A Reconstruction of Regional and Global Temperature for the Past 11,300 Years

Shaun A. Marcott,1 Jeremy D. Shakun,2 Peter U. Clark,1 Alan C. Mix1

Surface temperature reconstructions of the past 1500 years suggest that recent warming is unprecedented in that time. Here we provide a broader perspective by reconstructing regional and global temperature anomalies for the past 11,300 years from 73 globally distributed records. Early Holocene (10,000 to 5000 years ago) warmth is followed by ~0.7°C cooling through the middle to late Holocene (<5000 years ago), culminating in the coolest temperatures of the Holocene during the Little Ice Age, about 200 years ago. This cooling is largely associated with ~2°C change in the North Atlantic. Current global temperatures of the past decade have not yet exceeded peak interglacial values but are warmer than during ~75% of the Holocene temperature history. Intergovernmental Panel on Climate Change model projections for the Holocene (referred to as the Standard5×5 reconstruction, and do not affect the long-term trend in the reconstruction.

We took the 5° × 5° area-weighted mean of the 73 records to develop a global temperature stack for the Holocene (referred to as the Standard5×5 reconstruction) (Fig. 1, A and B). To compare our Standard5×5 reconstruction with modern climatology, we aligned the stack’s mean for the interval 510 to 1450 yr B.P. (where yr B.P. is years before 1950 CE) with the same interval’s mean of the global Climate Research Unit error-in-variables (CRU-EIV) composite temperature record (2), which is, in turn, referenced to the 1961–1990 CE instrumental mean (Fig. 1A). We then assessed the sensitivity of the temperature reconstruction to several averaging schemes, including an arithmetic mean of the data sets, a 30° × 30° area-weighted mean, a 10° latitudinal weighted mean, and a calculation of 1000 jackknifed stacks that randomly exclude 50% of the records in each realization (Fig. 1, C and D, and fig. S4). Although some differences exist at the centennial scale among the various methods (Fig. 1, C and D), they are small (<0.2°C) for most of the reconstructions, well within the uncertainties of our Standard5×5 reconstruction, and do not affect the long-term trend in the reconstruction.

In addition to the previously mentioned averaging schemes, we also implemented the RegEM algorithm (11) to statistically infill data gaps in records not spanning the entire Holocene, which is particularly important over the past several centuries (Fig. 1G). Without filling data gaps, our Standard5×5 reconstruction (Fig. 1A) exhibits 0.6°C greater warming over the past ~60 yr B.P. (1890 to 1950 CE) than our equivalent infilled 5° × 5° area-weighted mean stack (Fig. 1, C and D). However, considering the temporal resolution of our data set and the small number of records that cover this interval (Fig. 1G), this difference is probably not robust. Before this interval, the gap-filled and unfilled methods of calculating the stacks are nearly identical (Fig. 1D).

Because the relatively low resolution and time-uncertainty of our data sets should generally suppress higher-frequency temperature variability, an important question is whether the Holocene stack adequately represents centennial- or millennial-scale variability. We evaluated this question in two ways. First, we generated a single mean zero, unit variance white-noise time series and used it in place of our 73 records. The white-noise records were then perturbed through Monte Carlo simulations using the resolution and chronological uncertainty specific to each proxy record as well as a common 1°C proxy uncertainty. We composited a Standard5×5 global stack from these synthetic records and calculated the ratio between the variances of the stack and the input white noise as a function of frequency to derive a gain function. The results suggest that at longer periods, more variability is preserved, with essentially no variability preserved at periods shorter than 300 years, ~50% preserved at 1000-year periods, and nearly all of the variability preserved for periods longer than 2000 years (figs. S17 and S18). Second, spectral analysis indicates that the variance of the Holocene proxy stack approaches that of the global CRU-EIV reconstruction of the past 1500 years (2) at millennial time scales and longer (figs. S20 and S23).

Our global temperature reconstruction for the past 1500 years is indistinguishable within uncertainty from the Mann et al. (2) reconstruction; both reconstructions document a cooling trend from a warm interval (~1500 to 1000 yr B.P.) to a cold interval (~500 to 100 yr B.P.), which is approximately equivalent to the Little Ice Age (Fig. 1A). This similarity confirms that published temperature reconstructions of the past two millennia capture long-term variability, despite their short time span (3, 12, 13). Our median estimate of this long-term cooling trend is somewhat smaller than in Mann et al. (2) though, which may reflect our bias toward marine and lower-latitude records.

The Standard5×5 reconstruction exhibits ~0.6°C of warming from the early Holocene (11,300 yr B.P.) to a temperature plateau extending from 9500 to 5500 yr B.P. This warm interval is followed by a long-term 0.7°C cooling from 5500 to ~100 yr B.P. (Fig. 1B). Extratropical Northern Hemisphere sites (30° to 90°N), in particular from the North Atlantic sector, contribute most of the variance to the global signal; temperatures in this region decrease by ~2°C from 7000 yr B.P. to ~100 yr B.P. (Fig. 2H). By comparison, the low latitudes (30°N to 30°S) exhibit a slight warming of ~0.4°C from 11,000 to 5000 yr B.P., with temperature leveling off thereafter (Fig. 2I), whereas the extratropical Southern Hemisphere (30°S to 90°S) cooled ~0.4°C from about 11,000 to 7000 yr B.P., followed by relatively constant temperatures except for some possible strong multicablentennial variability in the past 2500 years (Fig. 2J). The Southern Hemisphere is represented by fewer data sets (n = 11) than the equatorial (n = 33)
and Northern Hemisphere (n = 29) regions, providing fewer constraints on characterizing the variability in our reconstruction for this region.

Trends in regional temperature reconstructions show strong similarities with high-resolution precipitation records, consistently associating greater warmth with greater wetness (Fig. 2, H to J). For example, extratropical Northern Hemisphere mid-to-high-latitude temperature correlates well with records of Asian monsoon intensity (14, 15) and the position of the Atlantic intertropical convergence zone (16) (Fig. 2H), tropical temperatures track precipitation proxies from speleothems in Borneo (17) and Indonesia (18) (Fig. 2I), and extratropical Southern Hemisphere temperatures parallel regional temperature changes in the extratropics (Fig. 2J).

**Fig. 1.** Comparison of different methods and reconstructions of global and hemispheric temperature anomalies. (A and B) Globally stacked temperature anomalies for the 5° × 5° area-weighted mean calculation (purple line) with its 1σ uncertainty (blue band) and Mann et al.’s global CRU-EV composite mean temperature (dark gray line) with their uncertainty (light gray band). (C and D) Global temperature anomalies stacked using several methods (Standard and Standard5x5Grid; 30x30Grid; 10-lat: Arithmetic mean calculation, area-weighted with a 5° × 5° grid, area-weighted with a 30° × 30° grid, and area-weighted using 10° latitude bins, respectively; RegEM and RegEM5x5Grid: Regularized expectation maximization algorithm-infilled arithmetic mean and 5° × 5° area-weighted). The gray shading (50% Jackknife [Jack50]) represents the 1σ envelope when randomly leaving 50% of the records out during each Monte Carlo mean calculation. Uncertainties shown are 1σ for each of the methods. (E and F) Published temperature anomaly reconstructions that have been smoothed with a 100-year centered running mean, Mann08Global (2), Mann08NH (2), Moberg05 (3), WA07 (8), Huang04 (36), and plotted with our global temperature stacks (blue band as in (A)). The temperature anomalies for all the records are referenced to the 1961–1990 instrumental mean. (G and H) Number of records used to construct the Holocene global temperature stack through time (orange line) and Mann et al.’s (2) reconstruction (gold vertical bars). Note the y-axis break at 100. The latitudinal distribution of Holocene records (gray horizontal bars) through time is shown. (I and J) Number of age control points (e.g., 14C dates) that constrain the time series through time.
were smoothed with a seven-point running mean for clarity. ITCZ, Intertropical Convergence Zone; EASM, East Asian Summer Monsoon; AISM, Australian-Indonesian Summer Monsoon.

The general pattern of high-latitude cooling in both hemispheres opposed by warming at low latitudes is consistent with local mean annual insolation forcing associated with decreasing orbital obliquity since 9000 years ago (Fig. 2C). The especially pronounced cooling of the Northern Hemisphere extratropics, however, suggests an important role for summer insolation in this region, perhaps through snow-ice albedo and vegetation feedbacks (21, 22). Such a mechanism that mediates seasonal insolation is plausible at these latitudes, where the fraction of continental landmasses relative to the ocean is high (~50% land from 30° to 90°N; 25% land from 30°N to 30°S; 15% land from 30° to 90°S).

We cannot fully exclude the possibility of a seasonal proxy bias in our temperature reconstructions (23), but a sensitivity experiment with an intermediate-complexity model (fig. S8) suggests that the effects of such a bias would probably be modest in the global reconstruction. The dominance of the northern signal in our global stack is consistent with Milankovitch theory, in which summer insolation would drive the planet toward eventual future glacial inception in the Northern Hemisphere (24), excluding any anthropogenic influence. Models support our finding of a global mean cooling in response to an obliquity decrease, though of lesser magnitude (25), and also support the idea about the sensitivity of the northern high latitudes to summer insolation (21).

Additional effects probably further influenced the evolution of climate through the Holocene. In the early-to-middle Holocene, the deglaciating Northern Hemisphere ice sheets would have modulated warming of the northern high latitudes relative to peak seasonal insolation (26, 27). Radiative forcing by greenhouse gases (primarily CO₂) rose 0.5 W/m² during the mid-to-late Holocene (Fig. 2D), which would be expected to yield ~0.4°C warming for a mid-range climate sensitivity (28). Response to such forcing may have been offset by opposing orbital insolation forcing that was greater than greenhouse gas forcing by up to one (annual) to two (seasonal) orders of magnitude over the course of the Holocene (Fig. 2, A to C). Northward heat transport in the Atlantic basin by the meridional overturning circulation (MOC) may have weakened since the middle Holocene (29), contributing to the strong cooling in the North Atlantic while dampening cooling in the mid-to-high latitude Southern Hemisphere due to the bipolar seesaw (30). Insofar as winter conditions influence the sources and strength of deepwater formation, a weakening MOC may partly reflect the increase in high northern-latitude winter insolation over the Holocene (Fig. 2A). Total solar irradiance reconstructed from cosmogenic isotopes (31) also varied by 0.5 to 1 W/m², and volcanic eruptions occurred throughout the duration of the Holocene (32, 33), although most of this variance is at higher frequencies than those resolved by our stacked temperature records, and the scaling of both is poorly constrained.

Although our temperature stack does not fully resolve variability at periods shorter than 2000 years, such high-frequency changes would only modestly broaden the statistical distribution of Holocene temperatures (Fig. 3 and fig. S22). Moreover, we suggest that accounting for any spatial or seasonal biases in the stack would tend to reduce its
variability because of the cancellation of noise in a large-scale mean and the opposing nature of seasonal insolation forcing over the Holocene, causing the Holocene temperature distribution to contract.

Our results indicate that global mean temperature for the decade 2000–2009 (34) has not yet exceeded the warmest temperatures of the early Holocene (5000 to 10,000 yr B.P.). These temperatures are, however, warmer than 82% of the Holocene distribution as represented by the Standard5x5 stack, or 72% after making plausible corrections for inherent smoothing of the high frequencies in the stack (6) (Fig. 3). In contrast, the decadal mean global temperature of the early 20th century (1900–1909) was cooler than >95% of the Holocene distribution under both the Standard5x5 and high-frequency corrected scenarios. Global temperature, therefore, has risen from near the coldest to the warmest levels of the Holocene within the past century, reversing the long-term cooling trend that began ~5000 yr B.P.

Fig. 3. Holocene temperature distribution compared to modern temperature and future projections. Shown are relative frequency plots of Holocene temperature anomalies in 0.05°C bins using multiple data subsets and reconstructions (colored lines), instrumental means for 1900–1909 and 2000–2009 CE (vertical black lines), 2100 CE projections based on various emissions scenarios (35) (black squares and gray bars give the best estimate and 66% confidence interval), and the Holocene median and 66% range from Standard5x5 + high-frequency stack (black square and blue bar). Projections in (35) were referenced to 1980–1999 CE, whereas we reference them to 1961–1990 CE here. Data sets are divided by proxy type: UK’37, Mg/Ca, and the remainder (Other); method: arithmetic mean (Standard) and RegEM; weighting: equal Northern and Southern Hemisphere weighting (0.5NH + 0.5SH), 5° × 5° grid, and 30° × 30° grid; to 1980

Strategies to better resolve the full range of global temperature variability during the Holocene, particularly with regard to decadal to centennial time scales, will require better chronologic constraints through increased dating control. Higher-resolution sampling and improvements in proxy calibration also play an important role, but our analysis (fig. S18) suggests that improvements in chronology are most important. Better constraints on regional patterns will require more data sets from terrestrial archives and both marine and terrestrial records representing the mid-latitudes of the Southern Hemisphere and central Pacific.

Exceptional Now
The climate has been warming since the industrial revolution, but how warm is climate now compared with the rest of the Holocene? Marcott et al. (p. 1198) constructed a record of global mean surface temperature for more than the last 11,000 years, using a variety of land- and marine-based proxy data from all around the world. The pattern of temperatures shows a rise as the world emerged from the last deglaciation, warm conditions until the middle of the Holocene, and a cooling trend over the next 5000 years that culminated around 200 years ago in the Little Ice Age. Temperatures have risen steadily since then, leaving us now with a global temperature higher than those during 90% of the entire Holocene.
