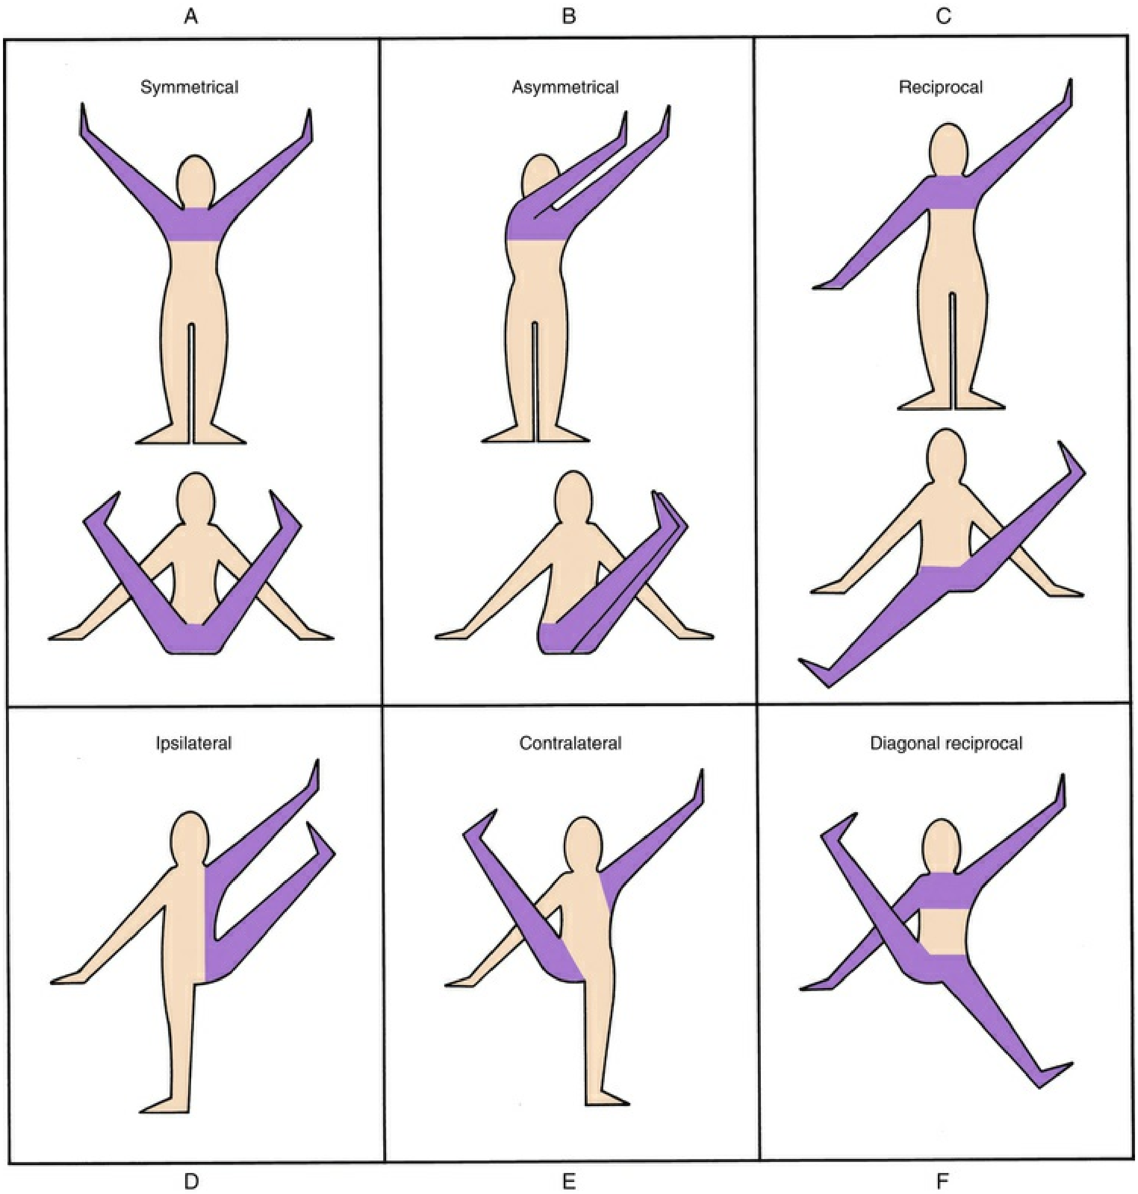

FIG. 31.10 **A,** Symmetric patterns. **B,** Asymmetric patterns. **C,** Reciprocal patterns. **D,** Ipsilateral pattern. **E,** Contralateral pattern. **F,** Diagonal reciprocal pattern. (From Myers BJ: Unit I: *PNF diagonal patterns and their application to functional activities, videotape study guide,* Chicago, 1982, Rehabilitation Institute of Chicago.)

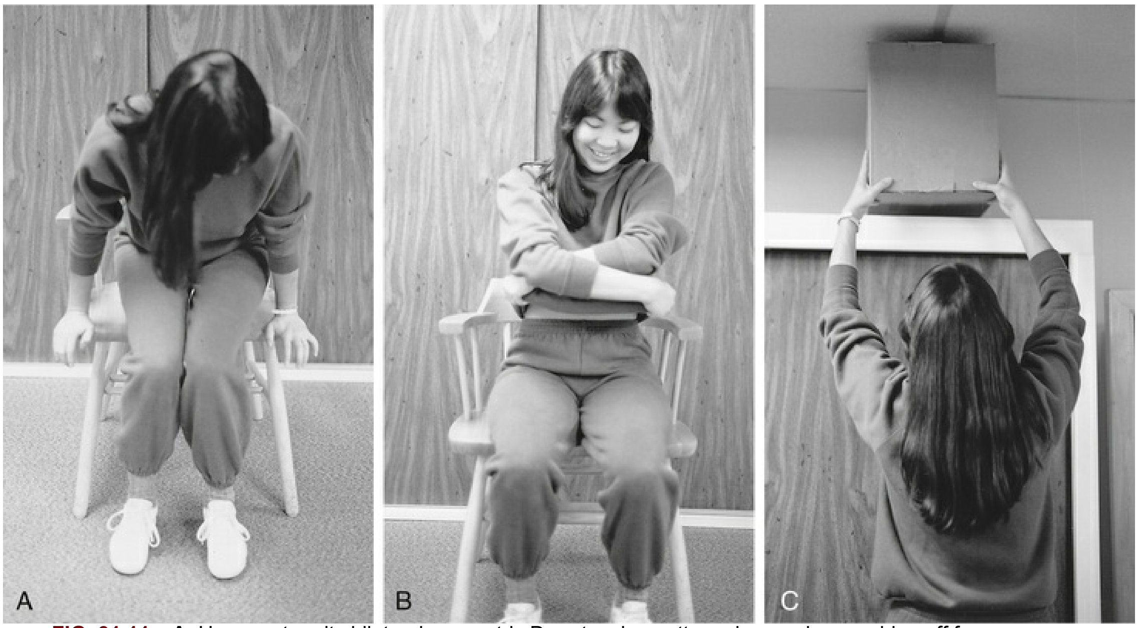

FIG. 31.11 **A,** Upper extremity bilateral symmetric D_1 extension pattern shown when pushing off from a chair. **B,** Upper extremity bilateral symmetric D_2 extension pattern used when starting to take off a pullover shirt. **C,** Upper extremity bilateral symmetric D_2 flexion pattern used when reaching to lift a box off a high shelf.

2. **Asymmetric patterns**: Paired extremities perform movements toward one side of the body at the same time, which facilitates trunk rotation (Fig. 31.10, B). The asymmetric patterns can be performed with the arms in contact, such as in the chopping and lifting patterns in which greater trunk rotation is seen (Figs. 31.12 and 31.13). Furthermore, with the arms in contact, self-touching occurs. This is frequently observed in the presence of pain or in reinforcement of a motion when greater control or power is needed.[97] This phenomenon is observed in the baseball player at bat and in the tennis player who uses a two-handed backhand to increase control and power. Asymmetric patterns with arms in contact would be beneficial for Leticia to control ataxia. Examples of asymmetric patterns are bilateral asymmetric flexion to the left, with the left arm in D_2 flexion and the right arm in D_1 flexion, such as when putting on a left earring (Fig. 31.14), and bilateral asymmetric extension to the left, with the right arm in D_2 extension and the left arm in D_1 extension, such as when zipping a left-side zipper.

3. **Reciprocal patterns**: Paired extremities move in opposite directions simultaneously, either in the same diagonal or in combined diagonals. If paired extremities perform movements in combined diagonals (Fig. 31.10, C), a stabilizing effect occurs on the head, neck, and trunk because movement of the extremities is in the opposite direction while head and neck remain in midline. During activities requiring high-level balance, the reciprocal patterns with combined diagonals come into play with one extremity in D_1 extension and the other extremity in D_2 flexion. Examples of this are pitching in baseball, sidestroke in swimming, and walking on a narrow walkway with one extremity in a diagonal flexion pattern with the other in a diagonal extension pattern (see Fig. 31.15). In contrast, reciprocal patterns in the same diagonal, such as D_1 in arm swing during walking, facilitate trunk rotation. Leticia needs to work with reciprocals of D_1 to improve rhythm of arm swing and trunk rotation during walking.

FIG. 31.15 A bilateral reciprocal pattern of the upper extremities is used to maintain balance when walking on a narrow walkway. (From Jupiterimages [via Thinkstock.com].)

Combined Movements of Upper and Lower Extremities

Interaction of the upper and lower extremities results in (1) ipsilateral patterns, with extremities of the same side moving in the same direction at the same time; (2) contralateral patterns, with extremities of opposite sides moving in the same direction at the same time; and (3) diagonal reciprocal patterns, with contralateral extremities moving in the same direction at the same time while opposite contralateral extremities move in the opposite direction (Fig. 31.10, D, E, and F).

The **combined movements** of the upper and lower extremities are observed in activities such as crawling and walking. Awareness of these patterns is important in the assessment of the client's motor skills. The ipsilateral patterns are more primitive developmentally and indicate a lack of bilateral integration. Less rotation also is observed in ipsilateral patterns. Therefore the goal in intervention is to progress from ipsilateral to contralateral to diagonal reciprocal patterns.

Several advantages exist to the use of the diagonal patterns in intervention. First, crossing of midline occurs. This movement is of particular importance in the remediation of perceptual motor deficits such as unilateral neglect, in which integration of both sides of the body and awareness of the neglected side are intervention goals. Second, each muscle has an optimal pattern in which it functions. For example, the client who has weak thumb opposition benefits from active movement in D_2 extension. Similarly, D_1 extension is the optimal pattern for ulnar wrist extension. Leticia should work in D_2 flexion after her Colles wrist fracture is stable. This pattern will increase range of motion and strengthen supination and radial wrist extension. Third, the diagonal patterns use groups of muscles, which is typical of movement seen in functional activities. For example, in eating, the hand-to-mouth action is accomplished in one mass movement pattern (D_1 flexion) that uses several muscles simultaneously. Therefore movement in the diagonals is more efficient than movement performed at each joint separately. Finally, rotation is always a component in the diagonals (eg, trunk rotation to the left or right and forearm pronation and supination). With an injury or with the aging process, rotation frequently is impaired and can be facilitated with movement in the diagonals. In intervention, attention should be given to the placement of activities so that movement occurs in the diagonal. For example, if the client is working on a wood-sanding project, trunk rotation with extension can be facilitated by placing the project on an inclined plane in a diagonal. Leticia can incorporate rotational movements into homemaking activities such as unloading the dishwasher.

Total Patterns

In PNF, developmental postures also are called total patterns of movement and posture.[66] Total patterns require interaction between proximal (head, neck, and trunk) and distal (extremity) components. The assumption of postures is important, as is the maintenance of postures. When posture cannot be sustained, emphasis should be placed on the assumption of posture.[96] For example, before the client can be expected to sustain a sitting posture, he or she must be able to perform lower developmental total patterns of movement, such as rolling and moving from side-lying to side-sitting.

The active assumption of postures can be included in OT activities. For example, a reaching and placing activity could be set up so that the client must reach for the object in the supine posture and place it in the side-lying posture. The use of total patterns also can reinforce individual extremity movements. For example, in an activity such as wiping a tabletop, wrist extension is reinforced when the client leans forward over the supporting arm. This would be a way to make homemaking activities part of Leticia's home exercise program for her wrist in the later stages of recovery.

Several facts support the use of total patterns in the PNF intervention approach.[66] First, total patterns of movement and posture are experienced as part of the normal developmental process in all human beings. Therefore recapitulation of these postures is meaningful to the client and acquired with less difficulty. Second, movement in and out of total patterns and the ability to sustain postures enhance components of normal development, such as reflex integration and support, balance between antagonists, and development of motor control in a cephalocaudal, proximodistal direction. Third, the use of total patterns improves the ability to assume and maintain postures, which is important in all areas of occupation.

Voss developed the sequence and procedures for assisting clients with developmental postures. In 1981 Myers developed a videotape that shows the use of the sequence and procedures in OT.[66] This video demonstrates more information on the application of the total patterns and postures to OT.

Procedures
