In addition to being used to account for place contrasts among vowels, vowel features have also been used to account for place contrasts among consonants (see also CHAPTER 75: CONSONANT–VOWEL PLACE FEATURE INTERACTIONS). This is traditionally done in two ways. Either some set of vowel features is used to determine what is called "secondary place of articulation," or they are used to determine primary place of articulation. We will begin with the former.

4.2.1 *Consonant secondary place*

It has long been observed that some languages make use of what is called secondary place (CHAPTER 29: SECONDARY AND DOUBLE ARTICULATION; CHAPTER 71: PALATALIZATION). This may be described as a less extreme constriction of the vocal tract occurring roughly simultaneously with a more extreme constriction at a different point along the vocal tract. This less extreme closure is approximately that of a glide and is often attributed to the specification of a consonant with an extra vowel feature (e.g. Chomsky and Halle 1968; Clements 1985; Odden 1991). Examples of secondary articulation are labialization (e.g. [tʷ]), palatalization (e.g. [tʲ]), velarization (e.g. [tˠ]), and pharyngealization (e.g. [tˤ]). Some languages claimed to have single secondary place contrasts are listed in Table 19.2.

Table 19.2 Sample of languages described as having secondary place distinctions

	labialization	*palatalization*	*velarization*	*pharyngealization*
Chipewyan	✓			
Russian, Irish		✓		
Arabic varieties, Ponapean			✓	
Arabic varieties				✓

Table 19.3 Sample of languages described as having multiple secondary place distinctions

	labialization	*palatalization*	*velarization*	*pharyngealization*
Nambakaengo	✓	✓		
Nupe		✓	✓	
Marshallese	✓	✓	✓	
Salishan, Caucasian and Semitic varieties	✓			✓
Caucasian and Semitic varieties		✓		✓

It has also been observed that each secondary place can contrast with other secondary places within a single language (Table 19.3).

4.2.2 Consonant primary place

There is also a long tradition of using vowel features to define consonant primary place. For example, Chomsky and Halle (1968) defined all postalveolar consonant places via a combination of vowel place and height features. What is interesting regarding the SPE features [±high], [±low], and [±back] is that while the former two are used by Chomsky and Halle to express vowel height and the latter to express vowel place, the three join forces to express a variety of primary consonant places when combined with [−coronal, −anterior], as shown in (8) (Chomsky and Halle 1968: 305). This mix of different types of vowel features to define "consonant place" makes one wonder if it makes sense to discuss place as a phonologically relevant concept at all, or whether "place" is simply a convenient descriptive label that is ultimately epiphenomenal. Further, if place is a phonologically relevant concept, then what is its phonetic grounding, given that phonetically disparate characteristics are used to define place in different contexts?

(8)

	palatals	velars	uvulars	pharyngeals
[high]	+	+	−	−
[low]	−	−	−	+
[back]	−	+	+	+

4.4.1 Consonant effects on vowels

In some languages, consonant place has a direct effect on vowel place. In those cases where the relevant consonant and vowel place are phonetically similar, this may be interpreted as assimilation and a sharing of the same feature by two major classes of segments (CHAPTER 81: LOCAL ASSIMILATION).

The first case we will look at is "vowel fronting" in Serbian. This involves the fronting of back mid vowels in some suffixes when following postalveolar coronal consonants.

(12) [ɔ] → [ɛ] / [t͡ʃ̠ d͡ʒ̠ t͡ʃ̠ʷ d͡ʒ̠ʷ ʃ̠ ʒ ɲ ʎ j] + __

(13)	a.	*Neuter noun nominative accusative singular* [-ɔ] ~ [-ɛ]					
		sel-o	[s̪ɛlɔ]	'village' ~	*polj-e*	[pɔʎɛ]	'field'
	b.	*Masculine instrumental singular* [-ɔm] ~ [-ɛm]					
		grȃd-om	[graːd̪ɔm]	'city' ~	*mȗž-em*	[muːʒɛm]	'husband'
	c.	*Genitive singular* [-ɔg] ~ [-ɛg]					
		dobr-og	[d̪ɔbrɔg]	'good' ~	*loš-eg*	[lɔʃ̠ɛg]	'bad'
	d.	*Masculine plural* [-ɔv-i] ~ [-ɛv-i]					
		grad-ov-i	[grad̪ɔvi]	'city' ~	*múž-ev-i*	[muːʒɛvi]	'husband'

As pointed out by Morén (2006a), Serbian's quite rich set of coronal consonants combined with this assimilation process suggest that the triggers and targets of velar fronting share a vowel "coronal" place feature. The importance to the present discussion is that these data complement other facts of Serbian to show that palatal consonants in this language are specified with a "vowel" place feature and no "consonant" place feature.

Another case comes from well-known restrictions on vowel quality allowed between two labial consonants in Cantonese (Cheng 1991; Hume 1991). As Cheng shows, non-low vowels must be front (i.e. [i e y ø]) within a syllable containing a coronal onset and coda. One account for this is that the two consonants must share their consonantal coronal place within the syllable domain and intervening vowels must become coronal as a result of feature spread through them. Unlike Serbian, these facts suggest that the front vowels make use of a consonant place feature, not a vowel place feature.

(14)	[kʰut]	'bracket'	[kʰyt]	'decide'
	[ho]	'river'	[hø]	'boots'
	[tʰuk]	'bald head'	[kʰut]	'bracket'
	[tʰok]	'to support'	[kot]	'to cut'
	[tʰyt]	'to take off'	*[tʰut]	
	[tʰøn]	'a shield'	*[tʰon]	

Khoisan languages have a similar relationship between consonants and vowels in that only back vowels can surface following velar and uvular consonants (including clicks) (Traill 1985).

To summarize, the Serbian, Cantonese, and Khoisan patterns suggest that "vowel place" and "consonant place" are occasionally convenient as descriptive labels, but vowels seem to be able to have "consonant place" and consonants seem to be able to have "vowel place."

4.4.2 *Vowel effects on consonants*

In addition to consonant quality affecting vowels, vowel quality can also affect consonants (Clements 1991; Hume 1991). The most obvious case is that of vowels causing secondary place to appear on adjacent consonants. There are numerous examples of this in the literature, and they have the general pattern illustrated in (15).[9]

(15) a. /t+i/ → [tʲi] b. /p+i/ → [pʲi]
/t+o/ → [tʷo] /p+o/ → [pʷo]
/t+ɑ/ → [tˤɑ] /p+ɑ/ → [pˤɑ]

Another type of vowel-to-consonant place interaction is when vowel place affects primary consonant place. Serbian "velar palatalization" is an example of this. As discussed in Morén (2006a), velar palatalization is a process by which velar obstruents become apical postalveolar when followed by some suffixes beginning with a front vowel.

(16) [k x g] → [t̠͡ʃ̠ʷ ʃ̠ ʒ̠] / __ + [i ɛ]

(17) a.	*Masculine vocative singular* [-ɛ]					
	vojnīk	[vɔjniːk]	'soldier'	~	*vojnīč-e*	[vɔjniːt̠͡ʃ̠ʷɛ]
	bôg	[bɔːg]	'god'	~	*bož-e*	[bɔʒɛ]
	siromāh	[ʂirɔmaːx]	'poor'	~	*siromāš-e*	[ʂirɔmaːʃ̠ɛ]
b.	*Diminutive* [-it̠͡ʃ(-a)]					
	krûg	[kruːg]	'circle'	~	*kruž-ić*	[kruʒit̠͡ʃ]
	rûka	[ruːka]	'hand'	~	*ruč-ić-a*	[rut̠͡ʃ̠ʷit̠͡ʃa]
c.	*Denominal* [-it̠-i]					
	muka	[muka]	'pain'	~	*muč-it-i*	[mut̠͡ʃʷit̠i]
	sûh	[ʂuːx]	'dry'	~	*sûš-it-i*	[ʂuːʃ̠it̠i]

Unlike some other Slavic languages, Serbian consonants cannot have secondary coronal place, so the effect of "palatalization" of velars is one of primary place change, not secondary place addition. As was the case with Serbian mid vowel fronting discussed in §4.4.1, velar palatalization suggests that the trigger and the target share a phonological place feature. However, the difference is that mid vowel fronting involves a consonant feature affecting a vowel, while velar palatalization involves a vowel feature affecting a consonant.

A final example comes from consonant epenthesis. In some varieties of English, there is consonant resyllabification or epenthesis in certain environments (Kahn 1976). This is sometimes called glide formation (CHAPTER 15: GLIDES), epenthesis, or consonant "intrusion," depending on the context and quality of the consonant – [j w], [ʔ], or [ɹ], respectively. The details regarding the conditioning environments and subtle dialect differences are beyond the scope of this chapter, but what is important here is that this type of phenomenon is widely distributed across the English-speaking world (Kahn 1976; McCarthy 1993; Uffmann 2007; Krämer

[9] While palatalization and labialization are quite common cross-linguistically, pharyngealization in the context of a low back vowel is not. However, this is found in some Arabic varieties as a reflex of emphasis spread.

For example, Matumbi initial underlying vowels surface as vowels when followed by a consonant, but they surface as glides when followed by a vowel (Odden 1996).

(21)	/u+teliike/	[uteliike]	'you cooked'
	/i+taabua/	[itaabwa]	'books'
	/i+a+tuumbuka/	[jaatuumbuka]	'they will fall'
	/i+otu+i+k+e/	[jootwiike]	'they have holes'
	/u+a+teleke/	[waateleke]	'you should cook'
	/i+ula/	[juula]	'frogs'

In feature theories where vowels and glides are the same segment in different syllabic positions, nothing need be said about place feature specification. However, in feature theories where vowels and glides are featurally distinct, then something must be said about their surface place similarities – especially if those theories postulate different place features for consonants and vowels.

Less obvious vowel–consonant alternations involve liquids. It is common among the Slavic languages to have alternations between a lateral and a vowel. For example, Serbian syllable-final laterals surface as mid back round vowels (Morén 2006a), while in Slovenian, they surface as a high back round vowel/glide (Morén and Jurgec 2007). The former is shown in (22).

(22)	*Serbian*				
	pev-ao	/pɛval/	→	[ˈpɛ.vaɔ]	'sang'
	orao	/ɔral/	→	[ˈɔ.raɔ]	'eagle'
	posao	/pɔs̪al/	→	[ˈpɔ.s̪aɔ]	'work'
	mišao	/miːs̪al/	→	]ˈmiː.s̪aɔ]	'thought'
	čitao-ca	/t͡ʃʷitalt͡s̪a/	→	[ˈt͡ʃʷi.taɔ.t͡s̪a]	'reader'

Ignoring the issue of how to establish the correct vowel height during vocalization, the unrounded anterior coronal lateral is clearly related to a surface vowel that is both back and round. This place relationship is not straightforwardly accounted for in some theories.

While one might argue that the Slavic data show alternations of underlying consonants with surface vowels, Yoruba seems to show the opposite. According to Akinlabi (2007), Yoruba [i] surfaces as [ŋ] following a vowel.

(23) /àwɔ́ ı wɔ́ tã́/ → [àwɔ́ ŋ̀ wɔ tã́]
flowing NEG flow finish
'that which flows (of gown) without end'

He interprets this as fortition, in which the high front vowel becomes a syllabic nasal so as not to require (perhaps not license) an onset. What is relevant to us is that a front vowel alternates with a velar nasal. Given that most feature theories assume that coronal is the default/unmarked place, it is not a trivial matter to explain why a coronal vowel alternates with a velar consonant.

Finally, vowels can also alternate with consonant secondary articulations.[13] As noted by Clements (1991), Etsako high vowels appear as secondary place on

[13] Similar alternations occur in Luganda (Clements 1991) and Matumbi (Odden 1996).

because they involve significant non-F2 effects. Closer inspection of physical and phonological parallels between vowels and consonants suggests that the traditional view needs to be reconsidered.

From a phonological perspective, vowel place features are relevant to seven major types of phenomena. I have discussed five of these, and each both supports and challenges some of the more common approaches to vowel place found in the literature. Combined, they suggest that we have a fairly good understanding of relevant phenomena and formalisms, even if we sometimes disagree about the details of data interpretation or which feature theory is best.

Finally, this chapter began by posing the question: "What is vowel place and what role does it play in the sound patterns of language?" To begin answering this question, we explored the phonetics and phonology of "place" more generally, as well as examined why some scholars make different choices regarding the relationship between phonetics and phonology and between vowels and consonants. We saw that vowel place is both simpler and more complicated than one might expect, and that more work is needed to resolve some long-standing and fundamental issues.

20 The Representation of Vowel Length

David Odden

1 Introduction

Length is the phonological correlate of durational differences between sounds, tied to the phonological concept "quantity." The concept of length usually considers duration segmentally, attributing length to particular segments (the vowel or consonant is the locus of the property "long" or "short," and not the syllable, foot, or word). Length being a phonological attribute, distinctions are discrete mental categories, not physical measurement, and, like most phonological attributes in generative theories, length is traditionally treated binarily.

Establishing vowel length in a language is not always straightforward. English is said both to have and not have vowel length, so that *peat* may be analyzed as having a long vowel (Halle 1977) as contrasted to *pit*, thus [iː] *vs.* [i], or the distinction can be treated as a tense/lax opposition (Chomsky and Halle 1968), thus [i] *vs.* [ɪ]. Because of the influence of voicing on vowels – they have shorter duration before a voiceless obstruent – English has a cline of four durational patterns, illustrated in *bead, beat, bid, bit*. Phonetic duration does not automatically translate into phonological length, and durational differences, especially ternary oppositions, are not necessarily of a continuous type (1, 2, 3, 4 units), but may instead reflect multiple, intersecting phonological phenomena.

Some languages distinguish "full" and "reduced" vowels. Chuvash (Krueger 1961) has two reduced vowels [ă ĕ], which contrast with full vowels [i y ɨ u a e o]; the two Proto-Slavic "yers" [ĭ ŭ] (see CHAPTER 122: SLAVIC YERS) are widely claimed to be "reduced," and a number of Ethiopian Semitic languages have multiple reduced vowels (Pam 1973). Rather than introducing a new orthogonal vowel property to the inventory of features, one which seems to never combine with independent length, the Chuvash vowels could be treated as short /a e/ *vs.* long /iː yː ɨː uː aː eː oː/. This would have the typologically peculiar consequence that all high vowels are long. However, in support of a prosodic distinction between these vowels, stress assignment is sensitive to the full/reduced distinction whereby reduced vowels are skipped over in favor of stressing full vowels.

Segmental influences on duration, discussed in Lehiste (1970), include tongue height, place of articulation, and stop/fricative properties of the following consonant, as well as pitch (especially under contrastive pitch movements), stress, and the fact of a syllable being open or closed. It can be unclear whether a perceptible durational pattern should be attributed to category change, so should we claim that, in the phonology, /bit/ *beat* → [bit] and /bid/ *bead* → [biːd] (similarly /bɪt/ *bit* → [bɪt], /bɪd/ *bid* → [bɪːd])? Or should we leave pre-voiceless durational adjustments to phonetics and have the output of the phonology be [bit], [bid], [bɪt], and [bɪd]? Answering these questions involves foundational issues in the theory of phonological and phonetic grammars that are well beyond the scope of this chapter. Unfortunately, many issues pertaining to the phonology of vowel length require understanding this relationship. If we cannot clearly identify "long vowels" contrasted with "short vowels," it will be difficult to develop a theory of how long *vs.* short vowels are represented.

A theoretical puzzle confronting linear (*Sound pattern of English*-type) theories of representation was how to resolve numerous contradictions in phonological length. The paradox is that long vowels sometimes behave as though they are single segments distinguished from short vowels by a feature, and sometimes they behave as though they are two segments. The resolution of this contradiction played an important role in the development of autosegmental phonology. The goal of this chapter is to familiarize the reader with the basic facts of vowel length and to attempt to explain them. §2 considers the fundamental problems pertaining to the featural treatment of vowel length. §3 shows how autosegmental representations resolve those problems, but also raise new questions as we attempt to make more precise the nature of the higher-level representational atoms that express length. Facts such as compensatory lengthening which seem to elucidate vowel length are often cited as evidence to support an autosegmental representation of length, but many autosegmental treatments of compensatory lengthening gloss over important details, a fact which undermines the explanatory value of the autosegmental account. On balance, it seems that the autosegmental account of length does broadly resolve the fundamental one-segment/two-segment paradox, but important details remain to be ironed out. Finally, §4 considers the claim that some languages have a three-way vowel length contrast. Such (rare) languages are potentially important for a theory of length; unfortunately, for the vast majority of such languages, so little is known that it is difficult to say that length ternarity is a real phenomenon, rather than an epiphenomenon arising from binary length and some orthogonal dimension.[1]

[1] A reviewer notes a number of substantive asymmetries in vowel length phenomena, some of which have at least implicitly influenced theorizing on length. For example, length is often related to syllable structure, such that long vowels appear in open syllables and short vowels appear in closed syllables, and there are rules of open syllable lengthening and closed syllable shortening. Furthermore, closed syllable lengthening or open syllable shortening appear to be unattested. Vowels may lengthen before voiced consonants, but they do not shorten before voiced or lengthen before voiceless. The latter fact is not widely attested in languages and appears not to have been elevated to the status of fact that it is agreed that phonological theories must explain, whereas the former fact, especially the widely attested prohibition against syllables of the type [XVVC_0], has had an impact on theorizing about vowel length, in that we have sought to reduce the generalization *[XVVC_0] to a general representational limit. The purpose of this chapter is to investigate the representation of length, not all facts relevant to length. It is just outside the scope of this chapter to investigate why no language has been attested with closed syllable lengthening, yet such questions are certainly germane to a widespread concern of representational theorizing, namely saying why certain kinds of rules exist, yet others are not found.

2 Segmental theories of representation

The classical *SPE* feature-theoretic account of vowel length is that long vowels are [+long] and short ones are [−long], thus rules affecting vowel length manipulate a feature on a par with nasality, rounding, or backness – for which a segmental transcription such as [a:] or [ā] would be appropriate. It was also recognized in works such as McCawley (1968) that long vowels could be represented as sequences of identical vowels, thus [aa].

Lithuanian evidence for treating long vowels and diphthongs identically is discussed in Kenstowicz (1970), which supports a representation of long vowels as adjacent identical short vowels. One argument is that rising and falling tones only appear on long vowels and diphthongs or else in syllables ending with a liquid or nasal, i.e. bisegmental vowel plus sonorant sequences. There are words like /kâimas/ 'village', /váikas/ 'child', with diphthongs, /kârtis/ 'pole', /kártis/ 'bitterness', with V + resonant sequences, and /matî:ti/ 'to see', /matǐ:s/ 'he will see', with long vowels. There are no level-H toned syllables with a diphthong, vowel plus consonant, or long vowel. In contrast, only level H or L (unmarked) appear on short vowels, as in /mésti/ 'to throw', /dúri:s/ 'door'. This pattern is explained if the language allows just one H on one segment within the word, where coda sonorants can bear tone, and crucially, long vowels are really two-segment sequences, thus /matíiti/, /matiís/, /káimas/, /vaíkas/, /kártis/, /kar̃tis/. If long vowels simply have the feature [+long], explaining the distribution of H tone becomes very complex.

Another argument for equating long vowels with vowel sequences is an accent shift before endings with an underlying initial H, which is described very simply as deleting the first of two adjacent H tones. This description only works if long vowels are represented as VV, and becomes more complex if stated in terms of monosegmental long vowels and a primitive rising/falling/level distinction. An H underlyingly on the last tone-bearing unit of the stem (retained before the toneless accusative singular suffix *-a:*) seems to shift to the underlyingly H-initial instrumental singular suffix, as illustrated by the alternation [pieʃtúk-a: ~ pieʃtuk-ú] 'pencil (ACC SG ~ INSTR SG)', the latter from /pieʃtúk-úo/.

(1)	*acc sg*	*instr sg*			
	pieʃtúk-a:	pieʃtuk-ú	←	/pieʃtúk-úo/	'pencil'
	mígl-a:	migl-ú	←	/mígl-úo/	'mist'
	vaík-a:	vaik-ú	←	/vaík-úo/	'child'
	pǒ:n-a:	po:n-ú	←	/poón-úo/	'master'
	kâim-a:	kâim-u	←	/káim-úo/	'village'
	vê:j-a:	vê:j-u	←	/véej-úo/	'wind'

In the final two forms in (1), the suffix H deletes for reasons not of relevance here.

Retranscribing long vowels as sequences and decomposing contour tones into H on V_1 *vs.* V_2 makes the nature of the alternation clearer: H deletes before adjacent H.

There are shortening rules in Lithuanian which treat long vowels and diphthongs analogously. One rule shortens a word-final falling-toned long vowel or diphthong, which accounts for alternations in adjectives in their indefinite and definite forms.

(5)	*'you should V'*	*'you should go V'*	
	ulubé	ukalubé	'ask'
	upakatike	ukapakátike	'shake down'
	ukatʃabánike	ukakatʃábanike	'be confused'
	utʃaŋgaále	ukatʃaŋgáale	'wonder'
	upapaákije	ukapapáakije	'grope'
	ulaambáte	ukalaámbate	'lick'
	ukeeŋgéembe	ukakeéŋgeembe	'dig up'

Similar arguments show the equivalence of long vowels and vowel sequences in Kuria tone assignment (Odden 1987). In short, there is ample evidence that long vowels act like two vowels.

Work by Pyle (1971), Kenstowicz (1970), and Fidelholtz (1971) also noted evidence for treating vowel length with a feature. Southern Paiute (6a) and Tübatulabal (6b) were often cited as illustrating different treatments of length according to language. In Southern Paiute, devoicing only affects one half of a long vowel (arguing for a sequence), but in Tübatulabal, reduplication of the first V copies vowel length (requiring a featural representation).

(6) a. mantʃáạqàạ 'to hold out one's hand'
maróọqwàj'ɨqwạ '(I) stretch it'

b. *telic* *atelic*
toːjlaːn oː-doːjlaːn 'to teach him'
togoːjˀan o-togoːjˀan 'to decoy it for him'

Sometimes long vowels act like both a single segment and a sequence in one language. Kenstowicz motivates a rule in Lithuanian rounding /aː/ to [oː], affecting the output of a rule lengthening vowels in certain verbs in the non-present. When the vowel is underlying short /a/, the surface result is [oː].

(7) tupʲú tuúpti 'perch'
drebʲú dreébti 'splash'
vagʲú voógti 'steal'

The problem is that the concept "long *a*" is difficult to capture in the sequence theory, since that theory says that length is not a feature that can be referred to. One would have to refer to "[a] which is preceded or followed by another [a]." Since arguments for the sequence theory succeeded because of the resulting simplifications, these complications are important.

Pyle (1971) shows that in West Greenlandic, lowering of high vowels before uvulars affects long and short vowels equally, thus /aluq/ → [aloq] 'sole', /puːq/ → [poːq] 'bag'. If long vowels were vowel clusters, we predict /puuq/ → *[puoq] – note also that vowel lowering does not skip a vowel, thus /ukiuq/ → [ukioq] 'year', not *[ukeoq]. Contrarily, though, a metathesis rule breaking up final consonant clusters ([meːraq]: /meːraq-t/ → [meːrqa-t] 'child (SG, PL)') does not apply when the cluster is preceded by a vowel sequence ([umiaq]: /umiaq-t/ → [umiat] 'canoe (SG, PL)'), or by a long vowel ([ikaːq]: /ikaːq-t/ → [ikaːt] 'scaffold (SG, PL)'). Thus, like Lithuanian, West Greenlandic supports both modes of representation.

between singulars and plurals, including lengthening, shortening, diphthongization, tone changes, vowel quality changes, consonant changes, and suppletion.[3]

(10)	*sg*	*pl*		*sg*	*pl*	
	gɔ́l	gɔ́ɔ́l	'clan'	dwɛ̤́l	dwɛ̤̀l	'temporary house'
	bó̤ó̤k	bó̤k	'animal skin'	jic	jì̤ì̤t̤	'ear'
	d̤ɔ̤k	da̤k	'boy'	ɲáŋ	ŋɛ̤ŋ	'crocodile'
	kwir	kwer	'road'	cìn	cì̤ì̤n	'intestine'
	dit	diɛt	'bird'	kèw	kèèt̪	'gazelle'
	ruon	run	'year'	kow	kuoot̪	'thorn'
	lwet̪	lwét̪	'lie'	kat	kɛ̤́ɛ̤́t	'shelter'
	bél	bel	'sugar cane'	diir	dɪ̤́r	'cricket'
	cók	có̤k	'foot'	wə́ŋ	ɣɔ́k	'cow'
	kàl	ka̤l	'fence'	tik	djà̤r	'woman'

Ladd *et al.* (2009) argue that there is some predictability, but nevertheless there simply is no length-switching rule, thus no such argument for treating length as a feature.

Another counterexample to the function/representation hypothesis is Tübatulabal reduplication (6b), which is not a segment quality rule but rather a prosodic rule, yet one that copies the length of the first root vowel in the same way that it copies vowel quality features. Any rule of prevocalic vowel shortening (as exists in Kamba) which specifically only applies to long vowels and not vowel sequences is a problem for the rule-functional claim. The reason is that a rule that lengthens or shortens a vowel is by definition a prosodic rule, and prosodic rules are hypothesized to always treat long vowels in the same manner as vowel sequences. In Kamba, long vowels shorten before another vowel, as illustrated below with the remote future prefix /-kâ:-/ (/-káa-/).

(11)		
	to-kâ:-tálâ	'we will count'
	to-kâ:-konà	'we will hit'
	to-ká-o-à	'we will buy'
	to-ká-i-o-à	'we will buy them'
	to-ká-.a.à	'we will divide'

As discussed in §4 below, Kamba contrasts identical-vowel sequences with long vowels. Forms like [tokáioà] demonstrate that the prevocalic shortening seen in the mapping /tokáa-o-a/ → [tokáoà] is not the result of a general vowel-cluster reduction rule. Only long vowels undergo shortening, thus long vowels are, contrary to hypothesis, not treated the same as vowel sequences.

A severe problem for a two-segment theory is posed by Gokana, discussed in Hyman (1982). A rule of postvocalic shortening shortens the 3rd singular object suffix, /EE/, seen in [bāē dìv-ēē] 'they hit him', whereas /bāè sà-EE/ becomes [bāē sà-ɛ̄] 'they chose him'. This poses the same problem as Kamba prevocalic shortening. In addition, Gokana inserts [r] between long vowels after the logophoric suffix, /EE/, seen in [bāè dīv-èè] '(they$_i$ said) they$_i$ hit (it)', whereas

[3] These examples were provided to me by the late Keith Denning, based on his fieldwork.

/bāè sīī-EE/ becomes [bāè sīī-rèè] '(they$_i$ said) they$_i$ caught (it)', but /bāè sā-EE/ surfaces as [bāè sā-ɛ̀] '(they$_i$ said) they$_i$ chose (it)' without r-epenthesis (and with postvocalic shortening), because insertion requires a sequence of long vowels.[4] When the logophoric suffix is preceded by a sequence of adjacent identical vowels – a long vowel, according to the vowel-sequence theory – there is no insertion, as shown by /bāè kɛ̃̄ɛ̃̄-ɛ̃̄-EE/ → [bāè kɛ̃̄ɛ̃̄-ɛ̃̄-ɛ̃̄] '(they$_i$ said) they$_i$ woke (it) up'. Gokana thus phonologically distinguishes true long vowels from adjacent identical-vowel sequences, which is not predicted to be possible by the sequence theory.

The theory that segmental rules always treat long vowels as monosegmental is also falsified by the Mackenzie dialect of Eskimo, noted by Pyle, which also lowers high vowels before uvulars but where /naluuq/ → [naluoq] 'throws out'. Various segmental rules of Southern Paiute treat long vowels as sequences, and can affect just one part of a long vowel, for example final devoicing noted in (6a), as well as a rule whereby /ɨ/ → [i] before [i] (which may later delete), where /ũnikʲaŋumɨɨts·i/ → [ũnikʲaŋumɨits·] 'after they had done so'.

Matumbi presents a worst-case scenario for segmental theories of length which attempt to attribute sequence-like *vs.* feature-like properties of length either to ordering or rule type. As noted above, the language gives strong evidence for the sequence theory, from tone assignment, which counts a long vowel as equivalent to two short vowels. The data of (5) omit one important type of stem, namely CVVCV, where the H would be word-final. In such cases, the predicted H tone is retracted to the penult, being realized as a rising tone.

(12)	u-kaáte	←	/u-kaaté/	'you should cut'
	u-toóle	←	/u-toolè/	'you should take'

To even coherently represent rising tone while explaining the robust constraint that contour tones only exist on long vowels, long vowels must be represented as bisegmental. Yet this tone-retraction rule must refer to the fact that the penult contains a long vowel, arguing for a feature representation of length. The rule only applies after long vowels and not adjacent VV sequences, as shown by [utaunè] 'you should chew', without retraction (cf. [ukataúne] 'you should go chew', showing that *u* can bear H). One cannot even impose an identity condition on the triggering penultimate vowel (i.e. "when preceded by a sequence of identical vowels"), thanks to the fact that the language lexically contrasts identical vowel sequences from long vowels, the former not triggering tone retraction ([baasá] ← /ba.asá/ 'envelope').

Matumbi has a rule which shortens long vowels in a phrasal head followed by a modifier. Vowel sequences do not simplify.

(13)	a.	nika-kálaaŋga	'I will go fry'
		nika-kálaŋga lí	'I will not go fry'
		nika-kálaŋga kinɟáambú	'I will go fry cassava leaves'
		nika-kálaŋga jóopáta eéla	'I will go fry to get money'
	b.	nika-táuna	'I will chew'
		nika-táuna lí	'I will not chew'

[4] Insertion only affects the logophoric suffix and the 2nd plural subject suffix /II/.

Assuming an ordered identical-vowel merger rule, such a rule would have to apply before shortening, so that long vowels could be created and thus referenced by a rule mentioning [+long] in the input and [−long] in the output. This is not ultimately tenable.

Tone assignment in the subjunctive occurs after shortening has applied, as the data below show – H is on the third surface vowel after the subject prefix, regardless of underlying length.

(14)	uʧaŋgaále	'you should wonder'
	uʧaŋgalé lí	'you should not wonder'
	upapaákije	'you should grope'
	upapakíje mundó	'you should grope in the bucket'
	ulaambáte	'you should lick'
	ulambaté mboópo	'you should lick the knife'
	ukeeŋgéembe	'you should dig up'
	ukeŋgembé kindoólo	'you should dig up sweet potatoes'
	ubeénde	'you should shout'
	ubendé ukumú	'you should shout at Ukumu'

In an ordered vowel-merging solution, vowel sequences must merge prior to shortening (to be targeted by shortening), and shortening precedes subjunctive tone assignment (which precedes retraction). But subjunctive tone assignment requires a sequence representation of long vowels, and is flanked by rules requiring a featural representation of vowel length.

Finally, Matumbi contrasts long vowels and adjacent identical vowel sequences, as in (15a), with true long vowels (which condition tone retraction and undergo shortening) *vs.* those of (15b), with sequences which do not trigger retraction or shortening.

(15)	a.	ntuúmbwi	← /ntuumbwi/	'canoe'	ntumbwí waáŋgu	'my canoe'
		ŋgaási	← /ŋgaasí/	'ladder'	ŋgasí jaáŋgu	'my ladder'
		ŋkaáte	← /ŋkaaté/	'bread'	ŋkaté ŋaáŋgu	'my bread'
	b.	baará	'ocean'		baará jaáŋgu	'my ocean'
		baasá	'envelope'		baará jaáŋgu	'my envelope'
		luusá	'permission'		luusá lwaáŋgu	'my permission'

While the insight that long vowels are in some sense like two vowels is correct, there are many reasons not to treat long vowels as literally a sequence of segments. Further developments in representational theory resolve the conflict in these insights.

3 Non-linear representations

When facts of this type were considered from the perspective of autosegmental and metrical phonology in the mid-1970s, it was obvious that, once the presumption of a one-to-one mapping between features and segments is abandoned, non-linear representations provide exactly the flexibility required to resolve these paradoxes. Just as a contour tone is represented as a many-to-one mapping between tones and vowels, a long vowel can be represented as a many-to-one mapping between something and a vowel. The crucial question is, what is that something which long vowels have two of?

3.1 Skeletal accounts

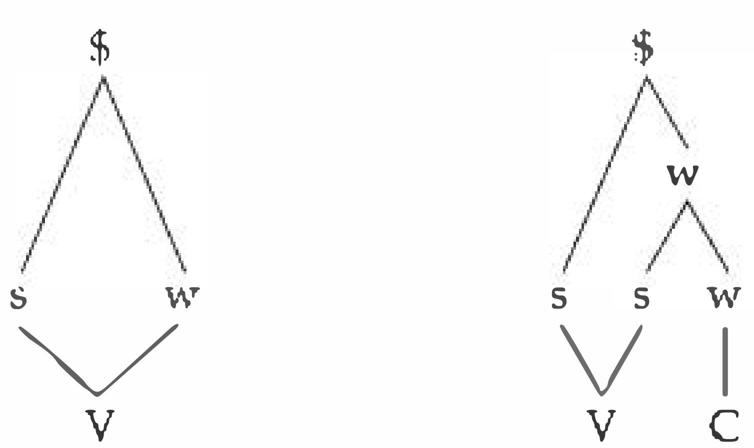
In McCarthy (1979: 34), long vowels were still seen as two-segment sequences, but with the imposition of higher structure including a rhyme. "Long vowel as unit" behavior, such as uniform lowering of long vowels before uvulars in West Greenlandic, is handled by applying the rule at the level of the rhyme. Rules may thus specify whether they apply at the segment level or higher, which yields an ambiguous treatment of long vowels. Long vowels as in Tiberian Hebrew [mala:ki:m] are represented as in (16), where a long vowel is two things (two segments) and one thing (one rhyme) at the same time.

(16)

Vowel lengthening is treated as node-adjunction within the rhyme, where the segment is filled in by automatic feature copying.

Ingria (1980) represents a long vowel as a single segment having two metrical positions.

(17) V: in an open syllable V: in a closed syllable



Since the focus of that article is compensatory lengthening arising from consonant deletions, little attention is paid to how underlying length is represented. It is simply noted (1980: 469) that "Each long vowel and consonant must contain the information that it is to be associated with two positions in the syllabic tree, whereas short vowels and consonants will be associated with only one position."

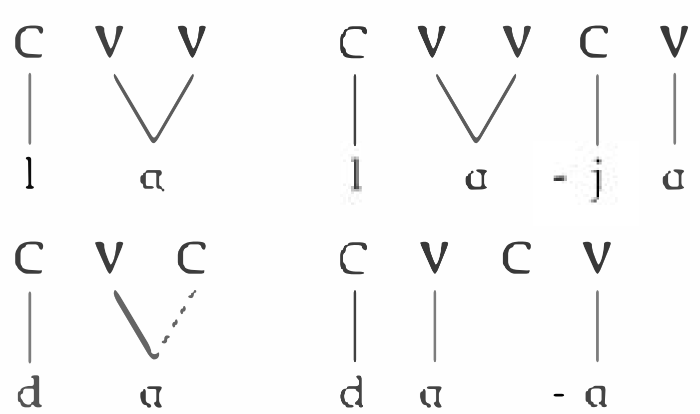
The earliest, most successful non-linear theory of length is CV theory, which is rooted in McCarthy's (1979) prosodic template proposal for Semitic morphology (see CHAPTER 108: SEMITIC TEMPLATES and CHAPTER 105: TIER SEGREGATION). McCarthy made a connection between vowels and V and between consonants and C (1979: 247), such that [syllabic] and [consonantal] are represented on the template tier rather than the segmental tier. McCarthy (1982) drops the feature [syllabic] but reintroduces the *SPE* feature [vocalic] to drive mapping of segments to the CV tier. The Clements and Keyser (1983) version of the theory fully phonologizes the CV tier as a strictly suprasegmental tier, containing only the formal elements C, V, which are independent of morphology, and dispenses with [syllabic]. A segment dominated by V is interpreted as a syllable peak, and a segment dominated only by C is interpreted as a non-peak.[5] The C/V distinction subsumes the functions of [syllabic], but is not identical to it. The feature [long] is also abandoned (1983: 12), and "long vowels are universally represented by means of the multi-attachment of a single vowel matrix to two positions on the CV-tier." The appeal of the theory is that it resolves the longstanding problem of the ambiguity of length, simplifies feature theory, and explains a problematic connection between syllabicity and compensatory lengthening, discussed below.

By reducing length to simple multiple-linking of prosodic atoms to segments, CV theory predicts the possibility of a further distinction in types of long vowels: a long vowel dominated by VC *vs.* one dominated by VV. This actually arises in Turkish, which contrasts two kinds of superficially identical long vowels.

(18)	*nom sg*	*pl*	*dat*	*poss*	
	lɑ:	lɑ:-lɑr	lɑ:-jɑ	lɑ:-sɯ	'la (musical note)'
	dɑ:	dɑ:-lɑr	dɑ-ɑ	dɑ-ɯ	'mountain'
	sɑp	sɑp-lɑr	sɑp-ɑ	sɑp-ɯ	'stalk'

The noun /lɑ:/ has a regular VV long vowel, and by regular principles of Turkish, the dative and possessive have the allomorphs /-jɑ/, /-sɯ/ after that long vowel, and /dɑ:/ has a long vowel arising from association to /ɑ/ of an empty C position which is part of the root.

(19)



The presence of the empty C triggers the suffix variant /-ɑ/, and the empty C syllabifies as the onset of the second syllable.

The theory draws substantial support from the fact that it gives a simple account of the difference – one never squarely dealt with in linear theorizing – between disegmental disyllabic [a.a] and phonetically distinct monosegmental monosyllabic [a:], as exists in Kamba. In principle, a monosyllabic long vowel dominated by VC could also behave differently from one dominated by VV, as is the case in Turkish, but the phonetic interpretation of the two long vowels would be identical, since "syllabicity" requires *some* V node to dominate the segment, not that *every* node dominating the segment must be a V.

[5] It is argued that certain long vowels in Klamath and Turkish are dominated by the sequence VC (see below), which is in line with the interpretation that any linkage to V causes a syllable-peak interpretation of the segment. However, a post-glide epenthesis rule is also posited (Clements and Keyser 1983: 135) in Klamath, whereby C-dominated /w/ becomes CV-dominated, and /wq'as/ → [wuq'əs] 'quartz'. It seems that only VC in the syllable rhyme is interpreted as a uniform syllable peak.

One significant argument for the CV theory of vowel length is its explanation for a Klamath puzzle noted by Kisseberth (1973), a rule shortening long vowels after a heavy syllable under certain conditions. The rule only affects vowels that arise from vocalizing a glide between consonants, not underlying long vowels or long vowels from vowel–glide sequences. This process applying to vocalized glides is seen in (20a), and not in (20b) with other long vowels.

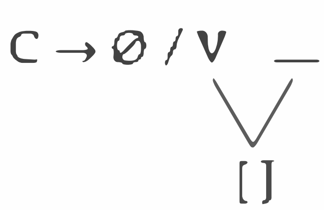
(20)	a.	mbotj'-a	'wrinkle'	/mbodj'-a/
		mbodiː-tk	'wrinkle up'	/mbodj'-dk/
		mbo-mpti-tk	'wrinkled up (DISTR)'	/mbo-mbodj'-dk/
	b.	jə-jdiːs	'spirit stones (DISTR)'	/ja-jadiː-s/
		sdə-sdiːn-k'a	'little heart (DISTR)'	/sda-sdajn-k'a/

With only one representation of "long vowel," it would be impossible to distinguish shortenable [iː] derived from /CjC/ *vs.* non-shortening underlying /iː/. CV theory explains this representationally, where an underlying long vowel is dominated by VV, but an underlying glide between consonants will, due to a separate rule of pre-glide epenthesis, be represented as VC.

(21)

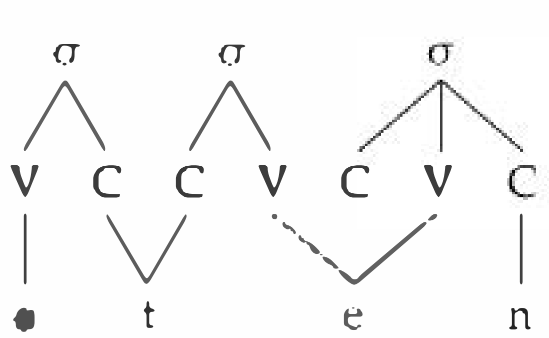
Clements and Keyser achieve the restriction on shortening in the formulation of the rule Vowel Shortening (1983: 171).

(22)



Parallel facts from Finnish are discussed in Clements and Keyser (1983) and Keyser and Kiparsky (1984), namely the anomalous treatment of certain long vowels with respect to gradation, vowel length alternations, and consonant gemination, which point to another representation of long vowels, as a monosegmental disyllabic VCV span, illustrated in the word [otteːn] 'grip (GEN SG)'.[6]

(23)



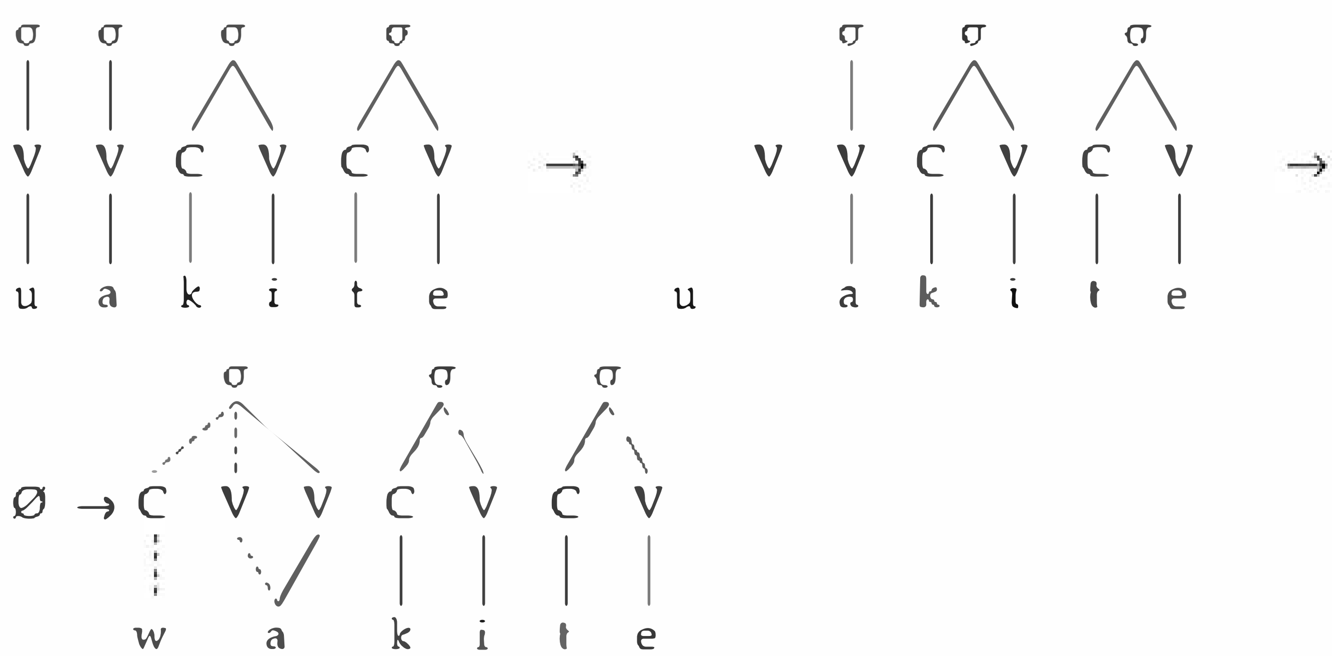
While the extra power of being able to distinguish VV and VC long vowels as well as monosyllabic and disyllabic versions of long vowels might seem to be a

[6] This type of representation is how Strict CV Phonology (Lowenstamm 1996) treats all long vowels.

A problem with the autosegmental theory of CL is the need to posit ad hoc conventions for glide formation in an onsetless syllable. The initial impact of this problem for the theory was reduced by the fact that Ganda does not have CL in such a context. In Ganda (and a set of closely related Bantu languages: see e.g. Odden 1995), there is no CL when an onsetless vowel desyllabifies, thus Ganda /o-a-gula/ → [wagula] 'you bought'; contrast /tu-a-gula/ → [twa:gula] 'we bought'. Clements (1986: fn. 1) treats this by a relabeling rule which directly changes word-initial V into C. Therefore, CL is not always a consequence of GF, even in languages like Ganda with vowel length and CL. Another language which presents this problem is Classical Sanskrit, where prevocalic high vowels become glides and do not cause lengthening of the following vowel (/iti abravit/ → [itj abravit] 'thus he said'). However, some vowel merger processes in Sanskrit do exhibit CL, namely the rule /ai au/ → [e: o:] (/ca iha/ → [ce:ha] 'and here').

In Matumbi, GF does take place in a context analogous to Ganda [wagula], as we observed in (26) with /u-ákite/ → [waákite] 'you hunted'.

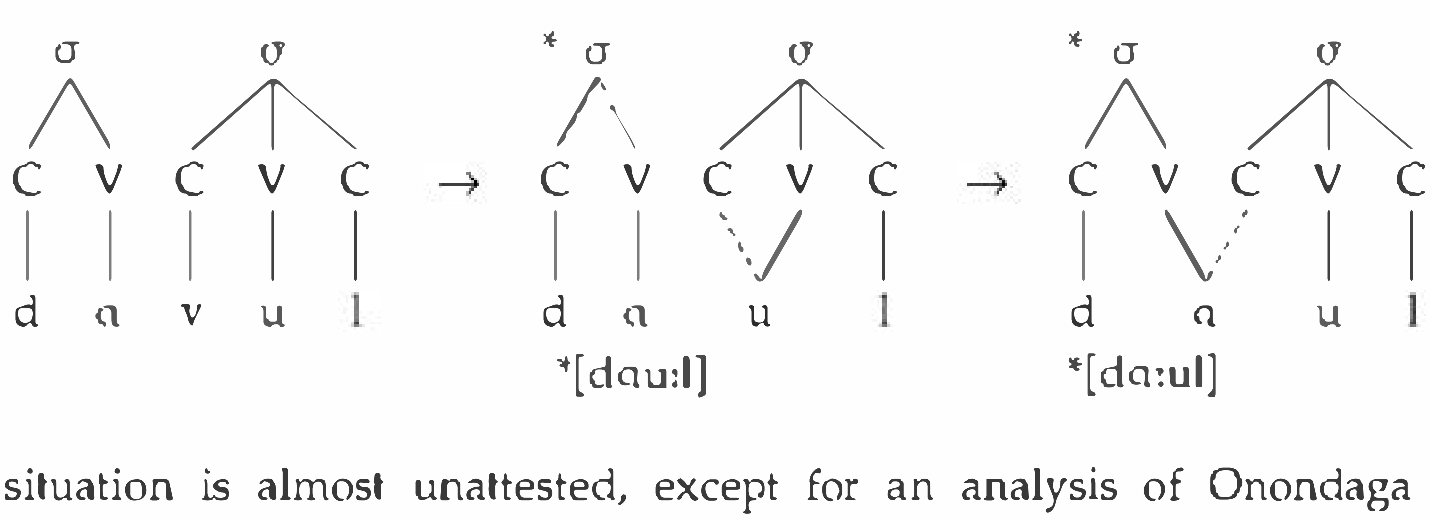
(33)



Creation of a C-slot is necessitated by the fact that CV positions always mediate between the segment and the syllable. This complicates CV theory by necessitating a convention inserting an onset which does not already exist, and is counter to the insight that CL is simply rearrangement of segmental and prosodic material.

CV theory predicts CL from deletion of an onset consonant, which in fact does not happen in Turkish and numerous other languages with CL associated with consonant deletion.

(34)



This situation is almost unattested, except for an analysis of Onondaga in Michelson (1986) where a vowel is lengthened when preceded by an empty C

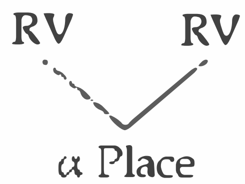
(37)

pɔdok	pɔd-pɔdok	'to be planting'
pa	pa:-pa	'to be weaving'
ca:k	ca:-ca:k	'to be bending'
onop	onn-onop	'to be preparing'
andip	and-andip	'to be splitting'

It does appear, then, that the C/V distinction is not strictly necessary, as long as one enriches underlying representations with higher-level structure with a nucleus node.

A conceptually related theory is that of Selkirk (1990), who dispenses with skeletal positions entirely and relies on "root node" to indicate length, so that a long vowel has two root nodes, but one set of shared place features.[7]

(38)



3.2 *Moraic accounts*

Building on the idea of generic prosodic positions, Hyman (1985) argues that one-to-many mappings between skeletal positions and segments should be further exploited, and proposes that onset consonants lose their skeletal position by joining to the position of the nuclear vowel through a universal Onset Creation Rule (OCR).

(39)

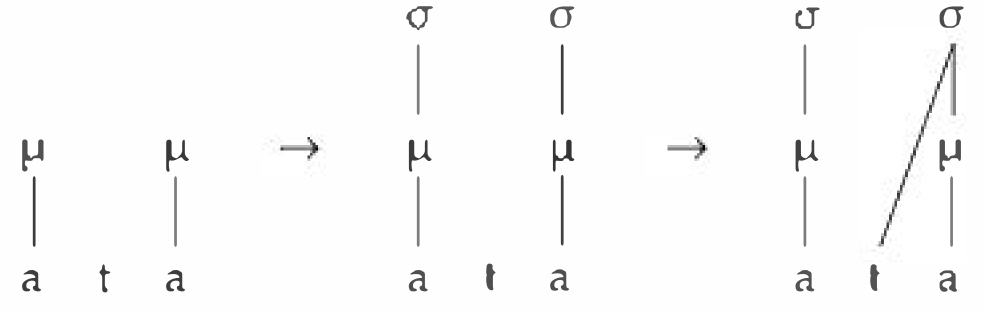
This theory of representation eventually develops into Moraic Theory.

Hyman's main concern is developing a syllable-free theory that still represents the notion of syllable-weight, a notion proposed by Kuryłowicz (1948) to unify syllables with long vowels or coda consonant for purposes of stress, tone, or prosodic morphology. Capturing the notion "heavy" in a theoretically coherent fashion had proven difficult (CHAPTER 57: QUANTITY-SENSITIVITY). Although "heavy syllable" correlates to branching, it has been challenging to say where such branching is relevant, since the onset is irrelevant to syllable weight (but see Davis, forthcoming), and a branching nucleus (long vowel) always defines a heavy syllable if a language has any notion of syllable weight, while a branching rhyme (XVC syllable) only sometimes does, and, furthermore, some languages (such as Lithuanian) distinguish sonorant rhymes as defining heavy syllables *vs.* obstruents for defining light ones. Hyman's theory of weight units (which he equates with the traditional mora) handles these facts quite simply, deriving onset-weightlessness from OCR (39), with a range of options regarding coda consonants which either leave coda consonants with their underlying weight unit (contributors to syllable weight), or merge that weight unit with the preceding vowel (codas are weightless).

[7] In Selkirk's theory, root nodes have intrinsic featural content, so that 'RV' would be [−cons, +son].

The notion of mora as the basic unit of phonological timing is developed more fully in McCarthy and Prince (1986), Hayes (1989), and Zec (1988). A strong argument for Moraic Theory over skeletal theories of length is advanced in Hayes (1989), who shows how a moraic theory of length coupled with the principle that onset consonants have no moraic value explains the onset asymmetry for compensatory lengthening, noted for example in Turkish /savmak/ → [sa:mak], but /davul/ → [daul], *[da:ul], *[dau:l] in Wetzels and Sezer (1986): see also (34) above. A characteristic of these later developments in Moraic Theory (exemplified by Hayes 1989) is that it is unnecessary to underlyingly assign weight units to all segments, and rather than postulating that every segment has a mora and invoking mora-trimming to merge the moras of onset consonants with those of a vowel, underlying representations will *typically* assign one mora to a short vowel and two to a long vowel; a consonant might have an underlying mora if it is geminate or syllabic (see CHAPTER 37: GEMINATES). The weightlessness of onsets then reduces to the fact that consonants ordinarily neither have an underlying mora nor do they receive one by rule, and instead directly syllabify to the left of a syllable by a syllable adjunction rule.

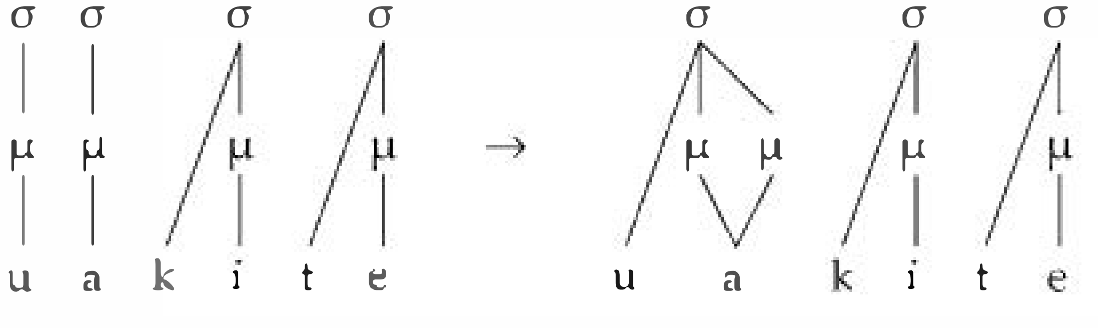
(40)



The generalization that long vowels always define a heavy syllable is a consequence of the moraic characterization of "heavy," namely having two moras within a syllable. Long vowels always have two moras; onsets do not contribute a mora (thus are weight-irrelevant), and coda consonants can vary in their influence on weight, depending on whether they receive a mora.

The moraic theory of direct attachment to the syllable without intervening timing units resolves the onset problem with skeletal theories of timing and CL. It was noted above that skeletal theories of CL do not provide a straightforward account of onset-creation co-existing with CL from GF in an underlyingly onsetless syllable. In (33) it was seen that GF in Matumbi results in compensatory lengthening of the following vowel, so /u-ákite/ becomes [w-aákite] 'you (sc) hunted', which required auxiliary insertion of C to syllabify the onset. The moraic theory accounts for this pattern easily, since the theory does not require prosodic positions for onset consonants: the high vocoid directly attaches to the syllable.

(41)



A final argument for the mora is mora-based tone systems such as that of Matumbi, where H is assigned by counting Vs – but only Vs – from the beginning of the verb. Skeletal theories face the problem of ignoring C-slots in tonal computations. Compare the problem of identifying the fourth "vowel" for Matumbi subjunctive tone assignment, given the representations of skeletal *vs.* moraic theories.

(42)	V C V C V C V C V u p a k a t í k e	μ μ μ μ μ u p a k a t í k e	'shake down'
	V C V C C V V C V u ʧ a ŋ g a á l e	μ μ μ μ μ u ʧ a ŋ g a á l e	'wonder'
	V C V V C C V C V u l a a mb á t e	μ μ μ μ μ u l a a m b á t e	'lick'
	V C V V C C V V C C V u k e e ŋ g é e mb e	μ μ μ μ μ μ u k e e ŋ g é e m b e	'dig up'

Moraic Theory directly represents the prosodic irrelevance of onset consonants via the fact that they project no prosodic unit, thus the fourth timing unit is easily identified. Skeletal theories require special interpretive procedures which render Cs or non-nuclear Xs invisible to the rule which scans for a fourth skeletal position.[8]

Moraic Theory constitutes an advance in our understanding of vowel length on various points: it resolves the problem of onset skeletal-position generation associated with CL, it explains why long vowels always define syllable weight, and it allows a simple representational account of mora-counting processes. Nevertheless, various problems with Moraic Theory have emerged in the literature, and if Moraic Theory is wrong as a theory, then it is wrong as a theory of vowel length. For example: Vago (1992) points to difficulties in a moraic analysis of Hungarian length; Tranel (1991) shows for a number of languages how the predicted weight/length equation is incorrect (geminate consonants do not uniquely contribute to weight); the notion of "weight" is vastly more subtle than the μ/μμ distinction implied by Moraic Theory (Crowhurst and Michael 2005).

It is proposed in Tranel (1991), Hume *et al.* (1997), Odden (1997), and Muller (2001) that prosodic theory needs both skeletal representations of length and moraic structure, a proposal which potentially allows preservation of the insights of both moraic and skeletal theories. A striking problem for Moraic Theory noted by Hume *et al.* is that in Leti, long consonants do not contribute to syllable weight as diagnosed by initial-stress assignment (which only affects long vowels).

(43)	tu'vuri	'kind of shell'
	'rɔː'nenu	'they eat turtle'
	vap'pure	'wild pig'
	ppu'narta	'nest's edge'

However, long vowels and consonants form a natural class in blocking a prosodic reduction process of "downgrading" with a range of segmental and stress

[8] Strict CV theory, which posits that all phonological strings are of the form (CV)*, does not face this problem since each mora is represented as an independent nucleus.

consequences. When the first word in a syntactically eligible structure contains only obviously light syllables, diphthongs, or non-geminate consonant clusters, as in (44a), downgrading is possible. When the first word contains a long segment, either a vowel or a consonant, downgrading is blocked.

(44) a.

Separate phrasing	*Downgraded*	
'sivi 'terannu	sɪvɪ 'terannu	'the egg of the chicken'
'spou 'ttɛnanne	spou 'ttɪnannɪ	'keel of the boat'
'ntutnu 'wai	ntutnu 'wai	'he lights the fire'

b. *No downgrading*

'nva:lu 'vatu	'he flings the stone'
'ppatne 'unne	'truck of the orange'

The problem then is that if length entails moraicity and weight is expressed by bimoraicity, we reach contradictory conclusions for Leti. A mixed theory with both skeletal position and moras, on the other hand, would allow heavy syllables (relevant for stress) to be defined with reference to bimoraicity, and length to be represented skeletally. In Leti, consonants including long consonants have no moraic value, whereas vowels do.

In general, the branching-prosody claim for representing long vowels is well supported, but evidence saying clearly what long vowels have two of is hard to come by.

4 How many lengths are there?

Nearly all languages with vowel length are treated as having two degrees of length, as predicted by Jakobsonian binary analysis, so reputed cases of ternary (or greater) length are of theoretical interest. The descriptive literature includes up to eight degrees of phonetic length in Finno-Ugric practices, reported in Sammallahti (1998). The question is whether that which distinguishes long and short extends in the same way to short, long, and overlong. Most languages with claimed ternary length have so little phonological evidence that we have only transcriptional distinctions to consider.

The most famous case of ternary length is Estonian, illustrated in (45). Diacritic notations of vowel length are regularized so that [vː] refers to long and [vːː] refers to extra-long. Estonian orthography does not represent the distinction between Q2 and Q3, except in stops.

(45)

saada	[saːːda]	'to get'
saada	[saːda]	'send!'
sada	[sada]	'hundred'

Lehiste (1966, 1970, 1978) and Prince (1980) show that segmentalizing this distinction obscures Estonian phonology, which is best treated as binary length intersecting with foot structure, where overlength (Q3) arises when one syllable exhausts the foot and plain length (Q2) results when a heavy syllable is followed by a syllable within the foot. In [saːːda], the long syllable exhausts a foot,

/(sa:)da/, whereas the long vowel in /(sa:da)/ is one of two syllables within the foot.

The strongest arguments for foot plus binary-length treatment come from an analysis of Estonian phonology: overlength only occurs in a stressed syllable; it affects computation of subsequent stresses; it is automatic on all final-stressed vowels; the distribution of overlength relative to plain length is not contrastive within the syllable (long vowels and consonants are either both Q2 or neither Q2, so syllables, and not segments, are overlong). See Prince (1980) for an extensive generative analysis. Foot structure also explains multiple surface lengths in Tiberian Hebrew: see the online appendix to this chapter for details of languages mentioned briefly here.

Applecross Gaelic (Ternes 1973) is another language claimed to have ternary length, but such phonological evidence as is available suggests that this results at least in part from higher-level foot-like prosody. Other languages claimed to have more than three degrees of length have been re-analyzed. Whiteley and Muli (1962) claim an actual four-way length distinction for Kikamba. Phonological analysis of Kikamba (Roberts-Kohno 2000) reveals that the durational differences are a fact, but analytically reduce to the fact that Kikamba has vowel length ([kokɔ̌mã] 'to lie down' *vs.* [kobɔ̌ɔ̀tà] 'to accomplish') as well as heterosyllabic identical vowel sequence ([kokɔ.ɔ̀mà], [kokɔ.ɔɔ̌tà] 'to pull'), pointing to one direction for re-analysis of multiple-length claims.

Multiple-length claims are sometimes grounded in vowel quality and tone facts. The German dialects around Dithmarschen and Stavenhagen (Hock 1986, citing Grimme 1922) have been said to have three vowel lengths, but Kohler (2001) points to vowel quality and tonal distinctions that make the claim for three lengths suspicious. Another case is Hopi, based on Whorf (1946), who mentions three lengths. Jeanne (1982) shows that there are two lengths and two contrastive pitches on long vowels.

Mixe dialects of Coatlán (Hoogshagen 1959) and San José el Paraiso (Van Haitsma and Van Haitsma 1976) present three vowel lengths, illustrated by the following Coatlán data.

(46)	poʃ	'a guava'	po:ʃ	'a spider'	po::ʃ	'a knot'
	pet	'a climb'	pe:t	'a broom'	pe::t	'Peter'

The longest quantity only appears in stressed syllables. Since the language has no vowel sequences, Kamba-style re-analysis into vowel cluster *vs.* long vowel would not be appropriate. Hoogshagen phonemicizes the contrast binarily as respectively /poʃ/, /po:ʃ/, /po:hʃ/. There is no direct evidence from rules that reveals how the three lengths behave phonologically. As discussed in the online version of this chapter, the distinction might lie in how coda consonants are prosodified. Two other languages said to have ternary length, where the phonological nature of that distinction is unclear, are Witchita and Yavapai, the latter case having been connected to distinctive pitch.

The most compelling case for ternary vowel length qua length and not an interaction between binary length plus an orthogonal property comes from Dinka, documented in Andersen (1987, 1993), Remijsen and Gilley (2008), and Remijsen and Manyang (2009). Certain grammatical categories cause vowel lengthening, and there are also lexical vowel length contrasts in verbs. Verbs in the past or 3rd singular have a lengthened vowel, with the consequence that within one and the same category, an underlyingly short vowel becomes long and an underlyingly long vowel becomes overlong.

(47) *Short stems* *Lengthened stems*

NEGATIVE	2SG	PAST	3SG	
tét	-tét	téet	-tèet	'pick'
tèet	-téet	téeet	-tèeet	'divulge'

Data of this sort show by processual analogy that the relationship Q1:Q2 is the same as Q2:Q3.

5 Summary

The first task in treating vowel length is distinguishing length from other properties. Difference in duration is what analysts usually pay attention to, but other segmental properties can have durational consequences. Phonological analysis of processes is necessary to argue for a surface difference of "length" *vs.* some other phonetic feature. Since some apparent instances of vowel length facts can (or must) be reduced to something other than length (foot structure in Estonian, or segment-to-syllable structure differences in Kamba), claims about length cannot gratuitously assume a duration-length equation.

The evidence for not representing vowel length with a feature analogous to [nasal] or [voice] is compelling, and numerous arguments support the "long vowels are two" theory, but it has been difficult to resolve what long vowels are two of. The initially attractive idea of long vowels being two identical segments does not work as a general theory of vowel length, because of the ambiguity problem (long vowels can act both like single segments and like sequences) and because languages can contrast a single long vowel with two identical short vowels.

With the addition of at least syllable structure, a coherent account of vowel length emerges, based on the idea that a long vowel is a single segment associated to two prosodic positions. Then the question arises, what are those positions: do they reflect a basic consonant *vs.* vowel distinction, or are they generic in nature? The evidence for a C/V distinction is weak in the face of a highly articulated theory of syllable structure, but the evidence for a highly articulated theory of the syllable à la X' syllable theory is weak in the face of a more stripped-down theory of the syllable with the somewhat richer theory of the timing positions offered by CV phonology. Moraic Theory has certain advantages over skeletal theories relevant to vowel length, in its treatment of compensatory lengthening of vowels, in particular the problem of onset-irrelevance. Various problems with Moraic Theory have been brought out; but these problems seem to center on problems for consonants, not vowel length. At this point, the conclusion that vowel length is represented by two higher-level entities linked to one lower-level thing seems firmly established, but the precise nature of those higher-level entities remains elusive.

ACKNOWLEDGMENTS

I would like to thank the editors and reviewers of this chapter, as well as Juliette Blevins, Anna Bosch, Sam Meier, Bert Remijsen, and Tobias Scheer for comments.

21 Vowel Height

Douglas Pulleyblank

1 Introduction

While all languages have vowels, and all vowels can be described as having a height,[1] actually defining vowel height turns out to be a rather interesting problem (see also CHAPTER 19: VOWEL PLACE). Consider the systems in (1).

(1) *Sample vowel inventories*

a. *2 vowels*			b. *5 vowels*			c. *7 vowels*			d. *10 vowels*		
ɨ			i		u	i		u	i		u
a			e		o	e		o	ɪ		ʊ
				a		ɛ		ɔ	e		o
							a		ɛ		ɔ
										ɐ	
										ɑ	

It would be fairly uncontroversial to assume that a two-vowel system such as (1a) distinguishes between two vowel heights and that a five-vowel system such as (1b) distinguishes between three heights (although see below). The number of "heights" in the seven- and ten-vowel systems, however, depends on various factors. One view of a ten-vowel system such as (1d) is that it involves three "heights" (high, mid, low) cross-cut by a tongue-root feature; an alternative is that such a system involves a highly differentiated height feature with six heights. A seven-vowel pattern such as (1c) presents more analytic indeterminacy. One possibility is to analyze such a pattern as a simplified version of the ten-vowel system: a three-height system with a tongue-root distinction in the mid vowels, or a four-height system with a differentiated height pattern as in (1d), but with four rather than six distinctions. An additional possibility is to consider the seven-vowel and ten-vowel systems to be qualitatively different: while a ten-vowel inventory like (1d) could be analyzed as involving three heights plus a tongue-root distinction, a seven-vowel inventory like (1c) could be seen as involving four heights (and no tongue-root distinction).

[1] This may depend partly on how we define vowels, since various segments may be syllable nuclei without being vocalic.

The following sections discuss sample phonological patterns involving vowel height, considering the types of factors that bear on the analysis of such systems, both phonetic and phonological, as well as the types of proposals that have been made in the phonological literature for the formal instantiation of vowel height. It will be shown that "height" for some researchers reflects the operation of a single parameter, while for others it is the manifestation of several largely unrelated variables.

2 Phonetics of vowel height

There are three basic ways of defining vowel height phonetically: articulatorily, acoustically, and auditorily (Ladefoged and Maddieson 1996). These three possibilities produce rather different pictures of what vowel height might mean, none of which correspond unproblematically to the categories that seem relevant for phonology. Articulatorily, "vowel height" might be taken to suggest a dimension based on the height of the tongue body. While this is a convenient simplification for pedagogical reasons (see Rogers 1991: 170, who defines [height] as "a multivalued feature distinguishing vowels by the position of the highest point of the tongue"), it turns out that tongue body height is only sometimes correlated directly with phonological vowel height (Ladefoged and Maddieson 1996). Different ways of approaching vowel height articulatorily are possible, but none reproduces straightforwardly the sort of vowel space usually assumed by phonologists.

A plausible explanation for this discrepancy could be that vowel height depends more on the acoustic properties of the vocal tract than on any specific articulatory means of achieving the appropriate effect (Elorrieta Puente 1996). According to this view, vowel height could be acoustically defined in terms of the first formant, i.e. F1. This position was taken by Ladefoged (1975: 265), who defined the "prime feature [height] as the inverse of the frequency of the first formant." Although in later editions of Ladefoged's book the section on prime features was removed, the definition of height as correlating inversely with the value of the first formant was maintained (Ladefoged 2006: 188). While certainly an accurate indication of height in many instances, such an acoustic definition of height also appears to be inadequate in a number of cases. One example involves the determination of vowel height in languages with tongue-root advancement/retraction. As shown by Lindau (1979), Ladefoged and Maddieson (1996), Gick *et al.* (2006), and others, some tongue-root harmony languages exhibit advanced mid vowels such as [e] that are "higher" (that is, lower F1) than the corresponding retracted high vowel such as [ɪ]. Such systems cannot assign vowels to a particular height solely on the basis of the value for the first formant.

Auditory characterizations of vowel height are adopted in much phonological work (Lindau 1978; Casali 1996). From introductory textbooks, to IPA charts, to research articles, we are accustomed to two-dimensional representations of vowels where "height" is represented on the vertical axis and backness is represented on the horizontal axis. In Jones's (1972) proposal for cardinal vowels, reference vowels were established on the basis of articulatory extremes ([i ɑ]), with additional reference points defined in terms of auditorily equidistant steps.[2]

[2] Jones (1972: 32) refers to "acoustically equidistant vowels," but it is clear that he means vowels as perceived by a trained listener.

While the examples in (11a) have a consistent [a] as their second vowel, those in (11b) alternate, exhibiting [u] in non-word-final position and [a] in word-final position. To postulate an underlying /a/ for (11b) would be problematic, since the vowel behaves differently from the consistent [a] of (11a). To postulate an underlying /u/ for (11b) is unproblematic, making the correct prediction that there should be no cases of this type with a word-final [u]. Hence such data motivate a pattern of word-final lowering to [a].

This case of lowering is different from the cases seen so far, in that it is positionally triggered, not assimilatory. In addition, additional forms raise an interesting issue.

(12) *Lardil front vowels*

	uninflected	*non-future*	*future*	
a.	tjempe	ṯjempe-n	ṯjempe-ɽ	'mother's father'
	wiṯe	wiṯe-n	wiṯe-ɽ	'interior'
b.	ŋin̪e	ŋin̪i-n	ŋin̪i-wuɽ	'skin'
	pape	papi-n	papi-ɽ	'father's mother'

Comparable to (11), some forms show an invariant [e], while others show variation between word-final [e] and word-medial [i]. As with (11), this can be analyzed as involving /e/ for (12a) and /i/ for (12b), in conjunction with a rule of lowering.

It appears from such data that the result of lowering is low when /u/ is the target but mid when /i/ is the target. While possible, it should be noted that the vowel inventory of Lardil is {i e a u}. It appears, therefore, that Lardil distinguishes between only two heights, with both [e] and [a] constituting "low" vowels.

4.2.3 *Chain shifts: One-step lowering*

Paralleling the cases of stepwise raising seen above, cases of stepwise lowering are also attested. Esimbi (Bantu, Niger-Congo; Cameroon) is an intriguing case (Hyman 1988). There are three underlying prefix vowels and eight underlying stem vowels, but the underlying pattern is obscured since the height of the stem vowel is transferred to the prefix, the stem itself surfacing uniformly high. This height transfer is illustrated with the prefix vowel /I/ "class 9 singular," "class 10 plural."

(13) *Esimbi class 9/10 nouns*

	singular	*plural*	
/i/	ì-bì	í-bi	'goat'
/u/	ì-sùmù	ì-sumu	'thorn'
/e/	è-gbì	é-gbi	'bushfowl'
/o/	è-nùnù	e-núnu	'bird'
/ə/	è-bi	e-bi	'canerat'
/ɛ/	ɛ̀-ɲìmì	ɛ-ɲimì	'animal'
/ɔ/	ɛ̀-fùmù	ɛ-fumù	'hippo'
/a/	ɛ̀-kìrɨ̀	ɛ-kirɨ	'headpad'

With the highest stem vowels /i u/, the prefix surfaces as [i]; with the next highest stem vowels /e o ə/, the prefix surfaces as [e]; with the lowest stem vowels to height. There are cases, however, where height assimilation involves a target becoming identical to a trigger with respect to its height specifications.

Consider lowering in Matumbi (Bantu, Niger-Congo; Tanzania; Odden 1991). When the causative suffix, which Odden analyzes as being underlyingly high and advanced (16a), (16b), (16g), follows a high retracted vowel, it is realized as high retracted (16c), (16d); when it follows a mid vowel, it is realized as mid (16e), (16f).

(16) *Matumbi*

a.	út-a	'pull'	út-ij-a	'make pull'
b.	jíb-a	'steal'	jíb-ij-a	'make steal'
c.	jʊ́joot-a	'whisper'	jʊ́jout-ɪj-a	'make whisper'
d.	bíɪk-a	'put'	bíɪk-ɪj-a	'make put'
e.	gɔ́ɔnʤ-a	'sleep'	gɔ́ɔnʤ-ɛj-a	'make sleep'
f.	ʧɛ́ɛŋg-a	'build'	ʧɛ́ɛŋg-ɛj-a	'make build'
g.	káat-a	'cut'	káat-ij-a	'make cut'

In a pattern of this type, the height assimilation involves trigger–target identity for height. Moreover, it should be noted that more than two "heights" are involved in this shift; identity is not a result simply because the system distinguishes only between high and non-high vowels.

4.3.2 *Harmony*

Whether harmonic patterns based on vowel height are considered common or rare depends in part on whether "ATR"-like systems are considered to be height harmony. If [ATR] is a height feature, then height harmonies are quite common; if [ATR] is a place feature, then "height"-based harmony systems appear less common (CHAPTER 19: VOWEL PLACE). Nevertheless, even abstracting away from cross-height harmony systems of the "ATR" type, harmonic systems based on height do occur; for discussion of a wide variety of systems, see Linebaugh (2007).

In this section, a small number of harmonic systems based on height are considered, including systems of the cross-height "ATR" type. It should be noted, however, that "harmony" is used as a descriptive term only: there is no incontrovertible reason to think that there is a formally definable type of phonological pattern corresponding to those patterns we consider to be harmonic (Archangeli and Pulleyblank 2007).

To start, C'Lela (Benue-Congo, Niger-Congo; Nigeria) presents a particularly interesting case of height harmony (Dettweiler 2000; Pulleyblank 2002). In C'Lela, within a morpheme, only vowels of like height may co-occur: high vowels may co-occur, non-high vowels may co-occur, but vowels of mixed height may not.[6]

(17) *C'Lela root-internal harmony*

	High vowels			*Non-high vowels*	
a.	d^{ə}tɨndi	'nest'	b.	kʋesa	'show'
	ʧ^{ə}rini	'charcoal'		ʧ^{ə}gjɔmbo	'eyebrows'
	k^{ə}piru	'flower'		d^{ə}ʋɛso	'broom'

[6] The raised schwa represents a short transitional vowel that Dettweiler (2000) considers "non-phonemic," appearing in certain types of consonant clusters.

(20) *Degema stems*

a. *Advanced*		b. *Retracted*	
gbodí	'catch'	fowɔ́	'be cool (of food)'
gurón	'postpone'	ganɛ́	'have as one's lover'
ɗimé	'submerge'	hɔβá	'bail out water from a canoe, etc.'
lebə́	'be partially ripe (of fruits)'	sɪgɔ́m	'jump with one leg folded'

Prefixes in Degema must agree in their tongue-root value with vowels of the stem. Consider, for example, noun class prefixes such as those in (21), where (21a) exhibit advanced values and (21b) retracted values.

(21) *Degema prefixes*

a. *singular*	*plural*		b. *singular*	*plural*	
u-túm	ə-túm	'tail'	ʊ-ɗɔ́m	a-ɗɔ́m	'marriage'
o-kpokí	i-kpokí	'money'	ɔ́-hɔ́hɔ	í-hɔ́hɔ	'fowl'
e-kúnési	i-kúnési	'bed'	ɛ-ɗɔ́ŋʷ	ɪ-ɗɔ́ŋʷ	'throat'
ə́-milíɓə	í-milíɓə	'night heron'	a-ɗʊ́	ɪ-ɗʊ́	'face'

Although less common than prefixes in Degema, suffixes also agree in their tongue-root value with the stem to which they attach. Consider examples of the gerundive.

(22) *Degema suffixes*

a. *Advanced*		b. *Retracted*	
ù-dér-ˈə́m	'cooking'	ʊ̀-tɛ́v-ˈám	'descending'
ù-vój-ˈɔ́m	'fetching'	ʊ̀-sɔ́l-ˈám	'jumping'

Overall, height harmony systems are amply attested and instantiate the typical range of variables discussed in the harmony literature: dominant/recessive *vs.* root-controlled patterns, transparency *vs.* opacity, directionality, and so on. There are also cases illustrating interesting interactions with stress; see, for example, Fitzgerald (2002); Walker (2005).

4.4 Neutralization

A large and interesting class of patterns involving vowel height is that of large-scale neutralization in languages where different vowel inventories are attested in different positions (Crosswhite 2001). An example is Catalan (Romance, Indo-European; Spain; Mascaró 1983):

(23) *Catalan vowel reduction*

Stressed			*Unstressed*		
/i/	'prim	'thin'	[i]	əpri'ma	'to make thin'
/e/	'serp	'snake'	[ə]	sər'pɔtə	'big snake'
/ɛ/	'pɛl	'hair'		pə'lut	'hairy'
/a/	'sak	'sack'		sə'kɛt	'small sack'
/ɔ/	'pɔrt	'harbor'	[u]	purtu'ari	'related to harbor (ADJ)'
/o/	'gos	'dog'		gu'sas	'big dog'
/u/	'ʎum	'light'		ʎumi'nos	'light (ADJ)'

As illustrated in (23), seven vowels are found in stressed positions in Catalan, but these distinctions collapse to three when the corresponding vowels appear in unstressed positions. In stressed positions, three or four vowel heights are distinguished, depending on one's analysis of the vowels [e o] *vs.* [ɛ ɔ]; in unstressed positions, a two-way vowel height distinction is observed. This case illustrates a general pattern where fewer vowel heights are exhibited in positions of reduction than in positions of full contrast (CHAPTER 79: REDUCTION). Note in this regard that the Catalan case exhibits no loss of "color" distinctions, that is, distinctions involving [back] and [round].

4.5 *Interactions between consonants and vowel height*

Although the focus of this chapter is vowels, not all issues of vowel height are restricted to vowels. There are numerous examples of consonant–vowel interactions where vowel height is relevant, involving vowels affecting consonants as well as consonants affecting vowels. Samples of both types are considered in this section. (See also CHAPTER 75: CONSONANT–VOWEL PLACE FEATURE INTERACTIONS for some related phenomena.)

4.5.1 *Vowels affecting consonants*

As a first example of vowels affecting consonants, consider assibilation in Canadian French (Romance, Indo-European; Canada; Dumas 1978; Walker 1984). The coronal stops [t d] surface without change when before non-high or back vowels (e.g. [taʀt] 'pie', [tɛm] 'topic, theme', [do] 'back', [dɑ̃] 'tooth'), but they become affricates before high front vowels or glides.

(24) *Canadian French assibilation*

[ts]			[dz]	
[i]	patsi	'small'	ʒødzi	'Thursday'
[ɪ]	tsɪg	'tiger'	ʒʏʀɪdzɪk	'legal'
[ɪ^{i}]	etsɪ^{i}ʀ	'stretch'	dzɪ^{i}ʀ	'say'
[j]	tsjɛd	'lukewarm'	dzjɛt	'diet'
[y]	tsynɛl	'tunnel'	ʀɑ̃dzy	'returned'
[ʏ]	tsʏb	'tube'	pɑ̃dzʏl	'pendulum'
[ʏ^{y}]	fʀitsʏʀ	'frying'	dzʏ^{y}ʀ	'hard'
[ɥ]	tsɥɪl	'tile'	ʀedzɥɪ^{i}ʀ	'reduce'

Assibilation takes place whether the trigger is rounded or unrounded, tense or lax, a monophthong or a diphthong, a vowel or a glide. Dumas (1978) takes this as evidence that the distinction between the tense vowels [i y] and their lax counterparts [ɪ ʏ] (which is determined allophonically by syllable structure) is not a difference of vowel height. Auditorily, he argues that there is no significant difference between the mid vowels [e ø o] and the high lax vowels. Consequently, if laxing involved a change in height, we would expect lax vowels not to be assibilation triggers; that they are triggers suggests that the laxing process affects a dimension other than height.

These examples constitute one small example from the large class of palatalization cases attested cross-linguistically (see CHAPTER 71: PALATALIZATION). They are of relevance to vowel height since height is a typical delimiter on the class of vowels that triggers such processes.

A rather different type of consonant–vowel interaction is found in Chumburung (Kwa, Niger-Congo; Ghana; Snider 1984): [l] (a lateral) and [r] (a "lightly-retroflexed alveolar flap") are in complementary distribution. For some speakers, the distribution is unrelated to vowels, with [l] occurring in word and noun-stem-initial position ([lɔ́sɛ́] 'difficult'; [kì-lìmpɔ́] 'shea nut') and in a syllable following another [l] ([lóolí] 'deep'), while [r] occurs elsewhere ([jono-ro] 'in (the) dog'). For some speakers, however, this allophonic pattern between [l] and [r] interacts with vowel harmony, a pattern in Chumburung that is largely analogous to the tongue-root harmony system seen for Degema in §4.3.2, with the difference that Chumburung has a single (retracted) low vowel. For the relevant speakers, medial [l] only surfaces after another [l] if the vowels are in the [+ATR] set:

(25) *Chumburung [l] ~ [r]*

a.	[+ATR]		b.	[−ATR]	
	làlàkwìʔ	'type of tuber'		làarɪ́	'waist'
	lóolí	'deep'		lɔ̀ɔrɪ́	'to remove seeds'
	àlúuláʔ	'red dye'		làarɔ́	'to lie across'

Alternations can be observed under suffixation.

(26) *Chumburung suffix alternations:* /-rɔ/ (LOCATIVE)

a. jono-ro 'in (the) dog'
b. kanɔ-rɔ 'in (the) mouth'
c. lɔ-rɔ 'in (the) sore'
d. laale-lo 'in (the) cattle egret'

Since the suffix-initial consonant is neither word-initial nor stem-initial, it would be correctly expected to surface as [r] in the default case (26a, 26b) and even after [l] if the vowel harmony class is [−ATR] (26c); if the suffix follows an [l], however, and if the harmonic class is [+ATR], then the suffix surfaces with [l] (26d).

This particular kind of case is irrelevant if [ATR] is not a height feature. The point, however, is that height and/or tongue-root distinctions in vowels condition a range of consonantal effects: palatalization, differences in liquids, differences between velars and uvulars (Li 1996), and so on.

4.5.2 *Consonants affecting vowels*

Elorrieta Puente (1996) considers a wide range of cases where consonants affect vowel height, identifying two principal types of cases: (a) raising, triggered typically by palatals, palato-alveolars, or glides; (b) lowering, triggered typically by uvulars, pharyngeals, laryngeals, or rhotics. (See also Vaux (1996, 1998) and Fitzgerald (2002) for cases involving laryngeal features; and CHAPTER 25: PHARYNGEALS.)

Consider first an example of raising, taken from Kikuria (Wiswall 1991; Elorrieta Puente 1996). The relevant example involves a pattern of vowel raising triggered by both vowels any consonants. When a mid vowel prefix appears before a non-high stem vowel, the prefix surfaces as mid.[7]

[7] The k~g alternations observed in the Kikuria data are due to Dahl's Law, an unrelated pattern of voicing dissimilation. See, for example, Davy and Nurse (1982).

(27) *Kikuria mid vowel prefixes*

oko-raara	'sleep'
oko-roma	'bite'
oko-gɛra	'weed'

In contrast, when such a prefix occurs before a high vowel stem, the prefix raises to high.

(28) *Kikuria raising: High vowel triggers*

uku-rugja	'chase'
ugu-siika	'close a door'

Of particular interest, the mid vowel of the prefix is also raised if the first syllable either contains a glide [j w] or a palatal consonant [ʧ ɲ].

(29) *Kikuria raising: Consonantal triggers*

ugu-tweeba	'forget us'
uku-bjoora	'remove from water'
ugu-ʧɔɔra	'draw'
ukuu-ɲandekera	'write for me'

In such cases, it is perhaps unsurprising that glides behave in a manner comparable to vowels, since glides are simply the non-syllabic counterpart of the high vowels that are canonical triggers of raising (CHAPTER 15: GLIDES). For the non-glides, the fact that palatals and alveo-palatals are triggers of raising in Kikuria but that velars are not is typical of such raising patterns cross-linguistically. Being "high" seems to be required of a consonantal trigger, but assuming that velars are also high means that simply being high is not sufficient in Kikuria.

With respect to lowering, the typical case is one where lowering is induced by the class of gutturals. Although this class may vary somewhat from language to language, it is generally defined by segments articulated in the post-velar region. Consider, for example, lowering in Gitksan (Tsimshianic; Canada; Brown 2008), illustrated here with plural reduplication. As seen in (30), there is a class of plurals formed by the prefixation of either C*i*(C)- or C*ix*-.

(30) *Gitksan plural reduplication*

saksxʷ	six-saksxʷ	'be clean'
dzam	dzim-dzam	'cook, boil (TRANS)'
ɬak	ɬi-ɬak	'be crooked'
gʷalkʷ	gʷil-gʷalkʷ	'be dry'

When the vowel of the reduplicative prefix precedes or follows a uvular or a laryngeal, the vowel lowers to [a].

(31) *Gitksan lowering*

dzoq	dzaχ-dzoq	'camp'
ɢetxʷ	ɢa-ɢetxʷ	'be diffiicult, be expensive'
ɢoːt	ɢa-ɢoːt	'heart'
hets	has-hets	'send'
ʔos	ʔas-ʔos	'dog'

The Gitksan pattern is one where lowering is triggered by uvulars and laryngeals. Perhaps more typical would be a case where vowels are lowered by a "guttural" class including pharyngeals (CHAPTER 25: PHARYNGEALS). Setting aside the presence/absence of pharyngeals, languages exhibiting lowering differ as to whether laryngeals are included (e.g. Arabic, Semitic, Afroasiatic; McCarthy 1994) or excluded (e.g. Nuu-chah-nulth, Wakashan; Canada; Wilson 2007); see Rose (1996).

Two final patterns touched upon here are ones where two input vowels merge into a single output vowel (coalescence) and where a single vowel splits into more than one component (diphthongization).

4.6 Coalescence

Patterns of vowel coalescence are frequently height-dependent. Consider the following examples from Anufɔ (Kwa, Niger-Congo; Ghana; Casali 1996).

(32) *Anufɔ vowel contact*

a.	/jɛ-i/	jɛː	'raise it'
b.	/ʤɔ-u/	ʤɔː	'cool you'
c.	/bu-i/	bwiː	'break it'
d.	/fa-i/	fɛː	'take it'
e.	/bo-i/	bweː	'beat it'
f.	/sɔ-i/	swɛː	'carry it'
g.	/fa-u/	fɔː	'take you'
h.	/bo-u/	boː	'beat you'
i.	/n-de-u/	ndoː	'I will take it for you'

Different subcases are of interest for different, though related, reasons. In examples like (32a), (32b), the output contains no discernible trace (other than length) of the high vowel in the input. In cases like (32c), (32e), (32f), labiality is never lost, resulting in a glide–vowel sequence when the first vowel of the sequence is labial and the second vowel is not. The cases of particular interest for vowel height, however, are ones like (32a), (32b), (32e), (32f), (32h), (32i), on the one hand, and (32d), (32g), on the other. In the former type, we see that the combination of a mid vowel with a high vowel results in a long mid vowel; in the latter type, we see that the combination of a low vowel and a high vowel also results in a long mid vowel. Note in particular that the output of a low–high sequence is neither low nor high, but an intermediate vowel.

The pattern observed in Anufɔ is typical in terms of what Casali (1996) refers to as "height coalescence." He observes that coalescence is frequent in cases where V1 is non-high (e.g. [a]) and V2 is higher than V1 (e.g. [i] or [u]), the result being non-high with the place properties of V2. The results in (32d), (32g) are canonical with respect to this pattern. For an in-depth discussion of such patterns, along with the identification of robust subpatterns, see Casali (1996).

4.7 Diphthongization

In patterns of diphthongization, vowel height is frequently an important variable, with diphthongs related to a set of corresponding monophthongs in ways

5.1 Features constituting "height"

As discussed in §2, there is no way a priori to decide that a particular feature should be a height feature. For example, [ATR] might be classified as a "height" feature if acoustics was taken as definitional (due to its effect on F1), but not as a "height" feature if articulatory tongue body height was taken as definitional. Consequently, theories vary as to whether [ATR] is included as a feature or not (Clements and Hume 1995; Vaux 1996), and if it is a feature, whether it is a height feature or not. For example, Clements (1990) and Clements and Hume (1995) discuss the possibility that [ATR] could be eliminated; Odden (1991) maintains a feature [ATR], arguing that it is under a "height" node that dominates [high], [ATR], and (perhaps) [low]; Parkinson (1996) proposes a "height" constituent consisting solely of instances of the feature [closed], with [ATR] analyzed outside of the "height" node as a place feature; Elorrieta Puente (1996: 6) considers that "height" involves a single feature composite of the dimensions "high–low, tense–lax, and advanced–nonadvanced tongue root." Similar issues arise about potential height features involving tenseness and peripherality.

An additional issue affecting featural analyses of height involves the division of vowels, particularly "lowish" vowels, into classes. Parkinson (1996: 117–119), for example, argues that although Njebi, Basaa and Efik all have the vowels {i e ɛ a ɔ o u}, the breakdown of the three inventories into vowel heights is different in each case.[8] For Njebi, as seen in (8) above, four heights need to be distinguished since vowel raising distinguishes between four classes: [a] raises to [ɛ]; [ɛ ɔ] raise to [e o]; [e o] raise to [i u].

(35) *Differing interpretations of comparable vowels*

a. *Njɛbi*		b. *Basaa*		c. *Efik*	
Height 1	[i u]	Height 1	[i u]	Height 1	[i ɨ u]
Height 2	[e o]	Height 2	[e o]	Height 2	[e ɛ a ɔ o]
Height 3	[ɛ ɔ]	Height 3	[a ɛ ɔ]		
Height 4	[a]				

In contrast, raising in Basaa involves only three heights: [a ɛ ɔ] raise to [e o]; [e o] raise to [i u]. Finally Efik distinguishes two heights: [i ɨ u] *vs.* [e ɛ a ɔ o]. Those vowels not distinguished by height are differentiated by place specifications like [labial], [coronal], and [pharyngeal]. Overall, establishing appropriate specifications for vowel height is a complex problem involving the analysis of both height and place and, depending on the theory, analyses of superficially similar inventories may vary considerably from language to language.

A number of proposals for height are considered below, including what the features are and how they are situated within a broader theory of feature composition and structure.

5.2 Features: [high] and [low]

Following Chomsky and Halle (1968; *SPE*), the dominant approach to vowel height over the years has been to base vowel height on the interaction of two binary features, [±high] and [±low].

[8] Not relevant to the point under discussion, Efik also has the central vowel [ɨ] and Njebi also has the central vowel [ə].

(36) *Feature definitions* (*SPE*: 394–395)

a. [±high]
High sounds are produced by raising the body of the tongue above the level that it occupies in the neutral position; non-high sounds are produced without such a raising of the tongue body.

b. [±low]
Low sounds are produced by lowering the body of the tongue below the level that it occupies in the neutral position; non-low sounds are produced without such a lowering of the body of the tongue.

Together, these features define three vowel heights, the possibility of [+high, +low] being ruled out by the definitions of the two features.

(37) *Defining vowel heights*

	High	Mid	Low
[high]	+	–	–
[low]	–	–	+

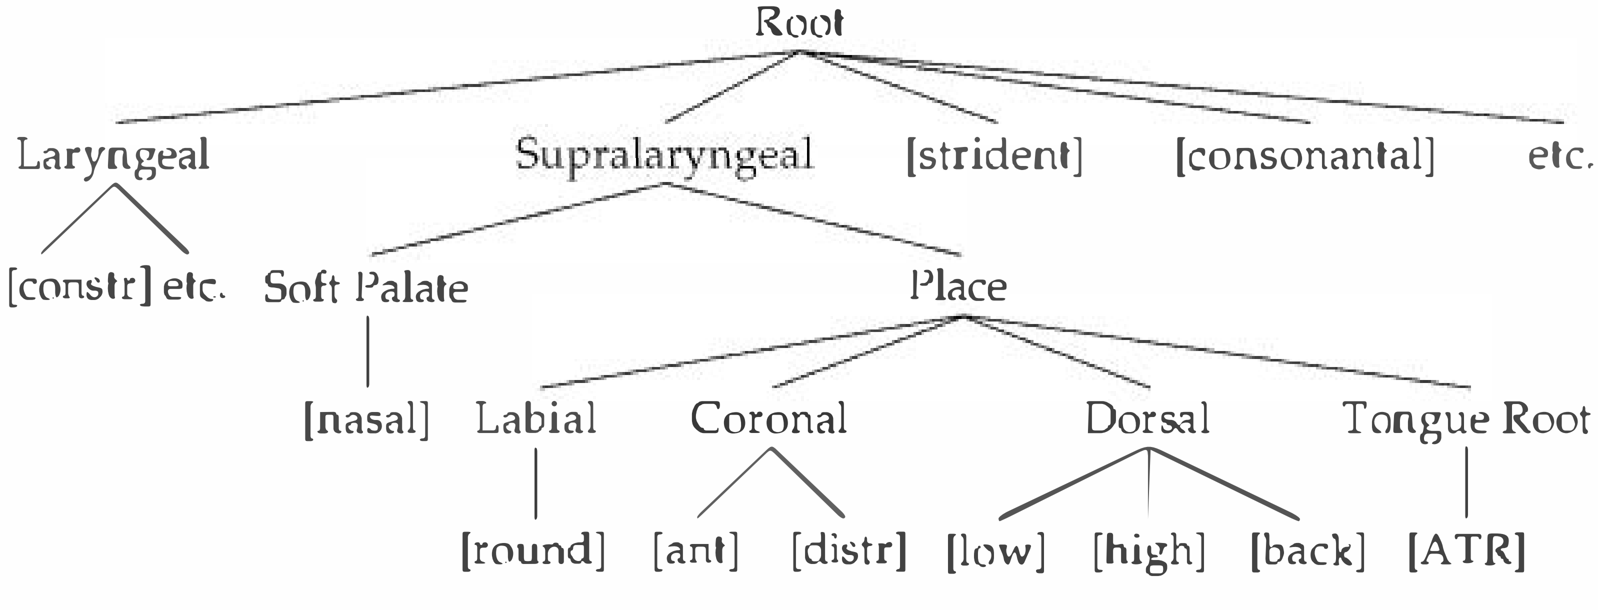
In defining a maximum of three vowel heights, this approach requires that additional, non-height features interact with [±high] and [±low] to define a full range of vowel contrasts. For example, [±tense] and [±covered] are proposed in *SPE*.

A particularly important point to note about this kind of theory (Parkinson 1996) is that vowel height plays no formal role: there is no class of "height" features in any formal sense. While it is possible within the *SPE* model for a rule to refer to the two features [±high] and [±low], such a pair has no formal status that is different from, say, [±high] and [±back], or [±high] and [±nasal]. Within that theory, distinctive features constitute an unstructured set, and any combination of features can constitute the set employed in a given rule.

5.3 *Feature geometry with [high] and [low]*

This lack of formal "height" features is a property that has continued to be adopted in numerous subsequent theories of vowel features. For example, in the influential work of Sagey (1986, 1990) on feature geometry, the features [±high] and [±low] continue to be assumed, assigned as two of the three features of the Dorsal articulator node.

(38) *The feature hierarchy in Sagey* (1990: 113)



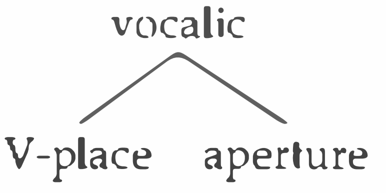
height 2	[e]	əje-é	'it's a spider'
	[ə]	əɲe-é	'it's me'[9]
	[o]	əwo-é	'it's you'
height 1	[ɛ]	ə̀ulɛ-ɛ́	'it's a weaver bird'
	[a]	àgbɛ̀-ɛ̀	'it's a load'[10]
	[ɔ]	ə̀sɔ́-ɛ́	'it's a horse'

If such assimilation is to be given "unit" status, then features for vowel height must be distinguished from vowel place, with a rule spreading specifically vowel height.

5.5 *Properties of a height class*

The response to arguments such as those presented in §5.4 has been to establish a vowel height node, labeled "aperture" by Clements (1990), which is independent of place (Clements 1990; Odden 1991; Wiswall 1991; Goad 1993; Elorrieta Puente 1996; Parkinson 1996; etc.). Typically, both place and height are considered to be daughters of a vocalic node. For example, Clements and Hume (1995) propose a vocalic node branching into place features ("V-place") and height features ("aperture").

(41) *Distinguishing place and height*



Of specific importance with respect to the characterization of vowel height, the featural content of the aperture/height node must be determined.

While the formal instantiations of this kind of proposal are relatively new, the conceptualization of speech sounds being composed of specifications for classes of features goes back to the International Phonetic Alphabet. As argued by Ladefoged and Halle (1988), the IPA constitutes a theory of segment structure, and in the IPA theory, vowel height is explicitly recognized as an important class. In the following sections, a sample of the proposals for formally characterizing the vowel height class are laid out.

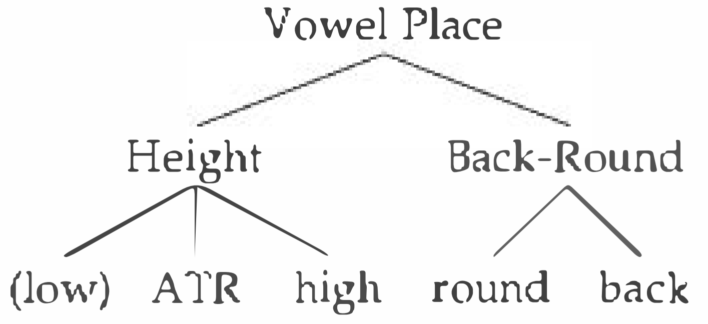
Ideally, a survey such as this one would carefully examine the arguments that have been presented for specific models, examining both successes and problems. Given the limited scope of this chapter, however, much of the discussion below will not go beyond a brief introduction. The reasons for this go beyond simple limitations on space. To adequately address the success of a given proposal, one needs to consider at least three things: (a) the validity of the empirical claims; (b) the predictions concerning natural classes, and how such predictions match the empirical generalizations; (c) how the theory of vowel height interacts with the overall theory of phonology. Examples of these considerations will be given below, but they will not be investigated in detail for each theory presented.

9 The stem vowel [ə] undergoes fronting by an independent rule (Clements 1990).
10 As with [ə], the stem vowel [a] undergoes fronting by an independent rule (Clements 1990).

5.5.1 *Grouping [high] and [ATR]*

Odden (1991) argues for grouping [ATR] with [high] under a "height" node.[11]

(42) *Height node*



As seen in Matumbi (§4.3.1), both the features [high] and [ATR] together are affected by height assimilation but not the feature(s) for backness and rounding; see the data in (16). On the basis of such data, Odden proposes that it is the "height" node that assimilates. In making the argument, Odden explicitly addresses the alternative possibility that assimilation is the combined result of assimilating [ATR] and [high] independently. He rejects such a "two-rule" analysis on two grounds. First, neither assimilation of [high] nor assimilation of [ATR] applies when the potential trigger is [ɛ] and the potential target is [u]; Odden suggests that this condition should be stated once, not twice. Second, morphemes that are exceptional to one type of assimilation are exceptional to both, again suggesting a unified analysis of the "two" processes.

The hierarchy in (42) is a natural development of the approach to vowel height in *SPE*, in that the features [low], [high], [back], and so on continue to be posited; see also Wiswall (1991) and Goad (1993). The distinction is that these features are assigned class status, with a bifurcation between the features defining height and those defining place.

A fundamental observation that can be made about this type of proposal is that vowel height as a class is defined by the interaction of formally independent sub-height features. Features like [high], [low], and [ATR] may function as three individual, independent features, or they may function together as the height class. In contrast with such an approach, numerous researchers have proposed that height should be viewed in a more integrated fashion, as will be discussed below. In discussing the various possible approaches that have been taken to gradient height, it is important to keep one central point in mind. Independent of one's precise proposals for vowel height, it is possible to consider [ATR] as being a height feature (and therefore integrated into the gradient height framework) or as being a place feature (and therefore independent of gradient height). The issue of tongue-root involvement is therefore a matter to be resolved in one way or the other for all proposals.

5.5.2 *Gradient height*

Amongst the early proposals for a gradient height feature are Ladefoged (1975) and Lindau (1978). A central argument in favor of gradience comes from chain shift cases such as those seen in §4.1.3, §4.2.3, and §4.7. Lindau (1978) discusses

[11] The feature [low] is parenthesized because Odden (1991) considers the evidence he presents to be inconclusive in this regard.

22 Consonantal Place of Articulation

Keren Rice

1 Introduction

An examination of the International Phonetic Alphabet chart (IPA 2007) yields a large number of consonantal places of articulation that are phonetically possible: bilabial, labio-dental, dental, alveolar, post-alveolar, retroflex, palatal, velar, uvular, pharyngeal, and glottal, as shown in Table 22.1.

Some identify even more places of articulation. Ladefoged and Maddieson (1996: 44), in a major work on sounds of the world's languages, present 17 places of articulation: bilabial, labio-dental, linguo-labial, interdental, laminal dental, laminal alveolar, lamino-post-alveolar (palato-alveolar), apical dental, apical alveolar, apical post-alveolar, sub-apical palatal (retroflex), palatal, velar, uvular, pharyngeal, epiglottal, and glottal. They divide these into five major target regions: labial (bilabial, labio-dental), coronal (laminal [linguo-labial, interdental, laminal dental, laminal alveolar, laminal post-alveolar], apical [apical dental, apical alveolar, apical post-alveolar], sub-apical [sub-apical palatal (retroflex)]), dorsal (palatal, velar, uvular), radical (pharyngeal, epiglottal), and laryngeal (glottal).

Table 22.1 The International Phonetic Alphabet (revised to 2005)

	bilabial	labio-dental	dental	alveolar	post-alveolar	retroflex	palatal	velar	uvular	pharyngeal	glottal
plosive	p b			t d		ʈ ɖ	c ɟ	k ɡ	q ɢ		ʔ
nasal	m	ɱ		n		ɳ	ɲ	ŋ	ɴ		
trill	ʙ			r					ʀ		
tap/flap		ⱱ		ɾ		ɽ					
fricative	ɸ β	f v	θ ð	s z	ʃ ʒ	ʂ ʐ	ç ʝ	x ɣ	χ ʁ	ħ ʕ	h ɦ
lateral fricative				ɬ ɮ							
approximant		ʋ		ɹ		ɻ	j	ɰ			
lateral approximant				l		ɭ	ʎ	ʟ			

My goal in this chapter is to examine several issues surrounding consonantal place of articulation. I begin with an overview of the types of evidence used to justify the major place groupings, and then examine the evidence for subclasses within these and asymmetries in patterning between different places of articulation. I then review the features used to describe places of articulation. I end with a discussion of some additional issues relevant to the study of place of articulation.

2 The major places of articulation: A phonological perspective

The goal of a chart like that in Table 22.1 or a list like that of Ladefoged and Maddieson (1996) is to characterize locations where constriction is possible. From the perspective of phonology, the points of constriction group into classes, with sub-places within a class, based on natural class patterning (CHAPTER 17: DISTINCTIVE FEATURES). As discussed above, Ladefoged and Maddieson (1996: 44) identify five major places of articulation: labial, coronal, dorsal, radical, and laryngeal. Other theories note a similar small number of major places. For instance, Articulator Theory and Revised Articulator Theory (e.g. Sagey 1990; Halle *et al.* 2000: §4) distinguish labial, coronal (tongue blade), dorsal (tongue body), and tongue root or radical. Element theory distinguishes labials, palatals, coronals, and velars (e.g. Harris and Lindsey 1995). While there are differences between these theories, they agree on the existence of major zones, and I begin with evidence for these.

In the following discussion I examine types of evidence for the division into labial, coronal, dorsal, radical (also called tongue root and pharyngeal), and laryngeal places of articulation, as well as the sub-places within each. Each section is organized as follows. I first present a phonetic description of the class. I next examine phonological evidence for the class, including distribution, harmony patterns, co-occurrence restrictions, and other phonological processes. I then introduce sub-places within the major place, asking if what are categorized as place distinctions are best analyzed as such from a phonological perspective.

Before turning to evidence for the individual features, I review one argument for places of articulation in the oral cavity being divided into labial, coronal, and dorsal, based on the major articulator involved. Sagey (1990), in an important work on place, presents an argument for this division based on complex articulations (CHAPTER 29: SECONDARY AND DOUBLE ARTICULATION). In a cross-linguistic survey, she finds that only a limited number of complex articulations occur. There are labial-velars (e.g. [kp]), probably the best studied. In addition, there are labial-coronals (e.g. [pt]), coronal-velars (e.g. [ǁ]), and labial-coronal-velars (tkw). Unattested are, for instance, complex articulations consisting of two labial type articulations or two coronal type articulations. The possible place combinations found, Sagey argues, present an argument for these three major places of articulation.

2.1 *Labial place of articulation*

Labial includes bilabial, articulated with the upper and lower lips, and labio-dental, articulated with the tip of the tongue and the lower lip; in addition, Ladefoged and Maddieson (1996: 44) include a linguo-labial place of articulation, articulated with the upper lip and the tongue, but they treat this as a type of coronal. This sound has not figured in the phonological literature, and I do not discuss it here.

(5) a. *Rotokas (North Bougainville)*

alveolar
t

b. *Yareba (Papuan)*

alveolar
t d dz s

c. *Finnish (Uralic)*

dental	alveolar
t̪ (d̪)	s

d. *Hungarian (Uralic)*

dental	palato-alveolar	palatal
t̪ d̪ t̪s̪ d̪z̪ s̪ z̪	ʧ ʤ ʃ ʒ	cç ɟʝ

e. *Pashto (Indo-Iranian)*

dental/alveolar	palato-alveolar	retroflex
t d ts dz s z	ʧ ʤ ʃ ʒ	ʈ ɖ ʂ ʐ

f. *Western Desert (Pama-Nyungan)*

dental	alveolar	retroflex

h. *Malayalam (Dravidian) voiceless stops/affricates*

dental	alveolar	palato-alveolar/ palatal	retroflex
t̪ d̪	t	ʧ ʤ	ʈ ɖ

i. *Kalasha (Indo-Aryan; only voiceless stops/affricates shown)* (Arsenault and Kochetov, forthcoming)

dental	palatal	retroflex
t ts	tɕ	ʈ ʈʂ

The above are representative of the coronal obstruent inventories found cross-linguistically, from Rotokas with a single coronal obstruent to the coronal inventories of languages such as Pashto, Malayalam, and Kalasha, with affricates and fricatives as well as stops.

2.2.2 *Evidence for coronals as a phonological class*

There is considerable evidence that coronals pattern as a class. I summarize some below.

A well-known argument for the class of coronals involves co-occurrence restrictions. Hall (1997: 5), following Davis and Hammond (1995: 163–164), argues that there are co-occurrence restrictions in most varieties of American English against the sequence coronal + [j] + vowel.

(6) p b m f v k g + j + vowel
*θ ð t d s z ʃ ʒ ʧ ʤ n l r + j + vowel

The prohibition includes all English coronal consonants, and holds of syllable-initial clusters. Thus, clusters with /j/ are not allowed if the first segment is coronal, irrespective of its sub-place of articulation; they are otherwise.

Dixon (1980) discusses a variety of types of evidence from Australian languages for grouping coronal consonants as a class. One argument is based on neutralization and variation amongst coronals (CHAPTER 80: MERGERS AND NEUTRALIZATION). Typical Australian languages show a four-way coronal contrast, subdivided into apicals and laminals, with each further subdivided. Dixon (1980) points out that the coronal subclasses in some Banjalang dialects, apical and laminal, neutralize intervocalically; the place contrast is maintained elsewhere and other places of articulation are not involved. There is often free variation between apical and laminal articulations for the stop, with the choice differing by dialect.

Hamilton (1993) offers evidence from Australian languages for the class of coronals based on phonological patterning. For instance, coronals provide an environment for a phonological process in Nunggubuyu (Heath 1984: 69–71), where a palatal deletes in a derived environment before a coronal; with a following labial or velar, deletion does not occur. In Walmatjari (Hudson 1978: 11–12), there are suffixes beginning with a retroflex lateral; following a coronal, the initial consonant of the suffix assimilates in place of articulation to the coronal; following a non-coronal, other changes occur, but the consonant does not assimilate.

Moving away from Australia, there are languages with co-occurrence restrictions on different coronal places of articulation. In Päri (Western Nilotic), dental and alveolar stops and nasals contrast, and do not co-occur within a root (Andersen 1988; Hansson 2010). This harmony is actively enforced in suffixed forms. In another Nilotic language, Dholuo, the co-occurrence restriction holds of the dental and alveolar stops; there is a single nasal that does not participate. Pohnepian (Austronesian; Rehg and Sohl 1981) has contrastive dental and retroflex stops; these do not co-occur within a root.

Assimilation provides evidence for the coronal class, as in the Sanskrit *nati* process. Basically, a retroflex triggers retroflexion of a following /n/. Retroflexion is transparent with respect to intervening labial and dorsal consonants, but is blocked if a coronal of any place of articulation (dental, palatal, retroflex) intervenes; see Hansson (2010).

(7)	a.	*non-coronal consonants between trigger and target*		
		iʂ-naː	iʂɳaː-	'seek (PRESENT STEM)'
		vrk-na	vrkɳa-	'cut up (PASSIVE PARTICIPLE)'
		kʂubh-aːna	kʂubhaːɳa-	'quake (MIDDLE PARTICIPLE)'
	b.	*coronal consonant between trigger and target*		
		mrd-naː	mrdnaː-	'be gracious (PRESENT STEM)'
		maɪj-aːna-	maɪjaːna-	'wipe (MIDDLE PARTICIPLE)'

In addition, in assimilation in Sanskrit a dental assimilates to an adjacent coronal, but not to other places of articulation; see §4.

There is thus clear evidence from several sources that in languages with more than one coronal place of articulation these can pattern as a class.

While in some cases evidence exists that all coronals of a language are in a single class – for instance, English (6) – the class of coronals may pattern together, but only within a manner class. An example comes from Nilotic languages (Mackenzie 2009; Hansson 2010), where harmony occurs between coronal stops and nasals, or just stops, depending on the language, but liquids and continuants do not enter into the harmony.

Stratification by manner exists in the consonantal root consonant co-occurrence restrictions in many Semitic languages, where sounds within a class are dispreferred within a root. While coronal sonorants and stops, for instance, co-occur, coronal fricatives rarely co-occur within a root.

(8) *Arabic coronal co-occurrence restrictions* (Rose 1996: 75)

coronal sonorants	l r n
coronal stops	t d (plus emphatic counterparts)
coronal fricatives	ʃ ʒ s z θ ð (plus emphatic counterparts)

See Coetzee and Pater (2008) for discussion of place/manner effects in Muna.

Phonological evidence thus exists for the class of coronals as a whole; in some cases the patterning of coronals is stratified by manner.

2.2.3 *Coronal sub-places of articulation*

Because coronals allow several subclasses, the internal structure of the coronal region has received detailed attention. For this we look to languages with four distinctive places of articulation within coronals, where the distinction commonly called apical/laminal receives wide support. Evans (1995: 727) notes that "There is an enormous amount of evidence – from phonotactics, morphophonemics, diachronic changes, and synchronic variation for these groupings," referring to apical (alveolar, retroflex) and laminal (dental, palatal) in the coronals of languages of Australia. Hamilton (1993) presents a variety of kinds of evidence for this subdivision.

Allophony presents one type of evidence. If there is a single apical and/or a single laminal place, allophonic variation may exist within it. For instance, in single laminal languages such as Watjarri (Douglas 1981: 203–204), alternations or variation between alveo-palatal and dental articulations occur, often conditioned by the following vowel. Some languages show variation in apical articulations, with non-contrastive alternation between alveolar and retroflex articulations in different vocalic environments; Wargamay is an example (Dixon 1980: 155–156).

Neutralization is a second type of evidence. In many Australian languages the two apical articulations neutralize to a single non-contrastive series word-initially, often symbolized as a retroflex but sometimes as an alveolar; Hamilton (1993: 32) remarks that only a few languages show an apical contrast word-initially. In some languages the laminal articulations neutralize syllable-finally, generally reported as palatal; Hamilton (1993: 33) notes that only a few languages exhibit this contrast syllable-finally.

Phonotactics treat apicals and laminals as natural classes: apical consonants are permitted in certain environments to the exclusion of laminals, and vice versa. For instance, in some languages both apicals occur as the initial member of a cluster, while laminals are not permitted in this position (e.g. Kalkatungu; Blake 1979); in other languages both laminals occur as the second member of a heterorganic cluster, while apicals are not allowed (e.g. Nunggubuyu; Heath 1984).

Phonological processes can reference apical or laminal. For example, Mara (Heath 1981) has a dummy syllable in certain cases between a prefix and a root when the root begins with an apical sonorant; it does not occur with other places of articulation, including laminals. In some languages a lenis laminal stop becomes a glide intervocalically; apicals are not affected (e.g. Djapu; Morphy 1983).

Local harmony occurs within the apical set and within the laminal set in some languages. In particular, clusters of heterorganic apical clusters and heterorganic laminal clusters are not permitted in some languages, while clusters of an apical and a laminal are allowed; Dhuwala-Dhuwal (Morphy 1983) is an example.

Dravidian languages also exhibit an apical/laminal contrast, as argued by Arsenault (2008). For instance, word-initial apicals, both alveolar and retroflex, are dispreferred in these languages, with only laminals occurring.

Serbian provides evidence for apical and laminal classes, and for cross-classification between them; see Morén (2006) and Radišić (2009). Serbian has coronal stops/affricates as follows (only voiceless stops illustrated).

(9) t ts ʧ tŝ

Evidence for constituency within the coronals comes from several processes. A process called iotation groups together the first and last of these as opposed to the other two: /t tŝ/ *vs.* /ts ʧ/. Mid-vowel fronting provides evidence for /ʧ tŝ/ as a class, with /ɔ/ fronted to [ɛ] in the environment of these places of articulation. Assuming that the first and fourth columns represent laminal articulations and the middle two apical articulations, based on descriptions of the sounds, apical/laminal provides the classes involved in iotation. The further back of the apicals and laminals (last two columns) provide the environment for mid-vowel fronting. Thus, while the Australian languages do not appear to provide evidence for cross-classification within the apical and laminal subgroups, Serbian does provide for such classification.

While the division of coronals into apical and laminal receives support from languages with four coronal sub-places, other divisions appear to be possible. In Tahltan (Athabaskan), there are four coronal places of articulation (Shaw 1991; also §6.1); only voiceless stops and affricates are indicated.

(10) t tθ ts ʧ

The latter three enter into harmony, with the plain /t/ excluded. Assuming that the affricates are stops in Tahltan, with the consonants in (10) distinguished solely by place of articulation, as Shaw argues, then the phonology does not appear to support a primary apical/laminal distinction.

There may be asymmetries between the number of coronal places of articulation available at different manners of articulation. Polish obstruents offer an interesting example. Voiceless symbols are shown; all have voiced counterparts.

(11)	t	ts	tʂ	tɕ
		s	ʂ	ɕ

The stops/affricates and fricatives at a place of articulation do not always pattern together phonologically. For instance, /t/ and /s/ undergo palatalization, but /ts/ (and other stop/affricates and fricatives) does not. In second velar palatalization, /k/ shifts to [ts], while [x] shifts to [ʂ]. Similarly, [t] and [s] both occur with high vowels [i] and [ɨ], while other coronal obstruents are restricted, with [ts ʂ tʂ]

(12)	t	tʰ	tʼ	alveolar
	s			alveolar
	s̪		s̪ʼ	dental
	sʷ		sʷʼ	labialized alveolar
	ʂ	ʂʰ		retroflex
	ɕ	ɕʰ		alveolopalatal
	ɬ		ɬʼ	lateral

In addition, it has palatals.

(13)	ç	çʰ		palatal

Hall, following Colarusso, argues that palatal fricatives are not coronal, based on phonotactic generalizations about consonant clusters. In a cluster, the first consonant can be a labial, a voiceless uvular fricative, or a voiceless coronal stop or fricative. However, clusters cannot begin with a palatal fricative. As Hall (1997: 16) notes, this would be surprising if the palatal fricatives were coronal, since all other coronal stops and fricatives occur as the first consonant in a two consonant cluster. This argument perhaps establishes the status of the palatal as a non-coronal, but does not establish what it is; dorsal is a logical choice.

2.3.2 *Evidence for dorsals as a phonological class*

Considerable evidence exists for dorsals (velars, uvulars, palatal fricatives) as a class from allophonic patterning, co-occurrence restrictions, and harmony.

Velars, uvulars, and palatal fricatives enter into allophonic relations (CHAPTER 11: THE PHONEME). Hall (1997) notes that in German, the fricatives [ç x χ] are in complementary distribution, suggesting a common feature: they are dorsals, varying by sub-place.

Co-occurrence restrictions present another type of evidence for a single class. Rose (1996), after Bessell (1992), shows that Interior Salish has co-occurrence restrictions on place and manner; the place restrictions are summarized in (14). Identical places of articulation are disallowed within a manner; in addition, velar and uvular consonants fail to co-occur.

(14) *labial V labial
*coronal V coronal
*velar V velar
*uvular V uvular
*laryngeal V laryngeal
also
*velar V uvular
*uvular V velar

Thus the velars and the uvulars interact in excluding one another.

In Arabic, co-occurrence restrictions hold of dorsals just as they do of labials and coronals, dispreferring the co-occurrence of velar and uvular stops [g k q]. Note also the co-occurrence restrictions on gutturals, discussed below.

Dorsal harmony, involving velars and uvulars, provides evidence for velars and uvulars forming a class. Hansson (2010) discusses several cases. In Misantla

Totonac (Totonacan), velar and uvular stops harmonize. The primary facts are given below; see MacKay (1999) and Hansson for details.

(15) *Misantla Totonac* (MacKay 1999)

/ut maka-ʃqat/	'ʔut ma'qaʃ'qɛt	's/he scratches X (with hand)'
/ut maka-paʃ/	'ʔut maka'paʃ	's/he bathes his/her hand'

A similar harmony occurs in the related Tlachichilco Tepehua.

(16) *Tlachichilco Tepehua* (Watters 1988)

/ʔuks-laqts'in/	ʔoqslaqts'in	'look at Y across surface'
/ʔuks-k'atsa:/	ʔuksk'atsa:	'feel, experience sensation'

Hansson (2010) argues that Bolivian Aymara (Aymaran) has dorsal harmony. The language has plain, aspirated, and glottalized stops at velar and uvular places of articulation with restrictions on phonation type as well as place; I abstract away from the former. While velars co-occur and uvulars co-occur, a velar and a uvular do not.

(17) *Bolivian Aymara* (de Lucca 1987)

 q-q, qh-qh, q'-q'
 k-k, kh-kh, k'-k', k'-k
*k-q, q-k (any laryngeal properties)

Hansson notes that dorsal consonant harmony is cross-linguistically rare. In order to ascertain whether this is true, it is necessary to examine the occurrence of dorsal harmony in languages with contrastive velars and uvulars.

Given the debate about whether the bilabial/labio-dental distinction involves place or manner (§2.1), one might ask if the velar/uvular distinction always involves place. Some processes point to the conclusion that place is the primary dimension of contrast in languages with this distinction. In spirantization processes, just as /p/ spirantizes to [f], /k/ spirantizes to [x], and /q/ to [χ]. In the Athabaskan D-effect, /x/ hardens to [k] and /χ/ to [q] (e.g. Ahtna). This process shows the importance of place of articulation in distinguishing velars and uvulars.

When there is not a contrast between a velar and uvular within a manner, an inventory with velar stops and uvular fricatives is sometimes found. For instance Welsh (Celtic; Ball and Müller 1992) has voiced and voiceless velar stops, [k g], and a voiceless uvular fricative, [χ]. Welsh has mutations (see CHAPTER 117: CELTIC MUTATIONS); in Soft Mutation, /k/ becomes [g], while in Aspirate Mutation, /k/ spirantizes, becoming the voiceless uvular fricative [χ]. This parallels mutation at other places of articulation: under Soft Mutation, /p/ becomes [b] and /t/ becomes [d]; under Aspirate Mutation, /p/ becomes [f] and /t/ mutates to [θ]. Basically, mutation triggers a manner change, maintaining place. Thus, while the stop and fricative differ in place and manner phonetically, phonologically they differ in manner, and the organization in (18) is appropriate:

(18) dorsal stop k g
 dorsal fricative χ

One can ask if a different phonological organization is possible, with a primary place difference realized as a manner distinction, as in (19).

(19)	velar	uvular
	k	x

If, for instance, a language existed in which there were co-occurrence restrictions on obstruents of like place, and [k]–[x] combinations were allowed, we might conclude that the [x] patterned as a distinct place of articulation, realized phonetically as a spirant.

To summarize, dorsal includes velars, uvulars, and likely palatal fricatives. Evidence for this class is based on allophony, co-occurrence restrictions, harmony, and other phonological processes.

2.3.3 *Laryngeals*

I now consider laryngeal consonants. There is considerable discussion of laryngeal consonants in the literature, where they are accorded two treatments. They are often considered to lack a place of articulation (e.g. Steriade 1987), and they are also considered to be a type of pharyngeal (e.g. Lombardi 2002). In this section I present evidence for placelessness; evidence for their pharyngeal nature is given in §2.3.4.

The primary argument for the laryngeal class, glottal stop, and [h] being placeless comes from laryngeal transparency. The following evidence, from Kashaya (Pomoan), is from Buckley (1994), summarized by Rose (1996: 100–101). Within a morpheme, vowels are identical across a laryngeal consonant (20a), while there are no general co-occurrence restrictions on vowels (20b).

(20)	a.	s'iʔi	'flesh'	he'ʔen	'how'	inaʔa	'food, eat'
		ni'hin	'to oneself'	behe	'bay nut'	juhu	'pinole'
		ʔaha	'mouth'				
	b.	du'weʔ	'yesterday'	n'uqa:ʧ	'get lost'	maʧe-	'hold with foot'

This is an argument for laryngeal placelessness, under the assumption that specified places of articulation block assimilation. If laryngeals lack a specified place of articulation, vowel features can harmonize across them.

Laryngeals can pattern as a class. There may be co-occurrence restrictions, as in Interior Salish (14). In addition, laryngeals often result from obstruent debuccalization, with stops neutralizing to [ʔ] and fricatives to [h], as in the historical development of Kelantan Malay (Trigo 1988).

(21)	*Standard Malay*	*Kelantan Malay*	
	ʔasap	ʔasaʔ	'smoke'
	kilat	kilaʔ	'lightning'
	balas	balah	'finish'

2.3.4 *Pharyngeal (radical, tongue root)*

The final articulation region identified by Ladefoged and Maddieson (1996: 37), radical, includes pharyngeal and epiglottal sounds, i.e. sounds articulated in the region below the uvula.

Transguttural vowel harmony occurs in some languages, illustrated with Iraqw (Cushitic).

(27) *Iraqw* (van der Hulst and Mous 1992: 103–104; Mous 1993: 37; Rose 1996: 77)

no harmony across non-gutturals			*harmony across gutturals*		
hamaatl-iim	[hamtliim]	'wash'	buuʔ-iim	[buʔuum]	'harvest pay'
baal-iim	[baaliim]	'defeat'	ufaaħ-iim	[ufaħaam]	'blow'

In D'opaasunte (Eastern Cushitic), a vowel is lower when the preceding consonant is guttural, ([χ ɢ ʕ' ħ ʔ h]); it is higher after other consonants (Hayward and Hayward 1989). Hayward and Hayward use "A," an archiphoneme, to represent this vowel.

(28) *D'opaasunte* (Hayward and Hayward 1989: 183–184)

ʔan ˈkod[ɛ]j	'I am working'	ʔan ˈʧ'oχ[a]j	'I am milking'
ʔan ħull[ɛ]j	'I am entering'	ʔan fAʔ[a]j	'I am loading'

In Standard Somali (Cushitic), a suffix has the form [-d] after a guttural ([q χ ʕ ħ ʔ g]) and [-t] elsewhere (Hayward and Hayward 1989: 184).

Laryngeals thus pattern as if they were placeless in some languages and as if they were guttural in others. Rose asks whether it is accidental how they pattern, or if there is a systematic way to determine this. She argues that laryngeals pattern with pharyngeals when pharyngeals or uvular continuants are present in a system; otherwise they pattern as if they lacked a specified place.

2.3.5 *Summary*

Dorsal consonants (velar and uvular) interact in many languages, and they also interact with further back consonants in some languages. As with labials and coronals, many questions remain, and I conclude with one. The sound commonly written with the symbol /ŋ/ is ambiguous in its patterning, in some languages patterning as a velar and in some as if it were placeless or laryngeal (e.g. Trigo 1988; Rice 1996; de Lacy 2006). Is this an appropriate analysis? Is it only the manner that represents these two places of articulation, perhaps better written as /ŋ/ and /N/, or can other manners of articulation also show this kind of ambiguity between patterning as a laryngeal and patterning as a velar?

2.4 Conclusion

In this section I have examined phonological evidence for the major places of articulation: labial, coronal, dorsal, radical, and laryngeal. In all cases, there is clear evidence for the class, and, at the same time, complexities involving such things as stratification by manner and interactions between place classes require further study.

3 Further constituency

We have seen evidence for five major places of articulation, three in the oral cavity and two further back. While there is general acceptance of this division in the literature, debate exists about whether these major places of articulation enter into relationships with one another, or, to put this another way, whether there is constituency among places of articulation (see CHAPTER 27: THE ORGANIZATION OF FEATURES). One might imagine that there is no relationship between them, with a flat structure. Alternatively, one might imagine that some of the places of articulation are more closely linked to one another than others are, with a constituent structure. I examine this with respect to labial, coronal, and dorsal, where two possible groupings are proposed. One involves grouping labials and dorsals to the exclusion of coronals, under a feature [grave] or [peripheral]. The other involves grouping coronals and dorsals to the exclusion of labials; the feature has been called [lingual]. One might imagine a grouping of coronals and labials to the exclusion of velars, a proposal that has not received support; see §5 on the controversy about the feature [anterior], which groups labials and front coronals.

3.1 *Oral and pharyngeal*

Before turning to these proposals, I briefly review proposals for the overall organization of place. McCarthy (1994: 223) argues within feature geometry for the bifurcation of place into two major constituents, which he terms Oral and Pharyngeal. Oral dominates Labial, Coronal, and Dorsal. Others have refined this proposal to, for instance, allow [RTR] as a dependent of Pharyngeal; see Rose (1996) for discussion of how to accommodate the guttural class.

3.2 *Grouping labials and dorsals*

Evidence is found in the literature for grouping labials and dorsals; see Hall (1997) for detailed references, including Jakobson *et al.* (1952), Jakobson and Halle (1956), Hyman (1973), Campbell (1974), Odden (1978), and Rice (1994). Hall gives the following evidence for labials and velars (and/or uvulars) patterning together, among others.

In Yurok (Algic), the 3rd person prefix is [ʔu] before non-coronals (labials, velars, labial-velars) and [ʔwe] before coronals. In Lhasa Tibetan the consonants [p k q] spirantize and voice intervocalically, while coronals do not. A vowel shift occurred in the history of Korean before labials and velars but not before dentals and alveo-palatals.

Many of the arguments presented by Hall are diachronic. There are also synchronic arguments for grouping labial and velar. One of the best-known arguments comes from Korean, where, in some speech forms, the coronal stop and nasal assimilate in place to a following adjacent consonant, and the labial stop and nasal assimilate to a following velar; the velar stop and nasal do not assimilate. If labial and velar are grouped together, their patterning can be understood: coronals assimilate to these places, identified as grave. In (29), a place of articulation assimilates to those to its right, but not vice versa. Thus a coronal (T) assimilates to both a labial (P) and a velar (K), while a labial assimilates only to a velar, and a velar does not assimilate.

(29) [T [P K]]

Lombardi (1996) identifies cases that suggest the need for grouping labials and velars (her [–coronal]) in post-lexical rules. For instance, between word sequences in Pohnepian (Rehg and Sohl 1981; Rehg 1984), a labial is realized as a labial nasal when followed by a labial, and a velar is realized as a velar nasal before another velar.

(30) *labial + labial*
e kala/p p/aan soupisek 'he'll always be busy'
e kala[m p]aan soupisek
velar + velar
e sai/k k/eŋwini 'he hasn't yet taken medicine'
e sai[ŋ k]eŋwini

However, with a sequence of coronals, the fiirst does not become a nasal.

(31) e mei/t t/aŋaaŋa 'Aren't you lazy!'
*e mei[n t]aŋaaŋa

Thus evidence for grouping labials and dorsals is both diachronic and synchronic.

3.3 Grouping coronals and dorsals

Arguments for grouping coronals and velars as linguals are also found. Rubach (1993), followed by Lombardi (1996), adduces evidence from Slovak (Slavic), where /æ/ backs to [a] post-lexically in an environment that Rubach calls [−labial]. There is a contrast between these vowels following a labial (32), but not elsewhere.

(32) masa 'mass'
mæso 'meat'

The diminutive suffix illustrates the alternation between [a] and [æ]. The suffix is a front vowel after a labial (33a), following a non-labial it is [a], with palatalization of the preceding consonant (33b, 33c).

(33)	a.	holub	'pigeon'	holub-æ	'young pigeon'
	b.	had	'reptile'	haad'a	'young reptile'
	c.	vnuk	'grandchild'	vnuutʃa	'young grandchild'

Rubach argues that the suffix is underlyingly front; it triggers palatalization and is backed following a coronal and a velar (see CHAPTER 121: SLAVIC PALATALIZATION).

The facts are complicated by the presence of a diphthongization process where /æ/ becomes [ia]. The forms in (34) show lengthening in the genitive plural, with /a/ lengthening to [aa].

(34) lano 'strong' laan (GEN PL)
pivo 'beer' pŭv (GEN PL)

While generally vowels lengthen in the genitive plural, diphthongization occurs in some environments, including with /æ/, which diphthongizes to [ia].

(35) hovædo 'beast' hoviad (GEN PL)
mæso 'meat' mias (GEN PL)

Many Slavic languages exhibit a third pattern: the velar can undergo a shift in place of articulation, resulting in a coronal. This is exemplified for Serbian in (45).

(45) a. *Serbian: First palatalization* (Radišić 2009)
ru/k/a + itsa   ru[ʧ]itsa   'hand'
pra/x/ + iti   pra[ʃ]iti   'dust'
b. *Serbian: Second palatalization* (Radišić 2009)
ɔra/x/ + i   ɔra[s]i   'nut'
pɛ/k/ + i   pɛ[ts]i   'to bake'

Coronals also shift their place of articulation in iotation, but remain coronal.

Thus, while in languages such as Catalan coronals shift to another major place of articulation in assimilation, in Sanskrit coronals are assimilation targets, but only assimilate to other coronals, and in many Slavic languages, coronals shift to other coronals and velars shift to coronals. To use the terminology of phonological markedness, based on such shifts we might identify the velar as unmarked in languages like Serbian, and the coronal as unmarked in languages like Catalan and Korean. Given the nature of the coronal inventories in languages like Sanskrit and Serbian, with more than one coronal sub-place allowed in assimilator position, one might conclude based on target asymmetries, as did Avery and Rice (1989), that coronals are unmarked generally, attributing their patterning in languages with more than one coronal sub-place to the fact that there is more than one sub-place. The existence of more than one coronal sub-place indeed appears to affect the patterning of coronals, and in the following discussion I set these languages aside and examine assimilation and neutralization in the absence of a rich coronal inventory, beginning with neutralization. I consider languages with labial, coronal, and dorsal places of articulation.

4.2.2 *Neutralization, epenthesis, and the emergence of the unmarked*

Neutralization is considered to yield the unmarked (CHAPTER 80: MERGERS AND NEUTRALIZATION). Languages with word-final neutralization are shown in (46). These languages exhibit passive neutralization, with morphotactics that disallow other places of articulation for stops word-finally. In addition to coronal stops, languages exist where only labial stops occur in this position, or where only dorsal stops are allowed in this position.

(46) a. languages allowing only a coronal stop: Saami, Finnish
b. languages allowing only a labial stop: Nimboran (Papuan; Anceaux 1965), Basari (Niger-Congo; Abbott and Cox 1966)
c. languages allowing only a dorsal stop: Quichua (Quechua; Orr 1962)

While there are statistical differences, with coronals (and laryngeals) more common as the only place of articulation allowed when no contrasts exist in stops word-finally, overall, the range of places of articulation occurs cross-linguistically in this position. If neutralization is a diagnostic for unmarkedness, and if coronal is universally unmarked, these patterns are unexpected. Epenthesis mirrors neutralization, with at least laryngeal, coronal, and dorsal consonants serving as epenthetic. While de Lacy (2006) and de Lacy and Kingston (2006) argue that dorsal

The sound pattern of English (*SPE*; Chomsky and Halle 1968) features have encountered serious criticism on both empirical and conceptual grounds. With respect to place, one challenge is the inability to define a class of labial consonants and round vowels (e.g. Campbell 1974). The feature [anterior] is also problematic, since anterior sounds in the *SPE* sense do not pattern as a natural class (e.g. Dixon 1980; Gnanadesikan 1994).

Sagey (1990), building on work by Halle (e.g. 1983), argues for four major places of articulation – Labial, Coronal, Dorsal, and Tongue Root (Radical) – expressed by monovalent features, dominating binary features. Building on Sagey, Halle, and others, Hall (2007: 332) gives a chart of obstruent places of articulation, which is shown in Table 22.2. I follow him in separating stops and fricatives, and show voiceless consonants only. The table perhaps represents an overall North American consensus about place of articulation features. Nevertheless, many issues remain; I list a few in (47).

(47) a. What distinguishes bilabials and labio-dentals? Hall leaves this open, suggesting that a feature [labio-dental] might be required.
b. How are palatals represented? Are all palatals coronal (see §2.2; Hall 1997)? Do all palatal sounds have the same representation? Similar questions can be raised for retroflexes.
c. Are [anterior] and [distributed] appropriate to distinguish coronal sub-places? In particular, the role of [anterior] remains controversial.
d. How are gutturals distinguished featurally?
e. Do features group into classes? In particular, do lingual and/or grave classes exist?
f. Is a mix of monovalent and bivalent features appropriate?

Table 22.2 Features for obstruent places of articulation (after Hall 2007). A check (✓) in a cell indicates the presence of a unary feature; in rows with checks, the absence of a check indicates the absence of this feature. In rows with + and −, absence of any mark indicates that the feature is not relevant for that sound

	p	t̪	t	ʈ	c	k	q	ts	tʃ	ɸ	f	θ	s̪	s	ʂ	ʃ	ç	x	χ	ħ
continuant	−	−	−	−	−	−	−	−	−	+	+	+	+	+	+	+	+	+	+	+
labial	✓									✓	✓									
round	−									−	−									
coronal		✓	✓	✓	✓			✓	✓			✓	✓	✓	✓	✓	✓			
anterior		+	+	−	−			+	−			+	+	+	−	−	−			
distributed		+	−	−	+			+	−			+	+	−	−	+	+			
dorsal						✓	✓											✓	✓	
back						+	+											+	+

high						+	−											+	−	
pharyngeal																				✓
strident								+	+	−	−	−	+	+	+	+	−	−	−	−

(49) q χ
k s
ts s
tɬ ɬ

The spirantization of the front velar to [s] is surprising, but otherwise a stop/affricate is realized as a fricative of the same place of articulation. If lateral represents a place of articulation, this pattern is unsurprising. Note also the development of the Proto-Athabaskan *ts series (*ts *ts^h *ts' *s *z) to a /tl/ series ([tɬ tɬ^h tɬ' ɬ l]) in Koyukon (Jetté and Jones 2000), a development which can be explained as a shift in place of articulation of the series.

6.2 *Consonant–vowel interactions*

I have not discussed consonant–vowel interactions, since this chapter concerns consonantal place; see CHAPTER 75: CONSONANT–VOWEL PLACE FEATURE INTERACTIONS. Flemming (2002) also addresses consonant–vowel interactions and the types of features required. To give a few examples, vowel-triggered palatalization can involve the addition of a secondary articulation; it can also involve a shift in primary place, with perhaps the most dramatic being the shift from a velar to a coronal, found in many Slavic languages; e.g. (45). There is often interaction between low vowels and dorsal sub-places, with low vowels conditioning uvulars (e.g. Xibe (Tungusic); B. Li 1996) or vice versa (e.g. Totonac; MacKay 1994). Low vowels or retracted tongue root vowels often interact with pharyngeal consonants; e.g. (26). Round vowels and labial consonants can pattern together, as in Igbo (§2.1). In addition, there are interactions between back vowels and retroflex consonants. Vowels and consonants may pattern together in natural classes as well, for instance, in conditioning rules.

There has been considerable debate as to how to handle such interactions. Clements (1991) argues for a unified theory of consonant and vowel place, as do element-based theories (see Harris and Lindsey 1995 for an overview), while others argue for distinct place features (e.g. Padgett 2002) for consonants and vowels.

6.3 *Evidence for innate features*

An important premise since distinctive features were introduced is that features are innate, with a small universal set. Much research has been directed at defining what set and identifying its phonetic foundations, with the understanding that an appropriate and complete set of features would allow an account of cross-linguistic sound patterning.

I have pointed out in various places that what is characterized as the same sound from a phonetic perspective can show different phonological patterning. To some degree this is dependent on the sound system of the language, a point that has long been observed, as the following quote from Trubetzkoy shows.

> The ambiguous character of lateral articulation, which causes such difficulties in *phonetic* systematization, is something that can quite easily be resolved in *phonological* systemization, the more so since the important thing here is only to establish to which other phoneme the particular "lateral" phoneme stands in a relation of opposition, and to determine the nature of such an oppositive relationship. (Trubetzkoy 1969: 140)

In the discussion of evidence for places of articulation, we have seen debate about how to classify particular sounds. For instance, what are phonetically two places of articulation might pattern as one, as with [p] and [f], where [p] is bilabial and [f] labio-dental, but they enter into co-occurrence restrictions, for instance, as a single place of articulation. Similarly, [k] and [χ] can form a pair in spirantization, despite the fact that one is velar and the other uvular.

In addition, what looks like a single place of articulation might pattern as two distinct places. This is dramatic in Polish (11), where the retroflex stop and the retroflex fricative differ in patterning.

Furthermore, a single place of articulation may be classified in two groups. For instance, there is evidence from co-occurrence restrictions that uvulars are both dorsal and radical, with stops patterning with velars and fricatives with radicals. Palatals appear to be divided between dorsal (fricatives) and coronal (other manners).

Cross-linguistically, coronals do not appear to be divided in the same way in all languages. While in many languages there is evidence for segregating coronal inventories into two main places of articulation, often characterized as apical and laminal, there are languages with similar contrasts, but this categorization does not seem to be appropriate.

Such variation in cross-linguistic patterning might be responded to in different ways. One path is to continue the search for a small set of universal features, seeking to revise and refine it and find ways of understanding whether there are foundations for different patternings, based, for instance, on inventory contrasts or prosodic position. The understanding of consonantal place has deepened over the years through this method.

An alternative has recently been proposed, to abandon the assumption that features are innate. Mielke (2005, 2008), among others, argues that features are not innate, but emergent (see also CHAPTER 17: DISTINCTIVE FEATURES). The limited number of features that is observed is not surprising, given the shape of the vocal tract and perceptual apparatus. Some ambivalence in patterning is expected for sounds that are phonetically ambiguous. It is thus perhaps time to challenge universality and focus on differences in patterning and what they reveal.

7 Summary

Consonantal place features are perhaps the best studied of all features, and the understanding of place of articulation has deepened over the years. There is little disagreement about the major regions of labial, coronal, dorsal, radical, and laryngeal, with evidence from numerous languages to support these distinctions. At the same time, some sounds do not appear to fit neatly into these classes. Labio-dentals might involve both a labial and a coronal component, and some gutturals pattern with both dorsals and radicals. The sub-places within these major places are less well established, with continuing debate particularly around the nature of the coronal sub-places.

There has been an attempt to identify a particular place of articulation as universally unmarked, based on patterning asymmetries. A good understanding of this requires a careful study of coronal inventories and contrasts, and it appears that much is determined by the language, although there are statistical differences

23 Partially Nasal Segments

Anastasia K. Riehl
Abigail C. Cohn

1 Introduction

Partially nasal segments, or those that are nasal for only a portion of their duration, contribute many interesting puzzles to the study of phonology. Prenasalized stops, such as /^{ŋ}g/ in the Fijian word /^{ŋ}gone/ 'child', or prestopped nasals, such as /^{p}m/ in the Arrernte word /a^{p}mər/ 'camp', challenge our notion of the segment. If a segment, which we typically think of as being composed of a bundle of features each with a single specification, can be composed of contrasting values for a particular feature (in this case [nasal]), this raises a whole array of questions about the nature of segments. We explore some of these questions in this chapter.

The question of what defines a segment has been a topic of considerable interest in the phonological literature, especially since Chomsky and Halle's (1968; *SPE*) characterization of segments as unordered bundles of features (building on Jakobson *et al.*'s 1952 characterization). Much attention in the phonological literature in the 1970s was given to rethinking and enriching this strict definition of phonological representation, leading to developments including autosegmental representation of tone and other phenomena, formally incorporating syllable structure and higher-order prosodic representation, and so forth. (See Anderson 1985 and Kenstowicz 1994 for a review of these developments, as well as CHAPTER 14: AUTOSEGMENTS; CHAPTER 17: DISTINCTIVE FEATURES; CHAPTER 27: THE ORGANIZATION OF FEATURES; CHAPTER 54: THE SKELETON; and many other contributions to the *Companion to Phonology*.) Particularly relevant in this regard is Anderson's (1974, 1976) discussion of partially nasal segments and his conclusion that such differences cannot be adequately captured through static features (such as *SPE*'s [delayed release]), but rather require direct reference to timing in the phonology, forcing a rethinking of the fundamental definition of the "segment."

There has also been an ongoing discussion in both the phonological and phonetic literature about the phonetic realization of partially nasal segments and nasal–stop clusters and whether or not these two types of NC sequences are phonetically distinct (Herbert 1986; Maddieson and Ladefoged 1993; amongst others). To the degree that such discussions address phonological entities, these issues are also directly relevant to our discussion.

We begin by framing some background issues in the remainder of this introduction, including phonological segmenthood and phonological *vs.* phonetic entities. In §2, we consider the types of partially nasal segments that have been reported in the literature. In the case of nasal–oral entities (NC), one of the central issues is whether these entities are unary segments or clusters, while in the case of oral–nasal entities (CN), a central question is whether such elements are part of the phonology as contrastive elements or only occur allophonically. In §3, we pursue the questions raised by the observed NC patterns and turn more specifically to the issue of unary segments *vs.* clusters, including the issue of their phonetic characteristics. Next, in §4, we address the topic of representations, considering the fit between the attested patterns and the various proposed representations. Finally, in §5, we conclude and offer directions for further research, considering the implementation of the phonological patterns, the role of co-articulation, and possible pathways of change over time.

At this point, we would like to introduce some terminology that we will use frequently throughout the chapter. The abbreviation NC stands for *nasal–oral sequence*, and similarly, CN stands for *oral–nasal sequence*, whether they constitute unary elements or clusters. *Unary* NC and *unary* CN (sometimes abbreviated ^{N}C and ^{C}N) refer to partially nasal sequences that constitute a single segment, while NC *cluster* and CN *cluster* refer to cases where the sequence constitutes two segments. When we wish to refer to a sequence in a generic sense, regardless of its phonological status, we use the terms NC *sequence* and CN *sequence*. We reserve the term *segment* for the unary cases. Where voicing is relevant, we indicate a voiced obstruent portion with a "D" (e.g. D^{N}) and a voiceless oral portion with "T" (as in e.g. NT).

The phonological segment, sometimes equated with the phoneme, is defined by Anderson (1976: 326) as follows: "A segment is usually taken to be a self-contained portion of an utterance which can be characterized in terms of one basic position of the articulatory organs." This is captured in *SPE* with unordered bundles of distinctive features, which are taken to define both the abstract contrastive elements – the phonemes – as well as the actual phonetic events, or phones. At issue is whether such representations – as phonological representations – include internal structure, capturing segment-internal timing.

Before we consider the types of partially nasal segments that exist in the world's languages, we need to be more explicit about the levels of representation for which such structures are being posited. Which types are relevant to the phonology? In other words, which may constitute phonologically distinctive elements, and which are only observed as a phonetic or allophonic result of the phasing of gestures? Clarifying this question is critical for characterizing a typology of such patterns, which in turn is needed to evaluate various representational proposals.

In the literature, many types of partially nasal elements have been described, but often it is not clear whether or not these are really phonological elements. Our interest here is in those cases where timing internal to the segment can result in a phonological contrast. In order to accurately assess which cases are contrastive, we need to separate out both those that result in partially nasal surface elements that are predictable (arguably either the result of phonological rules/constraints yielding allophony or gestural timing patterns), as well as those that have been mischaracterized as unary when they are actually clusters. The issue of allophony is taken up in §2, and the issue of unary segments *vs.* clusters is taken up in §3. We turn now to a review of possible cases.

Table 23.3 Inventory of prestopped nasals, oral stops and nasal stops in Central/Eastern Arrernte

	bilabial	*dental*	*alveolar*	*retroflex*	*palatal*	*velar*
prestopped nasal	ᵖm	ᵗ̪n̪	ᵗn	ʈɳ	ᶜɲ	ᵏŋ
oral stop	p	t̪	t	ʈ	c	k
nasal stop	m	n̪	n	ɳ	ɲ	ŋ

begins, so that by the end of the segment, it has the qualities of a plain nasal, and progressive nasalization may be manifested on following vowels. Prestopped nasals have been much less widely reported than prenasalized stops, and are not found amongst the sample of languages in UPSID. The best-known descriptions are found in Australian languages (Butcher 1999). They have also been reported in Borneo and other languages of the Austronesian family, as well as in some languages of the Austro-Asiatic and Amazonian families (see Blust 1997 for a review). These latter cases, however, are allophonic, and therefore do not provide evidence for prestopped nasals as phonological entities.

We now consider Arrernte, an Arandic language of Australia, as described by Butcher (1999) and Breen (2001), a language where prestopped nasals appear to be phonemic (see also Breen and Dobson 2005). The Central and Eastern dialects of Arrernte have a series of prestopped nasals at various places of articulation, in contrast with plain voiceless stops and plain nasals. No primary voicing contrast is observed for stops, as is characteristic of these languages. Table 23.3 contains the relevant portion of the consonant inventory.

These sounds occur word-initially and word-medially, although an inserted vowel usually precedes all initial consonants, and the language has been analyzed as having only VC(C) syllables (see Breen and Pensalfini 1999). Arrernte allows a limited range of consonant clusters as well, including sequences of nasals and homorganic stops. (4) contains (near-)minimal triplets of these sounds and corresponding plain stops and nasals.

(4) *Arrernte* (Butcher 1999)

	bilabial		*alveolar*	
prestopped nasal	aᵖmər	'gum tree'	aᵗnəm	'yamstick'
oral stop	apər	'camp'	atəɪn	'bursting'
nasal stop	aməl	'nest'	anəm	'staying'

The prestopped nasals in Arrernte are believed to have originated from plain nasals that were allophonically produced with a preceding oral portion when following a stressed oral syllable. Today these dialects are analyzed as having phonemic prestopped segments. Most other southern Australian languages, however, including for example Nukunu and Gupapuyŋu, have allophonic, not phonemic, prestopping.

As mentioned above, prestopped nasals have also been described in several Austronesian languages. For example, in Bonggi, a language of Sabah, Malaysia, within the oral–nasal group, where the nasal and oral portions are more or less prominent in comparison to one another. A distinction for the nasal–oral cases between a prenasalized stop and what is sometimes referred to as a *post-stopped nasal* (also *post-ploded nasal* (Blust 1997), *funny nasal* (Durie 1985), or *obstruent nasal* (Durvasula 2009)) has been claimed, while a distinction within the oral–nasal category has not, to our knowledge, been reported.

As we discuss in Cohn and Riehl (2008), we know of no languages where a compelling case for a phonological *contrast* has been made. Several Austronesian languages, including Rejang and Acehnese, have been argued to have sounds described as primarily nasal, with only a brief oral release (see Blust 1997 for recent review and references to specific cases). However, in phonetic and phonological studies of two putative cases, Acehnese and Sundanese, we find that the NCs are better analyzed, both phonologically and phonetically, as nasal–stop clusters, given that phonologically they pattern like other clusters and phonetically they have the duration of clusters rather than single segments, and their internal nasal–oral timing patterns do not show consistent differences with either ND clusters or prenasalized segments (as discussed in §3). The other type of case where such phonetic differences have been claimed is clearly allophonic in nature (e.g. the post-ploded nasals in some dialects of Chinese; see Chan 1987 and Chan and Ren 1987).

Thus we conclude that finer divisions of this sort within the phonology are not warranted. We follow Anderson (1976) in positing only two phonologically relevant types of partially nasal segments – *pre*nasalized and *pre*stopped segments. We know of no languages that contrast these two types, but we do not predict a priori that such a contrast would not be possible. Rather we expect this is because prestopped nasals are themselves very rare.[4]

2.2 *Other factors: Voicing, place, and manner*

2.2.1 *Voicing*

In the case of prenasalized stops, the majority of the segments reported are fully voiced. In the best-attested cases, the nasal and oral portions are not divisible in the sense that the oral stop portion cannot occur alone. This is the case for Tamambo, discussed above, as well as many other Oceanic languages. In such languages, the prenasalized stop series *is* the voiced stop series. Fully voiced prenasalized stops are also found in some languages that have plain voiced stops and nasals occurring independently, including Wolof. Many Bantu languages are also identified as falling into this category. (However, we take an alternative view, that the NCs are actually clusters (see §3).)

There are also descriptions of putative cases of prenasalized stops with a voiced nasal portion followed by a voiceless oral portion. However, there is a clear asymmetry between these two sorts of cases. While there are a number of clear and widely accepted cases of fully voiced unary ^{N}Ds, the reports of prenasalized voiceless stops are questionable. Sequences of nasals and voiceless stops do

[4] A proposal for laryngeal specification made by Golston and Kehrein (1998) and Kehrein and Golston (2004) that contrast is at the level of the subsyllabic unit, not at the level of the segment, cannot be extended to the nasal specification, as this would predict only one, not two, types of partially nasal segments.

phonologically relevant. We have argued that neither prenasalized stops nor prestopped nasals show a contrast in voicing. Both types of partially nasal segments may occur at various places of articulation, and most have the manner of articulation of stops or affricates, with prenasalized trills also being attested.

In conclusion then, we find that internal structure matters, but only in a very limited way. Specification for [nasal] affects a full segment or a part of a segment, but there are no finer distinctions in terms of the timing of the parts and no additional complexities in terms of differences in place, manner, or voicing. Partially nasal segments are unified in their specifications for voicing, place, and continuancy, as schematized in (5). As noted above, we know of no languages where both ^{N}D and D^{N} are attested contrastively, but we also know of no reason why a priori this would not be possible.

(5) *Possible phonological specifications for nasal*

	N	D	T	^{N}D	D^{N}
nasal	+	−	−	+ | −	− | +
cont	−	−	−	−	−
voice	+	+	−	+	+

In what follows, we focus primarily on those types that are potentially phonologically contrastive, but we will also have occasion to consider the role of timing as it leads to allophonic as well as contrastive patterns. We turn now to the issue of unary partially nasal segments *vs.* clusters, including a discussion of their phonetic properties, and how these may bear on the issue of phonological status.

3 Unary *vs.* cluster NC sequences

Now that we have documented the existence of at least some partially nasal segments, this opens a broader set of questions regarding the relationship of partially nasal segments to NC/CN clusters. The possibility of one sequence of sounds exhibiting a distinction between a single unit *vs.* two units raises various questions of interest to phonology.

There are two distinct yet interrelated issues to address. The first is whether or not the phonology provides evidence for two different patterns. The second is whether or not these different patterns, should they occur, have distinct phonetic realizations. In terms of phonetic characteristics, duration is the factor most commonly discussed (although other possible phonetic differences have been considered).

This discussion ties into broader concerns about the relationship between phonological timing and phonetic duration. Such issues have been widely discussed with regard to geminates *vs.* singletons. In *SPE*, two representations were available for geminates – two identical adjacent features matrices or a single matrix specified as [+long]. Subsequent work has strongly suggested that both aspects play a role (see Broselow 1995; CHAPTER 37: GEMINATES; CHAPTER 47: INITIAL GEMINATES for reviews). In the case of unary ^{N}Cs *vs.* NC clusters, some of the relevant questions parallel these discussions. However, we will argue that in the case of NCs, it is timing and not weight that is primarily at issue, even though, as discussed below, both timing and weight may play a role in a single language.

The phonetic realization of singletons *vs.* geminates has been discussed in a number of cases (see Ham 1998). However, the prior interpretations concerning the phonetic realization of unary NCs *vs.* clusters are much murkier. As discussed in §3.3, we argue that, if appropriate comparisons are made, there *is* a systematic durational difference between unary NCs and clusters.

In the following discussion we focus on prenasalized stops and NC clusters, rather than prestopped nasals and CN clusters, as all of the discussion that we are aware of has focused on the former. In addition, since we know of no cases where a contrast between ^{N}T and NT has been claimed, the discussion of the unary–cluster distinction is limited to voiced NCs, in other words ^{N}D *vs.* ND.

3.1 *The phonological distinction*

The first issue to consider is whether or not there are distinct phonological ND patterns. Here it is useful to observe data from two languages where ND patterns are quite different, English and Fijian.

In English, nasals and stops occur independently, and nasals and stops combine in both orders ND and DN. Importantly, the sequences are limited to positions where they will not violate the language's sonority sequencing constraints (CHAPTER 49: SONORITY; CHAPTER 53: SYLLABLE CONTACT). NDs may be medial where they are usually interpreted as heterosyllabic, as in *am.ber*; final where they decrease in sonority, as in *amend* (though /mb/ and /ŋg/ do not occur word-finally in English synchronically); but not word-initial, where they would violate constraints on sonority in English. NDs also appear across morpheme boundaries (*in-decisive*). These patterns suggest that the sounds are independent segments that cannot be tautosyllabic in an onset. Considering the facts as a whole, English NDs receive a straightforward cluster analysis.

The ND patterns in a language like Fijian look quite different (see e.g. Schütz 1985). In this language, all voiced stops and the alveolar trill are preceded by a nasal component; that is, [b d g] never occur independently, but only as [^{m}b ^{n}d ^{ŋ}g]. Voiceless stops, on the other hand, never occur with a preceding nasal. The ^{N}Ds occur word-initially, as in /^{m}bonu/ 'eel (sp.)', and medially, as in /vu^{n}di/ 'banana'. The language has no word-final consonants and no other consonant sequences, suggesting that all syllables are open. Taking the evidence as a whole, Fijian NCs are straightforwardly analyzed as unary. Based upon such data, there appears to be ample evidence for two different phonological patterns. We argue in §4, following many others, that these two different patterns require distinct phonological representations.

The discussion of ND patterning is complicated by a number of languages where the unary *vs.* cluster status of the sequences is less clear. One widely discussed case involves the Bantu languages. In many Bantu languages, ND sequences are found word-medially in intervocalic position (and sometimes to a limited degree word-initially, where the nasal is part of a prefix). Although their patterning suggests a cluster analysis (see Herbert 1986), the sequences are often analyzed as unary segments, due to the lengthening of vowels observed before the NDs. The following data are from Jita, a Bantu language, spoken in Tanzania (Downing 1996):

(6)	a.	oku-cuma	'to get wealthy'	oku-cu:ma	'to jump'
		oku-loja	'to try'	oku-lo:ja	'to visit the sick'

that can be interpreted as having such a contrast. One such language is Sinhala, which has series of voiced stops, voiceless stops and plain nasals, as well as a singleton–geminate contrast throughout the consonant inventory, and it allows for a wide range of consonant combinations, including ND and NT (see Coates and de Silva 1961; Feinstein 1979; Maddieson and Ladefoged 1993; Letterman 1997). While the NTs are uncontroversially considered clusters, there is an interesting distinction among the NDs, illustrated by pairs of words often transcribed as follows (following Letterman's 1997 transcription):

(7)	a.	/la^{n}da/	'thicket'	/landa/	'blind'
	b.	/ka^{n}de/	'truck (GEN)'	/kande/	'hill (GEN)'

In (7), there appears to be a contrast between a unary and a cluster ND. Further consideration of the phonotactic patterns reveals that the prenasalized stops pattern with singleton consonants and clusters pattern with geminates, for example:

				singular	*plural*
(8)	a.	/balal/	'cat'	[balala]	[balallu]
	b.	/poloŋg/	'viper'	[polə^{ŋ}ga]	[poloŋgu]

In (8a), addition of the plural suffix causes gemination of a preceding stem-final consonant, resulting in a long [ll]. When this suffix follows a prenasalized stop, the result is described as an ND cluster, as in (8b).

Given data such as that above, both Letterman (1997) and Maddieson and Ladefoged (1993) analyze the contrast in Sinhala as being one of a short *vs.* a long ND (although the details of their analyses differ), with Letterman describing the difference as one between a prenasalized stop and a geminate prenasalized stop. This analysis is consistent with Riehl's (2008) conclusion that ^{N}D and ND can only contrast in languages with phonemic length (see also CHAPTER 20: THE REPRESENTATION OF VOWEL LENGTH; CHAPTER 37: GEMINATES). In all cases known to us where a unary–cluster ND contrast has been posited, the languages also have phonemic length, including Fula (Arnott 1970; Maddieson and Ladefoged 1993) and Selayarese (Mithun and Basri 1986) (and likely other languages closely related to Sinhala). The linkage of the unary–cluster ND contrast with phonemic length appears to have the following explanation: since the only phonetic difference between the two cases is length of the nasal (discussed in §3.3 below), this is sufficient for a contrast only in those languages where length independently forms the basis of a contrast.[5]

3.3 *The phonetics of NC*

In recent years, how the phonological and phonetic components of grammar are related has been a topic of interest. The phonetic realization of nasal–obstruent sequences has been a part of these discussions, given that the same apparent

[5] Both an analysis that treats the contrast as one between a singleton and geminate prenasal and one that treats the contrast as between a prenasal and a cluster, could be accommodated under our view. Phonetically, we would expect the same realization, given the internal nasal–oral timing of all NDs, as discussed in §3.3.

sequence of phonetic elements (nasal and obstruent) can pattern as either one or two units in the phonology. Similar attention has been paid to the timing of geminates (see Ham 1998).

It has long been assumed that a unary NC, such as a prenasalized stop, should differ phonetically from a nasal–obstruent cluster in being of shorter overall duration. This assumption is entailed in the distinct symbols used for these sounds, e.g. [ⁿd] *vs.* [nd], where the raised nasal in the unary case implies a less significant nasal portion and shorter overall duration. Herbert (1986), in his monograph on prenasalized stops, includes "shorter overall duration" as one of the defining characteristics of unary segments.

More recently, however, the assumptions about differing phonetic characteristics between these two NC types have been challenged. Maddieson and Ladefoged (1993), for example, state that there is no clear evidence of a phonetic difference and that the issue is rather one for the phonology. However, a review of the literature reveals that there have in fact been very few studies that systematically investigate the question of phonetic difference. Perhaps the most commonly cited is an article by Browman and Goldstein (1986), comparing bilabial NC clusters in English with claimed unary bilabial NCs in Chaga. However, this study, which examines labial trajectories rather than duration per se, is far from conclusive. In short, claims about phonetic characteristics of NCs, whatever they may be, have until recently been unsupported by sufficient phonetic data.

Riehl (2008) conducted parallel phonological and phonetic studies of NC types in four languages, examining phonetic characteristics of NC duration, preceding vowel duration, and preceding and following vowel nasalization. Riehl found that total duration *did* differ significantly between unary and cluster NCs when appropriate comparisons were made (most relevant being the ratio of the duration of plain nasals to NC sequences), while the other characteristics were not consistently different. The graph in Figure 23.1 contains duration data from four languages,

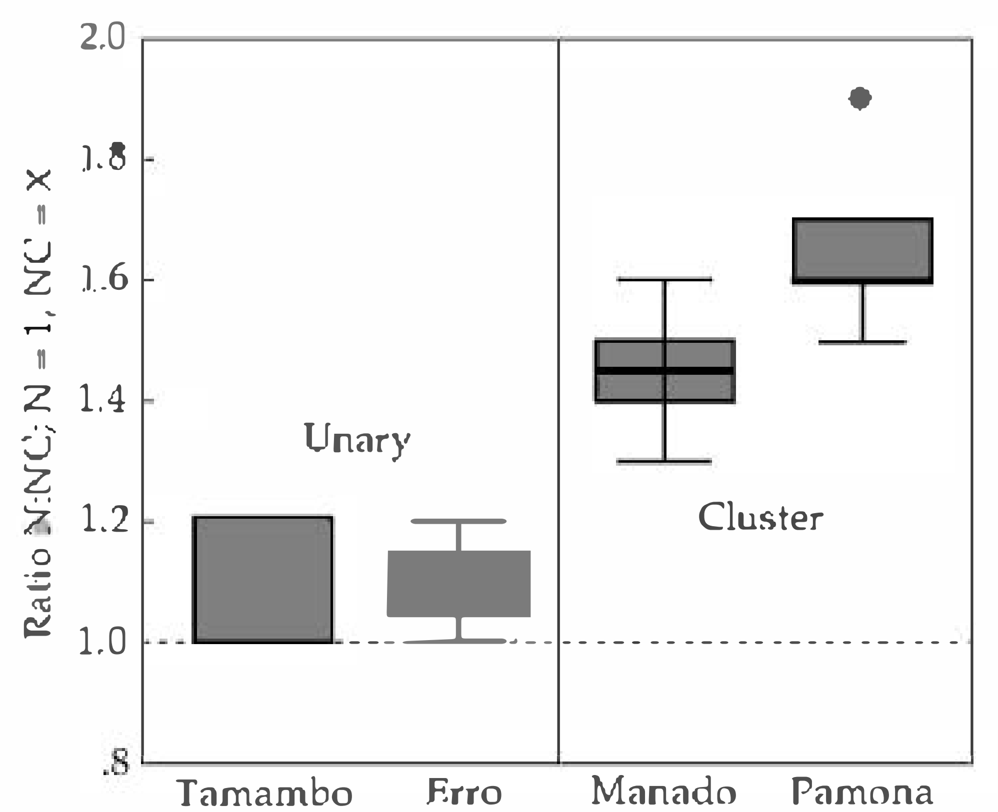

Figure 23.1 Ratio of total duration of plain N to ND sequences at the alveolar place of articulation in unary Tamambo and Erromangan and cluster Manado Malay and Pamona. Average values over ten repetitions of each target word by 4–6 speakers of each language. Duration of [n] = 1

5.2 The asymmetry between prenasalized and prestopped segments

Throughout the chapter, we have discussed the two types of partially nasal segments attested phonologically – prenasalized segments and prestopped nasals – in parallel, despite much greater documentation of ^{N}Cs than ^{C}Ns cross-linguistically. While we have acknowledged the paucity of information on the ^{C}N cases, we have not addressed the source of this imbalance. This imbalance raises several questions. First, are prenasalized stops truly more common cross-linguistically, or do we simply know more about the languages that contain them than we do about those that contain prestopped nasals? Second, if prestopped nasal segments are less common, is this simply accidental, or is there a principled explanation for why this is so? Third, if indeed the only evidence for prestopped nasal segments comes from those few cases identified above, is it possible that further examination of those cases will reveal that the contrastive cases are actually clusters and that there is no evidence for phonological unary prestopped segments at all? Having reviewed the literature as carefully as possible, we believe that the imbalance is neither due to a lack of appropriate documentation nor accidental, but more data is required to figure out why.

5.3 Pathways to change

The observed asymmetries between ^{N}C and ^{C}N and the possible phonetic motivations for these patterns lead us to consider what the pathways to change might be which result in partially nasal segments as part of a phonemic inventory of a language. Notably, the pathways of ^{N}C and ^{C}N seem to be different.

As discussed in §2.1 above, one characteristic pattern of unary ^{N}Cs is that they often constitute the only series of voiced stops in the language. As discussed above, such cases arguably arise as an enhancement effect where the addition of nasal airflow helps maintain full voicing as an enhancement of the voicing contrast (Ohala 1983; Iverson and Salmons 1996; Nasukawa 2005). The historical pathway for ^{C}Ns appears to be a result of co-articulatory timing. This pathway seems less likely to result in contrastive partially nasal segments, suggesting parallels to Cohn's (1993) observations of what circumstances result in contrastively nasalized approximants where weakening, not contextual nasalization, seems to result in the attested cases. Another pathway noted by a reviewer is partial denasalization of nasal stops, as observed for example in Athabaskan (e.g. Leer 1996). As we come to better understand the synchronic typologies of such cases, we can start to address the question of possible pathways to change.

5.4 Further directions

In closing, this chapter highlights the need for more data to better understand the cross-linguistic patterns of partially nasal segments and the implications of such patterns for phonological representations. This includes the continued documentation of less well-studied languages especially in underdocumented language families; the critical importance of understanding such data as part of a phonological system, not just as isolated elements; and finally the need for additional careful phonetic analysis that can inform not only the phonetic description of such cases, but also the phonology.

24 The Phonology of Movement in Sign Language

WENDY SANDLER

To watch a person communicating in a sign language is to observe a well-coordinated, multi-channel display of bodily motion. Most salient in this display is movement of the hands, which transmit lexical, morphological, and timing information. In coordination with the hands, motion of the mouth and lower face performs phonological, morphological, and gestural functions. Simultaneously, movement of the head and body provides a kind of prosodic shell to house the signing hands. Prominently embedded in this outer shell are the brows and eyes, whose movements provide intonation, the visual "tunes" of the message. The same physical articulators are all exploited by speakers as well, to augment the linguistically organized vocal–auditory signal.[1] But in sign language, it is these visually perceived actions that convey the linguistic signal itself, in a synchronized panoply of motion.

What are the primitives of movement at each level of linguistic structure? How are they organized? In what ways does the phonological organization of movement correspond to phonological properties of spoken languages? Can a comparison of the two help to separate universal linguistic properties from modality effects in language generally? How does the organization of such a system arise? These are the issues addressed in this chapter, which focuses on the phonological category of movement. The other two major phonological categories – hand configuration and location – are not the main objects of interest here.[2]

The first section describes the nature of movement in lexical signs, providing evidence for the existence and unity of movement as a phonological category. The section also provides a model for the representation of movement, briefly noting its strengths and weaknesses and those of alternative models. The goal of that section is to give the reader a feel for the nature of movement in lexical signs and for some of the issues involved in representing it phonologically.

[1] The term "speakers" as used here refers only to producers of spoken languages, while "signers" refers to producers of sign language.
[2] See Sandler and Lillo-Martin (2006) for a detailed overview of sign language phonology.

The morphology of sign languages exploits movement forms that are not found in simplex signs, a peculiarity of sign languages that is described in §2, where movement patterns in temporal aspect morphology are analyzed by means of morphological templates. The section also shows that morphological complexity is achieved not only by movement of the hands, but by movement of the mouth as well. A subsystem of the grammar in which movement appears to have certain analogic properties completes §2.

Also playing a linguistic role in sign language is movement of the upper face, head, and torso. These articulators provide prosodic and other cues, simultaneously with the lexical and timing information conveyed by the hands. The organization of movement in the service of prosody is the subject of §3, followed by §4, a brief comparison with the way speakers use visible movement.

While all established sign languages seem to exploit movement in similar ways, most likely due to the interaction of particular iconic and motoric underpinnings, evidence from a newly emerging sign language described in §5 suggests that these typological features are not "given" at the outset. Instead, lexical movement, obligatory in signs of established sign languages, takes phonological form only gradually, as the linguistic system as a whole emerges. §6 concludes the chapter by considering what the study of sign language phonology and movement might teach us about phonology in general, through a comparison of movement in sign language with phonological elements of spoken languages.

1 Movement in lexical signs

Examples of basic types of manual movement and their combinations that occur in lexical signs are illustrated in Figure 24.1. The examples are from Israeli Sign Language (ISL), except for Figure 24.1g, which is from American Sign Language (ASL), but the same types are found in other sign languages as well. The two types of lexical movement are path movement and internal movement of the hand or hands. Path movement is generated at the shoulder or elbow and results in moving the hand in a path through space. Internal movement is generated either by the wrist, resulting in orientation change, or by the fingers, resulting in a change in the shape of the hand.

Path movement can have the shapes [straight] (the default, shown in Figure 24.1a), [arc], or, in ASL, "7", the latter used primarily for initialized city names, in which the handshape is taken from the fingerspelled first English letter of the name (see CHAPTER 9: HANDSHAPE IN SIGN LANGUAGE PHONOLOGY for *initialization*), and also a rare "Z" shape, e.g. in NEVER and LIGHTNING in ASL. Lexical movement is constrained in the following ways: there is typically only one movement in a sign, performed on or near a single area of the body, the head, torso, arm, or hand. Another way to create a path movement is by moving the hand/s in a circle. Some researchers consider circling movement to be an additional movement feature in addition to [straight] and [arc], while others favor an analysis of circles as consisting of a sequence of arcs with different values for concavity, a point to which we return in §3. Lexical movements can also be characterized by the features [tense] and [doubled].[3]

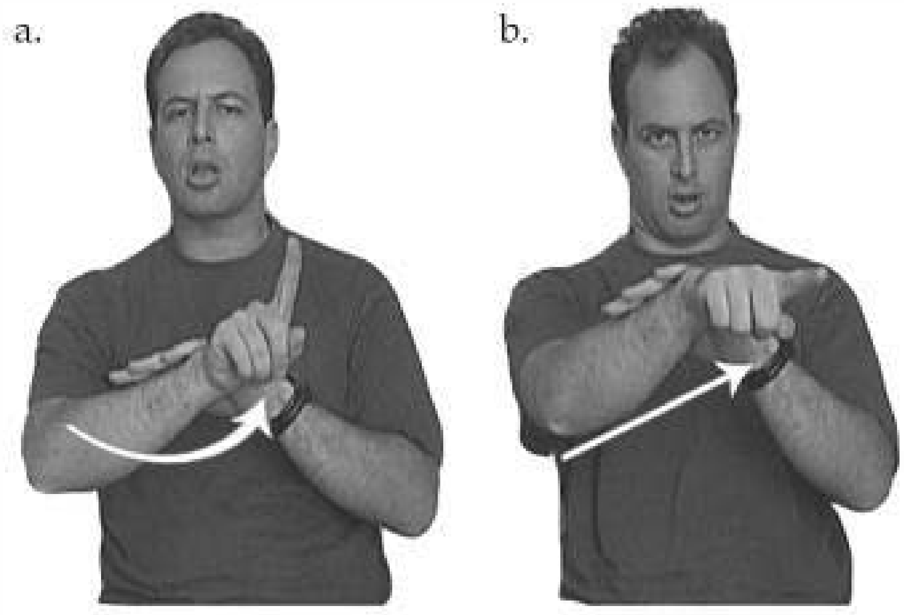

Figure 24.2 An ISL minimal pair differing only in movement shape

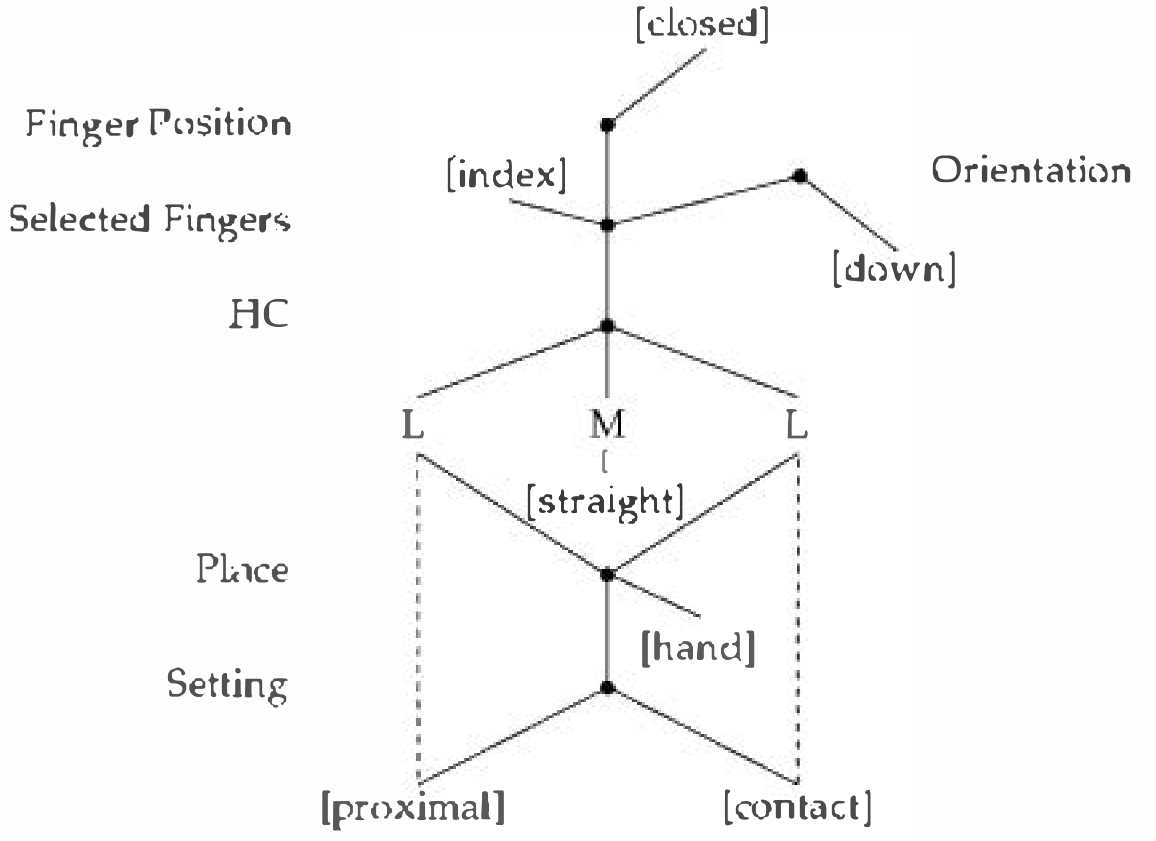
distinguished by single or doubled movement can also be found, but are also very uncommon.

A straightforward linguistic argument for a movement category is reference to movement in phonological constraints and processes. A constraint on a rule involving movement is the blocking of a particular agreement marker in verbs that have specified movement. In ISL, verbs are blocked from undergoing inflection for multiple object agreement if they are specified for any feature belonging to the class of (non-default) lexical movement features, such as [arc] (in the vertical plane), [tense], or [doubled][4] (Sandler 1996). In such signs, the verb is not inflected for multiple object agreement; instead, an object pronoun is used, and it carries the inflection. Since the multiple agreement form consists of a horizontal arc movement which is superimposed on the sign, it appears that its blocking by a specified movement feature such as [tense] or [doubled] is a constraint on movement complexity. Verbs of the relevant type with the most common path movement, the default straight path movement, all do undergo this inflection. Apparently, a similar constraint is active in ASL (Padden 1988).

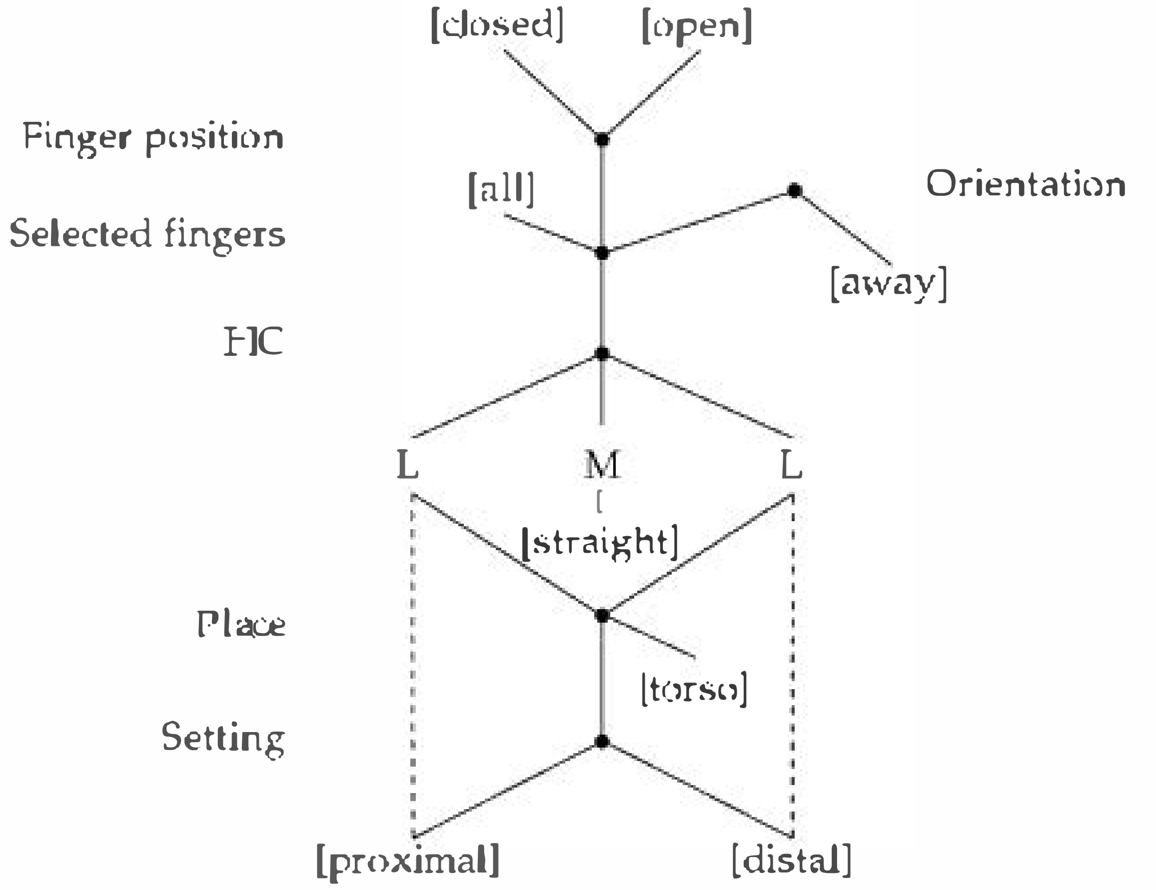
A morphological rule that refers to the movement category provides further evidence for the category in sign language phonology. This morphological rule of reduplication for Iterative and other temporal aspects reduplicates the final syllable of a sign. The rule refers to movement in the sense that a syllable is defined as consisting either of a single movement (path or internal) or of a simultaneously executed path and internal movement. Two movements in a sequence constitute two syllables. Most signs are monosyllabic, and are fully reduplicated when inflected for various temporal aspects. However, compounds may be disyllabic, and, if so, then the final syllable – with movement as its nucleus – is reduplicated (Sandler 1989). This is the case whether the movement in that syllable is path or internal, which in turn is an argument for unifying both types of movement in a single category.

4 [doubled] movement, named [restrained] in Sandler (1996), refers to lexical doubled movement, which differs from morphological reduplication both phonetically and phonologically.

(2) a. *Representations of ISL* JUST-THEN, *a sign with plain path movement*



b. *Representations of ISL* SEND, *a sign with path and internal movement*



The aspect of internal movement captured by this representation is its intimate connection to the hand, both physically and behaviorally, in the phonology. While path movement is achieved by movement at higher joints (elbow or shoulder), internal movement is achieved by movement of the fingers (handshape change; Figure 24.1b) or wrist (orientation change; Figure 24.1c). An argument for the intimate connection between internal movement and the category of hand configuration comes from assimilation in lexical compounds, where all hand configuration features spread, including their movement. A version of a compound meaning FAINT, composed of the signs MIND and DROP, illustrates this clearly, as seen in Figure 24.3.

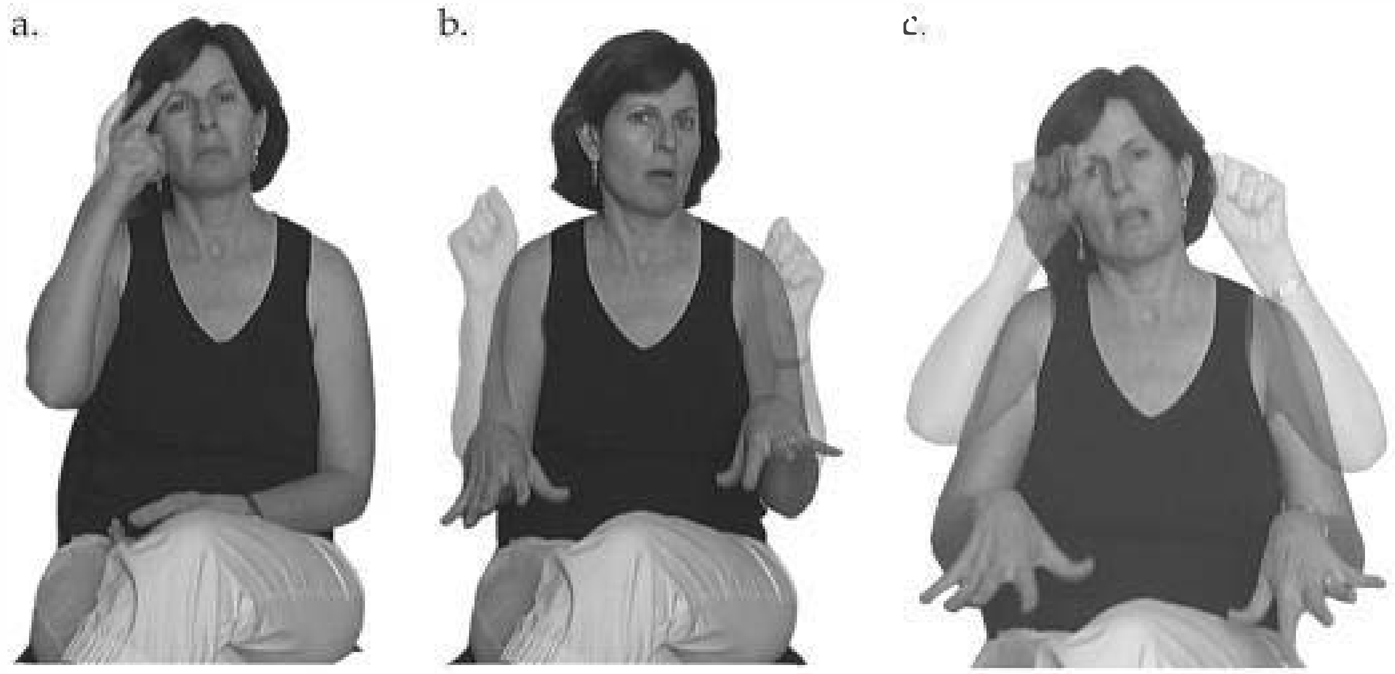


Figure 24.3 The ASL lexical compound, MIND^DROP = FAINT

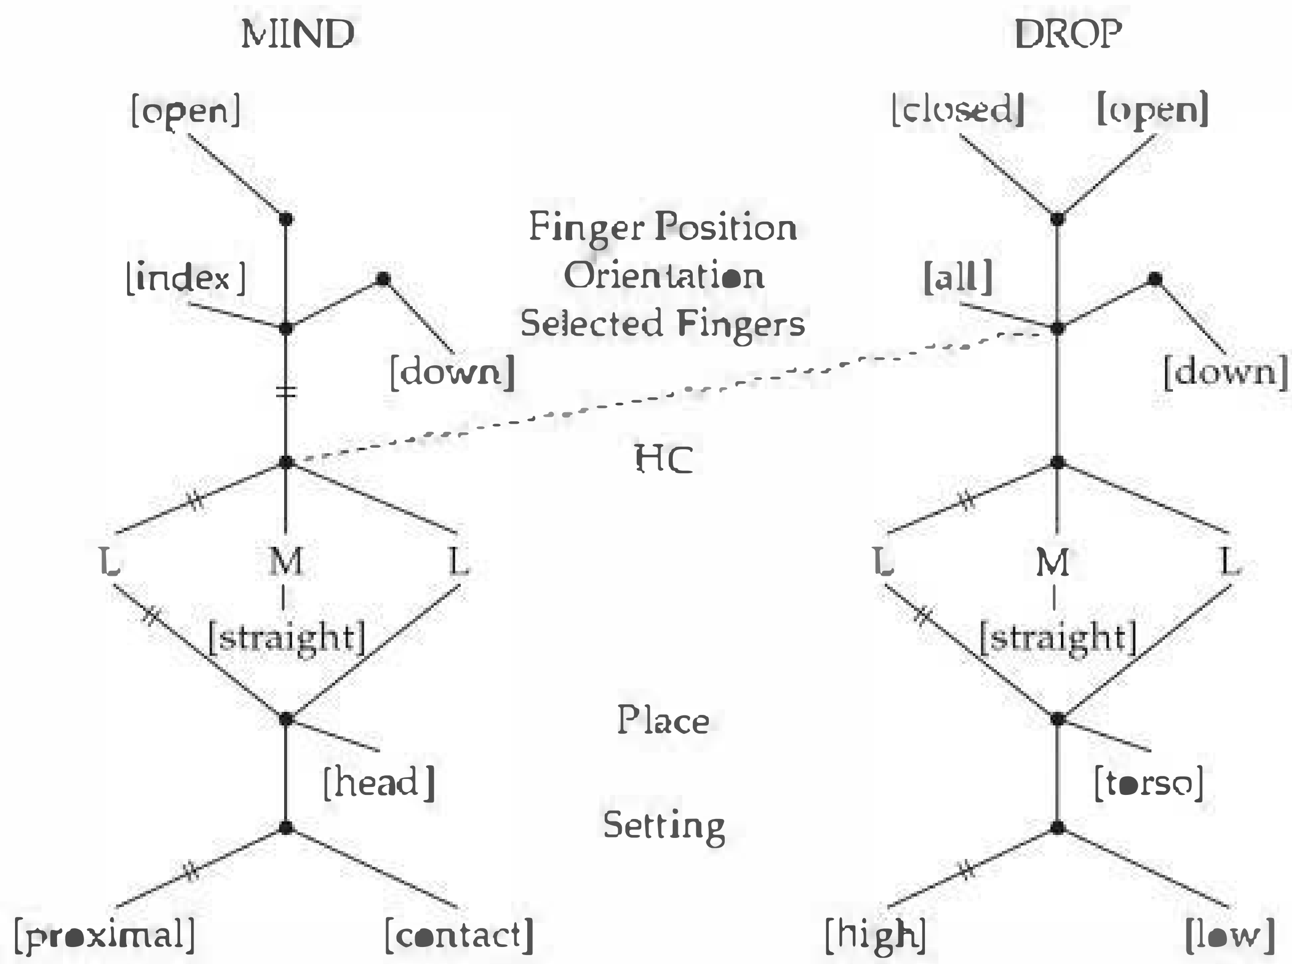
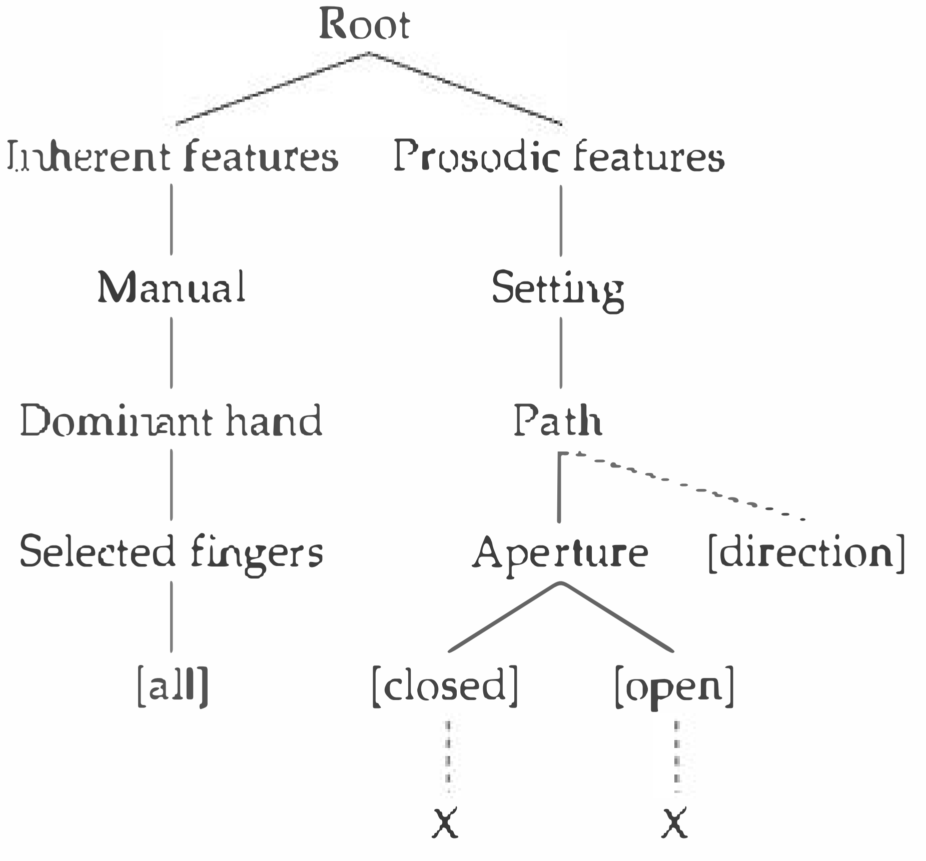
Example (3a) shows that the entire hand configuration node, with its branching features for internal movement, spreads regressively (dashed line), associating to the second location of MIND. The surface form of the compound is represented in (3b).

(3) a. *Representations of compound reduction: Truncation and assimilation of* MIND^DROP



(5) *Prosodic Model schema with internal movement (handshape change)*



Each of the two models accounts for a number of different theoretical and empirical phenomena in sign language phonology, and both models alleviate certain problems inherent in the Hand Tier model, in particular, the linearization problem, in which path and internal movement are not accommodated in a unified way. But each has disadvantages as well. Omitting a movement segment from the representation, as the Dependency Model does, makes it difficult to accommodate the durational effects on movement described in §3, and the distribution of the feature [contact], which can be realized on either of the Ls, on the M, or on all segments (Sandler and Lillo-Martin 2006). A coherent account of the syllable reduplication facts described above also provides a challenge for that model.

A drawback of the Prosodic Model lies in the segregation of the internal movement features from the hand configuration features in two separate branches of structure. In this way, the model sacrifices the phonetic and phonological integrity of hand configuration (the latter supported by the compound assimilation facts, for example). Doing away with a Movement segment, a representation inherited from the Dependency Model, presents the same problems for the Prosodic Model.

No model comfortably accommodates all the facts. Unfortunately, a detailed review of existing models of movement would take us too far from the goal here of introducing movement in sign language to a general linguistic audience, and interested readers are referred to the sources cited above, and to Sandler and Lillo-Martin (2006: ch. 13), for further illustration and discussion.

1.3 *Lexical movement and meaning*

A central property of phonological units is that they are meaningless. This "duality of patterning" of language – the division into a meaningful level of morphemes, words, and sentences, as well as a meaningless level of auditory or visual formational elements – has been called a basic design feature of human language (Hockett 1960). This property is what gives human language its ability to create vast vocabularies from a small number of primitive elements. Yet sign and locations remain unchanged, while the movement pattern alone is affected – by changes in shape, duration, rhythm, and number of iterations. Klima and Bellugi describe 11 aspects for ASL, which they distinguish from one another by means of the following binary features: reduplicated, even, tense, end-marked, fast, and elongated.

The system has certain key elements in common with the root and pattern morphology of Semitic languages, in which the consonants of the root remain constant, while the vowel pattern and the rhythm (expressed through gemination of different consonant or vowel positions in the morphological template) are altered to create different verb forms (see CHAPTER 105: TIER SEGREGATION; CHAPTER 108: SEMITIC TEMPLATES). The abstract vocalic and timing patterns constitute morphemes of voice or aspect and of verb form, such as (roughly) reflexive, causative, etc. Influenced by McCarthy's model for Standard Arabic (McCarthy 1981), a templatic treatment of ASL aspect proposes similar timing templates and movement features for the aspectual system of that language. Associating morphological features to the movement segment and geminating either locations or movements produce aspectual patterns (Sandler 1990). For example, the citation forms of the verbs GIVE and LOOK-AT are shown in Figure 24.4. Each has a plain straight movement with no special shape or timing qualities. If these verbs are inflected for temporal aspect, then the form gets its shape from the path movement feature and its timing from the aspectual template. For example, inflection for Durational adds a reduplicated circular movement to the base forms, illustrated in Figure 24.5. For any verb so inflected, the movement pattern for any given aspect is the same.

Both GIVE and LOOK-AT belong to the class of verbs which in many sign languages agree for subject and object or, more precisely, for source and goal (Padden 1988; Meir 2002). Agreement is realized by moving the hand(s), configured according to the feature specifications of the base verb, from a spatial locus associated with the source to a locus associated with the goal. The citation forms shown in Figure 24.4 are very similar to the inflected forms for I-GIVE-YOU and I-LOOK-AT-YOU. That is, the initial locus (1st person) is typically near the torso of the signer, the final locus (2nd person) is at a distal location in front of the signer and movement is from the signer toward the addressee. The spatial loci for 3rd person referents are typically established during the discourse, and consist of points in space which defy precise phonological representation.

a.

in the class of agreement verbs), while there is a conventionalized set of movement shapes and timing templates which determine aspect.

2.2 Mouth movement in sign language morphology

In addition to the infrequent lexical specification of mouth and movements, noted in §1 above, repeated tongue flap ("lalalala") plays a grammatical role in many sign languages, often marking predicates for iterative or exhaustive inflection, sometimes with additional manually produced inflection such as reduplication or horizontal arc. For example, in ISL, the horizontal arc of the exhaustive verb inflection can be accompanied by a rapid tongue movement of this kind (Meir and Sandler 2008).

A different tongue movement – side-to-side tongue wag – has been closely investigated in the Delayed Completive aspect in ASL (Brentari 1998). In this language, tongue wag is an allomorph of finger wiggle, marking the Delayed Completive aspect. This operation productively applies to telic verbs, with some phonological restrictions, and adds the meaning "delay the completion of x," where x is the base verb.

In addition to morphological functions, mouth shapes and movements perform prosodic and gestural functions (Sandler 1999, 2009; Boyes Braem and Sutton-Spence 2001). In fact, in these "manual" languages, the mouth is often in constant motion – not in the service of speech, but in the service of language.

2.3 Predicates of motion and location: A partly linguistic subsystem

Established sign languages typically have a subsystem within their grammars for designating location and motion of classes of referents. This system, called verbs of motion and location, classifier predicates, or classifier constructions, combines classifier handshapes with motions and locations in space. Identified and analyzed in the early years of sign language research (by Supalla 1982, 1986, and others), the system has subsequently been tackled by a number of other researchers of ASL and several other sign languages (see Emmorey 2003). The organization of these constructions clearly has conventionalized properties, and the system is apparently difficult to acquire by both first and second language learners.

In classifier predicates, there is a conventional set of handshapes corresponding to classes of referents (hence the term "classifiers"). Unlike the handshape category in lexical signs, which is a meaningless phonological unit, the classifier handshapes are meaningful morphemes, which fall into three categories. Size and shape classifiers class objects according to physical properties, like small and round, flat, or cylindrical. Handling classifiers mimic the shape of the hand or object (like a hook or tongs) handling another object, be it flat and thin, like paper, or thick, like a book, for example. Entity classifiers refer to semantic classes such as humans, small animals, legs, eyes, or vehicles. The handshapes in classifier systems are conventionalized, and vary from sign language to sign language; they are part of the grammatical system.

These classifier handshapes can combine with other classifier shapes on the non-dominant hand, an impossibility in lexical signs, in which the non-dominant hand too has meaningless phonological status and is strictly constrained in shape

[IF HE INVITE-ME PARTY HIS]$_I$	[I COME-TO PARTY HIS]$_I$	
Brow Raise		
Wide Eyes		
Tilt right		*Tilt left*
Head forward	*Head back*	
Head down	*Head up*	
Hold		*Hold*

Figure 24.9 Alignment of facial and head positions with the timing cues of the hands at the end of each intonational phrase produces salient and synchronized movement at the boundary. The timing cue in the text is cessation of movement (holding the signing hands still)

4 Movement of hands, face, and body in spoken language: A comparison

Unlike sign language, spoken language is usually not described in terms of movement of the face, hands, and body. Instead we think of language in the auditory modality as produced by the largely hidden vocal tract, suggesting that hearing people are not conduits of the variegated motion ensembles described above – and speakers may indeed look rather strange to deaf people. But that is not because speakers are static. They, too, make use of the head, body, face, and hands when they communicate, as the burgeoning fields of co-speech gesture and "visual prosody" reflect. Speakers of all languages and cultures use their hands rhythmically and imagistically to augment the linguistically organized signal in ways that have motivated a theory of co-speech gesture as integral to language (see e.g. McNeill 1992; Goldin-Meadow 2003; Kendon 2004). Speakers use the face and body as well to "punctuate" and augment their speech (see Swerts and Krahmer 2009 for a recent collection of articles on visual prosody). But the motions of the face and body that accompany speech, though rich, are not as finely tuned, conventionalized, or systematically coordinated as are the motions of prosody accompanying signed utterances. In sign language, these signals are organized into a linguistic system.[6] Current work on a new sign language gives clues to how such a linguistic system emerges.

5 Emergence of the movement category

The foregoing exposition leapt back and forth in rather cavalier fashion from ASL to ISL, with forays to SLN, as if the system being described were common to all sign languages. And indeed, while there certainly are language-specific differences, most of the characteristics of movement described in the broad description

[6] While sign languages organize motion of the hands, face, and body into a linguistic system, this does not mean that they do not also avail themselves of paralinguistic gestural elements corresponding to co-speech gesture. In fact, they do. A particular kind of iconic co-sign gesture in sign languages is commonly made with the mouth (Sandler 2009).

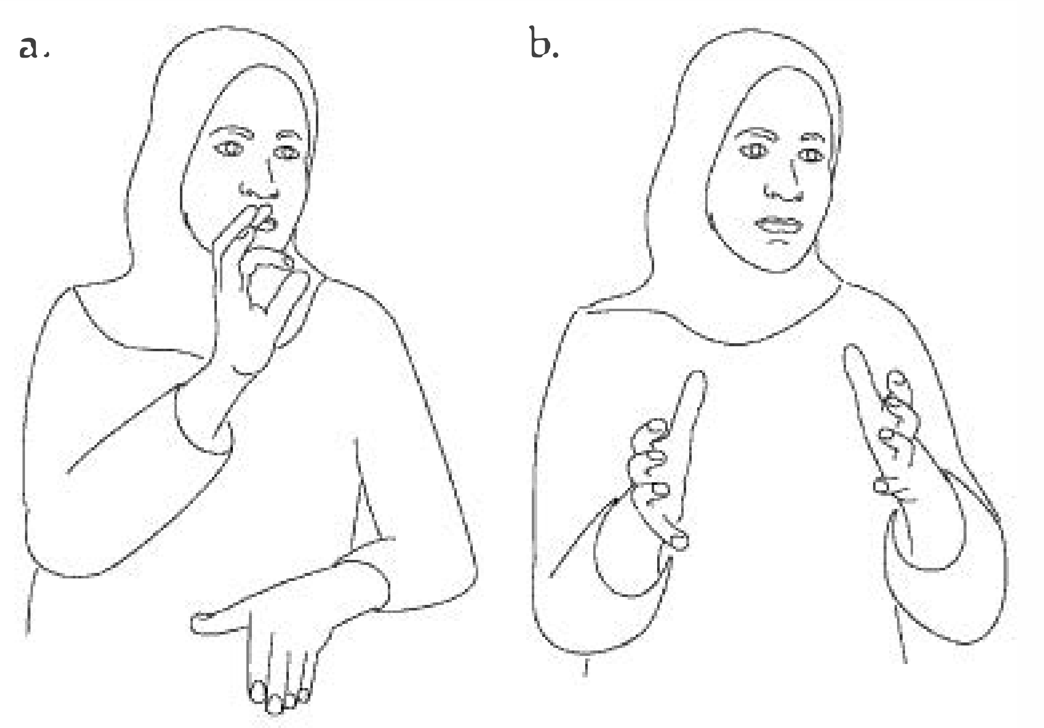

Figure 24.10 Al-Sayyid Bedouin Sign Language (ABSL) KETTLE, comprised of CUP and ROUND-OBJECT, as signed in an extended family with many deaf members

at some location with a transitional movement only – a phonetic possibility that established sign languages do not exploit. A system like that of ABSL does not need to count syllables, unlike ASL, for example (see §1), and has not arrived at LML signs as a (possibly perceptually advantageous) alternation between static and dynamic elements. In such a system, movements are not mandatory. Interestingly, in the third generation, among children who dwell in households with a deaf parent and deaf siblings, we begin to see mandatory movement emerging. Movement segments are introduced into everyday signs such as GOAT and KETTLE in these children, performed without movement by others in the village (Sandler *et al.*, forthcoming). KETTLE as signed in one household, a compound made up of the signs CUP and ROUND-OBJECT, is shown in Figure 24.10.

The second part of the sign KETTLE is typically signed by placing the hands in front of the torso in the configuration shown in Figure 24.10b. But a young girl in this household signed it differently, introducing a salient movement of the two hands toward each other, as shown in Figure 24.11. This movement is counter-iconic, as the kettle does not become any smaller. An epenthetic movement is introduced in the sign GOAT by two children in different deaf households that include a deaf parent (an unusual situation, as the gene is recessive). That sign is typically made with an "L" hand, by placing the thumb in contact with the temple – an iconic representation of a goat's horn. But the two children from deaf households whom we recorded introduced a repeated tapping movement at the temple. Again, the movement is not iconic. A goat's horn does not tap its head, and this movement can be seen as introducing a formal element that will ultimately be exploited in a phonological system.

6 Summary and conclusion

Perhaps a key to understanding sign language phonology, and movement as part of it, is to recognize the fact that no potential visual signal goes unexploited. But these signals, available to all humans, are molded in sign languages into a

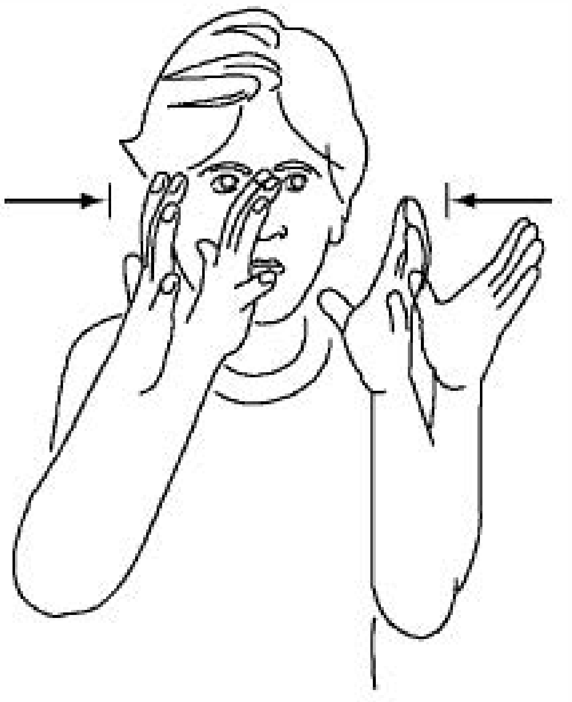

Figure 24.11 Movement epenthesis in ROUND-OBJECT by a small child in the family

well-disciplined vehicle for conveying particular kinds of linguistic information at different levels of structure.

Lexical signs must have some movement, even if it is only a default straight path, a requirement that implies an organizational advantage for the category – perceptual, articulatory, contrastive, or all three. Within signs, the primary movement is manual – either path, hand internal, or the two simultaneously – characterized by a small set of movement features.

More evidence for the existence of a movement category comes from morphological constraints and rules that refer to it. Aspectual morphology makes systematic use of movement patterns – templates of movement shape and timing that are comparable in some respects to the templatic morphology of Semitic languages. More freedom of movement appears to be available to the classifier predicate subsystem, which is exploited for types of discourse in which spatial relations and manners of movement are prominent, and which provides a vehicle for stylistic creativity, as in poetry.

As the hands move in space, assuming various configurations, they are sometimes accompanied by coordinated movement of the mouth, which can serve lexical, morphological, prosodic, or gestural functions. Above the lexical level, prosodic constituents such as the intonational phrase are marked by movement of the head and torso, and meaningful intonational arrays are overlaid on these displays by actions of the upper face.

Non-trivial similarities to spoken language phonological categories can be identified here: (i) signs must have an alternation between static and dynamic components, as spoken words must have consonants and vowels;[8] (ii) there is a limited inventory and combination of features in a given phonological category (here the movement category) within lexemes (CHAPTER 17: DISTINCTIVE FEATURES); (iii) constraints and rules may be appealed to in order to provide linguistic

[8] This comparison between Ls and Ms and Cs and Vs is not meant to imply that these categories have similar properties or distribution in the two modalities, because they do not. Rather, the comparison is much broader, reflecting the fact that these phonological categories manifest different rhythmic properties.

25 Pharyngeals

Kimary Shahin

1 Introduction

Pharyngeals are segments with primary or secondary articulation in the pharynx. They are sometimes referred to as "post-velars" (e.g. Bessell and Czaykowska-Higgins 1991; Bessell 1992). It is usually understood that the uvula is the topmost structure of the pharynx, and that the pharynx extends to, but excludes, the glottis (e.g. Carmody 1941 and Maddieson 2009, who states that the upper boundary is "around the uvula"). The term"pharyngeals" has been used in a second sense, to refer to segments, like [ħ ʕ], which are "pharyngeal" according to the IPA classification of places of articulation. They have been presumed to be articulated above the epiglottis and below the uvula. However, this is a misnomer because the place of articulation of those sounds is actually aryepiglottal, as will be explained (see CHAPTER 22: CONSONANTAL PLACE OF ARTICULATION for more general discussion).

Figure 25.1 provides a general idea of the geographic distribution of pharyngeal consonants, including the pharyngeal glide but excluding non-uvular rhotics like [r ɹ]. Figure 25.1 is based on the observations in this chapter, and the data of Maddieson (2005a, 2005b) and Chambers and Trudgill (1998). Regarding non-uvular rhotics, pharyngeal constriction has been observed for English [r ɹ] (e.g. McMahon *et al.* 1994; Scobbie 2009). However, identification of all languages with a pharyngeally articulated non-uvular rhotic is left for work elsewhere, and the areas for English are not marked in Figure 25.1.

Pharyngeal vowels, i.e. "low back" and "lax"/"–ATR" vowels, as will be explained below, probably have extensive geographic distribution.

Regarding inventory configurations, languages with primary pharyngeal consonants at more than one place of articulation tend to have large consonantal inventories, typically utilizing secondary articulations like lip rounding or glottalization, but not necessarily having a voicing opposition for obstruents. The presence of secondary pharyngeal consonants implies the presence of primary pharyngeal consonants, and it seems that no language with pharyngealized vowel phonemes also has pharyngeal consonant phonemes; see Maddieson (2009). Languages with pharyngeal consonants typically have derived secondary pharyngeal, i.e. "lax," vowels, due to vowel pharyngealization in the environment of a pharyngeal consonant (CHAPTER 29: SECONDARY AND DOUBLE ARTICULATION).

Figure 25.1 Geographical distribution of pharyngeal consonants, except for non-uvular rhotics

The aim of this chapter is to review the main issues in pharyngeal phonology. These can be expressed by the following questions: (i) what is the pharyngeal typology?; (ii) what is the articulation of pharyngeals?; (iii) what is their representation?

The answers to these questions as indicated by research so far will be summarized below. Where data examples are given, they will mostly just illustrate various patternings – for data that establish the patterns, see the sources cited for each pattern. Our discussion will incorporate the findings of Esling (1996, 1999, 2005) on the actual nature of pharyngeal articulation. It will also incorporate the findings of Miller-Ockhuizen (2003) regarding a superordinate class that includes both pharyngeals and glottals. Finally, although some comment will be made on the phonological representation of non-pharyngealized ("+ATR") vowels, *vis-à-vis* the phonological representations of pharyngeal segments, +ATR and −ATR vowel patternings (e.g. Casali 2008 and references therein) will not be illustrated, as full integration of Niger-Congo-type tongue root vowel harmony systems into an overall characterization of pharyngeal phonology is beyond the scope of this chapter.

All in all, it is an exciting time to be researching pharyngeals and, as we will see, there remains much work to keep phonologists, phoneticians, fieldworkers, and dialectologists busy for a long time to come.

2 Pharyngeal typology

Segments for which the pharyngeal articulation is primary have often been referred to as "gutturals" (especially for Semitic). I will refer to them with the more transparent term "primary pharyngeals." They include [q ɢ ʛ ɴ ʀ χ ʁ ħ ʕ ʜ ʢ ʡ]

Table 25.1 Co-occurrence of laryngeal consonants and vowels in Ju|'hoansi (from Miller-Ockhuizen 2003: 142, table XXIII). Copyright © 2003. From *The phonetics and phonology of gutturals: A case study from Ju|'hoansi*. By Amanda Miller-Ockhuizen. The data are here reproduced by permission of Taylor and Francis Group, LLC, a division of Informa plc

			V1				
			Non-laryngeal vowels	*Laryngeal vowels*			
			Modal	*Breathy*	*Glottalized*	*Epi-glottalized*	*Total*
C1	Non-laryngeal consonants	Voiceless	265	70	32	84	451
		Voiced	203	71	31	65	370
		Nasal	155	25	23	70	273
	Laryngeal consonants	Aspirated	254	2	1	11	268
		Ejective	169	0	2	0	171
		Uvularized	214	0	0	0	214
		Epiglottalized	132	0	0	0	132
		Total	1392	168	89	230	1879

The Ju|'hoansi glottals are /ɦ/, a set of aspirated consonants, a set of ejective consonants, a set of breathy vowels, and a set of glottalized vowels.[1]

The superordinate class in Ju|'hoansi excludes modally voiced segments. (This is interesting but will not be accounted for here.) In Ju|'hoansi, all the pharyngeals and glottals pattern together in a morphemic Obligatory Contour Principle (OCP) constraint: in root morphemes, none of the pharyngeal or glottal consonants can co-occur with any of the pharyngeal or glottal vowels. As it turns out, this is precisely as predicted by Esling's (2005) clarification of pharyngeal phonetics. On the basis of numerous data from several languages, he clarifies that the structures of the pharynx and the larynx are controlled by one articulatory structure: the "laryngeal constrictor mechanism." Miller-Ockhuizen refers to the superordinate class of pharyngeals and glottals as "gutturals." However, since "gutturals" is already established as a term for primary pharyngeals, I will refer to the class as "laryngeals," in the interest of descriptive transparency. In this terminology, "glottal" and "laryngeal" are not synonymous.

Miller-Ockhuizen's data showing the laryngeal OCP in Ju|'hoansi are presented in Table 25.1. As she explains (2003: 140), the OCP constraint holds over 1,900 distinct monomorphemic root morphemes, with only sixteen exceptions.

2.1 *The pharyngeal class*

The first type of evidence for a pharyngeal class comprising primary and secondary pharyngeals is from Arabic. In some Arabic dialects, including Northern

[1] A [ʔ] in the language is apparently an allophonic or phonetic effect (Miller-Ockhuizen 2003: 115).

Palestinian and Syrian, the feminine suffix occurs as [-i] or [-e], except when it is immediately preceded by a primary or secondary pharyngeal (Herzallah 1990). This is discussed as evidence for the overall pharyngeal class by McCarthy (1994), who illustrates it with Syrian data from Cowell (1964) and Grotzfeld (1965).[2] Some of his examples are:

(2)	ʔɔsːˤa	*ʔəsːˤe	'story'
	mniːħa	*mniːħe	'good'
	tˤabχa	*tˤabχe	'cooking'

A second type of evidence comes from cases of vowel pharyngealization. Maddieson (2009) explains what a pharyngealized vowel is when he states:

> ATR vowels are produced with a wider than expected aperture [between the tongue root and the back wall of the pharynx]. Vowels with a narrower than expected constriction can be labeled pharyngealized.

Thus, "lax" ("−ATR"/"RTR") vowels, written with IPA symbols like [ɪ ɛ ʊ ɔ], are pharyngealized (see also CHAPTER 21: VOWEL HEIGHT). Vowels are typically pharyngealized when they are adjacent to a primary or secondary pharyngeal. (Shahin 2002: 98 takes this as evidence that the feature that represents pharyngealization is optimally vocalic.) This is observed in Arabic (Gairdner 1925; Jakobson 1957; Shahin 2002) and in St'át'imcets (Interior Salish) (van Eijk 1997; Shahin 2002). It is illustrated for Palestinian Arabic in (3) and for St'át'imcets in (4).[3] In St'át'imcets, the immediately preceding vowel is affected. (In both languages, the vowel pharyngealization shows domain effects, and neutrality effects are observed in the Arabic.)

(3)	ħɪlu	*ħilu	'pretty'
	ʕʊlə	*ʕulə	'Ula (girl's name)'
	ðˤorˤə	*ðˤurˤə	'corn'

(4)	ʃʧʊʁʷ	*ʃʧuʁʷ	'stripe'
	mɪxˤæɬ	*mixˤæɬ	'black bear'
	ʧɜʁɘn	*ʧɘʁɘn	'to rip, tear something (TRANS)'

Bellem (2007: 58) suggests that vowel pharyngealization in Arabic is a phonetic effect. However, it is discrete (CHAPTER 89: GRADIENCE AND CATEGORICALITY IN PHONOLOGICAL THEORY). It is also grammatically visible, as it is sensitive to word-internal morphological structure (see Shahin 2002: 114–115). This means it is phonological. Bellem also suggests that it is an effect of vowel length, but this is not so because short vowels are not pharyngealized in forms parallel to those in (3) but without the pharyngeal consonants (see Shahin 2002: 181).

[2] The phonemic vowel inventory of colloquial Levantine Arabics like Syrian and Palestinian (including Bedouin) is /I: E: Æ: O: U: I E Æ O U/, where capital letter symbols encode the fact that the vowel will be realized as non-pharyngealized or pharyngealized ("tense" or "lax"), depending on the nature of the surface form in which it appears; see Shahin (2003) for discussion, as well as evidence that, at least in Palestinian, /E/ is actually /ɛ/.

[3] The phonemic vowel inventory of St'át'imcets is /I Æ U/. Capital letter symbols are used here as explained in fn. 2. The schwa, which has various realizations, including non-pharyngealized [ɘ] and pharyngealized [ɜ], is epenthetic.

(10)	ʔisʕatte	*ʔisʕɛtte	'lice (GEN)'
	t'Arʕ'ætte	*t'Arʕ'ɛtte	'tapeworms (GEN)'

Another pattern is avoidance of primary pharyngeals in coda position. This is observed in various Semitic languages. It is illustrated for Negev Palestinian Arabic and Tiberian Hebrew in (11) and (12), respectively.[10] These data are from McCarthy (1994: 214–215). (See McCarthy 1994 for data showing the avoidance in Hijazi Bedouin Arabic and Tigre.) In both Negev Arabic and Tiberian Hebrew, a vowel is epenthesized so the primary pharyngeal is realized in onset instead of coda position.

(11)	jahardʒ	*jahradʒ	'he speaks'
	ahalam	*ahlam	'I dream'
	bnaʁazil	*bnaʁzil	'we spin'

(12)	jahăpoːk	*jahpoːk	'he will turn'
	jeħĕzaq	*jeħzaq	'he is strong'
	joʕŏmad	*joʕmad	'he is made to stand'

Degemination of primary pharyngeals also occurs, in Tiberian Hebrew and Tigre. This is illustrated in (13) and (14), respectively, with data from McCarthy (1994: 216–217).[11] Compensatory lengthening (CHAPTER 64: COMPENSATORY LENGTHENING) occurs for the forms in (13).

(13)	meːʔeːn	*meʔʔeːn	'he refused'
	jeːħat	*jeħħat	'he marches down'
	raːʕiːm	*raʕʕiːm	'evil ones'

(14)	təbaʔasa	*təbaʔʔasa	'he quarreled'
	ləsˤʕən	*ləsˤaʕʕən	'he loads'

Other effects are also observed. For example, in Jibbāli/Shehri (South Arabian) "Conjugation B" verbs, a syllable with a primary pharyngeal onset attracts stress, and vowels flanking the primary pharyngeal are identical (Hayward *et al.* 1988; Hayward and Hayward 1989). Examples are seen in (15), from Hayward and Hayward (1989: 182).[12]

(15)	j'sɔ.'ʕɔf	*j'sɔ.ʕɔf	*j'se.'ʕɔf	'remove husks (IMPERF)'
	j'rɔ.'χɔs'	*j'rɔ.χɔs'	*j're.'χɔs'	'become cheap (IMPERF)'
	j'ðˤɔ.'hɔr	*j'ðˤɔ.hɔr	*j'ðˤe.'hɔr	'be finished (IMPERF)'

[10] The vowel phonemes of Tiberian Hebrew are /i e ɛ a ɔ o u/ (Malone 1993). In (12), the inserted vowel is schwa, with various colorings. In Negev Arabic, the effect is limited to cases where the primary pharyngeal follows [a].

[11] Rose (1996) states that the Tigre vowel phonemes are the same as Tigrinya's (see fn. 7).

[12] The Jibbāli vowel inventory is /i e ɛ a ə ɔ o u/ (Johnstone 1981).

2.3 *The secondary pharyngeal class*

Some patternings involve secondary pharyngeals and exclude primary pharyngeals. They typically involve domain, directionality, or neutrality effects, which can be quite complex.[13] Due to space limitations, none of those effects will be addressed here. (See CHAPTER 77: LONG-DISTANCE ASSIMILATION OF CONSONANTS.) The most extensively studied of these patternings is "emphasis spread" in Arabic (e.g. Harrell 1957; Younes 1982; Card 1983; Herzallah 1990; Davis 1995; Zawaydeh 1998; Watson 1999; Shahin 2002; Bin-Muqbil 2006). In Arabic, otherwise non-secondary pharyngeal consonants are pharyngealized, and the (short or long) low vowel is realized as [ɑ(ː)], when a secondary pharyngeal consonant occurs elsewhere in the word. Examples, adapted from Davis (1995: 473–474), are seen in (16), in which the underlying secondary pharyngeals are underlined. The underlying secondary pharyngeal set includes /kˤ/ (frequently phonetically realized as [q]) in several Arabic varieties, as seen from forms like [kˤɑːfˤ] 'the letter *qaf*' *vs.* [kæːf] 'the letter *kaf*'.

(16)	bˤɑlːˤɑːsˤ	*bælːæːsˤ	'thief'
	χˤɑjːˤɑːtˤ	*χæjːæːtˤ	'tailor'
	tˤwˤɑːlˤ	*tˤwæːl	'long (PL)'

Interior Salish "retraction harmony" (Bessell 1992, 1998; Doak 1992; van Eijk 1997; Shahin 2002) is similar. (The studies, other than Shahin's, mistakenly conflated this pattern with the vowel pharyngealization illustrated in (4).) St'át'imcets examples are presented in (17). In this language, the only consonant affected is /ʧ/, and the low vowel and epenthetic schwa are realized as [ɑ] and [ʌ], respectively. Affected segments are typically left adjacent to the pharyngealized consonant, although rightward cases seem to exist (Henry Davis, personal communication; Shahin 2010).

(17)	mʌkˤ'	*ɪnɜkˤ'	'to get stuffed, to eat too much'
	ʃkˤjɑxˤ	*ʃkˤjæxˤ	'drunk'
	ʧˤkˤʷænæʔ	*t̠kˤʷænæʔ	'lynx'
	ʔɑlˤʃˤɘm	*ʔælˤʃˤɘm	'sick, ill'

In Tsilhqot'in "flattening," the vowels /i ɪ u ʊ æ ɛ/[14] are realized as [ə̰i/e ə̰ɪo ɔ a ʌ] in the context of secondary pharyngeals. No consonants are affected (see Cook 1993; Hansson 2007). The pattern is illustrated in (18) with data from Cook (1993: 154).[15]

(18)	sˤə̰it	*sˤit	'kingfisher'
	ʧ'ɔxˤ	*ʧ'ʊxˤ	'porcupine'
	hegˤat	*higˤæt	'we shake it out'

[13] See, for example, Hansson (2007) on Tsilhqot'in.

[14] These six vowels are the underlying vowel set in this language (Cook 1993).

[15] I present Cook's data in IPA. Tsilhqot'inists typically transcribe the secondary pharyngeal velars as simple uvulars.

Finally, in Northeast and Northwest Caucasian languages, vowels are reported as lowered, centralized, or fronted in the environment of secondary pharyngeals (Catford 1983; Anderson 1997; Bellem 2005, 2007). No phonological data are available on this except for Kibrik and Kodzasov (1990, cited by Bellem 2005) in Russian. So here we reissue the call of McCarthy (1994) and Anderson (1997) for phonological data for these languages.

2.4 *The dorsal pharyngeal class*

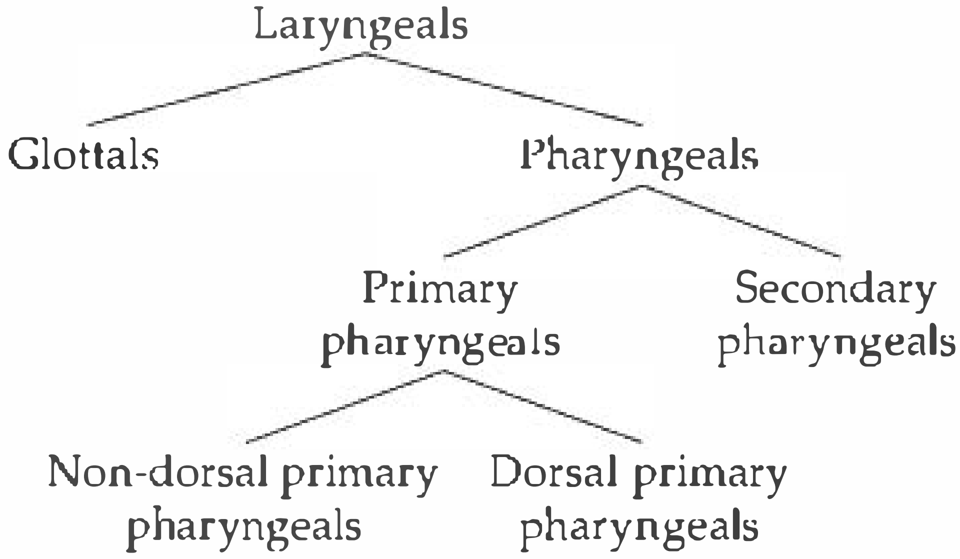
Dorsal primary pharyngeals (i.e. simple uvulars) and secondary pharyngeals can pattern as a class. In Palestinian Arabic, /i/ occurs as backed [u] in certain verb forms containing a root consonant from either group (Herzallah 1990; McCarthy 1994). This occurs most clearly in biliteral roots, as illustrated for typical rural dialects in (19).[16]

(19)	bˤɪsˤʊfːˤ	*bˤɪsˤɪfːˤ	'he lines up'
	bˤɪðˤʊmːˤ	*bˤɪðˤɪmːˤ	'he annexes'
	bɪʃʊχː	*bɪʃɪχː	'he urinates/defecates'

2.5 *Summary, and the issue of glottal primary pharyngeals*

The phonological data reviewed above support the pharyngeal typology in (20). The superordinate laryngeal class is included in the figure.

(20) *The pharyngeal typology, as a subgroup of the laryngeal class*



The superordinate class and its two subclasses are recognized in Halle (1992: 211), which presents a feature geometry with a class of laryngeals comprised of glottal and tongue root subclasses.

We now address the issue of glottal primary pharyngeals. In certain languages, as was illustrated in §2.2, glottal /ʔ h/ pattern as though they are primary pharyngeals. In other languages, for example, St'át'imcets and Tigre (Bessell 1992;

[16] The environment for this backing excludes non-pharyngeal /w/. For example, we have [wˤɪsˤɪl'] 'he arrived'. Interestingly, in Rwali Bedouin Arabic (Parkinson 1992: 114), /w/ is not excluded. In Rwali the word for 'he arrived' is [wʊsˤɪl].

McCarthy 1994; Shahin 2002), they do not. (It has sometimes been thought that glottals that are not primary pharyngeals can condition vowel lowering. This is assumed, for example, by Rose (1996), from supposed cases of lowering in Interior Salish. However, Montler (2004) and Shahin and Blake (2004) have shown that the lowering in those cases is a low-level phonetic effect.) The task has been to explain how glottals can be primary pharyngeals in some languages and not in others (Lindqvist-Gauffin 1969; Trigo 1991; McCarthy 1994; Nolan 1995; Zawaydeh 1999, 2004; Lombardi 2001; Shahin 2002, forthcoming; Borroff 2007). Most proposed solutions presume different representations for the two types of glottal. (Or, within Articulatory Phonology, they presume two types of gesture, e.g. Borroff 2007.) But the phonetic grounding (Archangeli and Pulleyblank 1994: 172) of the different representations has been unclear. Lombardi (2001) proposes that they have the same representation, but the difference in behavior falls out of optimality-theoretic constraint ranking.

No real solution to this problem has been possible without analysis of natural language articulatory data on glottal primary pharyngeals. This is presented by Shahin (forthcoming), using the Laufer and Baer (1988) Hebrew data, and data from Arabic. The analysis indicates that Hebrew and Arabic glottal primary pharyngeals are simply glottal, and lack the aryepiglottic constriction of the other primary pharyngeals. Shahin proposes that the glottals bear the feature of all primary pharyngeals, and so they pattern as primary pharyngeals, but that, at least in Arabic, a paradigmatic constraint forces phonetic non-realization of that feature.

3 Pharyngeal articulation

The first descriptions of pharyngeal articulation, beginning notably with the eighth-century descriptions of Sibawayh (Sibawayh 1966), were based on impressionistic data. Instrumental analysis, including X-ray,[17] MRI, ultrasound, electroglottography, electromagnetic articulography, velopharyngeal port transillumination, and study of jaw movement, has revealed much about the actual vocal tract configurations of these sounds. Likewise, acoustic analysis has shown much about the acoustic effects of the configurations. However, the application of laryngoscopy has permitted us to see behind the epiglottis. This has enabled a critical clarification of the fundamental nature of pharyngeal articulation (Esling 1996, 1999), namely that constriction of the aryepiglottic folds is the articulatory commonality of the overall pharyngeal class.

3.1 *The articulation of primary pharyngeal consonants*

Early laryngoscopic investigations indicated epiglottal activity for pharyngeal consonants (e.g. Laufer and Condax 1979, 1981; Laufer and Baer 1988). Pursuing their line of work, Esling (1996, 1999) has shown that the primary constriction of all consonants traditionally classified as pharyngeal or epiglottal is produced between constricting aryepiglottic folds as active articulator and the epiglottis

[17] Early X-ray studies include Panconcelli-Calzia (1920–1) and Marçais (1948), discussed by Jakobson (1957).

Czaykowska-Higgins 1987; McCarthy 1988; Hess 1998; Zawaydeh 1999, 2003, 2004; Zeroual *et al.* 2009).

However, the findings are rather inconclusive. The aryepiglottic constriction has not always been detected (Zeroual 2004). As stressed by Bellem (2007), extensive cross-linguistic articulatory study is needed. This should include canonical productions of the secondary pharyngeals, such as occur, for Arabic, during Qur'anic recitation.

Secondary pharyngeals in Northeast and Northwest Caucasian languages are described as being produced with pharyngealization (Hess 1992) and also tongue body advancement, or palatalization (Trubetzkoy 1931; Comrie 2005; Bellem 2009). This means they are articulatorily different from the secondary pharyngeal consonants of Arabic and Interior Salish.

Secondary pharyngeal consonants are often labialized (Mitchell 1960; Lehn 1963; Uldall 1992; Watson 1999). They might involve increased muscular tension in the mouth and throat (Lehn 1963; Bonnot 1977).

Secondary pharyngeal consonants have a lowered F2 (Obrecht 1968; Ghazeli 1977; Latimer 1978; Woldu 1981; Younes 1982; Card 1983; El-Dalee 1984; Bessell 1992; Shahin 2002). They also have a raised F1 (Bonnot 1977, 1979; Woldu 1981; Younes 1982; Shahin 2002). In Arabic at least, they have lowered pitch compared to their plain counterparts (Jakobson 1957). Vowels in the environment of secondary pharyngeal consonants in Northeast and Northwest Caucasian have been noted to have a raised F1, lowered F2, and lowered F3 (Bellem 2009).

3.3 *The articulation of pharyngeal vowels*

The vowel [ɑ] is a primary pharyngeal segment, as are [ə ʌ ɔ ɒ] (Esling 2005). This has often been noted, especially for [ɑ] (e.g. Delattre 1971; Whalen *et al.* 1999; Jackson and McGowan 2008). The primary pharyngeal vowels are produced with aryepiglottic constriction (Esling 2005). "Lax" vowels like [ɪ ɛ ʊ ɔ] are secondary pharyngeals, involving aryepiglottic constriction in addition to their primary oral articulation. For other types of secondary pharyngeal vowels, like the constricted tense register vowels of Yi (Tibeto-Burman), secondary aryepiglottic constriction has been observed (Esling 2005). Pharyngeal vowels in Northeast and Northwest Caucasian are often centralized (Bellem 2007).

Primary and secondary pharyngeal vowels have a raised F1; the plain counterparts of the secondary pharyngeal vowels do not have this (Lindau 1978; Hess 1992; Fulop *et al.* 1998; Shank and Wilson 2000b; Gick *et al.* 2006; Kenstowicz 2009). Pharyngeal vowels might also be distinguishable by F1 bandwidth or spectral tilt (see Hess 1992 and discussion in Casali 2008).

3.4 *The articulation of the superordinate laryngeal class*

The aryepiglottic constriction of pharyngeals results from the action of the aryepiglottic constrictor mechanism described by Esling (2005). (This mechanism is also referred to by Esling 2005 as "laryngeal constrictor," "laryngeal constrictor mechanism," and "laryngeal articulator.") Numerous articulatory data reported in Esling (1996, 1999, 2005), among others, have shown that this same mechanism is responsible for glottal gestures, too. This is explained by Esling (2005: 17–18):

For secondary pharyngeals, Card (1983) proposed [F2 drop]. But most phonologists have assumed that, like dorsal primary pharyngeals, they bear the feature [dorsal] (e.g. McCarthy 1994; Shahin 2002; Bin-Muqbil 2006; Gallagher 2007), eschewing the acoustically based feature. For the secondary pharyngeal consonants, [dorsal] and [pharyngeal] are both specified as a secondary articulation feature. A secondary pharyngeal consonant is also specified for some other feature that represents its primary articulation, e.g. [labial], [coronal], or [dorsal]. (Various proposals exist for the representation of secondary articulation features; see Hume 1992; Clements and Hume 1995; Shahin 2002: 16–17; also CHAPTER 29: SECONDARY AND DOUBLE ARTICULATION.) Bellem (2007) points out that the representation of secondary pharyngeals might be different across different dialects for the same language.

Primary pharyngeal vowels are specified like the non-dorsal primary pharyngeals, and also bear specification that identifies them as vowels. Secondary pharyngeal vowels are specified for [pharyngeal] as a secondary articulation.

Let us reconsider [ATR]. In Stewart's (1967) approach to Niger-Congo-type tongue root harmonies, vowels that are tense are [+ATR], and those that are lax are [−ATR]. The fact that [−ATR] vowels and [pharyngeal] vowels are the same indicates that [pharyngeal] is actually a binary feature, and that [+pharyngeal] is specified on consonants and vowels, and [−pharyngeal] is specified only on [+ATR] vowels.

It has been suggested that [−pharyngeal] vowels are specified for [lowered larynx] (Meechan 1992); however, a feature representing laryngeal height does not at present seem necessary in addition to [pharyngeal].

Within a Government Phonology approach (Kaye *et al.* 1985, 1990; Harris 1990, 1994; Harris and Lindsey 1995), the primary and secondary pharyngeals can be understood as all specified for [A] (Bellem 2007), an element that is realized phonetically as "pharyngeality" for consonants and as "*a*-color" for vowels. In Government Phonology, the element [I] is realized as "palatality" for consonants and "*i*-color" for vowels. Bellem uses [I] with [A] to characterize the "emphatic palatalization" of Caucasian secondary pharyngeals.

5 Conclusion

An understanding of pharyngeals in phonology involves, most basically, an understanding of their class and subclasses, as indicated by phonological data. It also involves an understanding of their articulation, and of the representations that are then posited from those representations. This chapter has surveyed what is known about these issues. Pharyngeals and pharyngeal phonology are much better understood than they were twenty years ago, but more work needs to be done. This includes cross-linguistic instrumental and theoretical study of secondary pharyngeal consonants – including, potentially, [r ɹ] – and investigation of all types for the pharyngeals of Northeast and Northwest Caucasian languages. Further work should also include study of Mian (Ok), Iatê (Macro-Ge), Hamer (Omotic), and Even (Tungusic), which are reported to have pharyngealized vowels (Maddieson 2009), but which are poorly represented in the phonology literature. Future research should also identify and test the phonological predictions of Esling's "oral-and-laryngeal" model of speech production.

ACKNOWLEDGMENTS

This chapter has benefited from helpful comments provided by two anonymous reviewers and the *Companion* editors. Language family names used in this chapter are consistent with the *Ethnologue* classification (Lewis 2009).

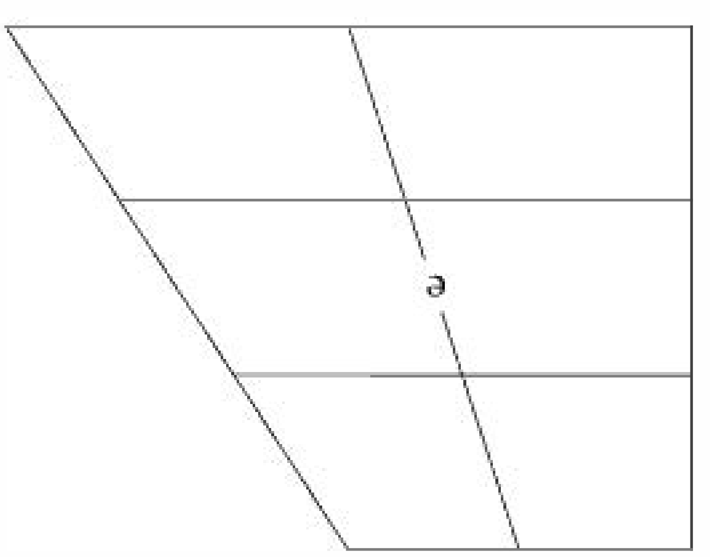
26 Schwa

Daniel Silverman

1 Introduction

Inspection of the chart of the International Phonetic Alphabet (IPA) would suggest that schwa is a vowel like any other; a central open-mid/close-mid unrounded vowel, slightly higher than [ɐ], slightly more central than [ʌ]: i.e. [ə]. Indeed, as the IPA chart necessarily provides idealized phonetic descriptions of its symbols, then, articulatorily speaking, schwa-qua-schwa is just as the IPA chart indicates, as in (1).

(1)



In practice, however, the label "schwa" has been applied to a phonological value that is especially variable in its phonetic properties. In terms of their quality, vowels labeled "schwa" vary to the extent of encompassing a large portion of the vowel space, while tending to gravitate toward the center of this space (see e.g. Browman and Goldstein 1992 for English schwa). This variability is usually a consequence of schwa's context: flanking consonants and vowels may have a significant co-articulatory influence on schwa's phonetic starting and ending postures, typically far more co-articulatory influence than on vowels of other qualities. In terms of duration – a phonetic property that the IPA vowel chart does not indicate – schwa is typically quite short, and this short duration may co-vary with its tendency to be co-articulated.

In acoustic terms, schwa's resonance structure may be modeled (as a first approximation) by a tube that has no significant constrictions anywhere along its length, such that its formants derive not from two tubes (and/or a Helmholtz resonator) as is the case for other vowels, but instead from one long tube (see e.g. Johnson 2003). Given a tube that approximates the length of an adult male vocal tract, this idealized version of schwa possesses formants at 500 Hz, 1500 Hz, 3500 Hz, etc. (Johnson 2003). However, since schwa's articulatory properties are so variable – typically, far more variable than other vowel qualities – its formant values vary in kind.

In phonological terms, schwa has been characterized as a completely underspecified "featureless" vowel by some (e.g. van Oostendorp 1995), and as "weightless" (lacking a mora) by others (e.g. Kager 1989). According to van Oostendorp's approach, for example, Dutch schwa's featureless status may be (i) derived by feature loss, especially when a full vowel reduces to schwa under stresslessness, or (ii) derived by epenthesizing a completely underspecificied vowel. Finally, (iii) its featureless status may be lexical in origin. As discussed by van Oostendorp (1995), Dutch possesses schwas of all three sorts.

Given its short duration and co-articulatory tendencies, schwa bears a phonetic similarity to the mere *audible release* of a consonantal constriction in the context of a following consonant. Indeed, certain epenthetic schwas may have their origin in consonantal release. Although such schwas may play an important functional role by providing acoustic cues to the first consonant in such consonant–consonant sequences, these schwas may, in fact, be "invisible" to the prosodic structure of the language, contributing neither to the syllable structure nor to the metrical structure of the system (Hall 2006).

Moreover, given its short duration and its consequent tendency to camouflage itself to its context through co-articulation, schwa may be confused with its absence, setting up a situation in which schwa–zero alternations may take hold in a system, for example, in Hindi (Ohala 1983).

This chapter is divided into three sections. First, I consider cases of schwa that have their origins in vowel reduction, taking Dutch (e.g. van Oostendorp 1995) and English (Browman and Goldstein 1992; Flemming 2007; Flemming and Johnson 2007) as case studies. Second, I consider cases of schwa that may have their origins in consonantal release, discussing Hall's (2006) findings and taking Indonesian (Cohn 1989) as a case study. Third, I consider two cases of synchronic schwa–zero alternation, one that unambiguously has its origins in (diachronic) schwa deletion (Hindi; Ohala 1983), and one that may be a case of (diachronic) schwa insertion (Chukchee; Kenstowicz 1994).

2 Reduction to schwa

Due to its short duration and its tendency to co-articulate, schwa is a likely outcome of vowel reduction in stressless domains.

2.1 *Reduction to schwa in Dutch*

Schwa in Dutch (Nooteboom 1972; Kager 1989; van Oostendorp 1995; among others) may be characterized as having three sources. Van Oostendorp (1995) calls these e-schwa (epenthetic schwa), r-schwa (reduction schwa), and u-schwa stressless). Most important, schwa's production cannot be accurately characterized as a simple V-to-V interpolation:

> [I]t appears that the tongue position associated with medial schwa cannot be treated simply as an intermediate point on a direct tongue trajectory from V_1 to V_2. Instead, there is evidence that this V_1–V_2 trajectory is warped by an independent schwa component [. . .] a warping of the trajectory toward an overall average or neutral tongue position. (1992: 41, 42)

Thus, the authors conclude that schwa is not genuinely targetless, but rather involves a tendency to gravitate toward the center of the vowel space as the tongue moves from preceding to following context.

In a study involving four American English speakers, Flemming (2007) also investigates the contextual variability of word-medial schwa (as in [səˈpʰoʊz] *suppose* or [ˈpɹ̥abəbl̩] *probable*). His spectrographic analysis shows again that medial schwas are highly variable as a consequence of their context, especially in terms of their F2 properties, the articulatory correlates of which are tongue fronting/backing and lip posture. F1 varies as well – as a consequence of tongue height – but this variation is less pronounced than that found for F2. The limited variation of F1 may be attributable to the fact that flanking consonants necessarily involve a mouth closing/jaw-raising gesture, thus lowering F1.

Overall, Flemming suggests caution in concluding that schwa is completely targetless, even on the F2 dimension, since it is possible that the starting point and endpoint of the F2 trajectory through schwa – despite this trajectory's apparent targetlessness – are influenced by the intervening schwa itself.

Flemming proposes that English schwa's variability is rooted in its short duration. As a consequence of its short duration, vowel quality distinctions are reduced, perhaps to the point of being neutralized. Once neutralized, co-articulation may be engaged in with few limits, as there are no longer any lexical contrasts that might be maintained by inhibiting such co-articulatory tendencies (see especially Öhman 1966 and Manuel 1990, 1999 on the inhibitory role that lexical contrast may play in co-articulation).

Flemming proposes that the origin of American English schwa is rooted in speaker production, invoking the "target undershoot" proposals of Liljencrants and Lindblom (1972). Still, the role of listener perception might be considered as well, since, as vowel duration decreases, the ability to discern quality distinctions is likely to decrease in kind (see, for example, Ohala 1981, Labov 1994, and Silverman 2006).

In sum, stresslessness feeds shortening, shortening feeds contrast loss, and contrast loss feeds co-articulation. Schwa results.

Flemming and Johnson (2007) find that, unlike word-medial schwa, schwa in word-final position (as in [ˈʧʰaɪnə] *china* or [ˈkʰamə] *comma*) displays a relatively consistent mid-central quality, though a certain amount of between-speaker height variation is observed. It is suggested that, since word-final schwa – unlike medial schwa – is in contrast with other vowel qualities (unstressed /i/ and /oʊ/, for example [ˈbeɪɾə̠] *beta*, [ˈpɹɪɾi̠] *pretty*, [ˈmaɾo̠ʊ] *motto*), it tends to be implemented in a more stable fashion so that contrasts here are reliably maintained. Flemming (2007) thus concludes that American English possesses two schwas: word-medial schwa, which is more variable, and word-final schwa, which is more stable.

Another possibility is that there is only one schwa in English, the variability of which is largely a consequence of its lexical context. Within-word motor routines are more frequently produced than are between-word motor routines. As such, they may be more susceptible to fixed co-articulatory effects than are between-word motor routines (see especially Bybee 2001 on the relationship between frequency and co-articulation). Since the context that follows word-final schwa varies in unconstrained ways (depending only on the phonological shape of the following word), its co-articulatory tendencies may be less entrenched, less routinized, than its word-medial counterpart. Consequently, word-final schwa may not as readily possess fixed co-articulatory properties. The result is that word-final schwa may display more stability than its word-medial counterpart, which, in turn, increases the likelihood of schwa maintaining its contrastive status with other vowels here. Thus, whereas Flemming proposes that schwa is more stable in word-final position because it contrasts with other vowel qualities, schwa might instead contrast with more vowel qualities in word-final position because it is more stable.

3 Release into schwa

When lexical or morphological structure brings two consonants together (. . . C_1(+)C_2 . . .), the identity of C_1 may, on occasion, fail to be successfully perceived by a listener. In the absence of consonantal release into a more open gesture – ideally, a vowel – cues that would otherwise be associated with the release of C_1 become jeopardized. Such cues include offset formant transitions and plosive burst frequencies associated with oral place of articulation, and the noise, pop, or low-frequency cues associated with aspiration, ejectivity, or voicing, respectively. In many languages, the loss of such cues sets the stage for merger or neutralization, such that C_1 loses its contrastive oral configuration, its contrastive laryngeal setting, or perhaps both (e.g. Lombardi 1991; Steriade 1997).

However, a very different diachronic route is taken in many other languages: in the context . . . C_1(+)C_2 . . . , C_1 is released into an excrescent vowel before the C_2 constriction is fully achieved, where "excrescent" refers to a particularly short interval of the speech stream that may be an artefactual consequence of repositioning the articulators as they move from one posture to another. Upon the release of C_1, the aforementioned cues that crucially rely on this segment of the speech stream are much more likely to be saliently encoded in the speech signal, and hence C_1 tends to be more resistant to neutralization or merger.

Phonetically speaking, if we assume that the survival of these C_1 cues is dependent in great part upon C_1 release, then this release is likely to become exaggerated over time, culminating in schwa: C_1əC_2. Schwa is short in duration, is subject to significant contextual co-articulation, and is consequently auditorily rather similar to the excrescent vowel of mere release. Hall (2006), for example, finds that inserted schwa and other so-called "intrusive" vowels – vowels that may have their origin in excrescence, but come to bear phonetic similarity to full-fledged vocalism – are more often encountered between heterorganic consonants, as opposed to homorganic consonants (see also CHAPTER 67: VOWEL EPENTHESIS). This is not an unexpected result: C_1C_2 homorganicity decreases the likelihood of C_1 release, since the articulators are likely to maintain their positions as C_1 is followed by C_2 in such homorganic clusters; employing Goldsmith's (1976) consequence of C_1 neutralization, then it might more likely possess C_1 "release," which might diachronically culminate in schwa or a vowel copy that may or may not be prosodically "invisible" (Martinet 1952; Hoenigswald 1960).

Indonesian is a language that seems to possess an "intrusive" schwa in the sense of Hall. As reported by Cohn (1989), monomorphemic Indonesian words possess right-to-left syllabic trochees, end-rule right, with initial dactyls in words with an odd number of syllables, excluding three- and (by necessity) one-syllable words. However, schwas are completely invisible to stress. Examples presented in (6) (Cohn 1989: 174) include both native Indonesian words and assimilated loans. Whether the loans should be characterized as possessing genuinely epenthetic schwa, or perhaps instead involve underlying schwa, remains an open question for now (see especially Silverman 1992 for proposals regarding the interpretation of apparently epenthetic vowels in loan phonology).

(6)	*All full vowels*	*Schwas and full vowels*		
a.	ˈσσ	əˈσ	bəˈri	'give'
			kərˈja	'work'
b.	σˈσσ	əəˈσ	sətəˈlah	'after'
c.		ˈσəσ	ˈgamələn	'Indonesian orchestra'
d.	ˌσσˈσσ	σˈσəσ	aˈpartəmen	'apartment'
e.		əˈσəσ	ʧəˈritəra	'story'
f.		əəˈσσ	pərəmˈpuan	'woman'
g.		σəˈσσ	kopəˈrasi	'cooperation'
h.	ˌσσˌσσˈσσ	ˌσəσσˈσσ	ˌdifərensiˈasi	'differentiation'
			ˌdivərsifiˈkasi	'diversification'

Significantly, Cohn reports that the distribution of schwa is largely predictable, and may thus be viewed as a consequence of epenthesis. In the parlance of Hall, Indonesian schwa is intrusive in nature: it is invisible to stress, and its presence is largely predictable. Note in particular that almost all schwas in (6) are found between heterorganic consonants, at least one of which is a sonorant.

Given its apparent predictability, the origin of Indonesian schwa might indeed lie in consonantal release into an excrescent vowel.

4 Schwa–zero alternations

As noted, schwa is typically short in duration, is subject to significant co-articulation, and, correspondingly, possesses few acoustic features that render it auditorily distinct from its surrounding context. As a consequence of schwa's auditory indistinctness, its *presence* in a given phonetic context may be susceptible to confusion with its *absence* in an otherwise identical phonetic context. When two or more auditory events are confusable with each other, a condition is set up that may lead to diachronic change. One plausible outcome of this particular situation may be the introduction of schwa–zero alternations: in certain acoustic contexts and/or under certain functional conditions schwa may diachronically survive, while in other acoustic contexts and/or under other functional conditions schwa may disappear. The question is: in what situations is the schwa likely to survive, and in what situations is the schwa likely to be lost?

4.1 *Schwa–zero alternation in Hindi*

The Hindi schwa–zero alternation is discussed extensively by Ohala (1983). Consider the forms in (7) (excerpted and modified from her tables 6.1 and 6.3). According to Ohala (1999), the vowel in alternation with zero is actually slightly lower than schwa: [ɐ]. It is transcribed [ə] in Ohala (1983), and herein as well, for the sake of internal consistency. Schwas that alternate and/or vary with zero are underlined.

(7)	a.	pitʃka	'squeezed'	pitʃək	'squeeze'
		pɪgʰla	'melted'	pɪgʰəl	'melt'
		dewrani	'brother-in-law's wife'	dewər	'brother-in-law'
		nəmkɪn	'salty'	nəmək	'salt'
		sɪski	'a sob'	sɪsək	'sob'
		hɪrni	'doe'	hɪrən	'deer'
		təɽpa	'cause to be restless'	təɽəp	'restlessness'
		wapsi	'on return'	wapəs	'return'
		upri	'pertaining to the top'	upər	'top'
		ubʈən	'an unguent'	ubəʈna	'to anoint'
		gərdʒila	'thunderous'	gərədʒna	'to thunder'
	b.	a+səməj	asəməj	'inopportune'	
		ə+ʃərir	əʃərir	'without body'	
		ɔ+kələŋk	ɔkələŋk	'spotless'	
		ku+ʃəkun	kuʃəkun	'bad omen'	

The generalization is that schwa alternates with zero in would-be VCəCV contexts (7a), provided that it is not the first vowel of the morpheme (7b). Ohala's synchronic characterization of this alternation is expressed with the linear rewrite rule conventions of Chomsky and Halle (1968: 121): "ə → Ø / VC __ CV. *Condition*: There may be no morpheme boundary to the left of the /ə/."

The first question to ask is whether the schwa–zero alternation in Hindi is a refllex of historic schwa *insertion* or historic schwa *deletion*. Fortunately, the historical record is very clear on this matter. Hindi schwa derives from Sanskrit [ə] and short [a]. In Old Hindi, this vowel, and some instances of other short vowels ([ɪ] and [ʊ]), alternated with zero in VCVCV: contexts (Misra 1967).

The route from short [a] to the schwa–zero alternation found today may be related to the fact that contrastively short low vowels, due exactly to their contrastively short duration, are quite likely to gradually rise: as a consequence of their attendant jaw lowering, it takes longer to implement low vowels than non-low vowels, and so *contrastively* short low vowels are thus especially susceptible to rising. Upon rising, they become more schwa-like, and are thus susceptible to confusion with their absence in certain contexts. One such context is VCəCV. Provided that phonetic confusion between VCØCV and pre-existing VCCV sequences does not induce undue semantic confusion (by inducing a significant amount of homophony), it is quite possible that the sound pattern may ultimately change from VCəCV to VCCV. This is the Hindi pattern.

Schwa is susceptible to confusion with its absence in many other acoustic contexts as well, such as when it finds itself flanked by more than one consonant on one side, for example VCCəCV and VCəCCV. Nonetheless, schwa usually does not delete in such contexts in Hindi. This may be related to the further possibility of medial C loss here. Were schwa to delete in a VC<u>C</u>əCV or VCə<u>C</u>CV context, the medial consonant might suffer a significant cue loss, as it would lack both approach cues and release cues. Thus, were VCCəCV or VCəCCV to become VC<u>C</u>CV, the sequence might be confused with VCCV. That is, the loss of schwa in these contexts may lead to a percept involving only two – not three – consonants. At this point, the chances of inducing homophony – hence confusion on the part of listeners – increase considerably, since in theory these lost medial consonants may possess many different values, and thus many words may rely on them to maintain their acoustic distinctness. Since speech signals that confuse listeners (as opposed to those that do not confuse listeners) are less likely to be reproduced as these listeners become speakers, the presence of confusing signals as part of the conventionalized speech repertoire may be passively curtailed (Martinet 1952; Labov 1994; Silverman 2006). This may have influenced the present-day Hindi pattern: VCCəCV and VCəCCV do not alternate with VCCV.

There are, however, patterned exceptions to the absence of schwa deletion in VCCəCV and VCəCCV contexts. Consider the forms in (8) (excerpted and modified from Ohala's (1983) table 6.6; underlined schwas vary with their absence).

(8)	kadəmbri ~ kadəmb<u>ə</u>ri	'a novel, name for a girl'
	ustra ~ ust<u>ə</u>ra	'razor'
	puɳɖrik ~ puɳɖ<u>ə</u>rik	'white lotus'
	məɲʤri ~ məɲʤ<u>ə</u>ri	'tiny cluster of flowers, name for a girl'

Hindi possesses variable schwa deletion in these forms, and thus indeed possesses sequences of three consonants that are a consequence of schwa loss. As stated, however, these exceptions are patterned, for as Ohala observes, schwa deletion here results in triconsonantal sequences that are also found elsewhere, and are usually of the form nasal–homorganic stop–sonorant. The development of schwa deletion in such forms is thus not completely unexpected: the phonetic properties of these particular triconsonantal sequences are readily recoverable from the speech signal, since the medial consonant here does not possess place features that are distinct from the preceding nasal, and thus it does not contribute place cues of its own. Consequently, not only are such sequences more likely to be found elsewhere, but also – and perhaps even as a partial consequence of their presence elsewhere – such sequences may more readily enter the language via developments such as schwa deletion. Indeed, as Ohala notes, "[T]hree-consonant clusters in native words are rather few, and in general, most two- and three-consonant clusters that we find at the phonetic level [. . .] occur due to the ə-deletion rule" (1983: 135).

4.2 *Schwa–zero alternation in Chukchee*

Another case of schwa–zero alternation is reportedly found in Chukchee. According to Kenstowicz (1994), Chukchee possesses a synchronic process of schwa insertion under varying phonological and morphological conditions. Consider the forms in (9). In (9a) the schwa precedes the morpheme boundary; in (9b) it follows. (Data

Schwa is often the result of vowel reduction. Its short duration and its consequent tendency to co-articulate make schwa a likely candidate for the vocalism of stressless domains.

Some schwas may have their origins in the audible release of a consonant, when this consonant is immediately followed by another consonant: cues to the phonetic content of consonants are more reliably communicated upon their audible release, ideally into a vowel. These schwas may or may not be visible to the prosodic structure of the language.

Perhaps as a consequence of its tendency to camouflage itself, schwa is especially susceptible to deletion, and thus may alternate with zero under varying conditions.

27 The Organization of Features

Christian Uffmann

1 Introduction

Early generative theory assumed that segments were specified by a bundle of distinctive features, but that there was no intrinsic order to these features, which were unordered lists. This position was not held for any principled reasons; it was born out of necessity, made explicit in *The sound pattern of English* (*SPE*; Chomsky and Halle 1968). In their discussion of distinctive features in chapter 7, Chomsky and Halle group them into sets of articulatorily related features but go on to state that

> This subdivision of features is made primarily for purposes of exposition and has little theoretical basis at present. It seems likely, however, that ultimately the features themselves will be seen to be organized in a hierarchical structure which may resemble the structure that we have imposed on them for purely expository reasons. (Chomsky and Halle 1968: 300)

It was the advent of Autosegmental Phonology (Goldsmith 1976, 1990; see also chapter 14: autosegments) that allowed the imposition of a hierarchical order on distinctive features by grouping features into sets that are characterized by similar articulatory properties and by common participation in phonological processes. These new models of segment-internal feature organization became known as feature geometries.

This chapter will outline the main models of feature geometry that emerged from the mid-1980s onwards and trace the relevant debates regarding specific proposals of feature organization. It will also look at the decline of these models in the wake of Optimality Theory in the mid-1990s and look at alternative proposals regarding how the generalizations that first motivated feature geometry could be captured differently in a constraint-based model of phonology. For reasons of space, theories of feature organization which mark a more radical departure from classical feature theory, such as Element Theory (Harris and Lindsey 1995), will not be discussed here.

The chapter is organized as follows: §2 will motivate the original feature geometry proposal by showing that phonological processes may target not just individual features but sets of features, and that these are cross-linguistically recurring sets. §3 will briefly outline the major models of feature geometry that were proposed and point out the major controversies surrounding them, showing that the early hopes for establishing a uniform and universal feature hierarchy had been overly optimistic. §4 will then outline how phonological processes are captured in feature geometry and how feature geometry provides a principled approach to non-local segment interaction, a problem which had dogged the classic *SPE*-type rule formalism. §5 turns to alternative proposals made within Optimality Theory on how the tendency of features to behave as sets can be re-formalized in non-autosegmental terms, as constraint interaction. §6 will point out future directions of research. First, however, we will motivate the idea that features are ordered into hierarchical sets.

2 Motivating feature sets

Sometimes, a process does not target just a single feature, but several at the same time. This set of features is not random, however; it recurs cross-linguistically, and also has a phonetic or articulatory basis, in that all members of the set share some phonetic property. A well-known and common process is that of nasal place assimilation, in which a nasal stop assimilates in place to a following consonant. The examples in (1) illustrate a case of (post-lexical) nasal place assimilation in English (see CHAPTER 81: LOCAL ASSIMILATION).

(1) *Nasal place assimilation in English*

in Sussex	[ɪn sʌsɪks]	*in Britain*	[ɪm bɹɪtn̩]
in Canada	[ɪŋ kænədə]	*in Europe*	[ɪɲ juːɹəp]
in France	[ɪɱ fɹɑːns]	*in theory*	[ɪn̪ θɪəɹi]

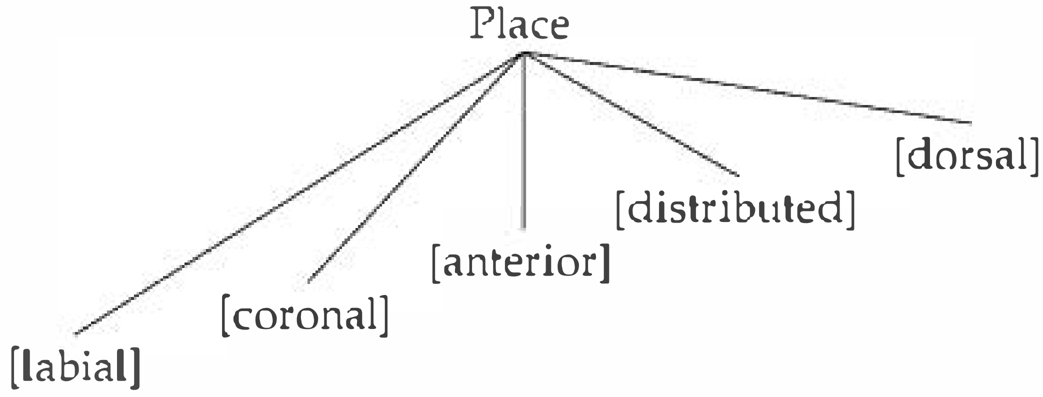
This process is structure-changing; the nasal assimilates to the exact point of articulation of the following consonant (CHAPTER 22: CONSONANTAL PLACE OF ARTICULATION). In traditional feature theory, this process can be expressed as the rule in (2) (see also McCarthy 1988: 86):

(2) *Nasal place assimilation:* SPE-*type rule*

$$\begin{bmatrix}+\text{nas}\\+\text{cor}\\+\text{ant}\end{bmatrix} \rightarrow \begin{bmatrix}\alpha\text{cor}\\\beta\text{ant}\\\gamma\text{distr}\\\delta\text{back}\end{bmatrix} \;/\_\_\; \begin{bmatrix}\alpha\text{cor}\\\beta\text{ant}\\\gamma\text{distr}\\\delta\text{back}\end{bmatrix}$$

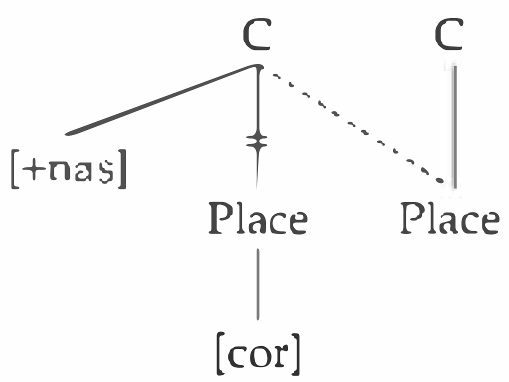
The problem with this rule is that the set of features in the structural change and the environment does not have any special status in the theory. It could easily be replaced by any random set of features, say [lateral, voice, distributed, continuant]. Yet such feature groupings are unattested cross-linguistically, while the above grouping is cross-linguistically common, and probably universal. In addition, as pointed out by McCarthy (1988), assimilation itself does not have a special status. Why do the features in the target of the rule acquire the values of an adjacent

(5) *The Place node*



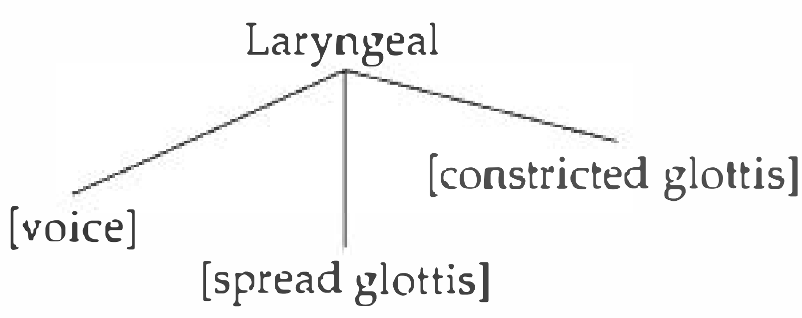
Example (6) shows how place assimilation can now be re-analyzed as a single operation, regressive spreading of the Place node. Features that are daughters of this node will spread along.

(6) *Place assimilation as Place node spreading*



A similar analysis is available for cases of laryngeal spreading or neutralization. Here, all laryngeal features are subsumed under a Laryngeal node, which can spread in assimilation or delink in cases of laryngeal neutralization.

(7) *The Laryngeal node*



Models of feature geometry generalize this approach: all features are contained within a tree-like structure. The next subsection will look at this approach more generally, and present a basic geometry which became a standard model in the second half of the 1980s. §3 will then introduce controversies regarding aspects of this structure.

2.2 *Feature geometry: Outline*

To summarize this discussion, we can formulate the following four axioms, which also characterize the research project that was embarked upon in the second half of the 1980s, the goal of finding a cross-linguistically valid model of feature geometry:

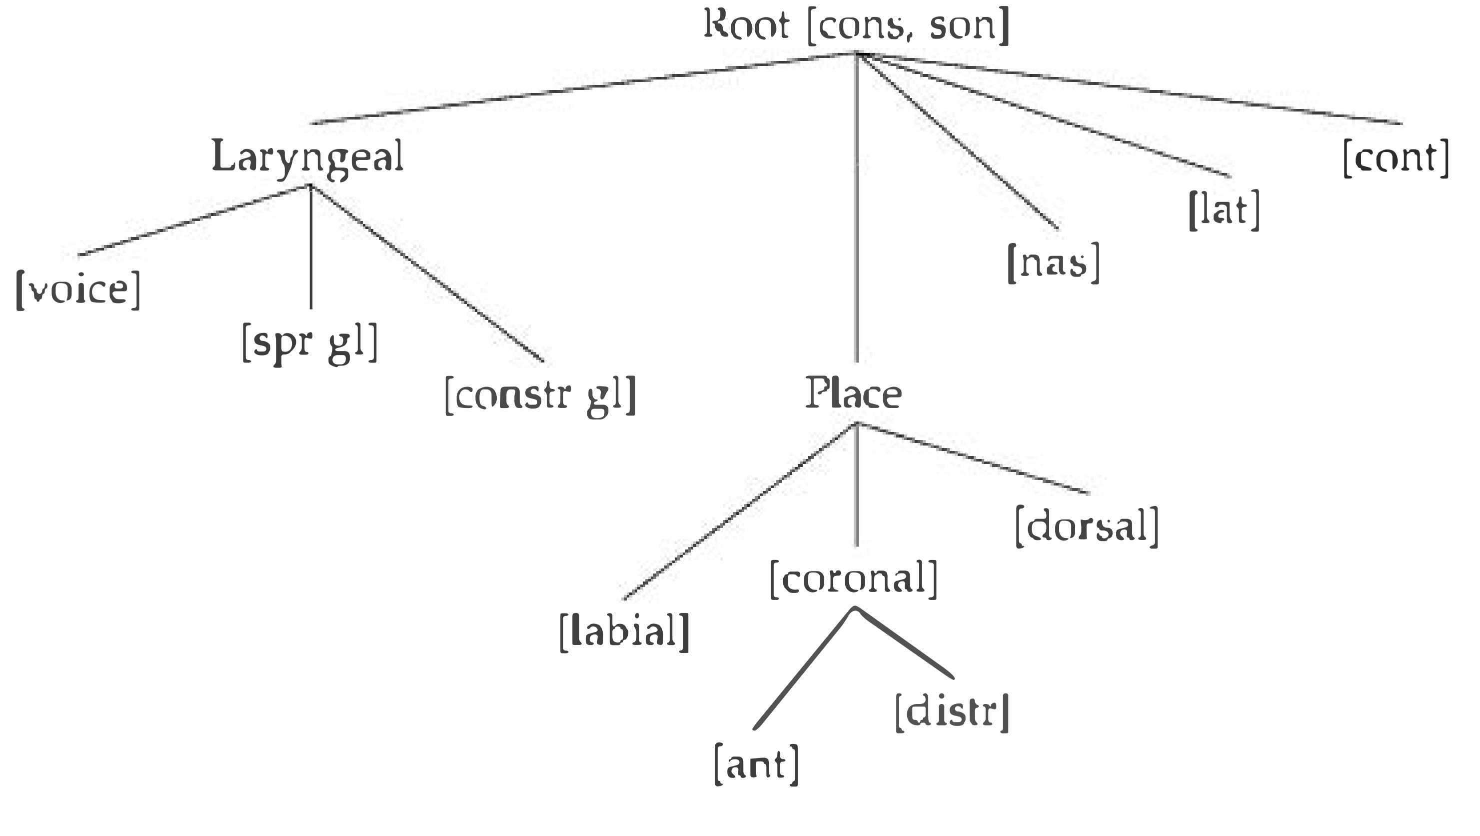
(8) a. Features are autosegments, residing on individual tiers.
b. Features can be grouped into sets or classes.
c. These sets are organized in a hierarchical structure, via intervening class nodes.
d. This structure, called a feature geometry, is universal.

The conceptualization of features as autosegments has important consequences for possible phonological operations, which are reduced to linking and delinking features and nodes. In addition, phonological processes perform individual operations only (Clements and Hume 1995: 250). A phonological rule can thus target an individual feature or a class node. Operations involving several features must consist of several rules (which can be motivated independently); alternatively, the features involved in the process form a single constituent, as dependents of a shared class node. One important motivation for positing feature-geometric structure therefore lies in constraining the notion of what a possible rule in phonology is. As was stated famously by McCarthy in an early article on feature geometry, "simply put, if the representations are right, then the rules will follow" (1988: 84).

The main goal of this research program is, however, to establish a universal geometry. The crucial task is therefore to establish exactly which features form sets. We have already seen that there are two types of evidence for grouping features under a class node. Most importantly, there is class behavior. If several features are targeted by the same process, as we have seen for place features and laryngeal features, this is interpreted as evidence that they are sisters of a superordinate node, which is targeted by this process. Secondly, there is also phonetic evidence: features which share a common articulatory property are grouped under a superordinate node. In the examples discussed so far, the evidence converges, but this is not necessarily the case, resulting in alternative proposals, which will be discussed in greater detail in §3.

At this point, it is pertinent to look at a widely assumed basic model of this geometry, to motivate it briefly, and then to proceed to open questions and controversial issues in §3.

(9) *A basic feature geometry*



The Laryngeal node has already been introduced; it is uncontroversial within the model. Different laryngeal features may be assumed (e.g. [stiff vocal folds], [slack vocal folds] replacing [voice], e.g. Halle 1995; Halle *et al.* 2000), but the general existence of a Laryngeal class node is undisputed.

The Place node has been modified slightly *vis-à-vis* (5), by grouping [anterior] and [distributed] under [coronal]. The main motivation for this move is that only coronals can be sub-specified for these features (distinguishing between alveolar/postalveolar and apical/laminal places of articulation). There is also evidence that when [coronal] spreads, it takes [anterior] and [distributed] with it; see §4 for a case of coronal harmony. Further subdivisions of the Place node are controversial, e.g. a Lingual node grouping [coronal] and [dorsal] together (see Keyser and Stevens 1994; Clements and Hume 1995; Hume 1996) or a Peripheral node as the mother of [labial] and [dorsal], corresponding to the traditional feature [grave] (Rice 1993; Rice and Avery 1993). See CHAPTER 22: CONSONANTAL PLACE OF ARTICULATION for a detailed discussion of place features.

A quick remark should be made regarding gutturals (uvular, pharyngeal, and laryngeal segments), which form a natural class in some languages, e.g. Arabic (see also CHAPTER 25: PHARYNGEALS). There is no uniformly accepted proposal as to how to represent them in the geometry. It has been proposed to include them under the Place node, through inclusion of one or several features like [pharyngeal] and [radical] (see Clements 1991; for an extended model, see also McCarthy 1994; Rose 1994), or to expand the Laryngeal node into a Guttural node, adding features like [ATR] (Halle 1992, 1995; see also §3). We cannot discuss evidence for either approach here, but simply state that the position of gutturals in the feature tree is an unresolved issue (see also CHAPTER 22: CONSONANTAL PLACE OF ARTICULATION).

The tree in (9) also shows that manner features are commonly not subsumed under one shared node, contrary to Clements's (1985) original proposal, which did recognize a Manner node. The reason, as discussed in detail in McCarthy (1988), is that manner features demonstrably never behave as a single constituent in phonological processes. For example, [nasal, continuant, lateral, strident] never spread as a group. It is therefore assumed that manner features associate directly with the Root node (e.g. McCarthy 1988; Rice 1993; Halle 1995; Halle *et al.* 2000, among others), or via an intermediate Oral or Supralaryngeal node (e.g. Clements 1985; Clements and Hume 1995). Processes targeting a manner feature are thus expected to target only one feature (there is no mother node that could be targeted). Two manner features stand out as special: [consonantal, sonorant] are properties of the root node itself rather than features with autosegmental properties (McCarthy 1988). The reason is that they never seem to spread or delink, unlike other features, and are therefore treated as separate.

3 Feature geometry: Controversial issues

For space reasons, this section cannot aim at a comprehensive overview of all the controversial issues regarding the shape of the feature tree. Rather, we will outline some of the debates, to give an overview of the major proposals that exist and to present the kinds of arguments used to motivate feature-geometric structure. We will focus on vowel features, perhaps the main dividing issue in the field, and add some remarks on manner features as well.

We have already seen that there are two main arguments for grouping features under a class node. First, phonological behavior: features that spread or delink together are grouped under a common node. Second, grounding in articulatory phonetics: features are grouped together that share an articulatory property, e.g. place of articulation or laryngeal setting. Strict application of the first principle can present conflicting evidence, though: groupings may be non-universal (found in some languages, but not others) or variable. Class behavior alone thus does not yield a universal geometry. We will see evidence for this in the discussion of manner features in §3.2. On the other hand, relying on the articulatory properties of features alone may not capture all groups of features which pattern consistently as a class. We turn to an example of this now in the discussion of vowel features.

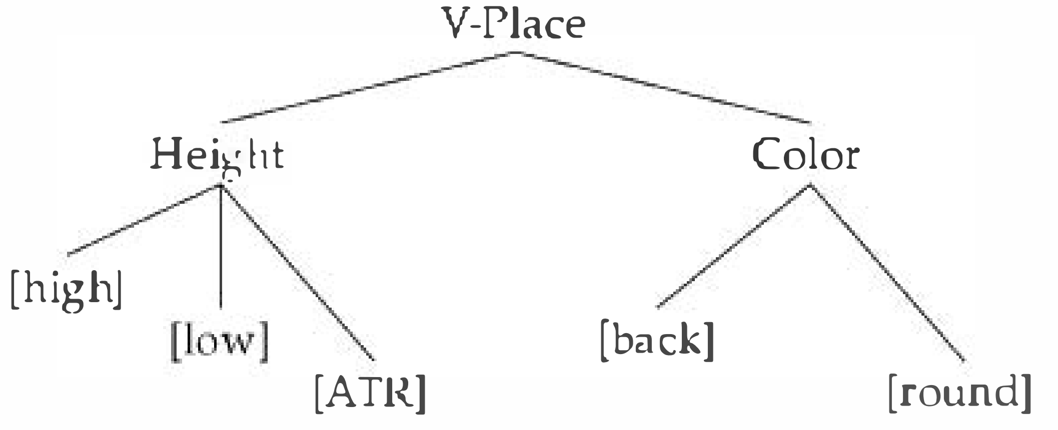
3.1 *Vowel features*

A major schism in feature geometry concerns the representation of vowels. This schism is an effect of the two opposing principles for establishing feature classes, articulation and phonological behavior. Articulator Theory (e.g. Sagey 1986; Halle 1992, 1995; Halle *et al.* 2000; Avery and Idsardi 2001) grounds the feature tree in articulation, while a different school maintains the primacy of phonological patterning (e.g. Hume 1990, 1992, 1996; Clements 1991; Odden 1991, 1994; Clements and Hume 1995), from which a different model, known as Unified Feature Theory, emerged. This section will outline the main differences between the two models and the reasoning behind them.

3.1.1 *Articulator Theory*

In Articulator Theory (Sagey 1986; Halle 1992, 1995), priority is given to articulatory considerations in the grouping of features in the geometry. "Articulator-bound" features (features that can be articulated by one specific articulator only, such as [voice], which is bound to the larynx, or [round], which can only be executed by the lips) are daughters of articulator nodes. This also provides a reason for why manner features are not subsumed under a class node but associate directly with the root node instead: they are articulator-free, that is, they can be executed by different articulators (features like [continuant] or [strident], for example). Only features that are articulator-bound, then, can be part of a set dominated by a class node, which corresponds to an articulator. The tree in (10) provides the basic geometry assumed in Articulator Theory. Note that the features [coronal, labial, dorsal] have been promoted to class node status. Features that are executed by one of these articulators are daughters of these nodes.

(12) *Vowel place features* (Odden 1991; adapted)



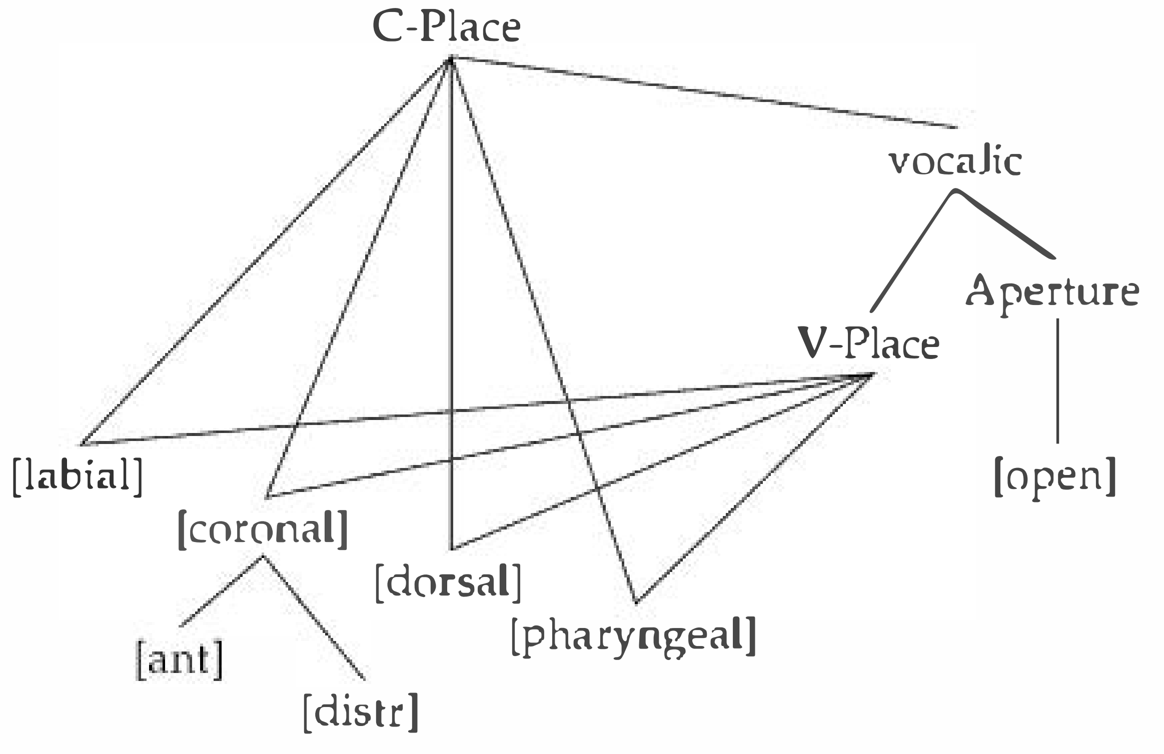
Odden argues that Articulator Theory makes the wrong predictions with regard to which vowel features can spread together. It predicts that [high, low, back] could spread together, to the exclusion of [round], by spreading the Dorsal node, although such a process is unattested. In addition, it cannot spread [back] and [round] in one single process, because they are daughters of different class nodes. He concludes that phonological patterning should guide decisions about feature grouping as much as phonetic (articulatory) considerations. He also offers a phonetic explanation for his proposal, but this explanation is grounded in acoustics and perception, rather than articulation. Both lip rounding and tongue backing have an effect on the second formant of a vowel, while tongue height has an effect on the first formant. The basic distinction between a Height and a Color node can thus be motivated perceptually.

Parallel to Odden's work, a more radical departure from traditional feature theory was developed by Clements and Hume (Hume 1990; Clements 1991; Hume 1992; Clements and Hume 1995; Hume 1996). They, too, assume a V-Place node, which is distinct from the C-Place node, but in addition they propose that vowel features be replaced by consonantal place features. They redefine the traditional features [back, round, low] in the following terms:

(13) [+round] = [labial]
[+back] = [dorsal]
[–back] = [coronal]
[+low] = [pharyngeal]

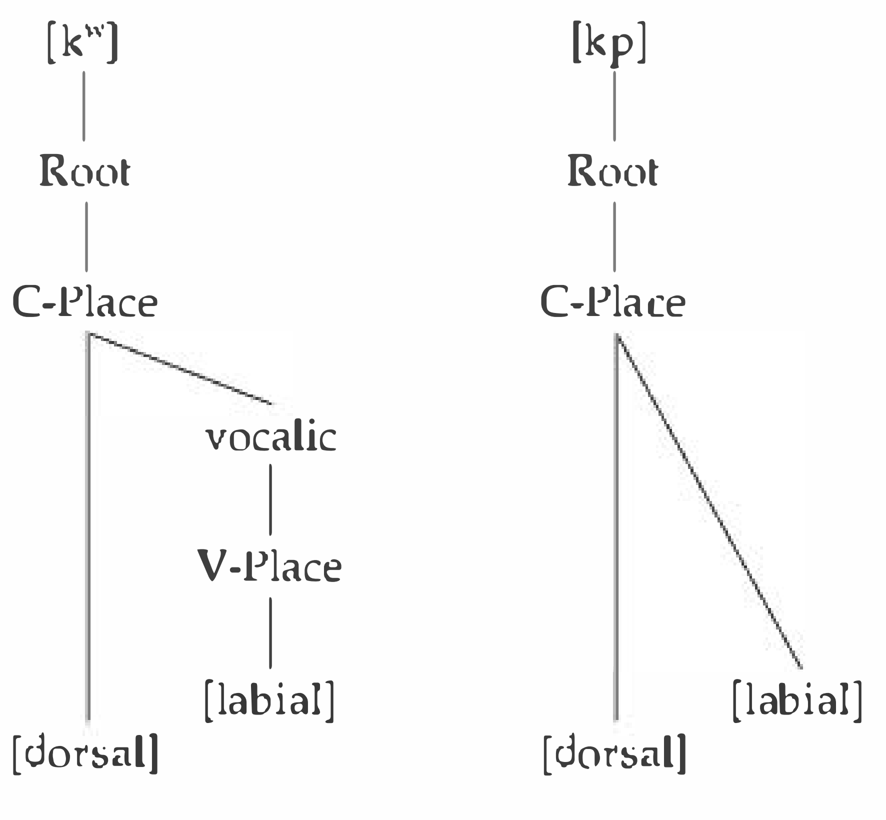
This redefinition is based on observed consonant–vowel interactions where, for example, round vowels and labial consonants, or low vowels and gutturals, form a natural class. Hume (1996) discusses evidence from Maltese where the imperfective prefix vowel changes, depending on the stem-initial consonant. Normally, the prefix vowel is determined by the stem vocalism; however, it is [i] before coronal obstruents (as in [ji-dlam] 'to grow dark', cf. perfective [dalam]), and /i/ is lowered to [a] before gutturals (as in [ja-ħdem] 'to work', cf. UR /ħidim/). With the new vowel place features, these can now be straightforwardly explained as the spreading of [coronal] and [pharyngeal], respectively. The geometry which Clements and Hume propose for vowel features is given in (14): consonants and vowels share the same place features; how the feature is realized phonetically depends on whether it is a daughter of the C-Place node or of the V-Place node. The Aperture node is a simplified version of Odden's (1991) Height node, containing recursive [open] features. For details on this node, see Clements (1991), Clements and Hume (1995), and Salting (1998). The resulting geometry is known as Unified Feature Theory (Clements and Hume 1995).

(14) *Feature geometry with unified features*



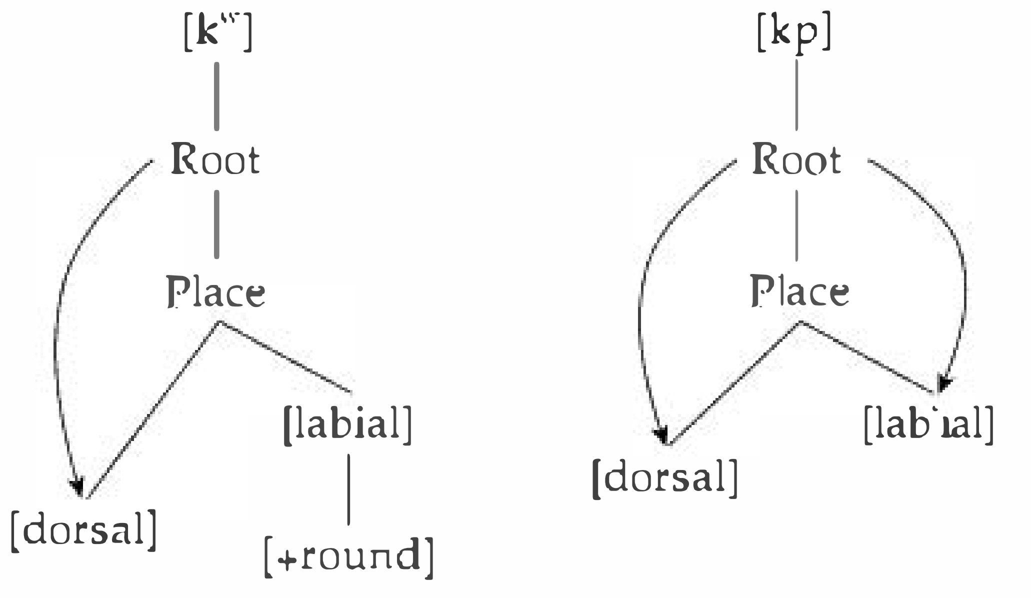
An additional advantage of the Unified Feature Theory model is that it can straightforwardly capture secondary articulations, such as labialization, palatalization, and pharyngealization, and distinguish them from double articulations, such as co-articulated stops. In secondary articulation, the major articulator is a feature dependent on the C-Place node, while the secondary articulation (such as palatalization or labialization) is expressed by a feature dependent on the V-Place node. The two representations in (15) illustrate this difference by comparing a co-articulated stop [kp] (no subordination of articulators) with labialized [kʷ] (secondary labialization). This representation also captures the observation that secondary articulations can function as blockers in vowel harmony; since they are vocalic articulations, they are expected to interact with processes targeting vocalic segments. See also CHAPTER 75: CONSONANT–VOWEL PLACE FEATURE INTERACTIONS; CHAPTER 71: PALATALIZATION; and CHAPTER 29: SECONDARY AND DOUBLE ARTICULATION for more detailed discussions of secondary articulations.

(15) *Secondary* vs. *double articulations* (Unified Feature Theory)



Articulator Theory does not offer a comparably straightforward way of distinguishing between primary and secondary articulations, but has to resort to a new type of phonological primitive, a pointer device, to indicate which of the two articulators is the main (or designated) articulator, as in (16).[1]

(16) *Secondary* vs. *double articulations* (Articulator Theory)



To summarize, there are thus two different proposals with respect to how vowel features are represented in the feature tree, based on two different organizing principles of the tree: articulatory grounding *vs.* constituency in phonological processes (providing evidence for a separate V-Place node and a unified set of features). This conflict has still not been resolved – on the contrary, it is exacerbated when manner features are taken into consideration as well.

3.2 *More on manner features*

To recapitulate from §2, manner features are not grouped under a shared class node, at least since McCarthy (1988), motivated in Articulator Theory by the observation that they are not articulator-bound.[2] This section will briefly look at some proposals that group individual manner features with other features, based on the same kind of argument that motivated the reconceptualization of vowel features in the previous section. We will see, however, that in the case of manner features there is conflicting evidence which has dealt a serious blow to the endeavor of finding a universal feature geometry.

Recall first one major distinction. While most manner features are analyzed as autosegments that associate directly with the root, without an intervening class node, the major class features [consonantal] and [sonorant] are granted special status; rather than being autosegments, they are viewed as part of the root node itself. The reason for this is that these two features never seem to spread or delink, as other features would. Their function instead is entirely classificatory, to distinguish vowels from consonants, and obstruents from sonorants. This, however,

[1] A solution to this problem (of adding a new type of representational primitive, the pointer) that stays true to the principles of Articulator Theory is suggested in Halle *et al.* (2000), where the set of features itself is expanded to distinguish between primary and secondary articulators (each articulator coming with two features).

[2] See Clements (1985) for the original proposal for a Manner node, and Morén (2003, 2007) for the reintroduction of a Manner node (on which more in §6).

which are consistent with an analysis that views [nasal] as variably associated with either the SV node or a Soft Palate node, with individual languages taking one of the two options. See CHAPTER 78: NASAL HARMONY for a review of these nasal harmony types and a summary of Piggott's arguments. Piggott's idea that feature dependencies may be variable, aiming at a "softer" approach to universals in feature organization, has not been pursued systematically, however. We will return to this point in the concluding section of the chapter.

3.3 *Interim summary*

By the mid-1990s it had become increasingly clear that the goal of finding a universal (and universally agreed upon) hierarchy of features could not be attained. The two major organizing principles of feature geometry, articulatory similarity and phonological patterning, do not always match up perfectly. While the basic structure of the geometry is fairly uncontroversial, there are diverging proposals regarding feature organization outside of the core sets of place and laryngeal features. Vowel features are a case in point: articulatorily diverse groups of vowel features nevertheless form phonological constituents (such as [back] and [round]). This does not mean that phonological patterning should always trump articulatory considerations, however: evidence from patterning can yield conflicting evidence as well, as we have seen in the case of manner features, which associate variably with other features in phonological processes. While Piggott (1992) explicitly allows such variability to account for the variable patterning of nasals, the idea of parameterizing the principles of feature geometry was never pursued systematically.

It may therefore not be surprising that the advent of a major new theory in the 1990s, Optimality Theory, stimulated a new research program to see how the feature-geometric generalizations could be captured differently and potentially more accurately within a theory of violable constraints, rather than a theory of (universal) representations. We will turn to these proposals in §5 and evaluate them critically, also in the light of advances in representational theory, in §6. First, however, we will turn to another aspect of feature geometry, which will be important for the overall evaluation of this research program, namely the way in which this theory has contributed to the understanding of phonological operations, besides proposing a new theory of phonological representations.

4 Non-local feature interaction

We have seen how phonological processes are formalized autosegmentally in feature geometry, as the spreading or delinking of a node, either a feature or a class node. §2 showed how place assimilation can be understood as the spreading of the Place node, taking all place features with it. More radical changes can also be formalized as a single operation; for example, debuccalization, i.e. the loss of oral features (as in /t/ → [ʔ]), can be formalized as the delinking of the Oral node, leaving only the Laryngeal node to specify a segment.

Feature geometry also allowed a breakthrough in the understanding of non-local interactions, that is, processes in which trigger and target are not directly adjacent. Traditional rule-based theory had a problem with capturing such non-local interactions: under what conditions can trigger and target be separated? How

Similar generalizations can be made for dissimilatory processes, which can also occur over a distance. The Obligatory Contour Principle (OCP), which prohibits identical adjacent feature specifications, is the trigger for dissimilation, but it does not necessarily hold over linearly adjacent segments but can also refer to two autosegments adjacent on their respective tier. See Odden (1994) for a typology of long-distance dissimilation. In essence, the same feature that can assimilate long-distance can also dissimilate. Laryngeal dissimilation is fairly common and can occur over a distance. For example, Dahl's Law in Eastern Bantu languages changes a voiceless prefix-initial stop to voiced if the stem-initial consonant is voiceless as well. Lyman's Law in Japanese prohibits more than one [+voice] obstruent in a word. Grassmann's Law in Indo-European dissimilates aspirated segments. Also common is liquid dissimilation, as in the following Latin examples:

(21) *Latin liquid dissimilation*

nav-alis	*fat-alis*	*crimin-alis*	*radic-alis*
sol-aris	*milit-aris*	*peculi-aris*	*line-aris*
flor-alis	*later-alis*	*plur-alis*	*sepulchr-alis*

These examples show that the denominal adjectival suffix *-alis* becomes *-aris* if preceded by an [l] in the stem which is not directly adjacent. Intervening [r] (as in *pluralis*) blocks the process. This can be understood as an OCP effect on the lateral tier: in **sol-alis* there would be two tier-adjacent instances of [+lateral]. Again, note the crucial role of underspecification: since [±lateral] is only contrastive for liquids, only they carry this feature. Hence, [r], being the only segment which is specified as [−lateral], is the only potential blocker of the dissimilatory process.

In sum, feature geometry does not just constrain possible operations in terms of which features spread together; it also provides an elegant analysis of non-local interactions for assimilation and dissimilation. At their relevant tier, the interactions are in fact local, involving adjacent autosegments. In addition, the proposal is falsifiable: any non-local interaction that cannot be made local on some tier constitutes counterevidence to the model. The question of whether there exist such counterexamples is still unresolved and a possible direction for future research. Conversely, any theory of phonology that wishes to abandon feature geometry must have an account of non-local interactions. It is these alternative proposals, which arose as a consequence of the emergence of Optimality Theory as a new model of grammar, to which we now turn.

5 Feature organization in Optimality Theory

The advent of Optimality Theory (OT; Prince and Smolensky 1993) allowed a fresh look at the generalizations that feature geometry is trying to capture by opening up the possibility that these generalizations could also emerge from a theory of constraint interaction (CHAPTER 63: MARKEDNESS AND FAITHFULNESS CONSTRAINTS). Consequently, there was a shift in interest away from feature geometry in the second half of the 1990s. This section will review and motivate that shift, and by default). Example (22) gives some examples, with the [−high] plural suffix [-ler, -lar] and the [+high] genitive suffix [-in, -yn, -ɨn, -un].

(22) *Turkish vowel harmony*

nom sg	*gen sg*	*nom pl*	
ip	ipin	ipler	'rope'
gøz	gøzyn	gøzler	'eye'
pul	pulun	pullar	'stamp'
at	atɨn	atlar	'horse'

Traditionally, Turkish harmony is analyzed as two separate processes. In feature-geometric terms, spreading is either of a single feature [back], or of the Color node, comprising [back] and [round] (adopting the proposal in Odden 1991, discussed above). Padgett suggests that there is only one process, which spreads Color features. This process always targets both features, although only [back] spreads if spreading of [round] would create a marked segment, i.e. [o] or [ø]. He achieves this by ranking a markedness constraint against non-high round vowels above a constraint SPREAD(Color), where the class Color comprises [back, round]. No spreading yields two constraint violations (one for each feature); spreading of [back] only yields one violation. Violation of SPREAD(Color) is therefore minimal and only licensed to avoid violation of the markedness constraint against non-high round vowels.

A feature-geometric analysis, in comparison, would predict what Padgett calls "sour grapes spreading": either all features spread (because the Color node spreads), or none do. The gradient behavior of spreading (spreading as much as possible while satisfying higher-ranked markedness constraints) can therefore not be addressed straightforwardly in a feature-geometric model (although a feature-geometric implementation is a possible option in OT, by spreading the Color node if possible, or only [back] if spreading of the Color node were to create a violation of the markedness constraint against non-high round vowels). There is an additional property to Padgett's analysis: the absence of feature-geometric structure means that non-local interactions (such as vowel harmony) can no longer be analyzed as local at the level of some tier. In vowel harmony, spreading therefore cannot skip intervening consonants, which have to participate in the harmony. All spreading is strictly local, although the effect of vowel harmony on a consonant may be imperceptible (see also Ní Chiosáin and Padgett 1997, 2001). Locality issues will be discussed separately in the next subsection.

Yip (2004, 2005) goes a step further than Padgett in showing that class behavior can be modeled solely as constraint interaction, without the need for feature classes as indices on features. She looks at the feature [lateral], whose status in the geometry has always been ambiguous, with conflicting proposals to group it either under the Coronal node or the SV node (cf. §3.2). She links this ambiguity to typological observations regarding the markedness of different types of laterals, finding that coronal laterals are less marked than dorsal laterals and that sonorant laterals are less marked than obstruent laterals, from which she derives two presumably universal markedness hierarchies. She then goes on to show that the observations that led to the proposals about the position of [lateral] in the feature tree (spreading of [lateral] with [coronal] or only to [coronal] targets;

spreading of [lateral] with SV or only to targets having an SV node) also fall out from interleaving these hierarchies with faithfulness constraints. Essentially, in Yip's approach a pro-spreading constraint like Spread or Share wants to spread as many features as possible, unless this creates an illicit segment (which is militated against by a highly ranked markedness constraint). The observation of variable class membership is thus re-analyzed as an epiphenomenon of the interaction of markedness and faithfulness constraints generally, and an effect of markedness scales on feature co-occurrence more specifically. (See chapter 31: lateral consonants for a more detailed sketch of this analysis.) Unfortunately, this approach has to my knowledge never been applied more generally, and its consequences have not been explored in depth. Future research should shed more light on whether Yip's approach is indeed a viable alternative to representational devices that encode class membership.

5.2 *Strict locality in spreading*

In sum, then, generalizations about class behavior can be made in OT without having to resort to tree structures that encode such behavior representationally, although some of the details may still warrant further research. The third point of the list of advances in feature geometry, non-local interactions, is a more controversial issue. We saw that Padgett (1995, 2002) has to analyze all spreading as strictly local, in the absence of complex autosegmental representations, a view that is applied and developed further, for example, in Ní Chiosáin and Padgett (1997, 2001), Walker (1998), Gafos (1999), and Baković (2000). In the case of vowel harmony, this implies that consonants also participate in vowel harmony. They argue that this is supported phonetically by co-articulation effects on the consonants (such as lip rounding in round harmony). While this may be a welcome simplification of the system (obviating the need for representational devices that introduce relativized notions of locality), it also introduces some complications. Ní Chiosáin and Padgett (1997, 2001) note that vowel harmony is cross-linguistically frequent, while consonant harmony is non-existent. It is thus necessary to have a mechanism that allows the propagation of vowel features through consonants while blocking the propagation of consonant features through vowels. They therefore co-index place features for degree of aperture. A [labial$_V$] articulation (rounding on vowels) can be co-articulated on a consonant, but a consonantal place feature like [labial$_C$] could not be co-articulated on a vowel, because it is stronger and would deprive the vowel of its vocalicness, a principle they ground aerodynamically in what they call the "bottleneck effect." See chapter 75: consonant–vowel place feature interactions for an elaboration of this idea of "inherent V-Place."

One problem with this approach is that distinctive features are commonly used to encode possible contrasts, but there are no languages that would contrast consonants with or without a vocalic co-articulation (which is different from secondary articulations like labialization, palatalization, etc.). Ní Chiosáin and Padgett therefore need an additional mechanism to rule out such unattested contrasts. Here they turn to Dispersion Theory (Flemming 1995), arguing that such potential contrasts are not well dispersed enough to survive into actual systems. This final point is probably most controversial, since Dispersion Theory has been criticized independently (see e.g. McCarthy 2002). Nevertheless, the idea of strictly local specified, providing a principled algorithm for underspecification (Dresher *et al.* 1994; Dresher 2009). See also CHAPTER 2: CONTRAST for an introduction. The application of this algorithm generates a hierarchical tree structure itself. If learners posit new features on the basis of contrast they observe within a set of segments, it is quite possible that the contrastive hierarchy will to some extent be reflected in an emergent geometry. For example, in a language in which all liquids are [coronal], the feature [lateral] may be used to contrastively subdivide the set of coronals. Consequently, learners may posit that [lateral] is a dependent of [coronal] in the geometry as well. In a language in which liquids are phonologically placeless, however, learners may posit that [lateral] subdivides the set of sonorants, as a dependent of the SV node. The ambiguity of [lateral], discussed in CHAPTER 31: LATERAL CONSONANTS, may thus reflect the system of contrasts in a language more generally. The concept of emergent features thus shows the potential for a new understanding of feature organization. Future research could shed more light on which aspects of feature organization are provided by UG, which are emergent via the phonetic content of features and which are emergent via the contrast encoded by a feature.

Finally, one additional direction for potential future developments should be mentioned, a recent challenge to the standard opinion that the anchor of features is the segment. In a detailed typological survey, Kehrein (2002) and Kehrein and Golston (2004) conclude that the anchor of laryngeal features is not the segment but rather the syllable constituent (onset, nucleus, coda), since they find no evidence for contrastive laryngeal specifications within syllable constituents in any language. The Laryngeal node is hence not formalized as a dependent of the segmental root node but as a sister of segmental root nodes, as a dependent of a syllable constituent like the onset. Non-contrastive differences across languages are relegated to phonetic implementation and the phasing of laryngeal gestures. If Golston and Kehrein are correct, this opens up the possibility for more research in the area. Are there other features that are not properties of segments but of higher prosodic categories, either universally or in individual languages? The once strict division between tree structure above the segment (prosody) and below the segment (feature geometry) would then become permeable, which in turn would have consequences for our understanding of locality in feature interaction. Seemingly long-distance interactions may be local not by virtue of tier locality but by virtue of the feature itself spreading higher up in the prosodic hierarchy. For now, however, this idea is mostly speculative.

In sum, the research program that was embarked upon in the mid-1980s, to investigate the possibility of segment-internal structure which organizes distinctive features into sets or classes, is far from finished. After peaking in interest in the early 1990s and a slow but steady demise when mainstream phonological interest shifted to the role of constraints in phonology instead, the program has seen some renewed interest more recently. With some original problems of orthodox feature geometry still unresolved and the promise of Optimality Theory to provide a more elegant and empirically superior alternative not having been fully realized, the issue of feature organization is still as alive as it was 20 years ago. New directions in research, as outlined in the final section of this chapter, may shed new light on the issue and bring us closer to a better understanding of feature organization.

28 The Representation of Fricatives

Bert Vaux
Brett Miller

1 Introduction

The phonetic properties of fricatives have recently received a great deal of attention (Shadle 1985; Ladefoged and Maddieson 1996: ch. 5; Johnson 1997: ch. 6; Stevens 1998: ch. 8; Maniwa *et al.* 2009; Ramsay 2009; among others). The *phonological* properties of this class of sounds, on the other hand, have, with a few notable exceptions, remained largely undisputed since the publication of Chomsky and Halle (1968), which itself essentially carries on the featural analysis of fricatives in Trubetzkoy (1939) and Jakobson *et al.* (1952). In this analysis, the class of fricatives is characterized by the distinctive features [−sonorant, +continuant].

Once one scratches the surface of the subject, though, a number of challenging questions appear:

(1) a. Do fricatives actually behave as a distinct phonological class?
b. Are all fricatives [−sonorant]?
c. Are all fricatives [+consonantal]?
d. Are all or any fricatives [+spread glottis] (or its equivalent)?

This chapter addresses these and other challenges by synthesizing what we have learned from traditional and contemporary descriptive and theoretical studies involving fricatives, with an eye towards determining what properties (if any) consistently characterize this phonological class and why. We shall see that the exact membership and feature characterization of the fricative class depends on how one defines the features involved, but that there are good phonological reasons for assuming the existence of a coherent fricative class defined by the features [−sonorant, +continuant] and including not only the relatively uncontroversial suspects {f v ɸ β θ ð x ɣ χ ʁ} but also what we can call the strident or sibilant fricatives {s z ʃ ʒ ʂ ʐ ɕ ʑ}. The laryngeals {h ʜ ɦ ħ ɧ} behave less uniformly: some of them pattern with fricatives in some languages and with sonorants in others. There is also variation within the fricative class for the features [spread glottis], [strident], [ATR], and possibly [consonantal], so these should not be included in the definition of the fricative class. Since the class appears adequately defined with the independently needed features [+continuant, −sonorant], we conclude on grounds of parsimony that this definition is preferable to one requiring the introduction of additional features such as [fricative].

We do not investigate stridency in this chapter, both because it does not characterize the class of fricatives as a whole and because it has been well dealt with by Clements (2006). Nor do we deal with tongue root advancement, which Vaux (1992, 1996) has suggested is a common attribute of voiced fricatives only by virtue of their membership in the class of voiced obstruents.

1.1 *Are fricatives a bona fide phonological natural class?*

Fricatives present a challenge to the ontology of distinctive feature theory, in that they possess a clear and unique phonetic identity resulting from turbulent airflow through a narrow constriction that is reflected in neither of the cornerstones of distinctive feature theory (CHAPTER 17: DISTINCTIVE FEATURES), (i) properties that are phonologically active, and (ii) properties that are necessary to distinguish a phoneme (or in this case a class of phonemes) from all others. The problem is this: if we were to postulate a phonological feature such as [fricative] to capture the distinctive phonetics of the fricative class, we would run afoul of criterion (i) by virtue of the fact that there is no evidence for such a feature being phonologically active; the attested range of phonological behaviors of fricatives can be captured by other independently required members of their feature complement, as we will see throughout the rest of this chapter. These same features suffice to distinguish the class of fricatives from stops, vowels, and so on; the feature [fricative] therefore is also not required by criterion (ii).

Before examining the phonological representation of fricatives, we should therefore consider first whether there is sufficient evidence for considering them to form a natural class. Is there anything that is truly distinctive phonologically about the set of fricatives, or are they simply what is left of the class of obstruents after one subtracts the stops? Do fricatives ever behave as a class to the exclusion of all other phonemes? The answer to this question is a qualified yes: many phonological phenomena specifically target or are triggered by the fricative set of the language in question, but (unsurprisingly), for a variety of historical and accidental reasons, none of the phenomena in question suffice to delineate the entire cross-linguistic class of fricatives.

Tiberian Hebrew spirantization, for instance, produces alternations between plain oral stops [p b t d k g] and fricatives [f v θ ð x ɣ] respectively, as in (1) (Idsardi 1998: 39), but does not produce alternations for the emphatic stop [tˤ] or for the guttural fricatives [ħ h]. The Tiberian Hebrew surface consonant inventory is given in (2), based on Rendsberg (1997) and Green (2004).

(2) *Tiberian Hebrew surface consonant inventory*

	labial	dental	alveolar	palatal	velar	pharyngeal	glottal
stops	p b	t d			k g		ʔ
fricatives	f v	θ ð	s	ʃ	x ɣ	ħ ʕ	h
emphatics		tˤ	sˤ		q		
nasals	m	n					
liquids		l r					
glides	w			j			

The interpretation of the emphatics is conjectural, and the positioning of the pharyngeals and glottals should be understood as arbitrary with respect to their [sonorant] values, which we will not investigate here (though we discuss the sonorance of laryngeals in various other languages in §2.2; see also CHAPTER 25: PHARYNGEALS).

(3) *Examples of Hebrew spirantization alternations*

a.	[t ~ θ]	√ktb	kaːˈθav	'he wrote'
	[k ~ x]		jixˈtoːv	'he was writing'
b.	[d ~ ð]	√gdl	gaːˈðluː	'they were great'
	[g ~ ɣ]		jiɣˈdaːluː	'he was being great'

The facts in (3) are not a problem for the notion that fricatives form a phonological class, because the phenomenon can be plausibly analyzed as involving spreading of [+continuant] from vowels to a following singleton segment specified with [+consonantal] and perhaps [−constricted glottis]. This is shown in the simplified spirantization rule in (4), which abstracts away from certain morphological and lexical exceptions (on which see Coetzee 1999; Green 2004).

(4) *Spirantization rule*[1]

[−cons, −constr gl][+cons, (−constr gl)]$_i$ X$_j$
|
[+cont]

If this analysis is correct (see further §2.1.2), we do not expect the guttural fricatives to have [−continuant] counterparts in Tiberian Hebrew; the rule only serves to produce fricatives from underlying stops, and has no effect on underlying fricatives such as the gutturals. Tiberian Hebrew spirantization therefore provides evidence neither for nor against the gutturals being fricatives rather than glides (i.e. obstruents rather than sonorants).

Nor can anything clear be inferred about the lack of spirantized allophones for the emphatic stops, though it seems likely that the emphatics had some trait such that their spirantized outcomes would have been fairly unusual, complex, or difficult sounds. No emphatics, and no other comparable class of non-participants, are to be found when one considers the spirantization processes reconstructed in Old Irish (Celtic: Thurneysen 1946) and observed synchronically in Shoshone and Southern Paiute (Numic: Charney 1993). These cases of spirantization could also be handled by (4) or by a very similar rule.

With these examples in mind, let us briefly consider additional phonological phenomena that can be reasonably said to target or be triggered by the class of fricatives. Perhaps the best-known case arguably stems from the difficulties language learners have in producing fricatives, which leads to a host of avoidance and mutation strategies by individual learners (CHAPTER 101: THE INTERPRETATION

[1] If the target is not specified [−constricted glottis], then emphatics will spirantize and need to be repaired. The analysis of emphatic stops as [+constricted glottis] (laryngeally constricted) appears reasonable because the range of articulations typically reconstructed for them (Rendsburg 1997: 73) is within the laryngeal tract (CHAPTER 25: PHARYNGEALS).

2 Feature specifications

Silbert and de Jong (2008) state that there is a problem with finding a parsimonious feature definition of fricatives: they maintain that because fricatives consist, in large part, of random turbulent noise, they present a challenge to attempts to ground our theory of phonological features in specific phonetic correlates. As far as we can tell, though, the phonological features that are generally considered to delineate the fricative class, [+continuant] and [−sonorant], do not encounter this problem (see also CHAPTER 8: SONORANTS; CHAPTER 13: THE STRICTURE FEATURES). Continuants can be defined straightforwardly as sounds with oral airflow egress, and obstruents as sounds with positive oral pressure buildup. Fricatives conform to both of these definitions, so there is no difficulty in correlating the feature specification of fricatives with well-established phonetic cues.

But do fricatives show evidence of being *phonologically* [+continuant] and [−sonorant]? And do they possess any other invariant feature specifications? In this section we consider phonological evidence bearing on the specifications of fricatives for [continuant] (§2.1), [sonorant] (§2.2), [consonantal] (§2.3), and [spread glottis] (§2.4).

2.1 *Continuance*

Continuance is perhaps the quintessential feature of the fricative class; in fact, Jakobson *et al.* (1952: 43) specified the feature value [+continuant] only for fricatives and not for vowels (or *h*, interestingly), making it effectively equivalent phonologically to Ladefoged's [fricative] feature. Chomsky and Halle (1968: 177) add {r l h} to the continuant set, but still exclude vowels (though their definition of [+continuant] in terms of not having enough constriction to stop airflow might lead us to expect otherwise).

Once we assume that vowels are [+continuant] and incorporate the feature [sonorant] (as Chomsky and Halle 1968: ch. 8 did), we are led to revise our classification of the fricatives to [+continuant, −sonorant]. But are either of these features phonologically active? In this subsection we provide evidence that [continuant] is active in fricatives, drawing on delinking and spreading of [+continuant] (stopping and spirantization, respectively), delinking and spreading of [−continuant] (deaffrication and intrusive stop formation, respectively), and delinking of [αcontinuant] (manner dissimilation). The interested reader can consult Cser (1999) for discussion of additional phenomena bearing on the phonological status of the feature [continuant]. Evidence involving [sonorant] is presented in §2.2.

2.1.1 *Stopping*

Let us first consider the cross-linguistically common process of stopping, which involves changing fricatives to corresponding stops and can be reasonably analyzed as delinking of [+continuant] with subsequent replacement by its complement, [−continuant]. This is common after nasals, as we already saw in Nivkh (and as occurs in Spanish, according to Baković 1994 and Kenstowicz 1994). It is also common as a positional and absolute neutralization process in first

(9) *Word-initial stopping deaffrication*

[dɛli]	*jelly*
[dʌmp]	*jump*
[dus]	*juice*
[dɪp]	*chip*
[diːʒ]	*cheese*
[dɛːə]	*chair*

2.1.2 Spirantization

Besides delinking in the patterns just described, the feature [+continuant] can spread to stop consonants, producing fricatives. In addition to the Tiberian Hebrew case mentioned in §1.1 we arguably find spirantization of this type in Spanish (Harris 1969), producing alternations of the sort in (10):

(10) *Spanish spirantization* (data from Baković 1994)

a.	[beso]	'kiss'	[ese βeso]	'that kiss'
			[el βeso]	'the kiss'
			[dar βesos]	'give kisses'
b.	[dato]	'date'	[ese ðato]	'that date'
			[el dato]	'the date'
			[dar ðatos]	'give dates'
c.	[gato]	'cat'	[ese ɣato]	'that cat'
			[el ɣato]	'the cat'
			[dar ɣatos]	'give cats'

According to Harris (1969: 39), the alternants "appear as continuants except initially and after homorganic noncontinuant sonorants." Scholars generally (e.g. Goldsmith 1981) analyze the system in terms of the feature [+continuant] spreading to underlying voiced stops from preceding [+continuant] segments, with the [l–d] cases being a bit of a problem. (We have encountered speakers who have [lð] in such cases, but the secondary literature appears to be unanimous on [ld] being the only option. See also CHAPTER 13: THE STRICTURE FEATURES.) Lozano (1979) and Baković (1994) invert the analysis, proposing underlying voiced fricatives that undergo fortition in syllable onsets under certain conditions. If they are correct, Spanish still presents evidence for [continuant] being phonologically active in fricatives; the only difference is that the Spanish facts are then an example of stopping (see §2.1.1) rather than spirantization. (But see Mascaró 1991 for a critique of these phonological solutions.)

Because the Spanish continuant allophones are often highly sonorous and even realized as glides (CHAPTER 15: GLIDES), it could be asked whether fricatives are phonologically involved in the alternation at all, or whether the fricative allophones are merely phonetically fortified variants of the glides. But the considerably different behavior of what are conventionally analyzed as underlying glides indicates that this is not the case. Although we have heard the Spanish glide /j/ realized with fortified variants [ʝ] and even [ʤ], the distribution of fricative realizations for /j/ and the strength of their frication appear to be much rarer and less salient than with the fricative realizations of /b d g/, suggesting that phonological [continuant] alternation in obstruents does indeed occur in Spanish.

data requiring it (Fallon 2002; Samuels 2009). This quandary raises the question: when if ever is it acceptable to analyze systematic and categorical (as opposed to variable or gradient) spirantization as [+continuant] spreading from vowels?

The assumption that spreading of otherwise active features must have a certain status in terms of contrast structure seems reasonable, since features can only spread if they are specified, and specification is widely assumed to relate somehow to contrastiveness (CHAPTER 2: CONTRAST). But to claim that vowels cannot spread [+continuant] because they never contrast for it is problematic. This assumption presupposes that there is an algorithm capable of exhaustively defining which features are contrastive in which environments in a given language by specifying them in a particular *order*, leaving the remaining features predictable from these and therefore (at least in some cases) never phonologically specified. Yet no successful algorithm has been developed for this task, *pace* Dresher (2009). The two-best known candidates, the Pairwise Algorithm and the Successive Division Algorithm, are critiqued in Samuels (2009: 77–94), and found to have serious problems. Samuels (2009) essentially abandons the search for such algorithms, while Parker's more limited discussion (CHAPTER 49: SONORITY) favorably highlights an application of the Successive Division Algorithm in Anywa and Dholuo. Crucially, this application makes order of specification depend on language-particular feature activity rather than on contrast as measured by any independent criterion.

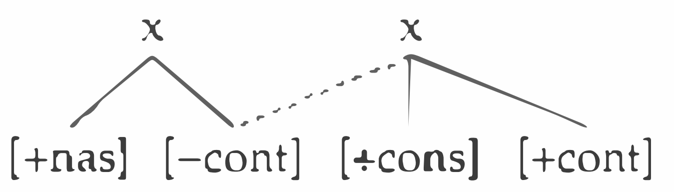
Hence, the argument that a feature cannot be active in a certain environment because it is not contrastive there must be suspended until a proper specification algorithm itself is established. This much is essentially acknowledged by Dresher (2009: 9, 209). After investigating possible algorithms for implementing the "Contrastivist Hypothesis" ("that phonological computation operates only on contrastive features"), Dresher concludes that phonological computation does apparently require non-contrastive features in some situations. Dresher recommends retaining the Contrastivist Hypothesis and a form of the Successive Division Algorithm (requiring a serial grammar theory) because they cover much or possibly most of the data, but once we allow exceptions, any data that are more elegantly treated in contravention of the hypothesis can also demand exceptional status, including spirantizations which can be analyzed as [+continuant] spreading from vowels.

It may eventually prove relevant to distinguish between two kinds of non-contrastive features, if only one of them seems needed in phonological representations. One kind is not predictable from context; an example would be archiphonemically underspecified features (on which see Inkelas 1995; Samuels 2009). The other kind is necessarily predictable from contexts: all vowels, for example, are necessarily continuant. We will not pursue the matter further here. For now it simply seems reasonable to accept cases of spirantization like those mentioned in this section as examples of fricatives produced by [+continuant] spread.

2.1.3 *Deaffrication*

Further evidence that [continuant] is active in fricatives comes from phenomena that delink [−continuant] specifications. Perhaps the most widespread process of this type is the more common variety of deaffrication, which deletes the [−continuant] closure phase of the segment, producing a fricative. We find examples of this in the Aslanbeg dialect of Armenian, which deletes the stop component of affricates in coda position (13).

(16) *Intrusive stop formation as* [−continuant] *spreading*



Here again, the analysis hinges in part on fricatives being [+continuant]; if they were not, the reasons for a preceding nasal changing a fricative into what is essentially an affricate would be unclear.

2.1.5 *Manner dissimilation*

Thus far we have seen evidence for spreading and delinking of [+continuant] and [−continuant], each of which implicates fricatives as being [+continuant]. The [+continuant] specification of fricatives is also revealed in dissimilation processes (CHAPTER 60: DISSIMILATION), such as we find in Modern Greek, where it can either trigger or undergo [continuant] delinking. In this language, voiceless stop + stop and (non-*s*) fricative + fricative clusters optionally dissimilate to stop + fricative (Newton 1972; Kaisse 1988), as in (17) (Tserdanelis 2001) (see also CHAPTER 13: THE STRICTURE FEATURES):

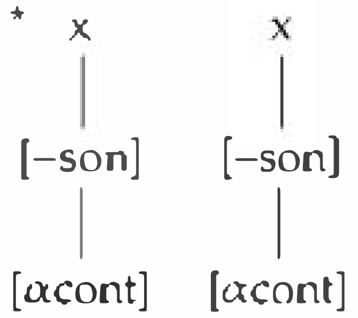
(17) *Modern Greek manner dissimilation*

a.	ptero	~	ftero	'feather'
	ktena	~	xtena	'comb'
	epta	~	efta	'seven'
	okto	~	oxto	'eight'
	ekpiisi	~	expiisi	'sale'
b.	xθes	~	xtes	'yesterday'
	fθinos	~	ftinos	'cheap'
	skefθika	~	skeftika	'I thought'
	anixθika	~	anixtika	'I was opened'
	fxaristo	~	fkaristo	'I thank'
c.	sxini	~	skini	'rope'
	pisθika	~	pistika	'I was convinced'
	sfoŋgos	~	spoŋgos	'sponge'
d.	trex-o	:	e-trek-sa	'I run (PRES : PAST)'
	kafsimo	~	kapsimo	'burning'
	kaθ-izo	:	e-kat-sa	'I sit (PRES : PAST)'

When the underlying cluster contains two stops, the first member changes into a fricative (17a), whereas in fricative clusters the second member becomes a stop (17b). Interestingly, obstruent clusters containing an /s/ invariably delink the [continuant] specification of the other segment (17c, d).

If we assume that stops and fricatives differ in being [−continuant] and [+continuant] respectively, we can interpret the dissimilation facts as OCP-driven delinking of [continuant] values, where the relativized version of the OCP here would look something like (18).

(18) *The OCP manner constraint for Modern Greek* (modified from Tserdanelis 2001)



How exactly violations of this constraint are repaired is a matter of some debate, but the specifics are not relevant here. The key for our purposes is that dissimilation processes of this sort only make sense if stops and fricatives are polar opposites delimited by a single binary feature, in this case [continuant]; other representational options such as [fricative] simply do not capture this sort of interaction insightfully.

In this subsection we have seen that the evidence from spreading and delinking of [±continuant], which surfaces in a broad range of phenomena from spirantization to deaffrication to intrusive stop formation to manner dissimilation, dovetails nicely with the assumption that fricatives are specified as [+continuant]. Competing theories that replace [+continuant] with [fricative], A_f, and the like tend to deal less well with these facts.

2.2 *Sonorance*

We next turn to the other feature value most commonly attributed to fricatives, [−sonorant]. This specification is presumably invoked to distinguish fricatives from the rest of the continuants, e.g. vowels and (in some languages at least) [l] and [r], which are [+sonorant] (CHAPTER 8: SONORANTS). Treating all fricatives as obstruents raises a couple of questions, however:

(19) a. Are the glottal continuants /h ɦ/ obstruents? If not, are they still fricatives?
b. Russian *v* patterns partly with obstruents and partly with sonorants; what is its [sonorant] value?
c. What is the relative sonority ranking of fricatives and stops?
d. Why is the boundary between voiced fricatives and homorganic glides sometimes unclear?

In this subsection we consider each of these issues in turn.

2.2.1 *Glottals*

Trubetzkoy (1939) classed all of the fricatives as obstruents. If the glottal continuants /h ɦ/ are obstruent, then they belong straightforwardly to the class of fricatives defined as [+continuant, −sonorant] segments. If, however, these segments are sonorant, as suggested by Chomsky and Halle (1968) and some of the ancient Indian phonetic treatises, such as the Taittirīya Prātiśākhya (1.13; Whitney 1871), then we must either exclude them from the fricative class or adopt one of the proposals in the literature for encoding fricativity directly, such as Ladefoged's

(1989) [fricative] feature, Articulatory Phonology's fricative gesture (Browman and Goldstein 1986), Steriade's (1993) fricative aperture node A_f, or Moren's (2003) consonantal manner feature [open]. Below we consider phonological evidence bearing on the sonorance of laryngeals, specifically the plain glottals (on the distinction see CHAPTER 25: PHARYNGEALS).

Glottals pattern with obstruents to the exclusion of sonorants in some languages and vice versa in others. The following examples and more like them can be found in the P-Base database (Mielke 2007). Sonorant examples include Kickapoo (Algic) and Supyire Senoufo (Niger-Congo). In Kickapoo, after any sonorant, including /h/ (the only glottal), the second member of a glide plus unaccented vowel sequence in either order is glottalized. In Supyire Senoufo, nasalized vowels can be preceded by only /Ṽ m n ɲ ŋ l ʔ/, and there are no other glottals or consonantal sonorants in the inventory. Obstruent examples include Jordanian Arabic, where only /ʔ h/ and other obstruents can be C_2 and only /m n r l/ can be C_1 in -C_1C_2# and -$C_1C_2C_3$-; Maltese, where only /ʔ h/ and other obstruents can be C_1 in #C_1C_2-; and Balangao (Austronesian), where obstruents including /ʔ h/ delete after the common prefix /maŋ-/. There is also evidence for [−sonorant] spreading from fricatives to the palatal nasal [ɲ] in the Nilo-Saharan language Bilaala (Olson and Schultz 2002).

Similar ambivalence is shown by /ɦ/. In Czech (Slavic: Mielke 2007; Dankovičová 1999), this segment is the only laryngeal in the language and participates in a regressive obstruent voicing assimilation to the exclusion of sonorants. This suggests that /ɦ/ is [−sonorant] in Czech. At the same time, in Oowekyala (Wakashan: Howe 2000), where /ɦ/ is again the only laryngeal in the inventory, the segment appears to be [+sonorant]. This is indicated not only by the fact that /ɦ/ is voiced like all of the sonorants and unlike any of the obstruents in the language, but more importantly, by the fact that /ɦ/ takes [+constricted glottis] root-initially before a reduplicant in the plural, like sonorant consonants but unlike obstruents. Furthermore, the laryngeal continuants [h] and [ɦ] appear to systematically avoid participating in the stopping and deletion phenomena in child phonologies discussed in §2.1.

If obstruence is cued by increased pressure in the vocal tract relative to outside air pressure, then cross-linguistic variation in the classification of glottals as obstruents or sonorants may be due to variation in whether this pressure buildup involves supraglottal impedance or not. In most sounds this is automatically the case, but with glottals it is not; hence, glottals will be sonorants if obstruents are defined by pressure buildup involving supralaryngeal impedance, and obstruents otherwise. Cross-linguistic variation in selection among phonetic cues for the definition of phonological classes is increasingly well established (Mielke 2008: 74–76; Samuels 2009: 70). On the application of this perspective to ambivalent glottal sonorance in particular see also Mielke (2009: 11–12).

In sum, the simplest solution of ambivalent glottal sonorance for the purpose of defining fricatives appears to be to retain the definition of fricatives as continuant obstruents, including glottal continuants in this class when they pattern with other obstruents and not otherwise. When glottal continuants are classed as fricatives on phonological grounds, an available phonetic correlate for [−sonorant] that is consistent with all members of the class is pressure buildup in the vocal tract. When glottal continuants are classed as sonorants on phonological grounds, Subsequent research has identified many additional phenomena consistent with the theory that voiceless fricatives are [+spread glottis] and voiced fricatives are [−spread glottis], but the above examples should suffice to make the point. Neither the traditional Hallean nor the Government Phonology representations of fricatives are able to account for facts of this type.

Beckman and Ringen (2009) and Nicolae and Nevins (2009) suggest a modification to the generalization proposed by Vaux (1998), namely that it holds only for languages where [spread glottis] is active; in languages where obstruents contrast for [voice] rather than [spread glottis], they say, voiceless fricatives are [−voice] (or unspecified for [voice] if it is privative). Both Beckman and Ringen and Nicolae and Nevins base their argument on the fact that in the [voice] languages they have examined phonetically (Finnish for Beckman and Ringen, Russian for both sets of authors), there is no devoicing of following sonorants by voiceless fricatives.

This suggestion (henceforth BRNN, after the surnames of the authors) is intriguing, but unfortunately relies on a single tenuous assumption, namely that if a language contrasts [spread glottis] in obstruents it must spread [spread glottis] from obstruents to following sonorants. The fact that two languages (Russian and Finnish) happen to conform to BRNN is hardly proof of its cross-linguistic validity. If BRNN is true, moreover, it makes an interesting prediction when taken in conjunction with the aforementioned finding that post-nasal voicing (PNV) avoids creating *[+nasal, +spread glottis] configurations (Vaux 1998): unlike in [spread glottis] languages such as New Julfa Armenian, where PNV does not target fricatives, it should freely target voiceless fricatives in languages possessing a [voice] rather than a [spread glottis] contrast in their obstruent system (i.e. systems like those of French, Japanese, or Modern Greek, which oppose unaspirated voiced and voiceless stops). This prediction is not borne out: though we know of one so-called [voice] language where PNV applies to fricatives (Nande; Hyman 2003), in all other cases known to us fricatives differ from stops in *not* undergoing PNV, exactly as we find in [spread glottis] languages and counter to the prediction of BRNN. In Modern Greek, for example, sequences of nasal consonant + voiceless fricative either delete the nasal (optional but preferred across word boundaries, as in /ton θe'o/ 'the god (ACC)' → [toθe'o]) or assimilate the nasal to the fricative in place of articulation, with no voicing (word-internally, as in /sin-xo'ro/ 'forgive' → [siŋxo'ro]) (Holton *et al.* 2004).

The BRNN typology has a phonetic dimension as well. Instead of showing that voiceless fricatives (or some of them) are [+spread glottis] only in languages where stops are [+spread glottis], their typology could be reinterpreted as showing that vocal fold abduction overshoots fricative release into a following sonorant consonant in languages where it also overshoots stop release into a following vowel. It is worth asking why we should use gestural overshoot from one segment into a neighboring segment as a diagnostic for that gesture's specification being phonological.

Van Oostendorp (2007) proposes a further modification for Dutch, wherein stops are opposed for [voice], but fricatives are opposed for [spread glottis]. This system is designed to account for the peculiar properties of voicing assimilation in Dutch, which seem to implicate length contrasts as well. If van Oostendorp's proposal is on the right track, we should be able to investigate whether Dutch voiceless fricatives trigger devoicing of following sonorants as a way to explore the BRNN theory further.

What emerges from the research documented in this subsection is that there is strong evidence for a distinction in [spread glottis] specifications between voiced and voiceless fricatives, at least in languages where [spread glottis] is phonologically active. This being the case, we cannot include [spread glottis] values in the set of invariant specifications for the class of fricative consonants.

3 Conclusions

We have argued that the apparently straightforward characterization of fricatives as [+continuant, −sonorant, +consonantal] and perhaps some value of [spread glottis] turns out on closer inspection to be problematic, but the simpler specification [+continuant, −sonorant] appears adequate if glottal continuants are allowed cross-linguistically variable and primarily phonologically determined membership in the fricative class. Fricatives are generally also [+consonantal], with some peripheral gray areas where the evidence is sparse (§2.3). Finally, it appears that voiceless but not voiced fricatives are generally [+spread glottis], at least in languages where the feature is contrastive, but on this point too the evidence is problematic.

29 Secondary and Double Articulation

Jeroen van de Weijer

This chapter deals with two categories of "complex segments," viz. consonants with secondary articulation, such as /kʷ/ or /lˠ/ (= /ɫ/ 'dark *l*'), and consonants that involve two articulations of equal status, such as /k͡p/. The main difference between these two types of sounds is that in the former there is a major ("consonantal") articulatory stricture on which a vowel-like minor articulation is superimposed, while in the latter the two articulations have a stricture type of equal status (typically, stop or nasal). While consonants with secondary articulation are very common in the languages of the world, consonants with double articulation are much rarer.

I will discuss these segment types in turn below: secondary articulation in §1 and double articulation in §2. I will focus on the phonological representation of both types of segments, as brought out by their function in phonemic inventories and their behavior in assimilation rules and syllable structure restrictions. Note, finally, that two other types of modifiication, which do not involve place of articulation but laryngeal setting, viz. aspiration and glottalization (or laryngealization), will not be covered in the present chapter (see CHAPTER 69: FINAL DEVOICING AND FINAL LARYNGEAL NEUTRALIZATION and CHAPTER 111: LARYNGEAL CONTRAST IN KOREAN for discussion). §3 offers a brief conclusion.

1 Secondary articulation

This section discusses segments with secondary articulation. After a short introduction to the phonetic phenomenon of co-articulation, which often gives rise to segments with secondary articulation historically, we will discuss and illustrate the four main types (labialization, velarization, palatalization, and pharyngealization). Then we turn to different ways in which such segments have been represented in the literature, starting from Chomsky and Halle (1968), through Clements and Hume (1995) and recent proposals in Dependency Phonology.

1.1 *Differentiating co-articulation and secondary articulation*

A common phonetic process is "co-articulation" (see e.g. Kühnert and Nolan 1999): the anticipatory shaping of the speech organs to accommodate sounds that will be articulated in the very near future. Co-articulation may also be perseverative, in which case it refers to the inertia of the speech organs after articulating certain sounds. For example, round vowels will typically impose their rounding on neighboring consonants, e.g. the /t/ and /n/ in a word like English *cartoon*, which has medial [t^w], while front vowels may impose a palatal quality on such consonants, as in *canteen*, with [t^j] (CHAPTER 71: PALATALIZATION; CHAPTER 75: CONSONANT–VOWEL PLACE FEATURE INTERACTIONS). We can refer to such processes as involving allophonic secondary articulation. Other types of secondary articulation are velarization ([$t^ɣ$]), which is similarly induced by back vowels, and pharyngealization ([$t^ʕ$]), which is associated with low vowels. If the secondary articulation on the consonant becomes independent of its triggering environment, its status may become phonemic (see Padgett 2003 for a description of this historical process in Russian; see also CHAPTER 121: SLAVIC PALATALIZATION). In this chapter we focus on phonemic types of secondary articulation. For instance, while the difference in velarization between clear *l* and dark *ł* is allophonic in English (which is, of course, determined not by vowel quality but (mostly) by syllabic position in this language, with clear *l* occurring in the onset and dark *ł* in the coda), in Marshallese, a Malayo-Polynesian language of the Marshall Islands, these two sounds are phonemic (Ladefoged and Maddieson 1996: 363); see also CHAPTER 31: LATERAL CONSONANTS.

(1) *Marshallese phonemic velarization contrast in laterals*

łał 'knock'
lał 'earth'

Note that in this language this particular type of secondary articulation occurs on a range of segments, viz. all the bilabials and all the coronals in the language (rather than just on the lateral illustrated in (1)), something which is quite common in languages (see Hinskens and van de Weijer 2003 for more examples and discussion). Other languages that have segments with phonemic secondary articulation are Russian (e.g. Kenstowicz 1994: 41; Padgett 2003) and Irish (Ní Chiosáin 1991, 1994, among others). In both languages, palatalized consonants contrast with velarized ones. Examples from Russian are given in (2):

(2) m^jat^j 'to rumble'
$m^ɣat^j$ 'mother'
$m^ɣat^ɣ$ 'checkmate'
$m^jat^ɣ$ 'rumpled'

Many dialects of Arabic have a contrast between plain and pharyngealized consonants, traditionally also referred to as "emphatic" consonants (see e.g. Watson 2002; CHAPTER 25: PHARYNGEALS). In Arabic these consonants vary between velarized and fully pharyngealized. Examples (taken from Sykes 2008) are given in (3):

(3) *Arabic minimal pairs*

pharyngealized		*plain*	
sˤafiːr	'whistle'	safir	'ambassador'
dˤam	'gloss'	dam	'blood'
tˤiːn	'mud'	tiːn	'fig'

The final common type of secondary articulation is labialization or rounding. This is especially common in dorsal (i.e. velar or uvular) consonants, although labial or coronal consonants may also be phonemically labialized. A language illustrating phonemic labialization is Kwakw'ala, a Wakashan language spoken on Vancouver Island (Grubb 1977; Ladefoged and Maddieson 1996):[1]

(4)

velar	*labialized velar*	*uvular*	*labialized uvular*
kasa	kʷesa	qesa	qʷesa
'beat soft'	'splashing'	'coiling'	'peeling'
gisgas	gʷesu	ɢaɢas	ɢʷalas
'incest'	'pig'	'grandparent'	'lizard'
xesa	xʷasa	χasa	χʷat'a
'lost'	a dance	'rotten'	'sparrow'
k'ata	kʷ'esa	q'asa	qʷ'asa
'writing'	'light (weight)'	'sea otter'	'crying'

The most common types of secondary articulation are thus labialization, velarization, palatalization, and pharyngealization. Since labialization does not involve the tongue body, it can be combined with other types of secondary articulation. Marshallese, for instance, is described as having, besides a range of velarized consonants, labio-velarized segments such as /nˠʷ/.[2] Labio-palatalization can appear as an allophonic variant of labialization in front vowel contexts (Ladefoged and Maddieson 1996: 356), and labio-dentalization has been described for Kom and Kuteb by Ladefoged (1968). Finally, Ladefoged and Maddieson mention sulcalization as a possible type of secondary articulation, involving deep grooving of the back of the tongue (Catford 1977). This occurs in English [s], but is not known to be a contrastive type of secondary articulation in any language.

Finally in this section, a note on terminology. The term "palatalization" can be used in at least two ways: (i) as a historical process in which coronal or velar consonants shift to palatal or palato-alveolar place of articulation under the influence of non-low front vowels, and (ii) as a synchronic or diachronic process in which consonants acquire a secondary palatal articulation (and sometimes also affrication). The latter type of change leads, or may lead, to a synchronic state in which some consonants have this type of secondary articulation. This is what is investigated here; see CHAPTER 71: PALATALIZATION for a description of the first type of palatalization (i.e. as a process), and CHAPTER 121: SLAVIC PALATALIZATION for an analysis of different palatalization rules in the Slavic languages.

[1] Ladefoged and Maddieson (1996) note that other sources report the plain velars and uvulars as palatalized.

[2] See for further discussion Hale (2000, 2007: ch. 5); Hale and Reiss (2008: ch. 6). The Marshallese pattern would appear to form a counterexample to Trubetzkoy's (1939) supposition that labialization and velarization never contrast on the same segment.

1.2 Phonological representation

This section deals with the question of how segments with secondary articulation should be represented in terms of features. First, we will investigate their representation in Chomsky and Halle (1968; *SPE*), from which we will move on to feature-geometrical approaches, and finally end with a discussion of secondary articulation in frameworks embracing the dependency relation.

1.2.1 *Preliminaries and* SPE

Pre-theoretically, segments with secondary articulation (usually consonants) would appear to involve some combination of a consonantal and a vocalic articulation. Recall that they are often formed as a result of phonetic co-articulation, involving some kind of "compression" of two segments into one: a front vowel may leave a "trace" on a neighboring consonant and, after the vowel disappears, secondary articulation remains. This suggests that they belong to a class of "complex segments," to which affricates (CHAPTER 16: AFFRICATES), prenasalized stops (CHAPTER 23: PARTIALLY NASAL SEGMENTS) and perhaps other segments, such as clicks (CHAPTER 18: THE REPRESENTATION OF CLICKS), also belong.[3] Such segments are usually analyzed as involving branching somewhere in their segmental representation:

(5) 

Although not all authors agree even on the existence of complex segments in phonological representations (cf. e.g. Kehrein 2002 for discussion), in the present section we will approach secondary articulation from a traditional segmental perspective, and discuss its representation in a number of theories.

Let us start with the representation of secondary articulation in *SPE*. Just like "syllable," the term "secondary articulation" does not appear in the subject index, although the topic is discussed in some detail (*SPE*: 305ff.). In *SPE*, the features [high], [low], and [back] play a dual role: for tongue body consonants (often referred to as dorsals) these features are used to distinguish between palatals, velars, uvulars, and pharyngeals, in the following manner (*SPE*: 305):

(6) *Dorsals in* SPE

	palatals	velars	uvulars	pharyngeals
high	+	+	−	−
low	−	−	−	+
back	−	+	+	+

All of the dorsal consonants are [−anterior]. Chomsky and Halle go on to investigate the role of the features [high], [low], and [back] for other classes of sounds (i.e. non-dorsals) and propose that they:

> may be used in a natural manner to characterize subsidiary consonantal articulations such as palatalization, velarization, and pharyngealization. These subsidiary

[3] And perhaps /s/ plus stop clusters, as a kind of "reversed affricates"; see van de Weijer (1996) and CHAPTER 38: THE REPRESENTATION OF SC CLUSTERS for discussion.

> articulations consist in the superimposition of vowel-like articulations on the basic consonantal articulation. In palatalization the superimposed subsidiary articulation is [i]-like; in velarization, [i]-like; and in pharyngealization, [a]-like. The most straightforward procedure is, therefore, to express these superimposed vowel-like articulations with the help of the features "high," "low," and "back," which are used to characterize the same articulations when they appear in the vowels. (*SPE*: 305–306)

A number of examples are given in (7) (from *SPE*: 307):

(7) *Secondary articulation in* SPE

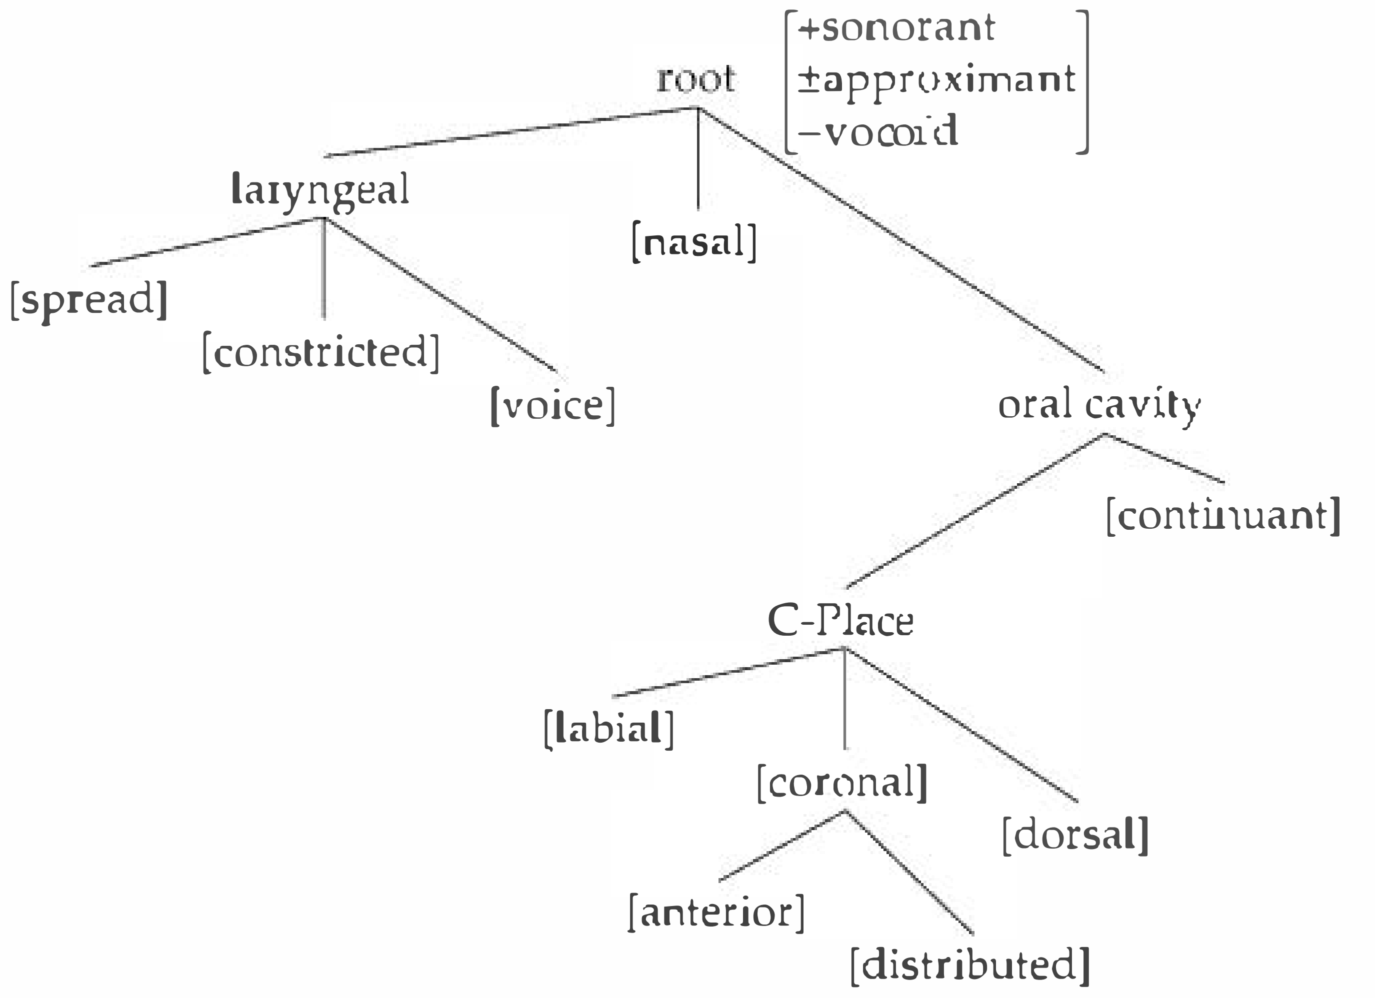
	anterior	coronal	high	low	back
palatalized labials	+	–	+	–	–
palatalized dentals	+	+	+	–	–
velarized labials	+	–	+	–	+
velarized dentals	+	+	+	–	+
velarized palato-alveolars	–	+	+	–	+
uvularized labials	+	–	–	–	+
pharyngealized dentals	+	+	–	+	+

Thus segments with secondary articulation are *not* analyzed as involving segmental branching in *SPE*: rather, the presence of certain vowel features with specific values will result in such segments. The rigidity of *SPE*'s feature matrix was criticized in Campbell (1974), who proposed a "complex symbol" representation for segments with secondary articulation (and for affricates). This and similar critiques led to the development of autosegmental phonology (Leben 1973; Goldsmith 1976; see also CHAPTER 14: AUTOSEGMENTS; CHAPTER 45: THE REPRESENTATION OF TONE), in which features could have scope over more than one segment, and in which opposite feature values could occur in the same segment (first illustrated for tonal features, and later extended to other features).

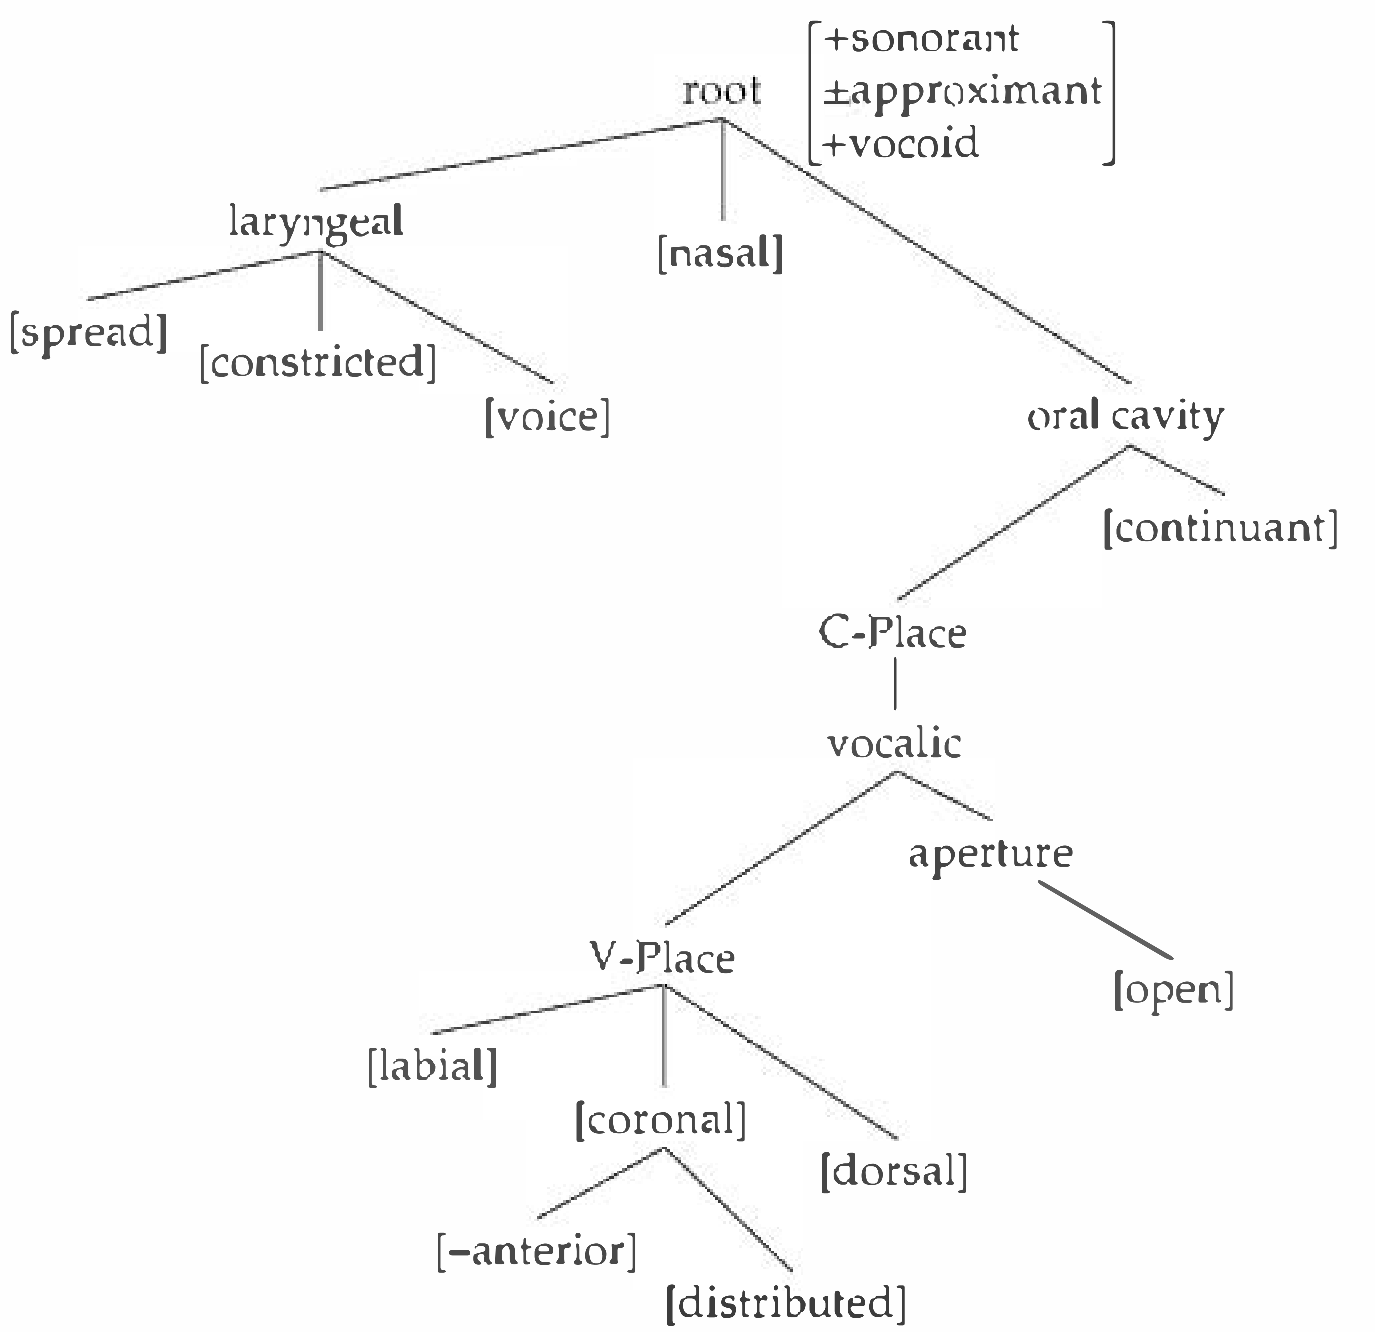
The representation of primary places of articulation and of secondary articulation in *SPE* raises obvious questions (CHAPTER 22: CONSONANTAL PLACE OF ARTICULATION). Velars are represented as [+back], i.e. non-anterior, non-coronal, consonants (*SPE*: 307).[4] Palatalized consonants are represented as [–back] consonants. At first sight, this would entail that palatalized velars are represented as [+back, –back], a combination of opposite values that is ruled out for other features as a simple articulatory impossibility. The same problem is pointed out by Campbell (1974), who argues that the problem is compounded by the impossibility, in *SPE*, of ruling out, for instance, a contrast between palatalized palatals and non-palatalized palatals without giving up the articulatory underpinning of the phonetic feature framework (cf. also McCarthy 1991: 82 in the context of the representation of guttural consonants). Campbell (1974) argues that such contrasts are found, e.g. in Livonian (which contrasts /ʃ/ and /ʃ^{j}/) and Mordvin, which contrasts /c/ and /c^{j}/.

[4] Note that the representation of velars as [+back] makes *prima facie* false predictions with respect to their behavior in vowel harmony: e.g. in a front–back harmony system all velars (plain or palatalized) would be predicted to act as blockers in a standard, autosegmental treatment of harmony. See below for the role of consonants with secondary articulation in vowel harmony processes.

(8) *Consonantal feature tree* (Clements and Hume 1995: 292)

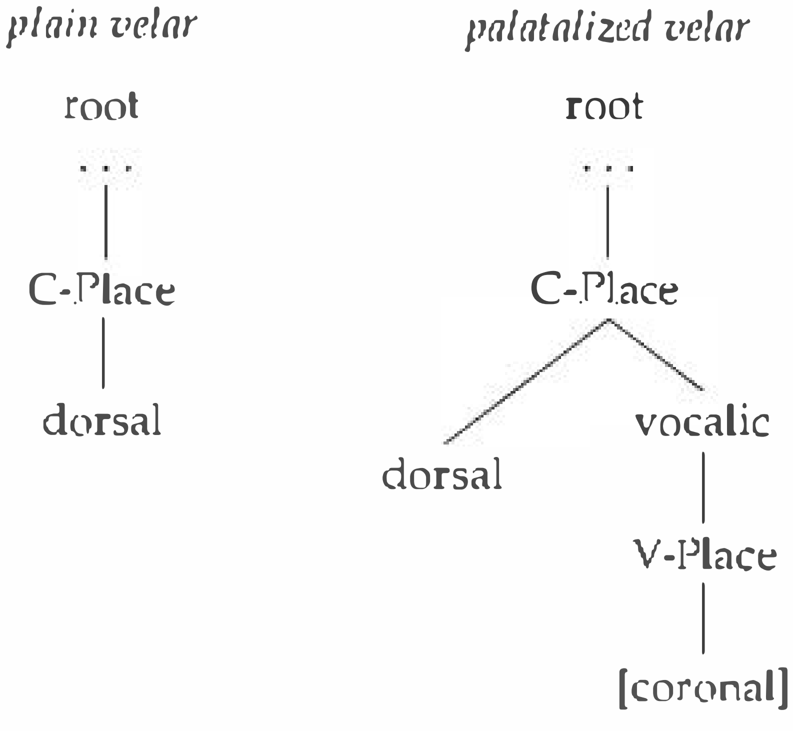


(9) *Vocoid feature tree* (Clements and Hume 1995: 292)



The representation of consonants with secondary articulation is an important point for Clements and Hume. In (10), I give the representation of a plain velar and a palatalized velar, on the basis of Clements and Hume (1995: 288):

(10) *Secondary articulation*



As (10) shows, consonants with secondary articulation are represented as branching structures (cf. (5) above): one part is labeled as relatively consonant-like and the other part as relatively vowel-like: the highest place node receives the interpretation of the major class features (C-Place in (10)). This gives us a welcome perspective on possible types of secondary articulation, because the set of features below the V-Place node is predicted to correspond to possible types of secondary articulation. This prediction is borne out: the presence of the features [labial], [coronal], and [dorsal] in such structures corresponds straightforwardly to labialization, palatalization, and velarization, respectively. Clements and Hume (1995: 287) note that the fourth common type of secondary articulation, that of pharyngealization (cf. (3) above), can be expressed by a feature [pharyngeal], which is not included in the tree model in (9): they discuss its arboreal affiliation (1995: 273ff.), and remain uncommitted as to its final locus (cf. also Hayward and Hayward 1989 and McCarthy 1991 on the feature [guttural] and the representation of this class of segments). Other, less common, types of secondary articulation may be captured by combinations of features under a V-Place node (such as concomitant labialization and velarization) or by the supplementary use of features below the aperture node (which regulates vowel height by way of $[open]_x$ features (which represent degree of openness in their model) in the absence of features like [high] and [low]), such as uvularization.

This model expresses in a straightforward way the phenomenon that co-articulation of a consonant and vowel in time may lead to phonemic secondary articulation: in such a case the vocalic place features will have become permanently part of the consonant in question. It also accounts directly for the role of consonants with secondary articulation in vowel harmony processes: for instance, consonants which are palatalized will introduce a [−back] feature on the harmony process, while velarized consonants will favor back vowels (see e.g. Clements and Sezer 1982 for a discussion of Turkish, and van der Hulst and van de Weijer 1995 for general discussion of this point). This is expressed by the fact that the vocalic features on a consonant with secondary palatalization will be on the same autosegmental tier as the vocalic features of vowels, and therefore predicted to interact directly.

Some further remarks can be made with respect to the representation of consonants with secondary articulation, which we will briefly discuss in turn. First, note that (8) and (9) present *two* distinct feature trees, with partly disjunctive feature sets, rather than one segmental tree for all segments. This has a number of formal consequences that we will not go into here (but cf. Casali 1995; CHAPTER 75: CONSONANT–VOWEL PLACE FEATURE INTERACTIONS). Although the proposal nicely captures the interaction between consonants with secondary articulation with vowels in vowel harmony, it does not technically predict interaction between e.g. primary labials and round vowels. Moreover, some stipulation may be needed as to the level(s) at which branching may or may not take place.

Secondly, as has been pointed out before in the literature (e.g. van der Hulst and van de Weijer 1995), the C-Place node in vowels seems to have only a diacritic function, in that it prevents consonant-to-consonant place spreading, while permitting vowel-to-vowel assimilation (as in vowel harmony, which spreads from truly adjacent vocalic node to vocalic node). The C-Place node in vowels is therefore the price that is paid for capturing the vowel harmony effect described above.

Finally, consider the fact that the two parts of a consonant with secondary articulation, i.e. the consonantal part and the vocalic part, seem to have an unequal status: the segment as a whole acts as a consonant in terms of its function in syllable structure and must be specified as such by way of major class features or otherwise. An alternative way of specifying the "inequality" of the two parts is explored below.

To conclude this subsection, feature-geometrical approaches are much better equipped than earlier theories to capture complexity in segmental representation in general, and of consonants with secondary articulation in particular.

1.2.3 *Dependency Phonology*

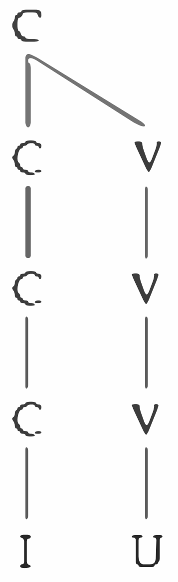
Central to frameworks such as Dependency and Government Phonology (see references below) is the insight that most or perhaps all linguistic structure is headed: syntactic phrases consist of specifiers, complements and heads, morphological constructions are (often) right-headed (cf. Williams 1981), a nucleus is obligatory in the syllable and there is a strong–weak relation between syllables in a foot. Headship is manifested in different ways (e.g. obligatoriness, phonetic prominence). It is only natural to extend this approach to intrasegmental structure, especially in the context of segments that appear to consist of two parts (relatively unequal in terms of degree of stricture in the case of segments with secondary articulation, relatively equal in the case of segments with double articulation; see §2).

In dependency- and government-inspired approaches (see Anderson and Ewen 1987; Harris 1990; Smith 2000; and many others), secondary articulation consists of the adjunction of a dependent Place feature onto an otherwise well-formed consonantal tree structure. This brings out the "secondary" nature of the secondary articulation rather well: the head of the structure is the consonant, so that this articulation will be primary in the traditional sense. An example from Smith (2000: 258) is given in (11):

(11) *Secondary articulation* (Smith 2000)

labialized coronal

/t^w/



In this display, the C components, dominating the place element I (= coronal), form the head of the segment and the V components, dominating U (= labial), form the dependent, in this case a vowel-like superimposition of rounding. The part on the left is a prototypical consonant, i.e. a voiceless stop (a sonorant, a fricative, or a voiced segment would have one or more Vs in its structure), and the part on the right is a prototypical vowel (a glide would again be an intermediate category, with one or more Cs in its structure). Such representations of major class have also been explored in the context of lenition processes, for instance (see e.g. Anderson and Ewen 1987; also CHAPTER 66: LENITION).

The main difference between feature-geometrical models and dependency representations like that in (11) lies in the use of the dependency relation itself. Besides being independently motivated – as pointed out above, headship plays an important role in many realms of linguistics – there are four clear advantages of putting this relation to use, which the feature-based approach lacks: first, it is immediately clear which articulation is primary and which is secondary: since the C branch is the head, the segment as a whole is a consonant – no stipulations of interpretation are necessary. A second advantage of making use of the dependency relation is that constraints are expected to hold on the dependent, where fewer contrasts are expected to hold than in heads (Dresher and van der Hulst 1998) (cf. the lack of frequency of vowel contrasts in weak position of a foot compared to that in stressed positions (CHAPTER 40: THE FOOT), or the fewer tonal contrasts in the same context; Yip 1999). A possible natural condition on dependent branches, for instance, is that they cannot be segmentally complex: this would express the fact that phonetically simple types of secondary articulation such as labialization, palatalization, and velarization are common and that combined secondary articulation types such as labio-velarization are very rare (cf. above), or might be phonologically derived. Finally, the head–dependent relation is binary. This means that a primary articulation can only be combined with one secondary articulation in a segment, while in the feature-geometrical model there is a priori no reason why a single C-Place node could not be combined with two or more V-Place nodes, each potentially dominating multiple features.

On the other hand, it is unclear if, or to what extent, representations like (11) can be interpreted autosegmentally, i.e. whether the different levels on which Cs and Vs appear are different, independent autosegmental tiers. If they are not, this framework loses some predictive power compared to feature-geometry approaches, for instance in the analysis of the behavior of consonants with secondary articulation in vowel harmony (cf. Ewen 1995). It remains a goal to combine both approaches into a single overarching theory.

1.3 *Conclusion*

In this section we have discussed the representation of segments with secondary articulation. After a discussion of such segments in traditional feature theory, we have seen that feature geometry models or dependency models, or a combination of these, have shed further light on the phonological behavior of such segments, with respect to both their occurrence across languages, and their behavior diachronically and synchronically. With these insights, let us turn to segments that combine two articulations of equal stricture, double articulations.

2 Doubly articulated segments

While in segments with secondary articulation the vowel-like superimposed articulation is really "secondary," that is, of lesser structure than the primary articulation, there is another class of consonants which involve articulation types of equal structure. This is the topic of the present section. We will discuss their occurrence in the languages of the world and their representation in modern feature theories.

2.1 *Labial-velars and other double articulations*

Double articulations which involve articulation types of equal stricture could, in principle, involve two stops, two fricatives, two nasals, or two other types of articulations. In practice, however, producing two fricatives at different places of articulation is very difficult (CHAPTER 28: THE REPRESENTATION OF FRICATIVES), and this option is not systematically employed by any known language.[6] Only a stop articulation (whether oral or nasal) seems to be robust enough to allow for execution at two different places at the same time. As regards place of articulation, labial-velar stops are relatively common, and most of this section will be concerned with these segments. Other double articulations are labial-coronals, which have only been demonstrated beyond doubt for Yeletnye (Papua New Guinea). Examples from Ladefoged and Maddieson (1996: 344) are given in (12):

(12) *Labial-coronals and labial-velars in Yeletnye*

labial-alveolar		*labial-postalveolar*		*labial-velar*	
t͡pənə	'lung'	t̠͡pənə	'horn'	k͡pene	'coconut bag'
n͡mdboo	'pulp'	n̠͡md̠boo	'many'	ŋ͡mgbo	'fog'
n͡mo	'bird'	n̠͡mo	'we'	ŋ͡mo	'breast'

[6] Cf. Ladefoged and Maddieson (1996: 329–330), who also discuss the well-known case of Swedish /ɧ/, which has been suggested to contain two simultaneous fricatives, but is probably better analyzed as a segment with secondary articulation; cf. Lindblad (1980); Ladefoged and Maddieson (1996: 171f.).

The fact that labial-coronals and labial-velars (see below) have been reported raises the question of whether coronal-velars might also exist. Ladefoged and Maddieson (1996: 345) are not aware of any language with segments that would fit this description, so that in effect all double articulations involve the labial articulator.[7]

The most typical examples of doubly articulated stops are the labial-velar stops /k͡p/ and /g͡b/, which are especially common in west African and northern central African languages (Ladefoged and Maddieson 1996: 333), and are also relatively common at the eastern end of New Guinea. Note that labial-velars may contrast with clusters of labial followed by velar, as in the following examples from Eggon, a Benue-Congo language spoken in Nigeria (Ladefoged and Maddieson 1996: 334):

(13) *Labials, velars, labial-velars, and clusters in Eggon*

single segments		*clusters*	
pom	'pound (VB)'	kba	'dig'
abu	'dog'	g͡bga	'grind'
aku	'room'	akpki	'stomach'
gom	'break'	bga	'beat, kill'
k͡pu	'die'	kpu	'kneel'
g͡bu	'arrive'	gba	'divide'

There are clear phonetic differences between the clusters and the individual stops, and individual consonants in the clusters may be affected by a lenition process (Maddieson 1981; Ladefoged and Maddieson 1996: 334).

Nasals preceding labial-velar stops are also typically labial-velar, i.e. they usually assimilate to both places of articulation. Note that in a number of cases the nasal only appears to assimilate to the dorsal place of articulation in the labial-velar (never, apparently, to the labial articulation alone, according to Cahill 1995). This is the situation reported for Kpelle (Kreidler 2001) and Gã (Padgett 2004: 387 and references cited there): in the latter language, assimilation of nasals to labial-velars within a morpheme is total (resulting in labial-velar nasals), while across morpheme boundaries only the velar place of articulation assimilates. Padgett takes this as evidence against class nodes (cf. also Padgett 2002). Although the proposal to abolish class nodes would in itself form a welcome restriction on the representational limits of the theory, it could also be construed as evidence in favor of class nodes: in the former process the whole class node spreads, and in the latter only the feature (as argued by Halle 1995). We will not pursue this here.

An interesting case of a potentially labial-velar segment that is much more common is that of the labial-velar median approximant [w], which occurs in English and in many other languages, while a labial-palatal glide [ɥ] is reported in languages such as French and Mandarin Chinese (CHAPTER 15: GLIDES). Note that there are very few languages that contrast a non-velarized labial approximant [β̞] with

[7] One type of articulation that could be considered as coronal-velar are clicks, which involve a coronal (or labial) articulation combined with a velar closure. Since clicks involve a non-pulmonic airstream mechanism, they will not be considered here (see CHAPTER 18: THE REPRESENTATION OF CLICKS for discussion). Another possibility is that simultaneous coronal and dorsal articulation might give rise to an articulation at a place in between these two primary places, such as palatal, retroflex, or palato-alveolar. See e.g. Keating (1988) for discussion from a phonetic perspective.

[w], or a non-labialized velar glide [ɰ] with [w] (see Maddieson 1984 for a handful of such cases). In most cases, [w] can be analyzed as underlyingly just labial with velarization added as a phonetic enhancement effect. That labial is primary in English [w] is borne out, for instance, by the fact that coronal nasals can become labial before [w] (e.g. [m] in *sandwich*; see Wells 2008) and phonotactic restrictions against initial *[bw], *[pw], *[fw] (cf. Kenstowicz 1994: 541 for similar reasoning).

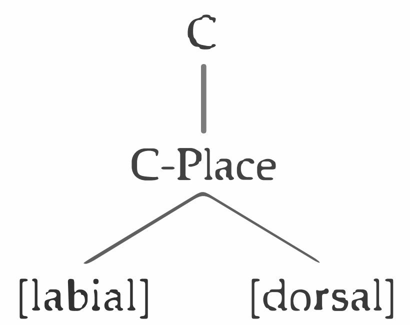
2.2 *The representation of segments with double articulation*

In this section we will briefly discuss a number of approaches to the representation of segments with double articulation, again starting with *SPE* and ending with dependency theories.

The representation of doubly articulated consonants is regarded as equivalent to secondary articulation in *SPE*, leaving the degree of rounding to phonetic implementation or perhaps contextual determining (*SPE*: 310). The implication is that there is no representational difference between consonants with a moderate degree of lip rounding, such as [k^w] and [g^w], and consonants with complete closure at the lips, such as [k͡p] and [g͡b]. This implication is clearly incorrect, however, since there are a number of languages that contrast labialized velars with labial-velars: such as Efik (Cook 1985) and Kpelle (Welmers 1962; Hyman 1973; Maddieson 1984). The inadequacy of the *SPE* proposal was also pointed out by Campbell (1974).

Thus the later feature-geometrical models and dependency-inspired proposals also improve on *SPE* in this respect, proposing that, instead of a vowel-like superimposition, two consonants of equal stricture are imposed on each other in cases like these. In Clements and Hume's model, this would entail representations like the following (cf. Clements and Hume 1995: 253):

(14) *Labial-velars*



The labial-palatals of Yeletnye would be represented with [coronal] and [dorsal] articulator nodes.[8]

Much as with secondary articulation, the question can be raised whether the two parts of the articulation have equal status in a doubly articulated segment. Is the representation in (14) primarily a labial or primarily a dorsal, or are both articulations truly on an equal footing? Recall that a nasal before a labial-velar sometimes assimilates to both parts, but sometimes only to the dorsal part,

[8] Note that if palatals are complex segments (cf. fn. 7), coronal-dorsals and palatals would have to have distinct representations.

30 The Representation of Rhotics

Richard Wiese

1 Introductory definition and overview

Rho is the name of the Greek letter <ρ>, corresponding to the Latin letter <r>. Rhotics, a loanword from Latin *rhotica*, are thus r-like sounds. The use of the classificatory term *rhotic* from the beginning of Latin grammar to present-day linguistics implies the existence of a class of such sounds. However, the fact that this class is named by referring to a particular letter of the alphabet is telling, as will be discussed below. Languages or dialects displaying some variant of the phoneme /r/ in contexts where other closely related languages or dialects do not show this sound (such as syllable-final position in Irish English in comparison to Standard British English) are also sometimes called rhotic languages or dialects, as opposed to non-rhotic ones.

This chapter will discuss rhotic sounds, their justification as a natural class in phonology, and related phenomena, first by introducing the class of rhotic sounds, largely by discussing their distribution in the languages of the world, and by discussing the justification for the term "rhotic", outlining cases in which rhotics clearly seem to work as a class in phonological patterning (§2), in spite of the high degree of variability. The chapter will then proceed to discuss possible definitions of the class of rhotics in articulatory or acoustic terms (§3). Such definitions will turn out to be rather unsatisfactory, and possible alternatives will be introduced in §4. Finally, the use of the related terms "rhotacism" and "liquid" will be exemplified briefly in §5. One important general context of the discussion of rhotics is the nature of the relationship between phonetics and phonology. This issue will be taken up in the final discussion.

2 The class of rhotics

There is an extensional definition of the class of rhotic sounds which simply enumerates them by identifying those sounds which are denoted in the IPA system of sound identification by some letter shape related to <r> or its capital counterpart <R>. This is actually the most common method of defining rhotics extensionally; see Ladefoged and Maddieson (1996: 216). In the most recent version of the IPA chart of phonetic symbols,[1] the symbols listed in (1) fulfill this criterion, and could conveniently be called "rhotics." The IPA tables, in addition, recognize a secondary quality of rhoticity for vowels, and give [ɚ], and the small hook, as for [ɑ˞ e˞], as examples.

(1) *Rhotics according to the use of r-like symbols in the classification of the IPA*

	Alveolar	Retroflex	Uvular
Trill	r		ʀ
Tap or flap	ɾ	ɽ	
Fricative			ʁ
Approximant	ɹ	ɻ	
Lateral flap	ɺ		

Empty cells in (1) are those for which the notational system of the IPA provides no straightforward, i.e. simple, symbol. However, most if not all sounds missing in the classification (of place and manner) present in this table actually exist, even if they are rare. For example, the uvular approximant rhotic, which is not recognized by the IPA system of notation as given in (1), is part of the inventory of Standard German and Danish. A possible notation for this sound is [ʁ̞], combining the symbol for the voiced fricative with the diacritic for lowering; another notation in common use is the haček (ˇ). Another rhotic mentioned occasionally is the retroflex trill [r̢] (Hall 1997: 105–106; Whitley 2003: 82), as in the Dravidian language Toda. Whitley in fact presents examples of rhotics for all of the empty cells in (1), except for the lateral flap row. Furthermore, he argues that alveolar, retroflex, and uvular voiced fricatives are rhotics when they are non-sibilant. The feature sibilant then allows for a distinction between sibilant fricatives [z ʒ ʐ] and non-sibilant (rhotic) fricatives [ř ɽ̌ ʁ̌].[2] The alveolar trills and taps/flaps may also be fronted, i.e. dental, symbolized [r̪ ɾ̪].

There is surprisingly little disagreement on calling the sounds symbolized in (1), as well as the additional types mentioned here, rhotics. According to this list of rhotic sounds and its concomitant classification, rhotics may be characterized by an alveolar, retroflex, or uvular place of articulation, and by one of five manners of articulation (trill, tap/flap, fricative, approximant, lateral flap). However, this classification in terms of articulatory categories does not lead to any uniform definition of the class of rhotics.

As a result, there is no principled way of excluding other potential sounds. For example, while the alveolar and uvular trills ([r ʀ]) are always included in this class, it is unclear why the bilabial trill [ʙ] is not. The same problem holds for the taps/flaps: if alveolar [ɾ] and retroflex [ɽ] are rhotics, why is the labio-dental flap not a rhotic? These sounds just mentioned are rare (just like some of the rhotics referred to above), but this cannot count as evidence. There is generally no obvious reason why the category of rhotics should be restricted to the coronal (alveolar/postalveolar) and dorsal (velar/uvular) places of articulation, to the exclusion of others. We also note that all sounds given in (1) are meant to be voiced, but

[1] The standard source for this chart is the *Handbook of the International Phonetic Association* (IPA 2007). Whitley's table 1 (2003: 82) has the same set of rhotics as those in (1).

[2] As there is no standard (i.e. IPA) symbol for rhotic fricatives, I will use the ones introduced here (recommended by Whitley 2003).

voicelessness may occur for rhotics and can of course always be symbolized by adding the diacritic [̥]. The one feature which all the sounds in (1) have in common is that they are consonants, but, as noted, rhotic/rhotacized vowels exist as well.

(1) therefore immediately gives rise to a number of questions, such as these: Is there anything special about these sounds, and is there any possible feature or feature combination shared by these sounds? Is this list of candidate rhotics complete? Why should only the particular combinations of place and manner in (1) be called rhotics? Is the use of sound symbols represented by a version of the letter <r> arbitrary or not? Do rhotics, under whatever definition, behave as a class of their own with respect to phonological patterning?

The reader must be warned that there are at best provisional answers to all of the questions raised here. We will attempt to offer such answers by examining the distribution of rhotics in the languages of the world (§2.1), discussing the unified phonological behavior of rhotics as a class (§2.2), and looking at rhotics with respect to their dialectal variation (§2.3). Featural descriptions that attempt to express the unity of rhotics are discussed in §3.

2.1 *Rhotics in the languages of the world*

A first approach to rhotics would be to investigate their frequency and distribution in the languages of the world. The work by Maddieson (1984) provides the basic information on the distribution of r-sounds in the languages of the world.[3] This database, containing 316 languages, reveals the figures shown in Table 30.1 on the distribution of rhotics.

According to this count, the majority of languages have rhotic phonemes. Languages for which no rhotic phoneme has been reported often show some rhotic either as an allophone of some other phoneme or in a peripheral area. Matumbi, for example, has no rhotic phoneme in the "core" vocabulary but allows /r/ in loanwords, according to Odden (2006: 199). In the typical case, a language has exactly one r-phoneme, and it is very rare for a language to have more than two rhotic phonemes. Well-known languages with two r-phonemes are Spanish (Harris 1969; Lipski 1990) and Catalan (Padgett 2003; Wheeler 2005: 24–34). In both languages, one r-sound is usually a flap, and the other a trill. In these languages, the two rhotics are in contrast in the position between vowels only, as illustrated in (2), while in all other positions the two r-phonemes are in complementary distribution.[4]

Table 30.1 Distribution of rhotic phonemes (Maddieson 1984: 83)

	Number of rhotic phonemes									
	0		1		2		3		4	
Languages in sample	74	23.3%	183	57.7%	51	16.1%	8	2.5%	1	0.3%

[3] Unfortunately, Haspelmath *et al.* (2005) contains no information on rhotic sounds.

[4] In classical generative phonology, the two underlying r-phonemes are often analyzed as a singleton /r/ and a geminate /rr/. Harris (1969: 50ff.) argues for this proposal from the phonotactic behavior of the two phonemes.

(2) *Two rhotic phonemes in partial contrast*

a. *Spanish* (Harris 1969: 46)

pero	['peɾo]	'but'	*perro*	['pero]	'dog'
torero	[to'ɾeɾo]	'torero'	*torrero*	[to'reɾo]	'lighthouse keeper'

b. *Catalan* (Padgett 2003: 2)

['miɾə]	'(s/he) looks at'	['mir:ə]	'myrrh'
['paɾə]	'father'	['par:ə]	'grapevine'

One of the languages reported to contain three rhotic phonemes is the Australian language Warlpiri. According to Jagst (1975) and Nash (1980: 66ff.), Warlpiri has two rhotic flaps, alveolar /ɾ/ and retroflex /ɽ/, and an approximant /ɹ/. Jagst (1975: 27) calls the two (alveolar and retroflex) flaps "vibrants," but in fact seems to interpret them as flaps/taps. He also analyzes further allophones, namely a trilled [r] for the flap /ɾ/, and a glide [ɻ̥] for the approximant /ɹ/. A similar situation, with three rhotic phonemes, can be diagnosed for other Australian languages, e.g. Maung, Arabana-Wanganura, and Kariera-Ngarluma, and a few other languages, such as Sedang (Austro-Asiatic).

Languages with more than three rhotic phonemes are exceedingly rare, if they exist at all. The one example in Maddieson's database is Irish Gaelic, for which a re-analysis in terms of two rhotic phonemes seems plausible (see Bammesberger 1982 and Ní Chiosáin 1994 for different proposals for such a re-analysis). In summary, there does not seem to exist clear evidence for a language with more than three rhotic phonemes (a point also made by Hall 1997: 109), and most of the languages with three such phonemes are located in Australia.

As a final point on the distribution of rhotic sounds, note that the alveolar trill [r] is the most common rhotic, taking up 47.5 percent of all rhotic phonemes, according to the database of Maddieson (1984: 79). In the more comprehensive *UCLA Phonological Segment Inventory Database*,[5] containing phonemic data from 451 languages, around 40 percent of all languages have a dental and/or alveolar voiced trill, and 20 percent of the languages display a voiced alveolar flap. Only four languages show a uvular trill, namely Batak, French, German, and Moghol.

The predominance of dental-alveolar trills remains something of a puzzle, given the effort and precise fine-tuning needed for the articulation of the alveolar trill. As noted by a number of phoneticians (e.g. Barry 1997; Schiller 1999; Catford 2001), trilled rhotic [r] requires a highly developed skill of articulatory control and execution. These authors tend to see other rhotics as underachieved or somewhat defective alveolar trills. The statistical dominance, and in fact prototypical status, of the alveolar trill among the rhotics is in striking contrast to the considerable difficulties it seems to raise for articulation.

Further facts on the distribution of rhotics within the overall set are conveniently summarized by Maddieson (1984: 82), on the basis of his database of 316 languages:

[5] Available (May 2010) at http://web.phonetik.uni-frankfurt.de/upsid.html.

(3) *Quantitative generalizations for rhotics* (Maddieson 1984: 82)

a.	An r-sound is likely to be voiced.	308/316	97.5%
b.	An r-sound is likely to be dental or alveolar.	273/316	86.4%
c.	An r-sound is likely to be interrupted.	244/282[6]	86.5%
d.	A retroflex r-sound is likely to be a continuant.	20/38	52.6%
e.	An approximant r-sound is likely to be retroflex.	15/28	53.6%
f.	A fricative r-sound is likely to be retroflex.	5/10	50.0%

Overall, these results give a good impression of the prototypical rhotic. However, the frequency of all other rhotics is sufficiently large to warrant their inclusion in the class of rhotics. None of the rhotics mentioned so far is unlikely to exist. The question of whether the class of rhotics can be restricted to the lingual sounds (from dental to uvular) tabulated in (1) across the different manners must remain open. Sociolinguistic studies of British English (Foulkes and Docherty 2000) have pointed to a widespread use of a labio-dental type of rhotic among younger speakers of English (especially in the South and East of England) characterized by the use of forms such as *red* [ʋɛːd]. Given that there is no definition for rhotics beyond the enumeration of its members, it cannot be ruled out that this constitutes a sound change leading from a rhotic to a non-rhotic segment.

2.2 *The unity of rhotics*

We saw above in (2) that in Spanish and Catalan there are two rhotic phonemes. The fact that the contrast between these two r-phonemes is suspended in all contexts other than intervocalic provides further evidence for the class: the neutralized phoneme is one or the other of these rhotics (see also CHAPTER 11: THE PHONEME; CHAPTER 2: CONTRAST). This is just one example of a general tendency: the common r-phoneme in a language is subject to allophonic variation, and the allophones are often from the class called rhotics.

Most of the evidence for rhotics constituting a distinct class in phonology comes from the areas of language variation and change. The status of rhotics as a phonological class is discussed by Lindau (1985), Hall (1997: chapter 4), and Walsh Dickey (1997: 90–101), who present the following types of evidence for the role of rhotics as a systematic class in phonological patterning:

(4) a. the influence of rhotics on neighboring vowels
b. the phonotactic unity of rhotics
c. their place in syllabic structure
d. the allophonic variation of rhotics
e. the phonemic alternations of rhotics.

(a) Rhotics, of all the types discussed above, tend to interact more closely with neighboring vowels than do other vowel-adjacent consonants (see CHAPTER 75: CONSONANT–VOWEL PLACE FEATURE INTERACTIONS). English provides one relevant

[6] The overall number of r-sounds is smaller here, because the sources do not always report the manner of articulation (Maddieson 1984: 78). More generally, underspecified information on r-sounds may have led to a predominance of prototypical r-sounds in the database, i.e. of alveolar trills.

example: before (actual or historical) /r/, only a limited set of vowel phonemes may appear. In Standard British English, for example, only lax vowels /ɪ ɛ ɑ u ɔ/ appear in pre-r position (e.g. *here, care, car, sure, more*), while all other vowels are neutralized to /ɜ/ (which may reflect a merger with historical /r/), as in *bird, word, heard.* The general tendency of rhotics not to undergo palatalization, as discussed by Walsh Dickey (1997) and Hall (2000), provides another example of (negative) rhotic–vowel interaction.

(b) As discussed by Walsh Dickey (1997: 91–92), rhotics in Australian languages are often prohibited from occurring in word-initial position (see CHAPTER 86: MORPHEME STRUCTURE CONSTRAINTS). One such language is Mullukmulluk, in which the two rhotic phonemes /ɾ/ and /r/ can appear in any position except word-initially (Birk 1975: 61). Given that Australian languages typically allow for two or three rhotic phonemes, this constraint focuses on rhotics as a class, and not on a single phoneme which happens to be a rhotic. There are other more detailed constraints on the placement of rhotics: for Warlpiri, Nash (1980: 76) notes that in a CVC sequence (with heterosyllabic Cs), the two consonants cannot be identical rhotic phonemes (i.e. two tokens from one of the phonemes /ɾ ɽ ɹ/). This constraint seems to have exceptions, but it still captures a pattern significant in its exclusive reference to the class of rhotics.

(c) For languages that allow clusters of more than one consonant to appear in onset and/or coda position, rhotics are typically assigned to the position immediately adjacent to the vowel of the respective syllable. That is, a template of the type CrVrC describes the phonotactic placement of rhotics rather well, with C standing for one or more consonants other than /r/. (8) below exemplifies such a patterning from German, but many languages with complex syllable constituents behave analogously (CHAPTER 49: SONORITY).

(d) In many languages, there is a great deal of allophonic variation for the usual single r-phoneme, with the allophones standing either in free variation or in complementary distribution. But the large number of these allophones are all drawn from the inventory of rhotic sounds. The Persian language (Farsi) provides an instructive example: the phoneme /r/ has trilled [r] as its main allophone according to Majidi (1986: 63–64, 2000: 41–43), but has three to four additional rhotic allophones in complementary distribution, as shown in (5). The phoneme /r/ in Persian does not have non-rhotic allophones.

(5) *Distribution of rhotics in Persian* (Majidi 1986: 63–64)

a. *flap* [ɾ] *intervocalically*
   /tare/ ta'[ɾ]e 'chive'
b. *voiced fricative* [ɹ̆] *in word-initial position*
   /ruz/ '[ɹ̆]uz 'day'
c. *partially or completely devoiced trills* [r̥] *adjacent to voiceless consonants and word-finally*[7]
   /babr/ 'bab[r̥] 'tiger'
   /xɒrkan/ xɒ[r̥]'kan 'collector of blackthorn'
d. *voiced trill* [r] *elsewhere*
   /arzɒn/ a[r]'zɒn 'cheap'

[7] Majidi (1986: 64) sees a tendency to distinguish the devoiced trills in terms of either partial or complete lack of voicing.

These counts demonstrate that, from one generation of dialect speakers to the next, up to 60 percent of rhotics are changed in their phonetic realization. What remains is a single rhotic phoneme in the respective word.

(6) *Intergenerational changes*

a. *Berg* 'mountain'

change in type of /r/	194/327 ≃ 60%
no change	133/327 ≃ 40%

b. *Rose* 'rose'

change in type of /r/	93/296 ≈ 31%
no change	203/296 ≈ 69%

c. *fahren* 'go, drive'

change in type of /r/	106/313 ≈ 34%
no change	207/313 ≃ 66%

Word-initial or syllable-initial rhotics change in about a third of the tokens, while rhotics in the coda, as in the lemma *Berg*, showed a large number of r-realizations for both generations of speakers. Furthermore, the most r-realizations changed across the generations. There is no reason to think that this phenomenon is restricted to this particular dialect. An even more striking case of such a change in rhotic realization is reported by Enderlin (1911: 168). In his study of the Alemannic (Swiss German) dialect of Kesswil, he notes that at the local school all 1st grade students had uvular [ʀ], while all 9th grade students had alveolar [r]. He also reports a 50 percent realization of both forms for 4th and 5th grade students.

In general, postvocalic, rhymal rhotics seem to be subject to more variation than rhotics in onset positions. In Table 30.2, these changes are classified according to the type of change found in the same dialect map, that for *Berg* 'mountain' in Bellmann *et al.* (1999: 463). The r-sounds listed next to "older generation" are those found for the older speakers; while the first row lists rhotics found for the younger generation. The check marks denote intergenerational changes for particular pairs of rhotics (i.e. in some particular location as selected in the dialect atlas) through the comparison of the two maps.

Table 30.2 r-conversions found for one lemma (*Berg* 'mountain')

		Younger generation						
		ɾ	ʀ	ʀ̥	ɹ	ə	ɐ	Ø
Older generation	ɾ	✓	✓	✓	–	✓	–	✓
	ʀ	✓	✓	✓	–	✓	–	✓
	ʀ̥	–	–	–	–	–	–	–
	ɹ	–	–	–	✓	✓	–	–
	ə	–	✓	✓	–	✓	–	✓
	ɐ	–	–	–	–	✓	–	–
	Ø	✓	–	–	–	✓	–	✓

all the subclasses. Similarly, Kohler concludes that a positive characterization of the phoneme /r/ in German, encompassing all its allophonic variations, is not possible, even for a single speaker: "only a negative characterization is possible" (Kohler 1995: 156).

Ladefoged and Maddieson (1996: 245) summarize on an even more pessimistic note:

> Although there are several well-defined subsets of sounds (trills, flaps, etc.) that are included in the rhotic class, the overall unity of the group seems to rest mostly on the historical connections between these subgroups, and on the choice of the letter "r" to represent them all.

This conclusion would deny the existence of rhotics as a phonetically defined class, and is rather pessimistic on the possibility of providing any coherent descriptions in phonetic terms. It falls back on the conventions of alphabetic writing, while these are themselves obviously in need of explanation. Conceivably, the spelling of some (class of) sounds by means of the letter <r> exerts some influence on the paths of historical change of these sounds. But to assume that this spelling has a pervasive cross-linguistic influence and thereby constitutes the sole basis of the development of a class of rhotic sounds worldwide does not seem to be well founded. Other well-documented sound changes such as spirantizations, consonant losses, or vowel shifts do not seem to be restricted by the spelling systems. For example, the Second Germanic Consonant Shift, changing /p/, /t/, and /k/ to fricatives or affricates (Iverson and Salmons 2006), was not prevented by the fact that the spelling of affected words was changed.

Both Lindau (1985) and Ladefoged and Maddieson (1996), while noting the lack of a convincing segmental definition, emphasize the role of rhotics as a phonologically relevant class, along the lines discussed in §2 above. In order to express this unity, Hall (1997) proposes to use a feature [±rhotic] as a classificatory feature for the rhotic/non-rhotic distinction. However, a substantive definition of this abstract feature does not seem to be available. In yet another attempt, Walsh Dickey (1997) proposes to define rhotics by means of the feature Laminal, the use of the tongue blade as opposed to the tongue tip, as an articulator subordinated in the feature hierarchy to the articulator Coronal, as presented in (7).

(7) *Feature structure of rhotics* (Walsh Dickey 1997: 106)

```
[liquid]
   |
Coronal
   |
 Apical
   |
Laminal
```

However, it is questionable whether all rhotics make use of this feature structure. It is certainly not the case for uvular rhotics. Furthermore, it is unclear why such a marked segment class (expressed here by a deep hierarchical stacking of several place features, as opposed to an underspecified representation indicating an unmarked class; see CHAPTER 27: THE ORGANIZATION OF FEATURES; CHAPTER 7: FEATURE SPECIFICATION AND UNDERSPECIFICATION) should be present in the majority of languages. The question of manner features for rhotics is even more pressing: if the degree of opening for rhotics may range from vocalic to fricative, as the survey given above seems to suggest, it is unclear how the class of rhotics may be characterized as a whole. Furthermore, this raises the puzzle how segments at the extreme ends of this dimension are to be classified: for example, when is a voiced uvular fricative [ʁ] a rhotic, and when is it not? The following section will propose an approach from a different angle. The failure to find a common denominator for rhotics in terms of acoustic or articulatory features does not preclude the possibility that it can be found eventually, but chances seem to be slight.

4 Alternative proposals

Featural descriptions proposed for rhotics, as discussed in the preceding section, have in common that they attempt to characterize rhotics in purely segmental terms. But we have already seen above that rhotics are tightly connected to their positions within larger phonotactic patterns, at least with respect to the conditions for their allophonic variants or for patterns of complementary distributions. This observation raises the question whether rhotics should in fact be described in terms of purely segmental categories, or in segmental terms at all.

An alternative view would be to capitalize on the observation that rhotics appear in a particular well-defined syllabic position, namely the one immediately adjacent to the vowel. This view, proposed by Wiese (2001), and previously by Selkirk (1984), relies primarily on the apparently uniform behavior of all types of rhotics in terms of their syllabic constraints, and suggests that this is in fact the defining and constant property of the class of rhotics. On this view, the search for constant segmental properties is futile, because it starts from an incorrect presupposition, i.e. that classificatory features are by necessity segmental features. In contrast, it seems that rhotics are very stable with respect to their phonotactic behavior. In particular, their slot in the structure of a syllable does not seem to change with a change in their segmental make-up. For example, Hall (1993) discusses a (lower Rhine) variety of German in which the rhotic phoneme, in coda position, varies between a vowel and a voiceless fricative (*Tor* [toɐ̯] 'gate' *vs.* *Sport* [ʃpɔχt] 'sport'). In other words, a fricative rhotic obeys the same constraints on syllabic placement as a trill or approximant rhotic, or even a rhotacized vowel. The proposal then is that rhotics are defined as a particular relative point on the sonority scale, the point between vowels and laterals.

Another pattern discussed in Wiese (2003) casts doubts on the segmental approach to rhotics as a class. (8) presents those onset clusters of present-day Standard German which consist of any stop followed by a sonorant (the velar nasal /ŋ/ is excluded from such clusters on principled grounds). Examples given in the cells of the table include rather marginal clusters (such as /pn/ or /tm/ occurring in a few rare words only), but in all of these rare cases, there is no tendency to replace the clusters in question by a more natural cluster or to break it up by a process of epenthesis.

(8) *Initial clusters of stop + sonorant in Standard German*

	/r/	/l/	/n/	/m/
/p/	*Preis*	*Platz*	*Pneu*	—
/b/	*braun*	*blau*	—	—
/t/	*Traum*	—	—	*Tmesis*
/d/	*drei*	—	—	—
/k/	*Kreis*	*klug*	*Knie*	*Khmer*
/g/	*grau*	*Glaube*	*Gnade*	*Gmünd*

Not all possible stop–sonorant clusters are attested. As shown in (8), /r/ can be combined with any of the existing stops, while all other sonorant consonants are restricted in some way or other with respect to the preceding stops. Basically, all homorganic clusters, such as /tl/ or /pm/, are ill-formed in (8), but there might be additional restrictions ruling out /bn/ and /dm/. For discussion of these, see Hall (1992: 65–80) and Wiese (2000: 261–269). But crucially, in contrast to the non-rhotic sonorants, no restrictions at all hold for stop–sonorant clusters involving /r/. As the examples in (8) demonstrate, this phoneme productively combines with any preceding stop, and none of the clusters involving /r/ is marginal. While it would be possible to simply make /r/ exempt from the ban on homorganic clusters, such a move would simply beg the question why this is the case. It seems more plausible to say that place features of /r/ simply do not count, or, in an underspecification approach to features, are not present (see CHAPTER 22: CONSONANTAL PLACE OF ARTICULATION; CHAPTER 7: FEATURE SPECIFICATION AND UNDERSPECIFICATION). The homorganicity ban in place for other sonorants cannot apply, then, leading to the complete set of stop–/r/ clusters shown in (8).

Similar patterns can also be demonstrated for other clusters in German (such as fricative–stop clusters), and for similar clusters in other languages (e.g. English, Italian, Basque, Lithuanian). This line of argumentation, arguing that rhotics are defined as those sounds which bear a sonority value between that of vowels (including glides) and the next lower sonority class, is supported by the fact that the freedom of rhotics to combine with a preceding stop is independent of the particular type of the r-phoneme present in the respective variety of German – place features as well as manner features of the rhotic phoneme are always irrelevant.

Finally, the proposal gives an answer to a puzzle noted above, namely that one and the same segment may sometimes be classified as a rhotic and sometimes not. This is particularly obvious in the case of voiced uvular fricatives: for Standard French, [ʁ] is generally seen as a rhotic; for Classical Arabic, what is apparently the same segment is not (Watson 2002: 13). But if rhotics are defined in terms of their phonotactic behavior, this is less mysterious: in French, the segment in question appears between obstruents and vowels, as in the initial cluster in *frais* [fʁɛ] 'fresh' or in the final cluster in *carte* [kaʁt] 'card', while in Classical Arabic the respective segment patterns with other fricatives in terms of phonotactics, even after the rhotic [r] as in *farġ* [farʁ] 'width'. In addition, Arabic has a tap or trill /r/ which is analyzed as a rhotic, because it behaves accordingly in terms of phonotactic patterning: e.g. San'ani Arabic *sirt* 'I/you (MASC SG) went'; *lribt* 'I fed' (Watson 2002: 67, 73). Dutch is another language which shows both a phoneme /r/ (with a great deal of variation) and a voiced velar or uvular fricative /ɣ~ʁ/ (see Booij 1995: 7–8).

be a considerable difference between these two levels. In some recent theories of phonology, emphasis has been placed on the seamless integration of phonetic and phonological representations. In the model of Articulatory Phonology, for example, all representations consist of articulatory gestures, i.e. movements in the vocal tract, which constitute the domain for phonological as well as phonetic representations (for a survey see Browman and Goldstein 1992; CHAPTER 5: THE ATOMS OF PHONOLOGICAL REPRESENTATION). In a treatment of English /r/ and its alternations with "zero," McMahon *et al.* (1994: 303) argue that /r/ consists of two articulatory gestures, a palatal constriction and a pharyngeal constriction. It remains to be seen to what extent this approach is adequate for other rhotics, in particular the prototypical trill and the uvular varieties. The discussion of rhotics in this chapter raises the question of whether a gestural – or any other – representation in terms of uniform and rather concrete units is possible for the characterization of rhotics.

31 Lateral Consonants

Moira Yip

Laterals are extremely common, and yet they are something of a phonological puzzle. For most consonants, there is fairly general agreement on which natural classes they belong to, and clear expectations of how they pattern in phonological processes. So for example [m] is Labial and [+nasal], and as such it patterns consistently with the other labials [p b], and the other nasals [n ŋ]. But for laterals this is not the case, as we shall see. Their behavior is highly variable across languages. This chapter gives an overview of their somewhat perplexing behavior, summarizes extant proposals for their phonological representation, and ends by advocating a proposal using violable constraints that allows for this variability.

I begin in §1 with some background on their articulation and acoustics, and how they are acquired by the child. §2 summarizes the types of laterals found in natural language. §3 surveys their roles in syllable structure. §4 discusses their sonorancy, voicing, and continuancy characteristics. §5 looks at alternations between laterals and other sounds. §6 asks whether there is a feature [lateral]. §7 looks at the positioning of [lateral] in a theory of feature geometry. I show that there are serious problems associated with any single choice of superordinate node, and instead in §8 I propose an approach based on violable feature co-occurrence constraints. §9 concludes.

1 Phonetics, perception, and acquisition

1.1 *Types of laterals and their frequency in the world's languages*

Over 80 percent of languages have one or more lateral consonants (Maddieson 1984). Laterals are defined by Ladefoged and Maddieson (1996: 183) as "sounds in which the tongue is constricted in such a way so as to narrow its profile from side to side so that a greater volume of air flows around one or both sides than over the center of the tongue." The palatograms in Figure 31.1 show clearly that the tip of the tongue makes contact with the roof of the mouth, but the sides do not.

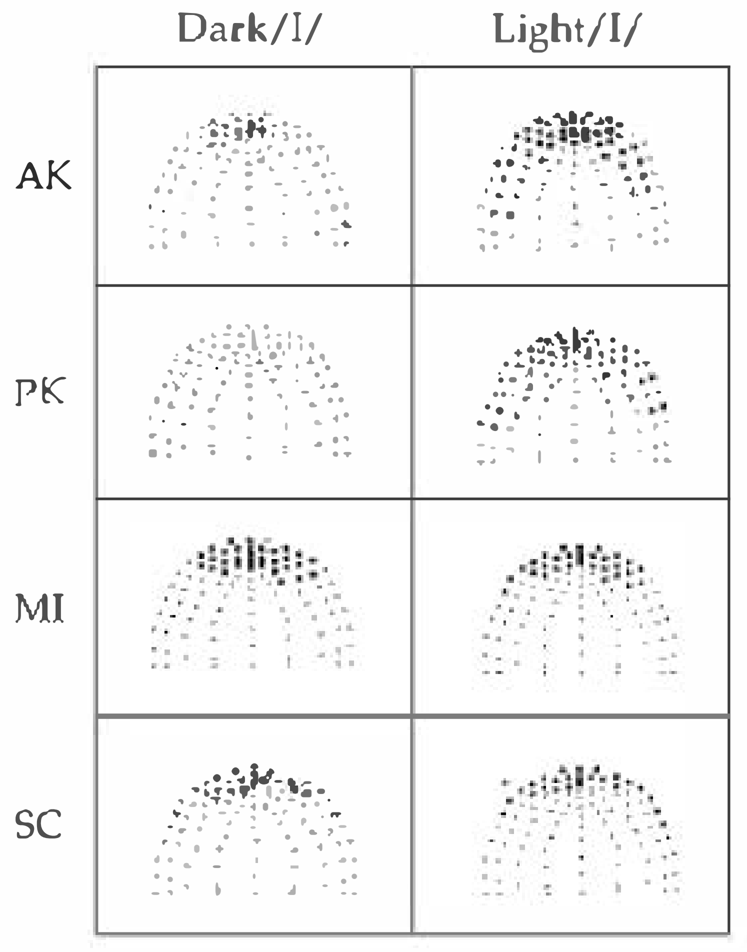

Figure 31.1 Linguo-palatal contact profiles of dark and light laterals for four speakers of American English, showing mid-sagittal contact in the alveolar and pre-palatal regions but no or limited contact at the sides. From Narayanan *et al.* (1997)

The approximant versions have some turbulence at the (incomplete) stricture; resonant versions like Standard German coda /l/ do not. Since the vocal tract is not fully obstructed in the typical approximant /l/, they are among the most sonorous of consonants (see CHAPTER 49: SONORITY). They frequently contrast with other sonorants, especially rhotics, and the class of laterals and rhotics is referred to as the liquids (see CHAPTER 8: SONORANTS). In other languages (such as Japanese) a language has only a single liquid, and it may vary between a lateral [l] and a more rhotic tap or flap [ɾ]. The variation may depend on context (such as syllable position) or they may be in free variation. Speakers of such languages famously have trouble perceiving and producing the difference between [l] and [r] when learning languages like English (see Iverson *et al.* 2003). There are also lateral obstruents, which will be discussed below.

1.2 *Articulation, acoustics, and acquisition of laterals*

Most laterals are dental or alveolar in articulation, but the tongue body is also frequently implicated, as shown for English by Sproat and Fujimura (1993). Gick *et al.* (2006) studied the articulation of laterals in six languages: Western Canadian English, Quebec French, Serbo-Croatian, Korean, Beijing Mandarin, and Squamish Salish. They found that all their laterals had an anterior tongue gesture in all syllable positions. More interestingly, in coda position all also have a dorsal gesture, which starts slightly earlier than the anterior gesture. Some, but not all, have a dorsal gesture in onset position too, in which case it is roughly simultaneous with the anterior gesture. The dorsal gesture in coda position may result from biomechanical causes, such as "active lateral compression of the

4.1 Sonorancy and voicing

There is general agreement that the vast majority of laterals are sonorants. But *how* sonorant are they? Based on widely accepted phonological evidence, Parker (2008) posits the following sonority hierarchy for sonorant consonants (see also CHAPTER 49: SONORITY):

(7) *Relative sonority of sonorant consonants*

glides > flaps > laterals > trills > nasals

Using data from Quechua (Peruvian) Spanish and US English, he then sets out to show that this ranking has a measurable phonetic correlate, namely acoustic intensity. Although he finds a very good statistical match for his overall notion, [l] in onset position frequently comes out as louder (and thus more sonorous) than the glides, contra expectations. Parker suggests that this is because the glides may become more "obstruent-like" in onset position, especially in Spanish. According to Harris and Kaisse (1999), this is rather pervasive. In Argentinian Spanish it is carried to an extreme, as shown by alternations such as *le*[j] 'law' *vs. le.*[ʒ]*es* 'laws'. But even in Castilian, the onset glide [j] frequently hardens to the non-strident palatal fricative [ʝ] or even to its non-continuant counterpart.

Once we look outside the prototypical approximant laterals, we quickly encounter laterals that are not sonorant at all. Examples of obstruent laterals include not only the obvious fricatives, affricates, and clicks, but also languages in which [l] patterns with the voiced obstruents, such as Southern Min, which has [l] instead of [d]. Modern Southern Min completely lacks [d]. Not only is [l] the modern reflex of historical *d, but underlying /p t k/ voice to [b l g] foot-internally (Hsu 1996), and /b l g/ nasalize to [m n ŋ] before nasal vowels. In some Bantu languages, like Ikalanga, historical *d has become /l/, and synchronically under velarization /l/ becomes the stop [gw], suggesting that it may still be an obstruent. (A reviewer correctly notes that in both these cases there could be intermediate steps involved, and /l/ may not be underlyingly obstruent.) There are even a few languages in which *all* the laterals appear to be obstruents: Tlingit for example has two lateral fricatives and three lateral affricates, but no lateral approximants.

Finally, turning to voicing, like other sonorants laterals are typically voiced, but voiceless versions are found, for example in Toda. The theoretical implications of the fact that most (but not all) laterals are voiced sonorants will be discussed in §7.

4.2 Continuants or not?

There has been little agreement as to whether ordinary approximant laterals behave like stops or like continuants, and thus whether they are [±continuant]. Alternations with stops are common, but alternations with fricatives do not seem to be found. Nonetheless, Holt (2002) argues that they are both [+continuant] and [−continuant] and Mielke's (2005) survey, as his title "Ambivalence and ambiguity in laterals and nasals" makes clear, finds an almost even 50/50 patterning as [±continuant]. He attributes this to their ambiguous phonetic cues, and suggests that it is precisely phonetically ambiguous segments that are likely to behave ambivalently in the phonology. I shall return to this issue in §9.

Mielke gives these examples of each pattern. In Basque, laterals (but not rhotics) pattern with nasals in assimilating in place to a following consonant. The class of segments that undergo the rule is [+sonorant, −continuant]. Mielke points out that there is no way to define this class other than by using [−continuant] to include /l/ and the nasals, but not /r/.

(8) /l/ *patterning with non-continuants in Basque* (Hualde 1991: 96)

egu[m] *berri*	'new day'
egu[n̪] *denak*	'every day'
egu[ɲ] *ttiki*	'small day'
gu[ŋ] *gorri*	'red day'
ata[l̪] *denak*	'every section'
ata[ʎ] *ttiki*	'small section'

(I will suggest an alternative explanation for the Basque case in §8.3.)

Conversely, in Finnish stems may end in the five coronals /t s n r l/. Before /n/-initial suffixes, [−continuant] /t/ *undergoes* total assimilation, but [+continuant] /s r l/ *trigger* total assimilation.

(9) /l/ *patterning with continuants in Finnish*
(Sulkala and Karjalainen 1992: 387–388)

		active potential	*2nd part active*	
a.	/avat/	[avannut]	[avannee]	'open'
b.	/pur/	[purrut]	[purree]	'bite'
	/nous/	[noussut]	[noussee]	'rise'
	/tul/	[tullut]	[tullee]	'come'

Mielke quotes Kaisse (2000) on the issue. She points out that the status of laterals hinges on whether [−continuant] is defined in terms of complete occlusion in the oral tract ("vowel tract" in *SPE*; Chomsky and Halle 1968: 318) or complete occlusion in the mid-sagittal region of the oral tract (see also CHAPTER 13: THE STRICTURE FEATURES). Laterals have complete occlusion only in the mid-sagittal region, not elsewhere, so they qualify as [−continuant] only under the latter definition. Mielke suggests that this makes laterals phonetically ambiguous, and that the boundary for the natural classes of [+continuant] and [−continuant] may vary cross-linguistically, placing laterals in different classes in different languages. The implication is that feature values may not be universally fixed for such segments, but may "emerge" on the basis of observable phonetic properties. One might also note that other rationales for cross-linguistic differences in feature specifications have been advanced, particularly the system of contrasts in the language in question. See Morén (2006) for an account on these lines for Serbian laterals.

5 Alternations involving laterals

When laterals alternate with other segments, it is usually with ones that are minimally different either articulatorily, acoustically, or both. Since most laterals are coronals, a small change in the type of closure so that it is complete will produce a coronal stop. If the lateral finds itself subject to nasal spreading, so that the velum is lowered, a nasal sonorant is the likely result. If the tongue shape is inverted, so that the closure is made with the sides but not the midline of the tongue, then a rhotic is formed. And if the closure is eliminated, but the tongue body remains high, a high vocoid results. Some of these changes also produce a sound that is acoustically still quite similar to the lateral, meaning that the change may have originally been driven in whole or in part by a misperception of the signal. All of these are common changes, and are discussed below.

5.1 *Stops*

In some languages, /l/ alternates with stops; more specifically, it appears to replace the voiced coronal stop /d/ in some contexts. In Palenquero Spanish (Piñeros 2003), /d/ is in free variation with [l] in some words:

(10) /d̪ed̪o/ → ['le.lo] ~ ['d̪e.ðo] 'finger'

In some Bantu languages, like Ikalanga, historical *d has become /l/, but under velarization /l/ becomes the stop [gʷ], suggesting that it may still be an obstruent. Conversely, in Southern Min (which has /l/ instead of /d/ in its phoneme inventory), if syllable-final /t/ ends up intervocalically (especially before an unstressed vowel), it voices and becomes not [d] but [l] (although descriptions vary, and as it is a brief flap or tap, it is not entirely clear how lateral its articulation is; see Hsu 1996).

5.2 *Nasals*

Historically, Cantonese had two distinct phonemes /l/ and /n/. Both could occur syllable-initially, as in the contrast between [lei] 'reason' and [nei] 'you'. Only /n/ could occur syllable-finally. However, in the last 50 years a gradual sound change has been taking place, and is now nearly complete for younger speakers (Bauer and Benedict 1997). Initial /n/ is being replaced by /l/, so that 'you' and 'reason' are now both pronounced as [lei]. As a result, [l] and [n] can be treated as allophones of a single phoneme, with [l] as the syllable-initial variant and [n] as the syllable-final one. However, actual alternations do not exist, because the language has essentially no resyllabification.

In the Min dialects of Chinese (including Southern Min, mentioned earlier), voiced stops and nasals are in complementary distribution, with [b g] occurring only before oral vowels and [m ŋ] only before nasal vowels. These data are from the Chaoyang dialect:

(11) bi:ʔ^{11} 'hide' mẽ:^{53} 'fast'

The language has no alveolar voiced [d], but the reflex of historical *d is [l] before oral vowels and [n] before nasal vowels. As a result [l] and [n] are in complementary distribution, and this is productive. In Chaoyang onomatopoeia, words are reduplicated and one onset is replaced by [l]. However, if the vowel is nasal it is replaced instead by [n]. See Yip (2001) for details.

leaving only the more vocalic Dorsal gesture (see CHAPTER 75: CONSONANT–VOWEL PLACE FEATURE INTERACTIONS).

A rather different but equally well-known case comes from the Cibaeño dialect of Spanish, in which both /l/and /r/ become the palatal glide [j] in coda position (Guitart 1985; Harris 1985; Alba 1988).

(15) *celda* [sejda] 'cell'
cerda [sejda] 'bristle'

Since the gesture that is preserved here is the Coronal one, Johnson and Britain's approach cannot deal with these facts unmodified. However, there is evidence that, unlike English coda /l/, Spanish coda [l] is clear, not dark, with a smaller Dorsal gesture. This might then explain why /l/ vocalizes as [j], not [w], although the picture is less clear if one studies a range of Spanish and Portuguese dialects. See Quilis *et al.* (1979) and Recasens and Espinosa (2005) for details.

Many dialects of Spanish, especially in Latin America, have replaced the palatal lateral [ʎ] by the glide [j]. This sound change is known as *yeismo*. (In Buenos Aires Porteño Spanish, this change has gone one step further in a change called *zheismo*, with [j] spirantizing to [ʒ]. See Harris and Kaisse (1999) for details.)

(16) *llorar* [ʎ]*orar* [j]*orar* 'to cry'
ella *e*[ʎ]*a* *e*[j]*a* 'she'

In Serbian, rather unusually, /l/ vocalizes to [ɔ]. See Morén (2006) for an interesting account within a Parallel Structures Model. Historically, vocalization of laterals is also common. In Germanic, compare English *old* to Dutch *oud*. In Polish, dark [ɫ] changed to [w] everywhere, even in onsets. In Romance, Latin *l has developed variously to [w/u], e.g. in French (*caldus* to *chaud*), or to [j/i] (in both onset and coda), as found in Italian *flos* to *fiore* and Portuguese *multus* to *muito*.

The inverse of vocalization of laterals, the lateralization of glides, seems to be much rarer (CHAPTER 15: GLIDES). Li (1974) documents a case in which *j > [l] in some Formosan languages, and a voiced coronal fricative [z ð] in others. Interestingly, in no case does *w > [l], even though in *l*-vocalization /l/ becomes [w] more often than [j]. This suggests that there must be a coronal gesture already present (as there is for [j]) for the creation of a novel lateral.

6 The feature [lateral]: Is it necessary?

Phonologists routinely use a feature [lateral] to distinguish /l/ from /r/, but some linguists (Spencer 1984, Brown 1995, and most recently Walsh Dickey 1997) have argued that it can be dispensed with. If a language has [l] but no [r], one might define [l] by the features [+consonant, +sonorant, −nasal], and [lateral] would be redundant. However, if [l] contrasts with [r], as it does in many languages, this will not suffice. They could perhaps be distinguished by the feature [continuant], with /r/ as [+continuant] and /l/ as [−continuant], but this is not without problems (see §4.2, and also van der Weijer 1995). Walsh Dickey (1997: 55) distinguishes them by means of Place features, with /l/ having complex Corono-Dorsal place and /r/ non-primary Laminal. Dissimilation of /l/ to [r] is loss of a secondary

Dorsal articulation. The lateral articulation of [l] is, for her, "a necessary phonetic consequence of a phonological Corono-Dorsal complex place structure." It is worth having a slightly closer look at her arguments and her proposal.

Walsh Dickey points out, correctly, that the strongest arguments for a feature come from its role in defining natural classes. The many languages with only one lateral can of course never offer this type of evidence. She lists three types of potentially significant evidence from languages with more than one lateral: (i) co-occurrence restrictions on different types of laterals; (ii) positional restrictions which cover all types of laterals in a language; and (iii) phonological processes which need to refer to all laterals, both sonorant and obstruent. She concludes that no such evidence exists, and I have also not encountered any convincing cases.

However, she pays a high price for the absence of [lateral]. In particular, she has to greatly complicate the internal structure of the coronal node by including Laminal (which in turn may or may not be [dental]), Apical (which in turn may or may not be [back]), and secondary Dorsal (which may have yet another Dorsal specification below it, to account for velarized "dark" laterals). Finally, any other sound which might have been thought to involve secondary Dorsal articulations, such as velarized coronal consonants, would require some extra specification if they did *not* have a lateral release. I therefore tentatively conclude that the feature [lateral] is still useful, and probably necessary.

Positive evidence for the feature [lateral] comes from its active role in the phonology of many languages, despite Walsh Dickey's claims to the contrary. In Eastern Catalan (and Sanskrit), for example, [lateral] spreads onto nasals to create a lateral nasal: /nl/ → [l̃l] in /son les tres/ → [sol̃les tres] (Mascaró 1976). There are well-known phonological processes that involve only [l] and [r], and in which they either dissimilate, as in Latin, where the suffix /-alis/ surfaces as [-aris] after a lateral root: *nav-alis vs. milit-aris* (Steriade 1987), or assimilate, as in Sundanese, where the infix /-ar-/ surfaces as [-al] after a preceding /l/: [k-ar-usut] *vs.* [l-al-əga] (see Cohn 1992 for details). Several of these processes are long distance, and can cross over other Coronals, making a Place feature account tricky. I conclude that the feature [lateral] cannot be dispensed with.

I should note that for the remainder of this chapter I shall treat [lateral] as a privative feature, but the results would not be materially affected if it were to turn out to be binary, as Steriade (1987) argues.

7 Feature geometry and the feature [lateral]: Two competing models

It has been proposed that distinctive features are related to each other by a hierarchical feature geometry (Sagey 1986, Clements and Hume 1995, and many others; see also CHAPTER 27: THE ORGANIZATION OF FEATURES). For example, the features Labial, Coronal, and Dorsal are dominated by a Place node. In such a model, we must then ask where the feature [lateral] is located. Early proposals spent little time worrying about the placement of [lateral], and tended to put it directly under the root node. Clements and Hume (1995: 293) opt for this, but admit that its position is open to dispute. Subsequently, two competing detailed proposals for the placement of lateral have been put forward, and are shown below: it might

Similar facts hold in Tamil (Beckman 1998), and in English: *we*[l̪θ] *wealth*, but *whe*[lk] *whelk*, although the English case may be purely phonetic, since it is not structure-preserving. The interesting fact is that in Basque and all these other languages laterals do not lose their laterality as the targets of Place assimilation, contra the predictions of the Coronal model.

Finally, there are languages in which Place contrasts are lost – a phenomenon described by Trigo (1988) and others as the delinking of the Place node – but laterality survives. In Caribbean Spanish (Trigo 1988: 71) place features are neutralized in codas: /d/ deletes, /s/ becomes [h], and all nasals become velar; /r/ and /l/ are unchanged.

(24)	a.	/βerdad/	→	[βerða]	'truth'	
	b.	/ines/	→	[ineh]	'Ines'	
	c.	/album/	→	[albuŋ]	'album'	(*optional*)
		/tren/	→	[treŋ]	'train'	
		/desdeɲ/	→	[desdeŋ]	'disdain'	
	d.	/tonel/	→	[tonel]	'barrel'	
		/par/	→	[par]	'pair'	

The data in this section are problematic for the Coronal model.

7.2 *The sonorant voicing (SV) model*

What about the sonorant voicing (SV) theory? Rice and Avery (1991) base their claims on three main arguments. Firstly, the SV node is the target node when lateral spreads to other sonorants. Secondly, a process of de-sonorantization can be seen as delinking of the SV node. Thirdly, rules which spread both nasality and laterality can be viewed as spreading the SV node (see Table 31.2).

Table 31.2 Predictions of the SV model

Prediction	*Under sonorant voicing?*	
	FOR	*AGAINST*
All laterals should be voiced sonorants	Laterals are usually voiced sonorants: *many languages*	Voiceless laterals: *Tahltan* Obstruent laterals: *Min, Bantu* Affricate laterals *Tahltan, Zulu*
SV spreading should spread [lateral]	Yes: *Sanskrit*	No: *Polish*
When [lateral] spreads, it should seek SV targets	Yes: *Toba Batak*	Laterals skipped by harmony that targets sonorants: no cases known
SV spreading onto laterals should remove [lateral]	Yes: *Itsekiri*	No: *English*
Loss of SV removes [lateral]	Yes: *Yagaria*	No: *Koyukon, Angas*

7.2.1 *Supporting evidence for the SV model*

Apart from the observation that most laterals are voiced sonorants, there are four other types of evidence in support of the proposal.

Firstly, SV spreading sometimes spreads [lateral], as in Sanskrit. Before laterals, all obstruents voice, and if they are coronal they also lateralize (Whitney 1889: 54; no examples of non-coronals are given):

(25) tat labhate → tal labhate
trin lokan → tril̃ lokan

Secondly, [lateral] spreading sometimes seeks SV targets to attach to, as in Toba Batak (Hayes 1986). Coronal sonorants assimilate to a following liquid:

(26)	*Spreading*	*No change*
	nr → rr	ln rn lr
	nl → ll	mr ml ŋl ŋr
	rl → ll	rr ll nn

If what spreads is the SV node, and if [lateral] is its dependent, then laterality will be carried along too.

Thirdly, when SV spreads onto a lateral target, replacing the original SV specification, the original lateral specification may be lost. The following facts from Itsekiri (Nigeria; Piggott 1991, cited in Brown 1995: 64) are often cited, and very similar facts hold in Southern Min Chinese and in Yoruba.

(27) lā → nā 'ask the price of'

This type of nasal harmony can be seen as spreading the superordinate SV node, carrying nasality with it, and removing the original SV node, laterality and all.

Fourthly, if an SV node delinks, lateral may be removed too, as in Yagaria. Here a coalescence process removes voicing and converts a sonorant [ʟ] to an obstruent [t], and in the process laterality also goes.

(28) gipaʔ-ʟoʔ → gipatoʔ 'at the door'

For further data on Yagaria, see §2, where these data are discussed in a different context.

7.2.2 *Counterevidence to the SV model*

There are various types of counterevidence to the SV model, as listed in the right-hand column of Table 31.2. The first problem is the existence of laterals that are not voiced sonorants, being either voiceless, obstruent or both. But there are other problems.

Firstly, SV spreading does not always spread [lateral]. The following data show a post-lexical process of voicing assimilation in Krakow and Posnan Polish (Dorota Glowacka, personal communication; Madelska and Witaszek-Samborska 1998):

(29) *brat* → *bra*[d] *Doroty/Natalji/Iwony/Luizy* 'brother of X'
syn → *sy*[n] *Luizy* 'son of Luiza'

Similar facts hold in all dialects between verbal prefixes and roots:

(30) s-kɔɲʧɨtɕ 'to end' z-bitɕ 'to break' z-lit̪ɨtɕ 'to count'

In the SV model, voicing in sonorants is represented by the presence of an SV node, and so this must be the active node that spreads. If [lateral] is under this node, it too should spread, but it does not, contra the predictions of the SV model.

Secondly, SV spreading into lateral targets sometimes leaves the laterality intact. This is the case in English, where liquids after voiceless aspirated stops become voiceless:

(31) [bl]*eak* [pl̥]*ease* [gl]*eam* [kl̥]*ean*
[br]*eam* [pr̥]*een* [gr]*een* [kr̥]*eam*

If sonorant voicing is denoted by the presence of an SV node, the devoicing would presumably mean that the SV node had been delinked, and one would then expect loss of [lateral] as well, but no such thing happens.

Thirdly, if the SV node of a lateral delinks for other reasons, rendering it voiceless, laterality should also be lost, but this is not the case in the Athapaskan language Koyukon (Rice 1994), which devoices syllable-final sonorants and continuants, including /l/. For the lateral, the result is a voiceless lateral fricative [ɬ]. Final stops are plain voiceless unaspirated.

(32) [nəɣælə] 'your (sc) trap' [xæɬ] 'trap'
[səʔɔɣə'] 'my snowshoes' [ʔɔx] 'snowshoes'
[nizuni] 'that which is good' [nizun̥] 'it is good'

Under the SV hypothesis, where [lateral] is under SV and devoicing of sonorants means removal of the SV node, laterality should also disappear, but it does not, contra the predictions of the SV model.

In the case of [lateral], then, the need created by theories of universal feature geometry to commit to a single location for the feature in all languages creates problems. Luckily, there are alternatives to these two proposals. Hegarty (1989) and Bao (1992) argue that [lateral] is simply a dependent of the Root node. Yip (2004: 5) goes further, and agrees with Padgett (1995, 2002) that (at least with respect to the behavior of [lateral]) features can be treated as an unstructured set of which [lateral] is a member, and that feature geometry as such is redundant. The next section lays out this proposal.

8 A feature co-occurrence constraint approach

8.1 Inventories

Suppose we capture the fact that the least marked lateral is a coronal sonorant by means of two universally fixed hierarchies of feature co-occurrence markedness constraints.

(33) a. *LateralObstruent >> *LateralSonorant
b. *LateralLabial >> *LateralDorsal >> *LateralCoronal

The idea is that these constraints are violated if a segment bears both features, at least if both are primary articulations. For example, the intention is that *LateralLabial bans bilabial or labio-dental segments with a lateral release. If the labiality is secondary, as in [l^w], it may be acceptable. Both the fixed rankings are phonetically grounded. Lateral release means the airflow is not easily obstructed, so lateral obstruents are more marked than lateral sonorants (33a), and lateral release is easiest if only the tip of the tongue is used to make closure, so coronals are the least marked laterals (33b).

Placing the faithfulness constraints at different points in these hierarchies gives us a typology of segmental inventories like those below:

(34) *Typology of lateral place of articulation*

a.	*LatLab >> *LatDors >> *LatCor >> Faith	Either no laterals (Maori), or placeless ones (Cambodian)
b.	*LatLab >> *LatDors >> Faith >> *LatCor	Common type, with Coronal laterals only (English)
c.	*LatLab >> Faith >> *LatDors >> *LatCor	New Guinea type, with velar and coronal laterals (Mid-Waghi), or perhaps palatal laterals
d.	Faith >> *LatLab >> *LatDors >> *LatCor	Laterals at all POAs (unattested)

(35) *Typology of lateral sonorants and obstruents*

a.	*LatObs >> *LatSon >> Faith	Languages with no laterals
b.	*LatObs >> Faith >> *LatSon	Common language type, with sonorant laterals
c.	Faith>> *LatObs >> *LatSon	Languages with both obstruent and sonorant laterals

In this way, we can correctly describe the inventories of laterals found in the world's languages, with the possible exception of Tlingit, which is reported to have lateral obstruents but no lateral sonorants. The complete absence of labial laterals also remains unexplained.

8.2 The spreading of [lateral]

How can these mini-grammars characterize the behavior of laterals shown in §7? First, let us consider the behavior of [lateral] in spreading processes, such as in Place assimilation or perhaps the spreading of SV under pressure from the Syllable Contact Law. Let us assume that assimilation involves a violation of the Ident family of faithfulness constraints, such as Ident-Place and Ident-Son, features are shared, but not laterality, and the segment remains a nasal. For full details, see Yip (2003, 2005).

We see then that variability in the spreading behavior of laterals in assimilation is handled without great difficulty by these minimally different OT grammars.

8.3 Laterals as the targets of spreading

I now turn to cases where lateral is (potentially) lost on the target of assimilation, or in neutralization. Whether or not it is lost depends on the relative ranking of Share-F and Ident-Lat, as shown below:

(38) a. Loss of [lateral] under (Place) assimilation: Educated Havana Spanish
Share-F >> Ident-Lat, Ident-Place

b. Retention of [lateral] under (Place) assimilation: Basque
IdentLat >> Share-F >> Ident-Place

A parallel analysis can be constructed for the cases in which SV spreading does or does not obliterate laterality.

The Basque case deserves a little more attention, because the Basque facts were used by Mielke to argue that laterals behave as [−continuant], since like nasals they undergo place assimilation, whereas [+continuant] [r] does not. Under the account offered in this section, however, there is another explanation available, as suggested by a reviewer. Nasals assimilate to all places, but laterals assimilate only to coronals, since *LatLab and *LatDors are high-ranked. Suppose there is also a set of constraints regulating the co-occurrence of a feature [rhotic], such that only a single rhotic exists. If these constraints and Ident[rhotic] all outrank Share-F, the rhotic will fail to assimilate, and continuancy need not be invoked.

Finally, laterality may or may not be lost when Place or SV is neutralized, for example in codas. Here the grammar is modeled on the ones in (38), but with *Coda-F instead of Share-F.

I have now outlined analyses that explain all the variation in the behavior of laterality, without reference to feature geometry, and using only rather simple markedness constraints on the co-occurrence of [lateral] with the various Place features, and with the feature [sonorant]. These interact with familiar faithfulness constraints and with markedness constraints that create pressure for change, such as Share-F, SyllableContact or *Coda-F. The clear preferences for coronal and sonorant laterals are captured by positing universal rankings of the relevant feature co-occurrence constraints. As always in OT, these constraints are violable, and this correctly predicts the observed cross-linguistic variation in lateral behavior that is such a problem for a fixed universal feature geometry.

9 Conclusion

The topic of this chapter has been laterals. As I hope is clear, they do not fit tidily into current phonological theories, especially when it comes to their distinctive feature make-up. Considering how common they are in language, this is something of an embarrassment. After all, they are neither unusual, prone to disappear over time, nor hard to acquire (that is, even if the child acquires them late, they get them sooner or later, which is more than can be said for [s] and [ɹ] for some speakers of British English). It is therefore incumbent on a good theory to accommodate them.

We have seen that their behavior is more variable across languages than that of most other sounds. So, for example, [t] always behaves like a voiceless coronal stop, and its distinctive features and their placement in the feature geometry are rarely if ever in dispute. So why should laterals be different, and are there other classes of sounds that exhibit comparable variability?

Variable behavior might be seen whenever the features are most readily produced and perceived on a certain type of segment, but can with some effort also be produced and perceived on sounds of other types too. For example, [strident] sounds, in which the turbulence produced at the point of constriction is sufficiently strong, and/or where the ensuing airstream then hits a sharp obstacle like the teeth, is easy to produce with the tip or blade of the tongue, but hard to produce elsewhere. We derive from this a constraint hierarchy *[Labial, strident] >> *[Coronal, strident]. Languages which contrast [f] and [ɸ], like Ewe, arguably violate the former as well as the latter. Turbulent airflow also requires a period of incomplete closure, or continuancy, so we also derive *[−cont, strident] >> *[+cont, strident]. Languages that violate the former have strident affricates, which have often been argued to be strident stops. In principle, then, the interactions of these constraints might also produce comparable variation to that we have seen with laterals.

For other features, no such variation is to be expected. [anterior] and [distributed] refine the type of contact the tip or blade of the tongue makes with the roof of the mouth. As such they can only be present in Coronals, and a sound that is [Dorsal, +anterior] is phonetically uninterpretable.

Mielke, by contrast, takes the variability in behavior of "ambivalent segments" like laterals to be an argument against universally defined distinctive features. Instead, he argues for "emergent distinctive features" based on phonetic similarity. Laterals, for example, may pattern with either continuants (16 languages) or non-continuants (61 languages) because, like continuants, they do not have totally blocked airflow, but like non-continuants they do have "a blockage of airflow past the primary structure." It is not clear how his proposals bear on those cases in §7.1 where the variability of laterals concerns their coronality rather than their continuancy, and thus where no appeal to variation in continuancy would seem to explain their behavior. It might be possible, however, to develop an extension of his approach from the starting observation that laterals are produced with both coronal and dorsal tongue gestures. Languages might therefore differ in which gesture they choose to interpret as a distinctive place feature for laterals. I leave the fleshing out of this idea for future research.

A substantial part of this chapter has focused on where the feature [lateral] sits in the feature geometry, but the proposal outlined in §7 and §8 makes no use of feature geometry at all. In this respect it is entirely compatible with the proposals of Padgett (1995, 2002), in which features form classes, but in which these classes are not embodied as superordinate nodes (with the exception of a root node). Instead of asking which node dominates [lateral], one would ask which class(es) of features [lateral] belongs to. There is then no reason why it might not belong to more than one class, for example Place and SV (or Manner), or to none. The feature co-occurrence proposal goes further, however, in that as far as [lateral] is concerned it does not even make use of feature classes. For die-hard proponents of feature geometry, I should note that it would be possible to combine the feature co-occurrence proposal with feature-geometric representations if other phenomena make this desirable, but only if [lateral] were directly under the root node.

The Blackwell Companion to Phonology is a major reference work drawing together 124 new contributions from leading scholars in the field. Led by a team of renowned international scholars, the *Companion* represents a diverse range of approaches and methodologies to key phenomena in phonological research. In contrast to other handbooks and reference works currently available for phonology, these volumes focus on phenomena and case studies that highlight past and ongoing debates in the field. Interdisciplinary connections, such as those with the social and computational sciences, are covered, as well as statistical and experimental techniques. The *Companion* will be a touchstone for future phonological theorists, giving an overview of data and insights which any theory of phonology should be able to cover.

Simultaneously offering broad coverage and a high level of detail, *The Blackwell Companion to Phonology* is a landmark work available in both print and online editions that will be indispensable to students and researchers in the field for years to come.

Phonology across Languages

32 The Representation of Intonation

Amalia Arvaniti

1 Introduction

It is a well-known truism that no utterance is ever produced in a strict monotone; all utterances, in all languages, show some pitch modulation. Such changes in pitch – impressionistically described as rises and falls – are due to changes in fundamental frequency or F0, the physical property of the speech signal that is determined by the basic rate of vibration of the vocal folds and gives rise to the percept of pitch.

Although pitch modulations exist in all languages, their origin and function differ, in that pitch patterns may be specified either at both the lexical and phrasal levels or only at the phrasal level, resulting in more or less dense tonal specifications, respectively (Gooden *et al.* 2009). The term *intonation* is used to refer to phrasal tonal patterns, while the terms *pitch accent* and *tone* are traditionally used to refer to lexical tonal specifications (chapter 45: the representation of tone). Simplifying somewhat, in languages like English, Italian, Greek, and many other European languages the entire F0 contour is specified at the phrasal level by means of a complex interplay between metrical structure, prosodic phrasing, syntax, and pragmatics; these factors determine where pitch movements will occur and of what type they will be. In languages referred to as *tone languages* – such as Mandarin, Thai, and Igbo – most syllables are lexically specified for tone and tonal changes affect lexical meaning; in languages often referred to as *pitch accent languages* – such as Japanese, Swedish, and Serbian – tone operates in a similar fashion, except that at most one syllable in each word is lexically specified for tone. In both tone and pitch accent languages additional tonal patterns are specified at the phrasal level. Here the focus is on languages without lexical tonal specifications, since it is the intonation of these languages that has been mostly examined.

Determining the structure of pitch modulation and the primitives that make up pitch contours in languages without lexical tone is challenging, since F0 changes are not as discrete and easily identifiable as in "tonal" languages, their connections to segmental material are less easy to determine, and associated meanings are harder to pinpoint since they deal with information structure and pragmatic interpretation rather than lexical semantics. The following examples illustrate these points. In Figure 32.1, two utterances are shown, *Me?!* and *A*

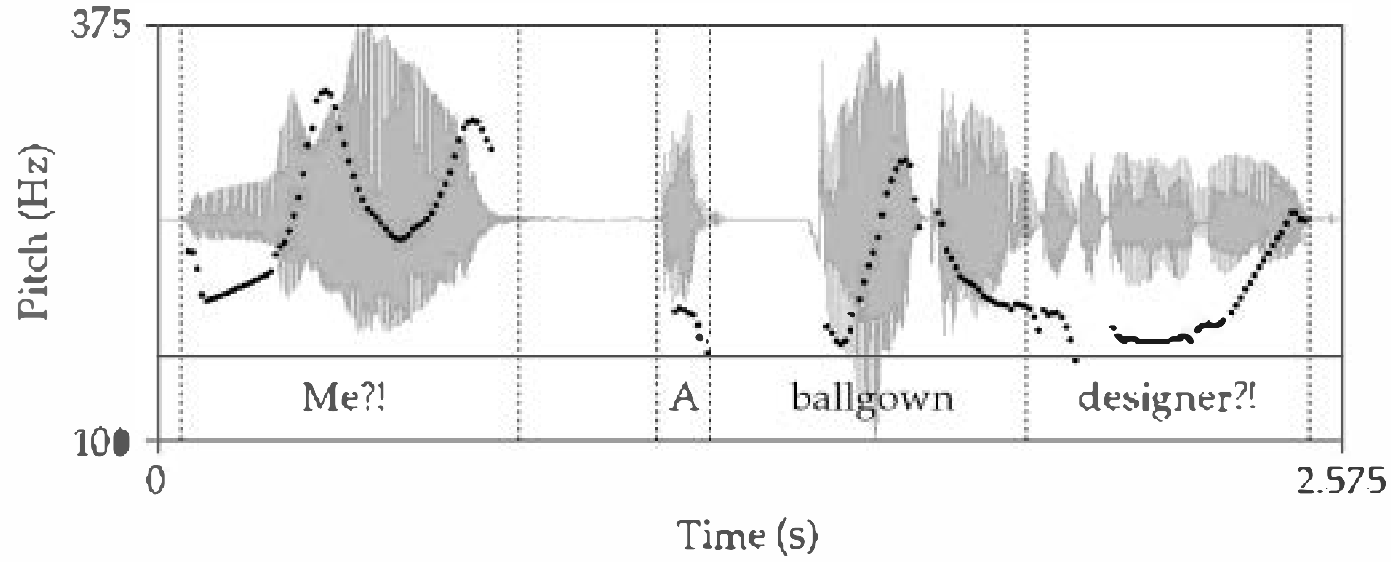

Figure 32.1 Waveforms and F0 contours of two English utterances illustrating the incredulity contour (Hirschberg and Ward 1992); on the left, *Me?!*; on the right, *A ballgown designer?!*. Vertical lines indicate word boundaries

ballgown designer?!, both using the rise-fall-rise melody that implies incredulity (Ward and Hirschberg 1985; Hirschberg and Ward 1992). They are plausible responses to a career advisor's pronouncement that, according to test results, designing ballgowns is the recommended career choice for the speaker, who has all along dreamed of becoming an aerospace engineer (for similar examples, see Ladd 2008: 45–46). Although the short contour can be informally described as rise–fall–rise, the longer contour cannot be described in a similar fashion, as it shows a long low-level stretch between a rise–fall and a final rise. In Figure 32.2, Greek contours very similar to the English ones in Figure 32.1 are shown, though in the case of Greek these contours are used for wh-questions (Arvaniti and Baltazani 2005; Arvaniti and Ladd 2009). As can be seen, the same issue with overall shape arises here as well. Further, as Arvaniti and Baltazani (2005) note, the Greek melody in Figure 32.2 can also be used for polite requests employing an imperative; e.g. [ˈðose sti maˈria ˈliɣo neˈraci] 'give Maria some water' (*lit.* give to Maria a-little water-DIM). Finally, Figure 32.3 illustrates two instances of another English melody: unlike the contours in Figures 32.1 and 32.2, which look different from each other but convey the same meaning in each case, the contours of Figure 32.3 are realizations of the same melody but convey different meaning, depending on the utterance: the melody used is

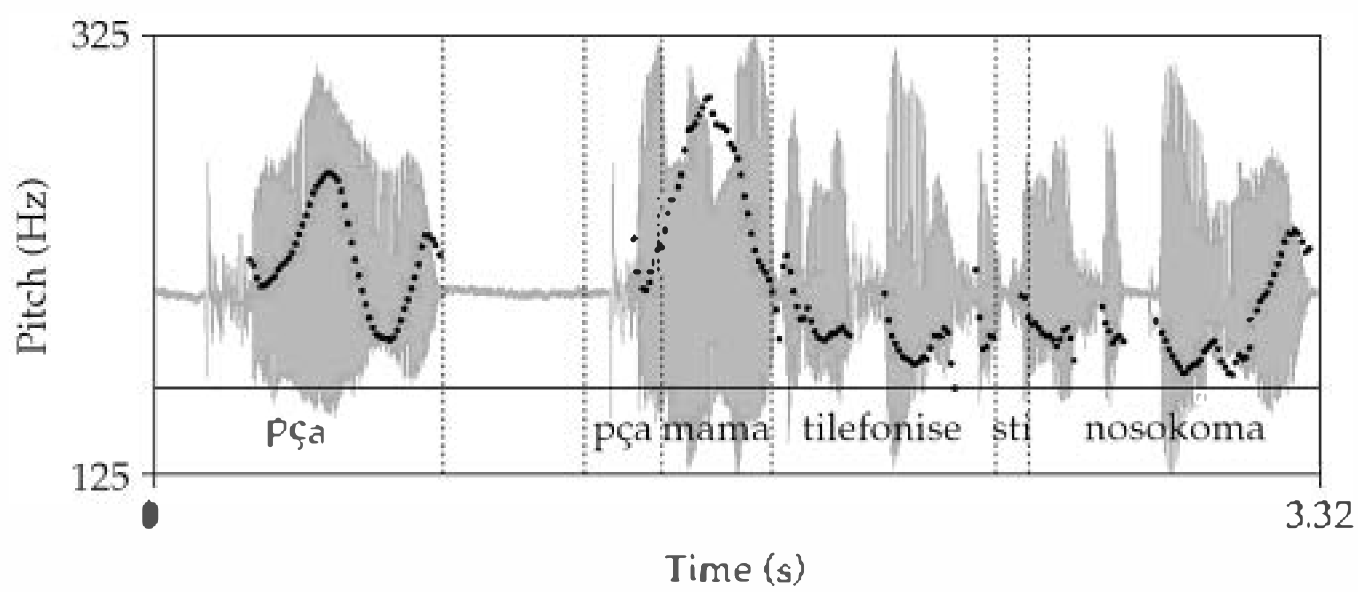

Figure 32.2 Waveforms, transcriptions, and F0 contours of two Greek wh-questions, on the left, [ˈpça] 'which (FEM)', on the right, [ˈpça maˈma tileˈfonise sti nosoˈkoma] 'which mom called the nurse?' Vertical lines indicate word boundaries

2.4 *Superpositional models*

In a number of configurational models, contours are said to be composed of two elements, a general trend and local perturbations which "ride" on this overall movement. This conception of intonation was also espoused by Bolinger, who distinguished *accentuation* from *intonation*, using accentuation to refer to pitch movements (*accents*) on stressed syllables, and intonation to refer to the general course of F0, "the rise and fall of pitch as it occurs along the speech chain" (Bolinger 1986: 194).

The IPO system is one such superpositional model, in that its primitives and contours are seen as localized movements superposed on a larger declination component, which is taken to be largely automatic and due to the drop in subglottal pressure during the course of an utterance (declination reset and local movements, on the other hand, are seen as actively controlled by the speaker; 't Hart *et al.* 1990: ch. 5). The exact role of declination and its physiology are still a matter of debate (see e.g. Pierrehumbert and Beckman 1988: ch. 3; Gussenhoven 2004: ch. 6), though evidence such as that provided for Japanese downtrends by Pierrehumbert and Beckman (1988) does not support the idea of declination playing as important a role as the IPO scholars envisioned.

Superpositional models have also been presented by Fujisaki (1983, 2004), Gårding (1983, 1987), and Thorsen (1980, 1985, 1986). Simplifying somewhat, in Fujisaki's system a *phrase command* results in the rising–falling course of F0 throughout an utterance (or a part thereof), with *accent commands* being responsible for more localized perturbations. Gårding (1983, 1987) posits grids (quasi parallel lines) within which most local F0 minima and maxima can be fitted; the overall range and direction of the grid (rising or falling or a combination thereof) reflect functional differences between utterances, such as the distinction between statements and questions. Similarly, Thorsen (1980: 1022) suggests that the rate of F0 drop in Danish is directly related to utterance function: "falling intonation contours are associated with declarative, intermediate contours with nonfinal, and flat contours with interrogative sentences." Due to the connection between communicative functions and overall F0 trends, the models of Thorsen and Gårding face similar issues to gestalt models with respect to meaning. On the other hand, Fujisaki's model, which does not rely on meaning distinctions, must resort to counterintuitive solutions – such as negative accent commands and phase commands that span linguistically arbitrary stretches – in order to adequately describe the course of F0 in languages other than Japanese (e.g. Fujisaki *et al.* 1997 on Greek; Fujisaki *et al.* 2005 on Mandarin; Gu *et al.* 2007 on Cantonese; for a discussion of these problems, see Ladd 2008: 23ff.; Arvaniti and Ladd 2009).

3 Pitch levels as primitives

3.1 *Early level-based models*

Descriptions of intonation by means of level tones date from the American structuralists (Pike 1945; Trager and Smith 1951; Hockett 1955; Trager 1961). In these systems, intonation is analyzed by means of four levels, extra-high, high, mid, and low. The level tones of these analyses are meant to be phonological abstractions equivalent to phonemes (CHAPTER 11: THE PHONEME); as such, they are said to be defined relative to each other, rather than each representing a specific pitch range.

These early analyses were heavily criticized by configurationalists, most notably Bolinger (1951), who questioned the claim that the four levels are relative, pointing out that if this assertion is taken at face value, it is not possible to distinguish combinations such as 123 from 234, although, theoretically, such combinations should be distinct. Thus, Bolinger concluded that level tones cannot be relative but must "rove each in its own bailiwick" (1951: 200), and set out to test this hypothesis by recording utterances in various *ways* (as Bolinger termed them, i.e. melodies differing in various aspects) and having listeners judge them for similarity or appropriateness for a given purpose, such as appeasing a child. His results showed that contours analyzed as contrastive in the system of Trager and Smith (whom he particularly targeted) are perceived as similar by listeners, while others, analyzed as allophones of the same basic melody, are considered by listeners to be contrastive. Bolinger used his results to argue that a system with four levels can be at the same time too powerful and not powerful enough to capture contrastive and allophonic variations in the intonational system of English. His results led him to reject level tone analyses as untenable and to propose instead that melodies are gestalts.

Bolinger's critique reflects the assumptions of concreteness and bi-uniqueness prevalent at the time. It is clear, for example, that Bolinger expected the different levels to faithfully represent the entire course of an utterance's F0, and to do so in such a way that the pitch range of each level did not overlap with that of others at any point in the utterance. Further, his comment that F0 forms "a continuous line that can be traced on a piece of paper" (Bolinger 1951: 206), coupled with his distinction between monotones, which he accepts, and level tones, which he does not (e.g. Bolinger 1986: 29), suggest that he expected a level-based representation to be phonetically realized as a series of sustained pitch levels. It is obvious that if these assumptions are adopted, a level-based analysis is unworkable on both phonological and phonetic grounds (on the latter, see Xu and Sun 2002; Dilley and Brown 2007).

Although Bolinger's critique was well accepted, it is fair to note that many of the assumptions he attributes to the structuralists are not found in their works. Pike (1945), Hockett (1955), and Trager (1961) all note that levels represent "only those points in the contour crucial to the establishment of its characteristic rises and falls" (Pike 1945: 26); with the exception of terminal junctures, these points associate with stressed syllables. Similarly, the structuralists noted that absolute pitch levels are not signifiicant as such, and recognized the existence of both level tones and contours (e.g. Trager and Smith's terminal juncture phonemes). Further, Pike (1945) discusses at length the fact that level tones need not be realized as a series of sustained pitches but can be realized as glides, especially when they are found close to each other, as happens in short utterances, for example. Nevertheless, as a result of configurationalist critiques, level-based analyses were largely abandoned in the following decades. Research within the generative framework focused primarily on the description of tone languages and no theoretical position was strongly taken in favor either of levels or of configurations with respect to intonation.

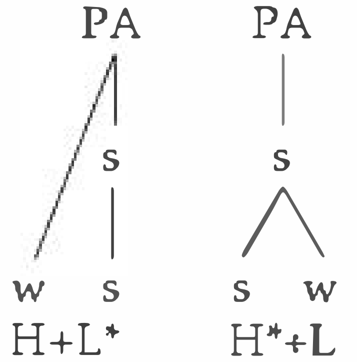
The role of underspecification cannot be underestimated: it leads to a clear understanding that the number of tones need not match the number of tone-bearing units (TBUs), so that both strings of tonally unspecified TBUs and instances of several tones associating with the same TBU are possible. Thus, in the AM framework, the two English contours in Figure 32.1 are both analyzed as L*+H L- H%. By using the same representation for these two contours, AM captures the fact that they are instantiations of the same melody, thereby generalizing beyond surface form. AM can also account for the systematic differences between contours like those in Figure 32.1, which, as mentioned earlier, were particularly problematic for the British school. In *Me?!*, all three tonal events must co-occur with the only syllable of this utterance; hence the obvious lengthening of *me* (720 msec) and the swift movement from one tonal target to the next. In *A ballgown designer?!*, L*+H is associated with the metrically strongest syllable in the utterance, i.e. *ball*, and it co-occurs with it (showing the peak delay expected for this accent; e.g. Pierrehumbert and Steele 1989; Arvaniti and Garding 2007). The H% is realized on the last syllable, which is the one showing a rise. The L-, which is associated with the ip boundary, spreads between the L*+H and H%, accounting for the fall and low-level stretch of F0 (for details on the realization of the L- in such contours, see Grice *et al.* 2000; Barnes *et al.* 2006). A similar analysis applies to the Greek wh-questions shown in Figure 32.2, analyzed as L*+H L- !H% (where !H refers to a downstepped H tone; Grice *et al.* 2000; Arvaniti and Baltazani 2005; Arvaniti and Ladd 2009).

Overall, the AM model avoids several pitfalls of previous analyses. First, by formally separating stress from intonation and providing a mechanism for their interaction, the AM model incorporates the insights of Bolinger about pitch accents without requiring distinct accentual and phrasal components to account for pitch contours. In addition, the use of only H and L tones avoids the problems noted by Bolinger (1951) with respect to level tones. At the same time, by treating the issue of pitch range as a matter of phonetic realization, AM avoids the problems that plagued the British analyses due to the confounding of linguistic and paralinguistic aspects of pitch range (cf. the disagreements regarding whether high falls and low falls are distinct entities). Further, by making explicit the separation between the phonetics and phonology of intonation, the AM model provides a principled account of the context-dependent variation of tones, a point that was not explicitly addressed in previous models, which mostly confounded contours and representations. Finally, the use of underspecification provides a parsimonious and elegant way of capturing both the similarities of melodies and the differences in phonetic realization that arise from the properties of the metrical structure with which a melody associates. In this way, the model can account for both local phonetic detail and abstract phonological form, something that configurational and full specification models cannot do (for extensive discussions of this point, see Pierrehumbert and Beckman 1988; Arvaniti *et al.* 2006a; Arvaniti and Ladd 2009). Finally, since the degree of underspecification can vary, AM can account for languages with dense tonal specifications, such as Mandarin, as well as for languages with more sparse specifications, such as English. In short, then, AM not only provides an answer regarding the nature of intonational primitives, but crucially addresses the even more fundamental question of what should be represented phonologically when it comes to intonation, an issue that most other theories have not tackled by focusing exclusively on faithful representations of entire F0 curves.

determined if none of the properties that may define them is stable. Finally, it is not clear how the notion of an indivisible unit can be defended for the Greek accents at all, since the beginning and ending points of the rise do not behave as one. Their relative autonomy is demonstrated by the fact that they align independently of each other and are not similarly affected by tonal crowding, which typically results in the undershooting of the L, while the realization of the H remains largely unaltered (Arvaniti *et al.* 2000). This pattern is difficult to account for if the rise is a unit, in which case one would more plausibly expect a curtailment of the entire pitch movement.

It is thus clear that dynamic tones cannot account for some of the attested patterns. On the other hand, level tones can be used not only for the representation of loosely defined rises and falls, as in Greek, but also for rises and falls that are more closely knit. Such units have been reported by Frota (2002) for European Portuguese. Specifically, Frota found that in the falling accent indicating broad focus, the H and L are timed with respect to distinct segments (similarly to the Greek case), but the fall of the accent indicating narrow focus shows a constant timing relationship between the H and L tones (similar to that discussed by Pierrehumbert 1980 for L*+H and L+H* in English). This difference between the two accents of European Portuguese can be represented by means of a hierarchical representation of tones shown in (1), as first proposed by Grice (1995a, 1995b) and adopted by Frota, or it can be treated as an issue of phonetic realization, as argued in Arvaniti *et al.* (2006b). Either way, it is clear that while level tones can adequately describe all attested tonal patterns, dynamic tones cannot. In short, then, both the empirical evidence and phonological considerations of parsimony and descriptive adequacy make a theory based on level tones preferable.

(1)



5 Conclusion

The original debate about levels *vs.* configurations (Bolinger 1951) focused on the issue of whether melodies are gestalts or should be seen as composites of primitives. Independently of this distinction, Bolinger's views, espoused by many before him and since, are based on the idea that intonational contours should be represented in their entirety, either as a series of primitives, or as a "line [. . .] on a piece of paper." Current understanding suggests that couching the problem in these terms is misleading, as neither type of representation is likely to be correct: as shown, gestalt approaches cannot account in a satisfactory manner for either intonational meaning or intonational form; yet representations that fully specify the course of F0, either in terms of dynamic tones or in terms of levels, do not fare much better. Due to the particularities of intonation, especially the fact that its realization depends on the metrical structure of the utterance with

33 Syllable-internal Structure

Anna R. K. Bosch

> There is no simple discovery procedure for determining phonological syllable structure (which, like phonological representations in general, may not be in a one-to-one relationship with systematic phonetic syllabification, and which may not necessarily conform to native speaker intuitions about syllable division). The nature of the mechanism which assigns syllabification (defines possible syllables) for a given language is an empirical hypothesis, whose confirmation depends on the extent to which linguistically significant generalizations can be expressed under it (Feinstein 1979: 255).

1 Introduction

Although the syllable has been used by generations of linguists both in language description and in phonological theory, it is still surprising to see the variety of opinions and arguments on the topic. As Einar Haugen expostulated as early as 1956, "everyone talks about syllables, but no one seems to do anything about defining them" (Haugen 1956: 196). Since that time we have had fifty years or more of attempts to outline and define the syllable and its constituents, perhaps without coming much closer to solid agreement. Although the terms syllable, onset, rhyme, nucleus, and coda remain in common usage among phonologists, we cannot yet point to invariant acoustic or articulatory evidence for these constituents. As Haugen continues, "the only real basis for assuming their existence is that speakers of the language can utter them separately, dividing utterances into sequences that seem natural when pronounced alone." We point to this evidence again and again as certain proof that there is "something" called the syllable; perhaps the everyday linguistic knowledge of the speaker is the single constant throughout phonological research on syllable structure. And yet, as Feinstein emphasizes in the quote appended above, we also draw a certain distinction between the "speaker's syllable" and the "phonological syllable." The phonological syllable is defined empirically by "linguistically significant generalizations," while the speaker's syllable is defined simply and automatically (when the decision is indeed simple and automatic) in careful speech, or by a number of – also empirical – experimental methods exploring external evidence, such as language games and other speaker behavior (CHAPTER 96: EXPERIMENTAL APPROACHES IN THEORETICAL PHONOLOGY).

As Goldsmith (1990) points out, there are at least two competing, or perhaps parallel, views of the syllable that have influenced phonological theory over the past century or more: just as light can behave as both wave and particle, the syllable too has been shown to demonstrate both a wave-like property based on sonority (CHAPTER 49: SONORITY), and a piece-like, or chunk-like, division into smaller constituents, such as onset and rhyme. While there are still good reasons to hold on to a wave-shaped understanding of the syllable, defining the syllable and its properties with reference to the peaks and valleys of sonority shaping each one, the present chapter will nonetheless focus exclusively on theories of the syllable which specifically address the question of constituent structure. The question of syllable structure can be understood as a question about the nature of linguistic representation (cf. Anderson 1985); as Anderson claims, "most of the history of twentieth-century phonology is the history of theories of representations, devoted to questions such as 'What is the nature of the phoneme, morphophoneme, morpheme, etc?' " (Anderson 1985: 9), to which we might add the question that concerns us here: "What is the nature of the syllable?" This chapter begins with a brief historical sketch tracing the early arguments in favor of different representations of syllable structure, followed by an overview of different models of the internal structure of the syllable. A final section reviews the conclusions of experimental studies as they adduce evidence for or against internal constituents of the syllable. (See also CHAPTER 109: POLISH SYLLABLE STRUCTURE; CHAPTER 115: CHINESE SYLLABLE STRUCTURE; CHAPTER 56: SIGN SYLLABLES.)

2 Early twentieth-century discussions of syllable-internal structure

Early twentieth-century linguists asked themselves the same question, "what is the nature of the syllable?" Saussure proposes an impressionistic account of the syllable as composed of a succession of explosive and implosive articulatory movements; while all speech consists of an alternating series of these movements, the syllable boundary itself is marked by "the passage from an implosion to an explosion in a chain of sounds" (Saussure 1922). Arguing for the syllable as a unit of phonology, he reasons that "the regular coincidence of a mechanical principle and a definite acoustical effect assures the implosive-explosive combination of a right to existence in phonology" (1922: 57). Saussure goes so far as to claim that these opening and closing articulatory motions, which he distinguishes from acoustic sonority, are themselves the irreducible units of the syllable; further, a close examination of Saussure's diagrams demonstrates that he considers the vocalic peak to form a part of the implosion, hinting at something like a rhyme: "Whenever a particular phoneme is more open than the following one, the impression of continuity persists; . . . an implosive link, like an explosive one, obviously can include more than two elements if each has wider aperture than the following one" (Saussure 1922: 56). Saussure's footnote demonstrating the syllabification of the word *particularly* is noteworthy, presenting an early sketch of an onset-rhyme division within the syllable: a vowel and following tautosyllabic consonant are both "implosive," according to Saussure's terminology, while the prevocalic consonants are "explosive." (Superscript arrow-heads indicating explosion [<] and implosion [>] are placed immediately above each alphabetic graph in Saussure's text.)

(1) < > > < >> < > < > > < >
[p a r t i k i u l a r l i]

Kuryłowicz develops a notion of syllable structure which was clearly influenced by Saussure, referring to "the initial (explosive) consonant group and the final (implosive) consonant group as they relate to the vocalic center"[1] (Kurylowicz 1949). Here Kuryłowicz quite explicitly associates the structure of both "semantic" and "phonic" systems, presenting a "table of correspondence," or equivalence, which presages hierarchical structure within the syllable, as in (2), in parallel with the semantic functions of subject, predicate, etc.

(2) *Table of correspondence* (Kuryłowicz 1949, reprinted in Hamp *et al.* 1966: 230, translated A. R. K. Bosch)

semantic system	*phonic system*
proposition	syllable
predicate	vowel
subject	initial consonant group
additional information	final consonant group, etc.

That is, just as a proposition consists of subject, predicate, and additional information, a syllable can be seen to consist of initial consonant group, vowel, and final consonant group. Peak and coda are grouped into a constituent in Kuryłowicz (1948), on the basis of co-occurrence restrictions which are found between peak and coda, but not between onset and peak.

Although the term "vocalic peak" is already in use by the time of Saussure's writing, Selkirk (1982) credits Hockett (1955) with the terms "onset" and "coda"; the use of "rhyme" to refer to the conjunction of peak and coda is attributed to Fudge (1969), although of course the informal usage of this term to describe poetic form dates from the seventeenth century.[2]

3 Evidence for constituents within the syllable

Reviewing arguments for syllable-internal structure from Saussure onward, we find that evidence for structure within the syllable is typically modeled on evidence for the syllable itself; in a comprehensive overview of syllable theories, Blevins (1995) outlines four traditional arguments in favor of the syllable itself as a constituent. She notes that (a) the syllable has been employed as the domain within which phonological processes or constraints may apply; (b) the syllable edge is identified as the locus for the application of processes or constraints; (c) the syllable itself may be picked out as a "target structure," e.g. for the application of language games or for the assignment of stress or tone; and finally (d) field linguists recount that native speakers can express intuitions regarding

[1] "le groupe consonantique initial (explosif) et le groupe consonantique final (implosif) par rapport au centre vocalique" [translation A. R. K. Bosch].

[2] The *Oxford English Dictionary* cites Samuel Butler (1663), "For Rhime the Rudder is of Verses, With which like Ships they stear their courses."

the number of syllables per word or utterance. So, for example, nasalization may spread within a syllable (a); a syllable-final consonant may be devoiced (b); syllables may be independently manipulated in language games such as the French Verlan (c); finally, field linguists commonly report formal and informal studies of speakers who are easily able to count syllables, or who pause between syllables when exaggerating slow and careful speech (d).

All these are common examples of the utility of the constituent "syllable"; however, not all of these arguments provide evidence for sub-syllabic constituents. Upon closer examination, only (a) and (c) usefully apply in evaluating syllable-internal constituents. First, as argued in (a), the constituents onset or rhyme have been argued to serve as phonological domains: Davis (1992) argues from Italian that the choice of the article (*il* or *lo*) depends on the constituent structure of the following onset (CHAPTER 55: ONSETS; CHAPTER 38: THE REPRESENTATION OF SC CLUSTERS). And the constituent structure of the rhyme – short vowel, long vowel, or vowel + consonant – may play a crucial role in stress assignment in quantity-sensitive languages. In addition (as argued in (c)), the separate constituents onset and rhyme may be singled out as "target structures" for the application of language games. In the American children's game "ubby dubby," popularized by the 1970s television show *Zoom!*, the sequence [əb] is inserted between each onset and rhyme: *hello* becomes [həbɛləbou]. Numerous language games play on the identification of onset and rhyme as target structures, and studies suggest that speech errors may operate on onset and rhyme sequences as single units (see discussion of experimental evidence, below). Thus evidence for sub-syllabic constituents derives primarily from data suggesting that onset and rhyme function as phonological domains or as target structures for other linguistic behavior. However, when we return to examine common evidence for the syllable as a constituent, parallel arguments for syllable-internal structure are not as convincing. Evidence such as (b) that refers to syllable-edges as targets (e.g. devoicing a syllable-final obstruent; CHAPTER 69: FINAL DEVOICING AND FINAL LARYNGEAL NEUTRALIZATION) in fact says nothing about syllable-internal structure per se: a syllable boundary, without reference to constituent structure, could identify this position (see Steriade 1999, for example). And finally, evidence in (d) from slow or careful speech by native speakers may provide clues as to syllable count or syllable boundaries, but generally provides little insight into sub-syllabic constituents, without additional manipulations such as we find in studies of language games, etc.

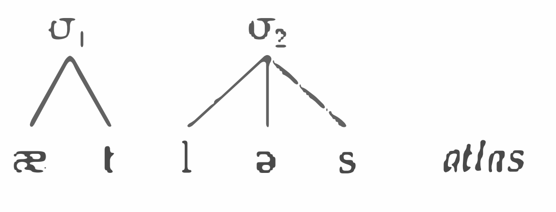
Nonetheless, we frequently uncover parallels between discussions of syllable structure and discussions of syllable-internal structure. This is made explicit within the framework of prosodic phonology (Selkirk 1982; Nespor and Vogel 1986): here the internal structure of the syllable is seen as a natural extension of the higher-level prosodic structure, to which the syllable naturally belongs (see CHAPTER 40: THE FOOT; CHAPTER 51: THE PHONOLOGICAL WORD; CHAPTER 84: CLITICS; CHAPTER 50: TONAL ALIGNMENT). After laying out arguments for the syllable as a constituent, Selkirk goes on to conclude that:

> The same three reasons leading to the postulation of the syllable can be shown to motivate the existence of privileged groupings of segments within the syllable which must be thought of as constituent-like linguistic units themselves . . . an internally-structured tree quite analogous to a tree representing syntactic structure (Selkirk 1982: 237).

3.1 "Flat" models of syllable-internal structure

Various models of syllable-internal structure have been proposed over the past century of linguistic study, from an entirely flat structure consisting primarily of syllable boundary markers to a more highly articulated hierarchical structure. Kahn (1980), for example, proposes the simplest two-tier flat structure consisting of syllable nodes (σ_1, σ_2, etc.) on one tier, associated directly with the segments of phonetic (or phonological) representation, as in (3).

(3) *No internal constituent structure* (e.g. Kahn 1980)



For Kahn, the discrete segments are "associated" with the syllable node, and among his syllable-building principles is one akin to the no-crossing constraint of Goldsmith's (1976) autosegmental phonology; "given the way the term 'syllable' is understood, it would seem nonsensical to speak of discontinuous syllables" (Kahn 1980: 36). Kahn explicitly cites Goldsmith manuscripts from 1974 and 1975, and in a footnote outlines his claim that he himself is working in an autosegmental framework, "because all theories of the syllable, including my own, are 'autosegmental' in that they involve parallel analyses of phonological material into (traditional) segments and syllables" (Kahn 1980: 61; see also CHAPTER 14: AUTOSEGMENTS).

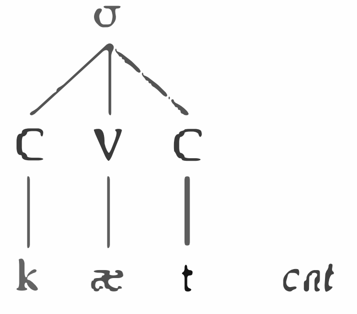
A contemporary version of Kahn's flat structure is echoed in a recent textbook, Hayes (2009). Hayes takes a non-committal position on the internal structure of the syllable: while he prefers constituent (tree) structure to the simple use of boundary symbols to identify syllables, he makes no claim about constituency within the syllable. Introducing the terms onset, coda, and nucleus, he explains that

> In some theories, the onset, nucleus, and coda are described as constituents (they are daughters of the syllable node σ, and dominate segments). This book will use "onset," "nucleus," and "coda" merely as useful descriptive terminology (Hayes 2009: 251).

In diagrams throughout this textbook, as in Kahn (1980), segments are dominated directly by the syllable node itself, without intervening structure.

A related flat structure with an intervening CV tier is proposed by Clements and Keyser (1983) in (4) (see also CHAPTER 54: THE SKELETON).

(4) *Syllable with intervening* CV *tier* (e.g. Clements and Keyser 1983)



Among the options that do incorporate some representation of internal structure, however, ternary branching structure represents perhaps the simplest

This is essentially what Venneman (1972) terms the "Law of Initials": that "medial syllable-initial clusters should be possible word-initial clusters" (Venneman 1972: 11); or what Bell (1976) terms "the Kuryłowicz condition," that "initial and final clusters of medial syllables conform to the same constraints as those in initial and final syllables" (Bell 1976: 255).[6]

On the other hand, there are languages which place more restrictions on word-internal consonant clusters, and allow extra consonants at word edges, such as Polish (Kenstowicz 1994: 262ff.). A number of chapters in Féry and van de Vijver (2003) tease out just these inconsistencies between word-internal clusters and clusters found in either word-initial or word-final position (Cho and King 2003; Green 2003; Kiparsky 2003; Wiltshire 2003). See also Dixon (1970) and many others, as well as CHAPTER 36: FINAL CONSONANTS.

3.4 *Moraic phonology and syllable-internal structure*

While the syllable itself has been in wide use throughout the past century or more, clear arguments providing evidence of the internal structure of the syllable are less common than one might expect. Many arguments which state a convincing case for the syllable as a phonological unit in fact fail to motivate syllable-internal structure. The constituent structure of onset, rhyme, nucleus, and coda intersects in complex ways with a moraic theory of syllable organization, as sketched in (14) below. While a moraic analysis often appears to supersede one employing syllable structure, in fact the notion of moraic weight is interwoven with an understanding of syllable structure, in particular the structure of the rhyme.

(14) *The mora in the prosodic hierarchy*

Prosodic Word
|
Foot
|
Syllable
|
Mora

The mora provides a useful means of representing syllable weight, in quantity-sensitive languages where this is required. In languages such as English or Latin, a syllable with a short vowel is monomoraic, while syllables with a long vowel (VV), or vowel + coda consonant (VC), are bimoraic. We note, however, that only consonants in the rhyme may be moraic; onset consonants never contribute to

[6] Recall that in this article Bell argues against "the distributional syllable." Nevertheless, he does not entirely conclude that phonology can do without the syllable: "Let us, however, guard against too narrow a view, against confusing a tool with the problem. 'Defining the syllable' and 'proving the existence of the syllable' are pseudo-problems. Segment organization is the problem. If assumption of a syllabic unit leads to explanation of regularities of segment organization, so much the better. If not, we will be awaiting a more general theory of organization, and the syllable may enter the museum's Hall of Scientific Constructs, taking its place beside ether, the noble savage, and the like" (Bell 1976: 261).

syllable weight (CHAPTER 47: INITIAL GEMINATES; CHAPTER 55 ONSETS). Thus we return to some notion of constituent structure within the syllable, if only to identify the domain in which moras are projected. Furthermore, whether the mora truly serves as a "constituent" is unclear; while the syllabic nucleus is typically affiliated with a mora, the affiliations of onset and non-moraic coda consonants are less clear. Non-moraic elements are sometimes associated with the syllable node directly, or sometimes argued to share the mora with the nuclear vowel. Essays in Ziolkowski *et al.* (1990) demonstrate the range of arguments regarding moraic structure within the syllable. Hyman (1985) originally suggested that a syllable-initial consonant links to the mora of the following vowel, creating what looks like a "body–coda" structure. More commonly, the syllable-initial consonant is assumed to associate directly to the syllable node, as in Hayes (1989) and many others. For a more recent position favoring the mora, Yip argues explicitly that the evidence in favor of the constituents onset and rhyme "is scanty and inconsistent" (Yip 2003: 779), and relies on a moraic model of the syllable to account for the behavior of pre-nuclear glides in English and Mandarin Chinese. I leave it to other contributors to this *Companion* to tease out the intricacies of moraic phonology in more detail (see CHAPTER 39: STRESS: PHONOTACTIC AND PHONETIC EVIDENCE; CHAPTER 40: THE FOOT; CHAPTER 41: THE REPRESENTATION OF WORD STRESS).

4 Experimental studies

Experimental studies, both of acoustic properties of speech and of human behavioral responses to syllabification tasks, have also been constructed to explore this question of the nature of the syllable. The great majority of experimental work over the past fifty years involves studies of simple syllabification, with a view to accounting for syllable boundaries. Most of these studies place a particular focus on the syllabification of an intervocalic consonant or consonants; see for example studies on Dutch, Finnish, German, French, Japanese, and English (e.g. Fallows 1981; Gillis and DeSchutter 1996; Schiller *et al.* 1997; Berg and Niemi 2000; Content *et al.* 2001; Goslin and Frauenfelder 2001; Ishikawa 2002; Redford and Randall 2005). Still, a number of experimental studies have been adduced to test the validity of the internal constituents of the syllable; the majority of these studies focus on the primary constituents of onset and rhyme. Evidence regarding hierarchical structure within the syllable is mixed, with arguments drawn from language games (both "traditional" and invented/experimental), slips of the tongue, perceptual studies, investigations with children, and other experimental paradigms (CHAPTER 96: EXPERIMENTAL APPROACHES IN THEORETICAL PHONOLOGY) to investigate whether onset, rhyme, nucleus, and coda are or are not syllable constituents.

A series of experiments by Treiman and co-authors argue in favor of an onset–rhyme structure, based on subjects' performance on various word games (Treiman 1986; Fowler *et al.* 1993; Treiman *et al.* 1994; Treiman *et al.* 1995). Most recently, Kapatsinski (2009) claims to show from an experimental study that English speakers are able to learn rhyme–affix associations more easily than body–affix associations, basing this argument on the claim that associations should be easier to learn within rather than across constituents, given a hierarchical structure to the syllable. However, Pierrehumbert and Nair (1995) replicate Treiman's word game paradigm merely substitutions of segmental units – errors in "selection" – but instead may be examples of gestural intrusion or mis-timing (Pouplier and Goldstein 2005).

Various studies conducted on languages other than English appear to show that if there is an onset–rhyme distinction it may be a language-specific one; experiments with native speakers of Korean indicate that Korean syllables "contain a cohesive CV or body unit, in contrast to the VC or rhyme unit of English" (Yoon and Derwing 2001); one of the five experiments described here studied preliterate children, indicating that literacy could not be a confounding factor. A study involving Chinese–English bilingual children found "a preference for matching body over rime in Chinese, and for matching rime over body in English," concluding that there must be cross-language differences in processing spoken syllables (Wang and Cheng 2008).

Acoustic studies have examined timing relationships within the syllable to identify syllable constituents. Conducting an acoustic study on English disyllables and casual speech vowel reduction, in triplets of words such as *support/sport/s'pport* (reduced *support*) Fokes and Bond (1993) conclude that there were no invariant acoustic cues determining syllabicity. While the authors concede that *sport* and *s'pport* may in fact be phonetically distinct, the study found no invariant cues to distinguish them. Certainly, attempts to isolate acoustic or articulatory invariants of the syllable date from as early as Stetson's (1928) "chest pulse" theory; however, there is no current consensus on either acoustic or articulatory definitions of the syllable, let alone of structure internal to the syllable. While Selkirk (1982: 340) set the stage for a good deal of ensuing research with her note that "other phonological, or shall we say phonetic, phenomena such as duration and closeness of transition between segments might also be taken as revealing of the immediate constituent structure of the syllable," we still find very little clear evidence of any invariant property pointing to syllable-internal hierarchical structure.

5 Conclusion

Despite the lack of phonetic evidence for invariant acoustic or articulatory measures of syllable structure, research in this area too continues apace. As Ladefoged noted:

> There is no single muscular gesture marking each syllable . . . (but) there is evidence . . . that speakers organize the sequences of complex muscular events that make up utterances in terms of a hierarchy of units, one of which is the size of a syllable; and it is certainly true that speakers usually know how many syllables there are in an utterance. We will therefore assume that a neurophysiological definition is possible, even if one cannot at the moment state it in any way (Ladefoged 1971: 81).

Even those who argue against the use of syllable structure to account for phonotactics acknowledge the usefulness of the terms referring to syllable-internal structure: onset, peak, coda, and even rhyme. "Syllable structure, whether directly perceived or inferred, is an undeniable aspect of phonological representations," claims Steriade (1999), although she goes on to argue against employing syllable constituents in a phonological analysis, concluding that syllable position "does not condition segment realization." Steriade argues instead that knowledge of syllable structure, and syllable edges in particular, derives from or is founded on the speaker's perception of word-based phonotactic regularities. Her claim is essentially that we have put the cart before the horse in arguing that phonotactic constraints are built upon syllable structure; instead, these phonotactic regularities may be precisely what allow us to identify syllable position.

In any case, the labels we use to identify internal constituents of the syllable – onset, coda, and rhyme – remain convenient terminology, and seem likely to remain in common usage. Nevertheless, it also seems clear that a conservative view of linguistic structure – a view shaped by Occam's razor, perhaps – would concede that these terms, while useful, may not be supported by empirical evidence. Acoustic and experimental studies offer only mixed results, while language-specific phonological studies continue to differ widely in their use of (and claims for) some particular organization of syllable-internal structure. How we use syllable structure to represent the patterns and organization of human language will differ depending on the questions we ask and the problems we confront in the specific languages we investigate. Syllable structure may turn out to be an organizational tool, rather than an object available for independent manipulation.

34 Precedence Relations in Phonology

Charles Cairns
Eric Raimy

1 Introduction

"Precedence" in phonology refers to the fact that elements occur in ordered sequences. An understanding of precedence relations is key to explicating notions of locality, adjacency, and left–right asymmetries, which have played significant roles in the phonological literature, especially since the advent of autosegmental phonology (Goldsmith 1976; CHAPTER 14: AUTOSEGMENTS). McCarthy (1989: 71) writes "nonlinear phonology imposes strict requirements of locality on phonological rules," and "locality … ensures that the elements referred to in phonological transformations and constraints are adjacent at some level of representation."

We must agree on a common set of questions in order to compare and contrast linguists' notions of precedence relations, a requirement that presupposes a formal framework. Since the earliest days of phonology, the sequential nature of speech and the progression of letters across the printed page have been assumed to be sufficient to understand precedence. It is always salutary to explicate tacit assumptions, so this chapter explores the implications of a formally rigorous understanding of precedence. The formal rigor is supplied by graph theory, a branch of mathematics that we will use to unpack the question of what it means for phonemes to appear in an ordered sequence (Wilson 1996 is one of several good introductions). Phonology is concerned with the characteristics of precedence in human language, so graph theory itself can be no more than a useful tool. But because graph theory is an explicit mathematical model that provides specific and well-understood possible answers to questions of precedence, we explore its implications in this chapter.

Once we have introduced the relevant aspects of graph theory, we go on to examine a sample of the claims and assumptions that have been made in the literature on phonological precedence, with varying degrees of explicitness. In particular, we examine the characterizations of various approaches to autosegmental phonology within graph theory. We will further explicate the nature of precedence in phonology by considering the basic operation of deletion. All phonologists must take as bedrock assumptions that phonemes appear in a sequence and that there exist phonological processes with the capacity to delete phonemes from a sequence. One interesting result of this exercise is that commonly assumed antagonistic theories of phonology converge on a common model of deletion.

Before proceeding, we first ask if precedence relations are primitives of phonological representations or if they are derived. Van der Hulst (2008), for example, proposes that precedence relations can be derived from underlying syllables. Consider a highly articulated theory of the syllable with labeled nodes, e.g. Fudge (1969, 1987); Cairns (1988); see also CHAPTER 33: SYLLABLE-INTERNAL STRUCTURE. The idea is that if at the lexical level featural information such as [back] or [coronal] were stored in syllabic nodes like onset and rhyme, then perhaps the number and order of phonemes on the surface could be predicted from the inherent order of syllabic constituents. There are at least four natural limits to deriving precedence relations from syllable structure. First, syllabification is not always exhaustive; many languages are known to have sequences of unsyllabified consonants (Bagemihl 1991; Czaykowska-Higgins and Willett 1997; Vaux and Wolfe 2009). Second, it would in any case be necessary to specify the order among syllables. Consider the English loan from Tamil *catamaran*; hypothetical **matacaran* and **tamacaran* would serve as equally plausible loans into English, yet they differ from the existing word only by syllable order. The possibility of using foot structure to order syllables only moves this question higher in the prosodic hierarchy and requires more prosodic information to be stored in the lexicon. The necessity of stipulating explicit sequencing information in the lexicon cannot be escaped.

Third, reference to precedence relations at the segmental level is necessary to properly account for phonotactic constraints. Blevins (2003), building on Steriade (1999), shows numerous compelling examples where phonological sequencing generalizations and cross-linguistic universal patterns refer to properties of the phonological string and not to syllable structure. Of course, as Blevins points out, there are many cases "where phonotactic constraints and syllable structure appear to converge." She suggests that "this is because syllabifications are derivative of phonotactics, not vice versa" (2003: 393).

Finally, we are encouraged in our focus on segmental precedence by the fact that resyllabification is rampant throughout phonology and phonetics; the effervescence of the syllable makes it a poor candidate for the bearer of lexical precedence relations.

§2 sketches the basic elements of graph theory and their application to phonology. §3 presents the complications that arise in connection with considering precedence relations in autosegmental phonology and provides a plausible explanation of why the Obligatory Contour Principle (OCP) is so variably valid. §4 demonstrates how investigating the process of deletion in graph theory illuminates how different theoretical models of phonology converge on the same understanding of deletion in phonology. §5 demonstrates how theories of phonology that view segments as entities that occur in real time can benefit from the consideration of precedence in graph-theoretic terms. §6 shows how graph theory can illuminate issues in phonology such as the "no crossing constraint" and local *vs.* long-distance adjacency. §7 illustrates some extensions of graph theory approaches to different phonological and morphological phenomena. §8 concludes this chapter.

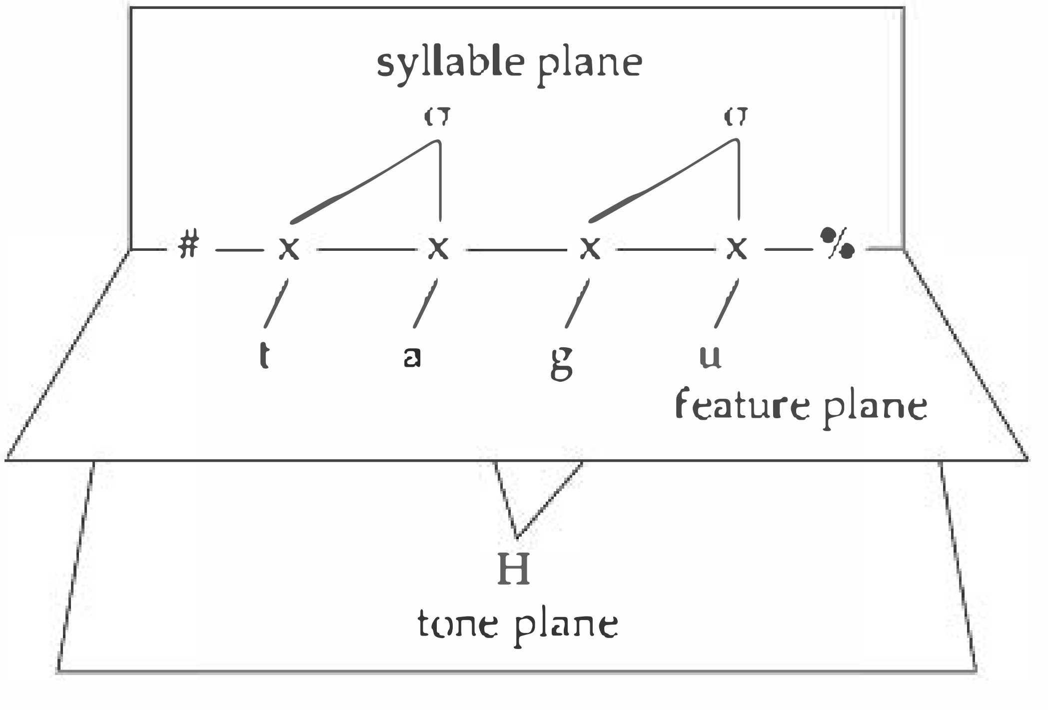
2 Precedence relations and graph theory

Phonologists differ about whether to view a phonological sequence as a string of discrete, point-like objects or as a series of possibly overlapping segments which exist in real time; Trubetzkoy (1939) described phonemes as essentially timeless (*zeitlos*), abstract entities like the dits and dots of Morse code, where each unit is unaffected by the producing process (although possibly influenced by proximal symbols). The alternative view, that phonological patterning is defined by the dynamic articulation of actual speech, goes back to Sweet (1877), Sievers (1881), and Saussure (1916). This serves as the fundamental assumption of such schools of thought as Articulatory Phonology (Browman and Goldstein 1986, 1989, 1990a, 1990b; CHAPTER 5: THE ATOMS OF PHONOLOGICAL REPRESENTATIONS), which views the elements that appear in phonological sequences to be events in real time.

The consensus that phonetic sequences involve continuous, overlapping elements does not extend to more abstract levels of phonology. Theories of morphological operations such as reduplication and infixation and of many phonological processes such as morphophonemics, deletion, etc., generally operate on representations made up of discrete, point-like objects, and these theories have achieved considerable descriptive success; we will proceed on this basis and turn to the event-based outlook later.

Consider the representation of the Margi word /tágú/ 'horse' (from Kenstowicz 1994: 312) in a generic version of autosegmental phonology in (1). This is a picture of what Coleman and Local (1991: 309) call "paddlewheel graphs." It is drawn so as to induce the reader to visualize three half planes, each emanating from a common line. The three-dimensional metaphor is useful because it helps us break down general questions of precedence into smaller and hence more manageable ones. This imagery can be misleading, however, because, as Coleman and Local (1991) demonstrate, autosegmental representations are not necessarily three-dimensional (i.e. non-planar, as defined in §6) in a mathematical sense.

(1) *Paddlewheel graph of Margi* /tágú/



Lines are referred to as "tiers" in autosegmental phonology, and the line defined by the intersection of the three planes depicted in (1) is the "anchor tier." The anchor tier contains the string of symbols # x x x x %, where # and % indicate the beginning and end, respectively, of the phoneme sequence (we ignore these now, but return to them below).

Elements are also arrayed in tiers on the "feature plane," the "syllable plane," and the "tone plane" of (1). The feature plane is shown with the alphabetic symbols *t, a, g, u* in lieu of the familiar feature trees (we employ this notation throughout the remainder of the chapter); in §3 we will see that this is more complicated than

(2) a. t — a — g — u

b. vertices: {t, a, g, u}

edges (unordered): {t a, a g, g u}

(2a) and (2b) contain the same information. (2a) depicts the graph in a visual manner, while (2b) defines the graph as a list of vertices and a list of edges. Each edge is defined by a pair of vertices, and these pairs are set off typographically from each other by commas in (2b). A list of edges suffices for many graphs, because the vertices can be determined from the list of edges. Note that the lists of vertices and edges are literally lists and not sets.

Because the edges in (2b) are undirected, it is called an undirected graph, where the two vertices that define each edge are unordered with respect to each other; for example, the edge {t a} is equivalent to {a t}. Because this type of graph contains information only about adjacency of vertices and does not specify any order, it appears to be a poor candidate for a model to represent phoneme strings. For one thing, lexical representations must contain ordering information. Consider the existence of pairs of words like *cat* and *tack* in English. The adjacency pairs (undirected edges) for these two words are identical; both words have the edge set {t æ, æ k}.

Beyond the obvious fact that ordering is distinctive is the observation made by de Lacy (2007) that if phonological graphs were undirected, we would predict that mirror-image rules or constraints like those that appeared in early versions of *SPE*-type phonology would be commonplace. An example would be rules of the form $x \rightarrow y$ / {z __, __ z}, as suggested by Bach (1968), Langacker (1969), and Anderson (1974). This means that x is rewritten y if it either precedes or follows z. If we were to adopt undirected graphs as the representation for phonological forms we would predict, contrary to fact, that mirror operations should be the most common operations found in phonology.

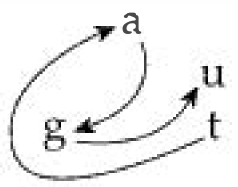
Because a theory containing only undirected edges cannot distinguish between *cat* and *tack* and makes false predictions about the directionality of phonological operations, we consider graphs where the vertices that specify each edge are ordered with respect to each other. Information about sequential order can be added to the graph in (2) by making it a "directed graph" (or "digraph"), as in (3). An edge in a digraph is an ordered pair of vertices; the vertex mentioned first in an edge specification precedes the one mentioned second.

(3) a. t → a → g → u

b. vertices: {t, a, g, u}

edges (ordered): {t a, a g, g u}

c.



(3a) is the graphic representation of the information in (3b). Because the edges in (3b) are ordered, they specify that *t* precedes *a*, *a* precedes *g*, and *g* precedes *u*. (3a) is not the only diagram consistent with (3b), however; for example, the diagram in (3c) is equally consistent with (3b), but not as convenient to read as (3a). They are formally equivalent; in fact, (3a), (3b), and (3c) all represent the same *g* or *u*, so in this sense it is true that if *t* precedes *a* and *a* precedes *g*, then *t* precedes *g*.

Before concluding this section, note that it is convenient to add explicit beginning and end symbols, which we represent as # and %, respectively. Positing these symbols allows us to say that all vertices on the anchor tier that are of degree two are available for serving as phonological segments, and only the abstract terminal symbols are of degree one. These symbols are also convenient to define the environments of initial and final segments, needed by many phonological processes. Also, chain graphs supplemented with special beginning and end symbols allow for the definition of free *vs.* bound morphemes: a free morpheme like *tagu* is a chain graph with # and % at beginning and end; a bound morpheme would lack one or both of these symbols. The graph in (4) is the type we will use to explicate precedence issues when we consider deletion in §4.

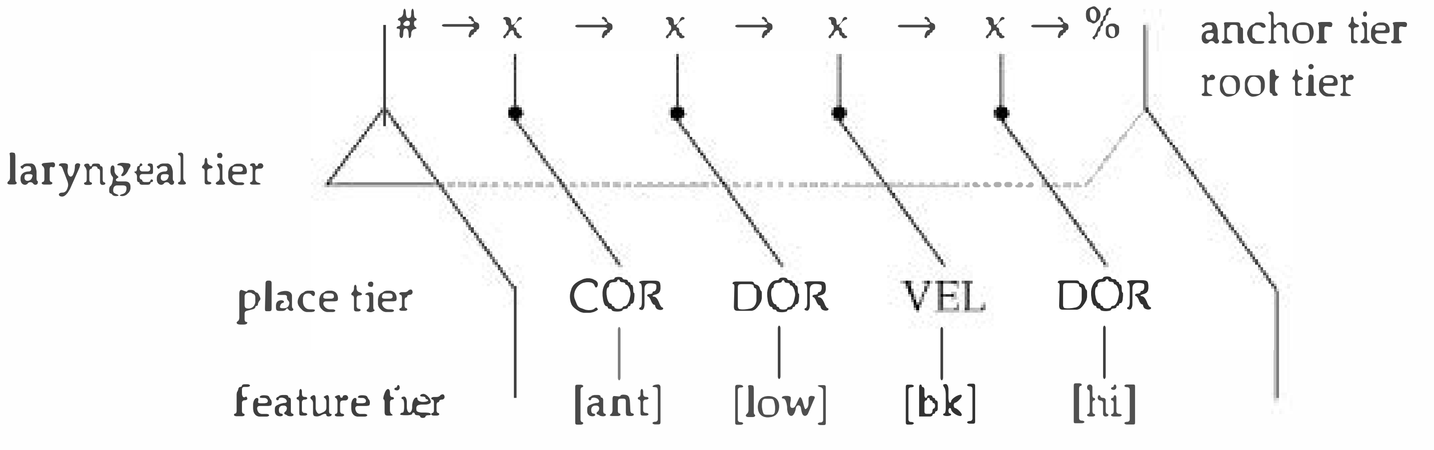
(4) a. # → t → a → g → u → %
b. vertices: {#, t, a, g, u, %}
edges (ordered): {# t, t a, a g, g u, u %}

This section has described the basic principles of graph theory as they apply to notions of phonological representations held by virtually all schools of thought in phonology. The overwhelming majority of phonologists operate on the assumptions, usually tacit, that sequences of phonemes have the properties of asymmetry, irreflexivity, and (in the qualified senses explicated above) transitivity, and the preceding paragraphs have shown that these are best understood in graph theory, where they derive from the properties of directed chain graphs. However, as stated at the beginning of this section, we have been considering only precedence relations on the anchor tier of (1). We now turn to a consideration of precedence relations in autosegmental phonology.

3 Precedence relations and autosegmental phonology

In the preceding section we adopted the expository convenience of depicting phonological content of segments on the anchor tier by means of phoneme symbols. This was a shorthand way of showing feature trees, sketched in (5), which is an elaboration of the diagram in (1). This section is devoted to analyzing the precedence relations among elements that are on different tiers, and we will see that this exercise provides insight into the OCP. A brief explanation of (5) is in order first.

(5) *Schematized autosegmental representation of* [tagu]



violate the requirement that phonological representations be equivalent to connected graphs; floating elements would be represented by vertices that are not connected to the rest of the graph. Consequently, "floating" features must be connected to the rest of a phonological representation; this seems to be consistent with current thinking on this topic (see CHAPTER 82: FEATURAL AFFIXES).

We will assume that precedence is encoded only on the anchor tier for the remainder of this chapter. This view improves our understanding of Odden's (1986, 1988) critique of the OCP as a language universal: in general, the OCP appears to behave in a cross-linguistically arbitrary way, because the locality of distinctive features is mediated by the timing tier. Consequently, whether two elements are adjacent or not must be determined either directly from the list of edges or by calculating whether a walk exists between the two elements. The implementation of a walk appears to coincide with proposals about "searches" in phonology by Mailhot and Reiss (2007), Samuels (2009), and Nevins (2010) (see §7). This perspective has the advantage that it supplies one universal account of adjacency, which has two different specifications: two elements are adjacent if they either share an edge or if there is a walk connecting them. Each language-particular process must, of course, specify which definition of adjacency is required for its application. The existence of two ways of specifying adjacency is plausibly a major reason why the OCP appears superficially to be so variably valid.

4 Deletion and precedence

Deletion is a fundamental phonological phenomenon that must be accounted for by any phonological theory. The naive view of deletion is that segments can be simply eliminated from a representation without any complicating entailments; this is based, of course, on the conception of precedence portrayed by the left to right array of symbols across the printed page. Deletion is far more complicated when we consider how precedence structures are altered when a segment is deleted. For purposes of explicating how deletion affects precedence relations, we return to using our Margi example and suppose that a phonological process of Margi were to delete the *g* from *tagu*. It does not matter what triggers this operation, nor in what phonological theory this operation is described; we are interested here in specifying precisely what it means to delete a segment when it is considered as a vertex in a directed chain graph.

In this section we describe the two characterizations of deletion (see CHAPTER 68: DELETION) that are possible within directed chain graphs. One consists of skipping over (or underparsing) the segment to be deleted, and the other involves merging two segments into one. Both appear to be empirically attested. A particularly significant part of this presentation is that two models of Optimality Theory (Containment and Correspondence) as well as the derivational model known as Precedence Based Phonology (Raimy 2000, 2009) converge on the representations and operations revealed by a graph-theoretic explication.

Without considerations about the nature of precedence, (11a) presents the naive mapping between representations undergoing the deletion of *g*, where the symbol ">" means merely "becomes," without reference to the nature of the operations involved. The question at hand is: once precedence relations are specified, how exactly does (11b) become (11c)?

All graphs representing phonological structure must be interpreted by some sort of phonetic implementation mechanism, so the question now before us is how to assure that this mechanism follows the added "*a* to *u*" precedence relation, and not the old "*a* to *g*" precedence relation. There are two general solutions to the favoring of the newly added precedence relation and they differ in whether computation in phonology is "parallel" or "derivational." "Parallel" computation is the type found in the containment model of OT, where there is a GEN function that creates a list of different candidates; there is also the EVAL function, which determines which candidate is the most harmonic given a language-specific ranking of CON. In this model, GEN would be free to create candidates that contain any number of novel precedence relations that do not exist in the input. Therefore, GEN will generate candidates with underparsed segments, and these candidates would indicate that phonetic implementation will follow the "deletion edge" and not the edges associated with the deleted *g*. Whether candidates with detours might emerge as the most harmonic will be the result of parochial constraint interactions. In short, preference for newly added precedence links that produce deletion can be implemented easily in the containment model of OT.

This approach to deletion can be straightforwardly carried over to the Correspondence model of OT (McCarthy and Prince 1995). The difference between the implementation of deletion by underparsing in the Containment and Correspondence models of OT is in the status of a representation with conflicting precedence specifications as in (13). Whereas the Containment model can directly produce this type of representation as its output with the effect that segments that are "detoured" around are the underparsed segments, the Correspondence model can produce the chain graph in (11c) directly from (11b) by deleting the vertex *g* and by adding the new edge {a u}, operations freely performed by GEN. This computation requires the comparison of both (11c) and (11b) in order to determine the MAX, DEP, and CONTIGUITY violations. Thus it appears that the Containment and Correspondence models of OT converge on deletion as the addition of a new precedence link.

Preference for newly added links and consequent deletion can be implemented in a derivational model of phonology by imposing an order on the list of edges. Recall that (13) is not a directed chain graph, a requirement for phonetic implementation. We return to this point in §7, but for now note that, as Idsardi and Raimy (forthcoming) point out, a derivational theory of phonology requires representations to have the characteristics of a directed chain graph only at the interface between modules. "Serialization" is a process that creates a walk from the beginning symbol # to the end symbol %; this walk creates a representation that is a directed chain graph. Idsardi and Shorey (2007) propose that serialization is a walk that uses the order of the list of edges to make decisions about which precedence link to follow when there is a choice. Thus, in (13b), when the walk reaches the *a* vertex, it must choose between following either the {a u} or the {a g} edge. This choice will be made by the order of the edge list, because one of these edges will be "first" and thus will be followed. In order for an added precedence link to produce deletion effects it must be added to the list of edges in a manner which places it before the precedence links associated with the segment to be deleted.

We emphasize that the detour approach to deletion is virtually the same in three theories of phonology, i.e. the Containment and Correspondence models of OT and the derivational model. The differences among the phonological theories arise only from specific details on how the deletion process is actually computed in the different models.

A second approach to deletion is also possible in graph-theoretic terms and can be understood as involving a type of coalescence, as suggested by de Lacy (2007) for OT. Another way to map a representation like (11b) to (11c) is to merge two of the vertices into one, without any addition of new precedence relations. We must first decide whether the "deleted" segment is merged with the preceding or following segment. For purposes of explication in our hypothetical example we merge the deleted *g* with the preceding *a*. The operation of vertex merger will be broken into steps in (14), so that important questions can be identified.

(14) *Deletion as vertex merger*

a. # → t → a → g → u → %
 vertices {#, t, a, g, u, %}
 edges (ordered) {# t, t a, a g, g u, u %}

b. # → t → [ag] → u → %
 vertices {#, t, [ag], u, %}
 edges (ordered) {# t, t [ag], [ag] [ag], [ag] u, u %}

c. # → t → [a] → u → %
 vertices {#, t, [a], u, %}
 edges (ordered) {# t, t [a], [a] u, u %}

(14a) presents the representation for *tagu* as in (4). Vertex merger (14b) coalesces every occurrence of *a* and *g* into a new vertex *ag*. This produces the representation in (14b), where the merger of the *a* and *g* is indicated by the [ag] composite segment. The inevitable result of this is the production of the edge {ag ag}, or the edge that loops back onto itself, thus violating the constraint requiring irreflexivity. This reflexive edge will produce a geminate or long version of the composite [ag] segment. Although this is not the desired result for plain deletion, this situation produces compensatory lengthening effects (Hayes 1989; Sloan 1991: 80–87) in a straightforward manner without recourse to moras (see §7).

The final steps that are required to produce (14c) are to eliminate the looping back arrow if it is not desired and to specify the phonetic interpretation of the vertex *ag*. There are a number of ways of accomplishing the former, one of which is to specify a parameter that allows languages to eliminate any "ref.exive" edges (edges that are defined by two mentions of the same vertex) whenever they are formed. Any theory of phonology that has the resources to separate the melodic content of a segment from its timing slot easily handles the phonetic interpretation aspect of this process. Some languages retain features of both segments in the composite vertex; for example classic coalescence in Sanskrit /a/ + /i/ > /e/. In our example, we want the segment to simply be interpreted as *a*, which will require some extra statement.

The preceding description of deletion in connection with compensatory lengthening and coalescence is theory-neutral, and will be implemented differently in different theories. The point is that considering explicit precedence relations shows how deletion, coalescence, and compensatory lengthening are deeply connected regardless of how different theories focus on the various surface effects of deletion.

One question that arises from this discussion is whether there is an embarrassment of wealth in the representational possibilities offered by graph theory to produce deletion. It appears that all the ways of accomplishing deletion are attested in different languages. For example, Tohono O'odham vowel syncope in reduplication is best characterized by the detour approach (Raimy 2000: 113–114). Chumash /l/-deletion (Raimy 1999: 82–83) exhibits deletion that is best characterized with the coalescence approach, as are examples of classic coalescence. Some languages appear to have both options available in competition with each other (Indonesian nasal assimilation; Raimy 2000: 99–112). Consequently, all of the analytical options based on different representational opportunities appear to be attested. Questions about deletion are thus typological in nature, where phonologists should ask which kind of deletion any particular instantiation in a particular language exhibits: does the type of deletion that occurs correlate with compensatory lengthening and/or coalescence processes, and what diagnostics are there to distinguish the different types of deletion?

An important theme of this section is that making precedence relations explicit via graph theory is useful to all theories of phonology. This should not be misunderstood as suggesting that there are no differences among different theories of phonology; our point is that specific differences with respect to precedence can be identified explicitly through differences in the necessary graph structures. Put another way, graph theory provides a reasonably neutral lingua franca to discuss and explore the nature of precedence in phonology. Of course, up until this point we have been discussing phonology whose elements are discrete, timeless entities; we now turn to considering the role of precedence in theories that view segments as containing real-time articulatory gestures.

5 Precedence and discrete point theory

One assumption in the preceding sections of this chapter that can and should be called into question is that phonology operates strictly on abstract discrete elements. This is the standard assumption in the class of theories of phonology that we will call formal phonology. Not all theories of phonology make this assumption. According to the theory of Articulatory Phonology (Browman and Goldstein 1986, 1989, 1990a, 1990b), vertices represent "gestures," i.e. abstract representations of dynamic articulatory events or actions. Thus the basic elements exist in real time, and are not abstract, timeless points. Such theories are also amenable to graph-theoretic representation, because they can be seen to have multiple precedence structures, one for each articulator in a segment. In fact, from a precedence structure point of view, it may be just the difference of whether there is a single abstract precedence structure or multiple more concrete articulator based precedence structures that produces an overall precedence structure that allows or disallows overlap.

Gafos (2002) argues that it is the nature of precedence that is at issue in the formal *vs.* gestural models of phonology. Gafos (2002: 270) observes that "the phonologically relevant notion of time is *overlap* of dynamic units"; this is in contrast to "linear order of static units [being] the only relevant notion of time in phonology." Both approaches still order phonological elements; they differ only in the nature of the precedence graphs. For formal phonology, the vertices are segments that are timeless points, and overlap is not definable. In gestural phonology, the vertices are gestures that have both spatial and temporal aspects, so there is a more complicated relation of overlap. Bird and Klein (1990) explicitly develop the model of precedence for phonological representations that can overlap. Another way of conceptualizing precedence in gestural phonology is to assign weight to the edges in a precedence graph to indicate the amount of overlap between each gesture; alternatively, the weights may indicate the actual time span between the gestures.

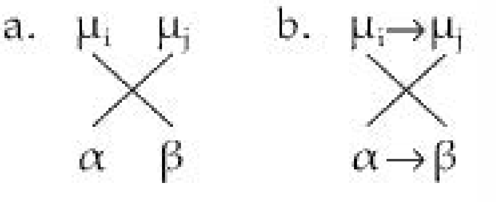
Any model of phonology can be cast by precedence graphs. Different models of phonology simply argue for or assume different characteristics for the relevant precedence graph. The different approaches to phonology – formal and gestural – are only incompatible if one assumes that either model will account for all phonological phenomena. Both models are necessary in their own domains and provide insights into different aspects of phonology. Formal phonology with atemporal segments represents phenomena closer to the morphology–phonology interface, while gestural phonology represents phenomena closer to the phonetics–phonology interface.

6 Graph theory as a tool for phonology

One major advantage of adopting graph theory as the formal underpinning of precedence in phonology is that it supplies general and specific knowledge that can be applied to uniquely phonological questions. Two topics in phonology that directly benefit from general knowledge of the nature of graphs are the no crossing constraint and locality in phonology.

The no crossing constraint originates in Goldsmith (1976: 27) as the statement "Association lines do not cross." Archangeli and Pulleyblank (1994: 39) present this constraint as a ban on the representation in (15a), which we augment with explicit precedence relations in (15b).

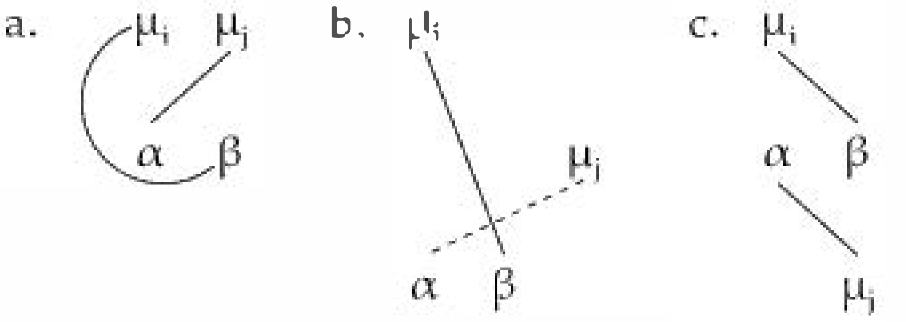
(15) *The no crossing constraint* (Archangeli and Pulleyblank 1994: 39)



The problem with (15) is that it appears to encode conflicting precedence relations. The association lines indicate that α and μ_j occur together, as do β and μ_i. The two tiers thus provide conflicting information about which feature precedes the other feature, because it encodes both $\alpha \rightarrow \beta$ and $\beta \rightarrow \alpha$. Two assumptions dictate that (15b) is ineluctably derived from (15a): that the left-to-right array of printed symbols encode directed edges and that association lines must be straight.

Coleman and Local (1991) argue that the no crossing constraint is an incoherent concept in autosegmental phonology, in part because there is no mathematical justification for insisting on straight lines; that restriction is merely a convention for drawing diagrams and has no formal content. (15a) is formally equivalent to all the diagrams in (16), which do not portray a no crossing constraint violation. (16a) is a graphic trick making an association line curved; (16b) makes the diagram appear three-dimensional, and (16c) simply moves one of the elements to the other side of a tier.

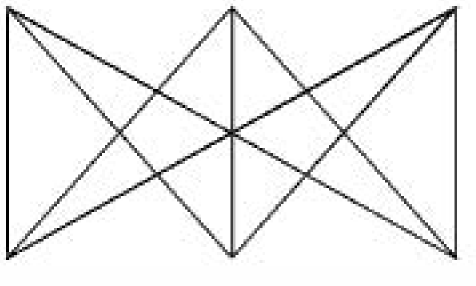
(16) *Graphic workarounds*



More importantly, Coleman and Local argue that the no crossing constraint implies that autosegmental representations must be "planar," an important question of graph theory that bears directly on when lines cross or not.

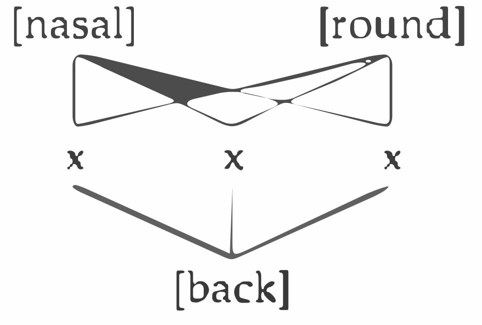
Kuratowski (1930) proves that two kinds of graph cannot be drawn within a single plane without lines crossing. One is the $K_{3,3}$ graph in (17). This is a bipartite graph, which means that the vertices can be partitioned into two sets such that each edge of the graph has one end in one set and the other in the other. The presence of a $K_{3,3}$ graph structure means that the graph which has it is "non-planar" if the lines are not to cross. According to Kuratowski's Theorem, a graph is non-planar if and only if it contains either the subgraph $K_{3,3}$ or K_5 (see Kuratowski 1930 for the K_5 graph, which does not appear to be relevant to phonology).

(17) *Kuratowski's $K_{3,3}$ graph*



Coleman and Local (1991) establish that most supposedly three-dimensional (non-planar) representations in the literature are in fact planar; on the other hand, they also point out that phonology must countenance non-planar representations. The autosegmental representation of the word *room* in Guyanese English in (18), adapted from Coleman and Local (1991: 330), is an example of a non-planar graph (i.e. it contains a $K_{3,3}$ graph); the three features [nasal], [round], and [back] are on independent tiers and each is associated with all three segments. The first x-slot represents the phoneme /r/, the second /u/, and the last /m/. Coleman and Local report that the three features depicted here spread to each of the three segments independently of one another, and therefore each should be on a separate tier. It is not possible to depict these associations in two-dimensional space without lines crossing.

(18)



The import of Coleman and Local's work is that autosegmental representations can be non-planar, which means that different distinctive features will not be able to cross lines by definition, because the association lines will be in different planes. The practical result is that phonologists must be explicit about the nature of precedence in phonological representations and distinguish between conventions on drawing convenient diagrams and formal properties of precedence.

Restrictions on precedence relations in phonology do not necessarily reside in the representations themselves but may result from how they are implemented. Graphs are "abstract data structures" (Aho *et al.* 1985) that can be implemented in many different ways. The manner of implementation affects what operations are easier (or possible) to perform than others. For example, we have so far portrayed phonological representations as a list of vertices (*x*-slots and associated features) and edges (precedence relations) as the basis for implementation. Some scholars (e.g. Heinz 2007) use adjacency tables as the basis for implementation, as exemplified for *tagu* in Table 34.1 (which is technically a local adjacency table). An adjacency table is made by listing the vertices of the graph as the headers for columns and rows and indicating in each cell whether the relevant precedence relationship holds or not.

The row headers in Table 34.1 indicate which segment precedes the column headers; Table 34.1 encodes that *t* is the word-initial segment, because no segment precedes it, indicated by the lack of any mark in the *t* column; *t* precedes *a*, as indicated by the mark in the *t* row's *a* column, *a* precedes *g*, and so on. This type of precedence encoding makes information about immediate precedence easily accessible, reflecting the frequency of phonological operations that are strictly local. A drawback to this type of precedence encoding is that long-distance relationships required to account for phenomena like long-distance assimilation and vowel harmony (see CHAPTER 77: LONG-DISTANCE ASSIMILATION OF CONSONANTS; CHAPTER 91: VOWEL HARMONY: OPAQUE AND TRANSPARENT VOWELS; CHAPTER 118: TURKISH VOWEL HARMONY; CHAPTER 123: HUNGARIAN VOWEL HARMONY) must be calculated by a walk (see §2) through the representation.

Adjacency tables can encode "transitive precedence." Table 34.2 does this by marking in each row all of the other segments that a particular segment precedes

Table 34.1 Immediate adjacency

		follows			
		t	a	g	u
precedes	t		x		
	a			x	
	g				x
	u				

Table 34.2 Transitive precedence

		follows			
		t	a	g	u
precedes	t		x	x	x
	a			x	x
	g				x
	u				

Just as there are two distinct ways to produce the deletion of a segment, there are two distinct ways to epenthesize a segment. The first way is to explicitly add precedence relations to and from a new segment from the relevant points in the representation. This would take (19a) and produce the representation in (20).

(20) $\# \rightarrow t \rightarrow a \rightarrow g \rightarrow u \rightarrow \%$, with $a \rightarrow r \rightarrow g$ (r below a and g)

The new structure added to (19a) to produce (20) is offset by having the segment *r* below the underlying segments. Notice the parallels between (19) and (13a), and recall that the actual graphic layout does not matter. The difference is that deletion is detouring around an old segment, while epenthesis is detouring through a new segment. Another parallel between the epenthesis and deletion representations is that both need to be "serialized" to resolve the precedence conflict present in them. As earlier in the chapter, all models of phonology have the relevant resources to produce the proper output to this form.

"Fission" is to epenthesis as coalescence is to deletion. To see this, consider the explicit representation of x-slots and melodies in (21), which shows the splitting of an x-slot to produce a new segment.

(21) a.

$$\begin{array}{cccccccccccc} & & t & & a & & g & & u & & \\ & & | & & | & & | & & | & & \\ \# & \rightarrow & x & \rightarrow & x_i & \rightarrow & x & \rightarrow & x & \rightarrow & \% \end{array}$$

b.

$$\begin{array}{cccccccccccccc} & & t & & a & & & & g & & u & & \\ & & | & & | & & & & | & & | & & \\ \# & \rightarrow & x & \rightarrow & x_i & \rightarrow & x_j & \rightarrow & x & \rightarrow & x & \rightarrow & \% \end{array}$$

This type of epenthesis raises the question how the new x-slot is formed without taking the associated melody along with it; reasons of space preclude a full exposition of this question here beyond pointing out that the interpretation of a bare x-slot will be determined on a language specific basis (see CHAPTER 67: VOWEL EPENTHESIS; CHAPTER 58: THE EMERGENCE OF THE UNMARKED). The differences between these two types of epenthesis suggest differences in the type of epenthetic segment. The approach in (20) supports a prespecified type of epenthetic segment, which cannot be derived from markedness conditions, while the approach in (21) suggests an "Emergence of the Unmarked" (McCarthy and Prince 1994) type of epenthetic segment, because an empty x-slot needs to be interpreted. A final note is that just as the coalescence approach to deletion creates an intermediate representation that can account for compensatory lengthening effects, so this fission approach can also account for simple segment lengthening effect by fissioning the melody along with the x-slot.

If segmental length is encoded on the x-tier as opposed to being marked by a mora (see Ringen and Vago 2010), there are two representations for true geminates (Hayes 1986; Schein and Steriade 1986) that follow naturally. The structure in (22a) is the traditional multiply linked melody representation, while (22b) is a novel looped segment representation for a geminate.

A minimal extension of the epenthesis as addition of a precedence link produces infixing phenomena. Toba Batak infixation, taken from Halle (2001), is presented in (25) (stress is suppressed for expository purposes).

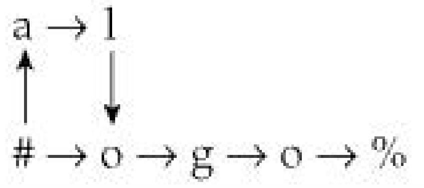
(25) *Nominalizer* -al- *in Toba Batak*

batuk	*b-al-atuk*	'ladder'
ogo	*al-ogo*	'wind'

This infixing pattern can be described as the affix *al* preceding the first vowel of the form. Whether *al* appears as an infix or a prefix is derived from whether the first vowel of the form is in word-initial position. This variation does not change the positional generalization about where this affix is concatenated to the base. (26) provides the precedence graphs for the examples in (25).

(26) a.

b.



As with previous examples, the addition of the affix *al* produces a representation that violates the characteristics of a chain graph, which forces the representation to be serialized at some point in time. See Yu (2007) for further discussion of infixation.

Our last example of (morpho)phonological processes that are illuminated by explicit precedence graphs is from Spokane, in (27). Repetitive morphology in Spokane is interesting because it combines elements of infixation and reduplication. The content of the repetitive morpheme is /e/; it appears to infix if the root begins with two consonants (27a), but causes reduplication if the base begins with a single consonant (27b).

(27) *Repetitive morphology in Spokane* (simplified, from Bates and Carlson 1992)

	repetitive	*base*			*repetitive*	*base*	
a.	petax	ptax	'spit'	b.	sesil	sil	'chop'
	qesip	qsip	'long ago'		kekul	kul	'make'

The precedence graphs that capture this behavior are shown in (28).

35 Downstep

Bruce Connell

1 Introduction

Downstep is a pitch-lowering phenomenon that is widely recognized to occur in tone languages, particularly those of sub-Saharan Africa, in which it was first identified. It is also attested in several languages of the Americas, though only very rarely in Asia. The concept of downstep has also more recently been extended to account for phenomena associated with intonation in non-tonal languages,[1] and is indeed perhaps better known to non-specialists in this context. Downstep is most commonly described as the lowering influence of a low tone (L) on a following high tone (H), such that a new, lower, "ceiling" is set for all subsequent Hs within a specifiable domain or prosodic unit. One of the early and still primary areas of debate in the study of downstep pertains to the sameness or otherwise of downstep as effected by a surface L as opposed to an underlying or floating L. Another area of interest has to do with the implications of its recurrent and cumulative nature for the analysis of contrastive tone levels; a language with only two apparent contrastive lexical levels (e.g. H, L) will manifest several intervening levels in actual speech, including situations in which a H occurring late in an utterance may be realized at a lower pitch than a L early in the same utterance. Another debate centers on the analysis of downstep applying to tones other than H; while the paradigm case is the lowering of H in a language with two tones (H, L), downstep does occur in languages with more than two tones, and in some such languages, cases of downstepped mid (M) and L tones are also attested. Whether such cases parallel downstepping of H remains moot. In addition, there are apparent cases of "upstep," a tone raising phenomenon that ideally would be symmetrical to downstep in the details of its realization, though few if any of the attested cases are precisely so.

[1] An anonymous reviewer suggests the term "non-tonal language" is a misnomer, given that "there is no essential qualitative difference between tones based on their origin in the lexicon or in phrasal phonology." While I am sympathetic to the view that "non-tonal" is problematic, the claim that "there is no essential difference" is contentious. This discussion is outside the scope of the present chapter, but Hyman's (2001: 1368) definition of a tone language serves to distinguish the two types of language, a tone language being one, "in which an indication of pitch enters into the lexical realization of at least some morphemes."

Discussion as to how best to characterize downstep from a theoretical perspective has benefited from and contributed to general phonological theory, with proposals being shaped by phonetic and phonological approaches. This debate remains unresolved, with some scholars advocating the view that downstep is best accommodated in the phonetic implementation component (e.g. Poser 1984; Beckman and Pierrehumbert 1986; Pierrehumbert and Beckman 1988), and others arguing that it is phonological (e.g. Snider 1998, 1999).

The discussion of downstep was particularly fruitful in the 1960s and then again through the 1980s and 1990s, with the advent of autosegmental phonology (CHAPTER 14: AUTOSEGMENTS) and feature geometry (CHAPTER 27: THE ORGANIZATION OF FEATURES). Since then the debate has subsided somewhat, though two good general presentations of downstep have appeared in recent years, in Yip (2002) and Gussenhoven (2004). The most recent detailed argument for a particular theoretical approach to downstep is Snider (1999).

This chapter characterizes downstep and related tonal phenomena, summarizing with representative data the key issues and current views. In doing so, I draw on those sources just mentioned, as well as several other published (and some unpublished) studies that have contributed to our understanding of downstep.

The remainder of the chapter is divided as follows. §2 is an overview of work leading to the recognition and study of downstep in tone languages. This section defines the key terms used in the discussion, presents relevant illustrative data, and introduces some of the important theoretical issues involved. The third section then discuss downstep-related issues, including its distribution, downstepping of tones other than H and in languages with more than just H and L tones, and downstep in non-tonal languages. What triggers downstep is discussed in §4, phonetic aspects of downstep in §5, and issues pertaining to upstep and H-raising in §6. A particular personal concern has been the inconsistent and conflicting use of terminology found in the discussion of downstep and related pitch phenomena, and its importance for developing an adequate understanding of these phenomena; these issues are examined in §7. §8 presents instrumental evidence from the Bantoid language Mambila that bears on a resolution to the issues discussed in §7.

Inevitably, some aspects of the topic receive fuller treatment than others; in particular, the substantial literature in which the notion of downstep is used in the analysis of non-tonal languages does not get the attention it deserves. This is in large part due to space constraints, but it is to some extent also a reflection of my own expertise and familiarity with the subject, as well as an attempt to address a perceived imbalance in the general theoretical phonology literature; while downstep is primarily a phenomenon of tone languages, it has perhaps received greater attention for its operation in non-tonal languages, and this aspect of the discussion is more accessible to the general reader. For related discussion, see also CHAPTER 45: THE REPRESENTATION OF TONE; CHAPTER 114: BANTU TONE.

2 An overview of downstep in language study: Phonological issues

2.1 *Early studies*

The phenomenon now known as downstep was first noted in print well over a century ago, by Christaller (1875: 15). In his discussion of Fante (Kwa, Ghana)

(1) a. idiɣ(e) ɔbɔŋ ke ŋkut [¯ ¯ ¯ ¯ ¯ ¯ ¯]
'It isn't a *mosquito* that I see.'
b. idiɣ(e) ɔbɔŋ ke ŋkut [¯ ¯ ¯ _ – – –]
'It isn't a *piece of cane* that I see.'
c. idiɣ(e) ɔbɔŋ ke ŋkut [¯ ¯ ¯ – – – –]
'It isn't the *chief* that I see.'
d. ekpeɲɔŋ edi ufɔk [_ ¯ – – – – _]
'Ekpenyong came to the house.'
e. ekpeɲɔŋ emen inuen ɔɲɔŋ edi ufɔk [– ¯ ¯ ¯ – – – – – – – – – _]
'Ekpenyong picked up the bird and came home.'

The first three sentences, which differ only in the italicized words (i.e. the tone pattern of /ɔbɔŋ/) show, in (1a) all Hs, in (1b) Hs where an intervening L has conditioned a lowering of following Hs, and in (1c) a similar lowering of the last four Hs, though without a preceding L to effect the lowering. Sentences (1d) and (1e) show successive lowering of what are analyzable as Hs, with only the initial and final tones being L. The "terracing" seen with the Hs in these two sentences shows the classic effect of downstep.

These data reveal the unsatisfactory nature of an analysis that sees the lowered tones as M. First, such an analysis would require /ké ŋꜜkút/ 'that I see' in sentences (1a)–(1c) to be identified first as HHH (1a) and later as MMM (1c); in (1b), while the tones of /ké ŋꜜkút/ are phonetically similar to those in (1c), they are best treated as HHH, since they represent a conditioned lowering. Further, the successive lowering in (1d) and (1e) would require a number of mid tones (i.e. Ms of different heights), with /édí/ 'came' bearing a different, lower, M in (1e) than in (1d).

Winston examines briefly a different solution, which contrasts non-low and low, with non-low tones divided into H and M, and with restrictions on the distribution of M, but finds this equally awkward. He instead proposes "two distinct systems of contrasting tonal units" (1960: 187): first, H *vs.* L, which accounts for sentence (1a) *vs.* (1b), and second, "a unit of 'downstep'," which operates only in the context of HH, and accounts for sentence (1a) *vs.* (1c). Winston draws attention to the fact that not only does downstep distinguish sentences, but it is phonemic in its own right, as the words /ɔ́bɔ́ŋ/ 'mosquito', /ɔꜜbɔ́ŋ/ 'chief', and /ɔ̀bɔ̀ŋ/ 'cane' demonstrate. His analysis is also insightful in that it focuses attention not on the nature of the tones themselves – e.g. the last four tones of (1a)–(1c) – but on the relation between these tones and preceding tones; the drop is the realization of downstep.

2.3 *Automatic and non-automatic downstep*

As mentioned, the Efik data included instances of "non-automatic" downstep, in which a H is lowered by an underlying or floating L, and the lowering of a surface H tone under the influence of a preceding surface L, termed "automatic" downstep. These terms were introduced in Stewart (1965) and continue to be used, though many writers use (simply) downstep to refer to "non-automatic" downstep, and "downdrift" when referring to automatic downstep. As discussed below in §7, however, there are in fact different tonal processes grouped together as downdrift, and the use of downdrift in referring to automatic downstep as well

(1979) proposed an alternative view, which helped to lay the foundation for most current views of downstep. Clements's proposal saw terracing as "the result of intonational processes applying to the tone level frame itself, rather than directly to individual tones" (1979: 358). The occurrence of actual downstepped tones was restricted to initial position in sequences in which pitch was lowered, but they have the effect of precipitating a (downward) register shift, re-establishing the levels at which subsequent tones within a given prosodic unit are realized. Whether this shift affects all tones (i.e. H and L, and M in a three-tone system) within a given prosodic unit, or just H, became an empirical and language specific question.

2.5 *Downstep in autosegmental phonology*

The development of autosegmental phonology (Leben 1973; Goldsmith 1976) provided the rest of the foundation for our current understanding of downstep and related tonal phenomena. Perhaps the key contribution of autosegmental phonology to our understanding of downstep was its ability to represent tone on a separate tier, and consequently different tone types on different tiers. Several authors have contributed to this debate and its development, exploiting this insight in different ways and to different degrees. Among them are Hyman (1979, 1993), Clements (1983, 1990), Stewart (1983, 1993), Pulleyblank (1986), Yip (1989, 1993), Snider (1990, 1999), and Clark (1993). The most recent and most detailed of these contributions is that of Snider (1999), who provides a proposal for an understanding of downstep that lays considerable emphasis on the incorporation of upstep as a phenomenon to be accounted for by the same means as downstep, as well as a critique of the related approaches, at least where they differ from his own.

Snider's (1999) proposal is presented within the theoretical framework of Register Tier Theory (RTT), which exploits the mechanisms of autosegmental phonology and feature geometry, and their tiered and hierarchical representations. RTT incorporates a Register tier admitting two features, h and l, a Tonal tier with two features, H and L, a Tonal Root Node tier (TRN), and a Tone-Bearing Unit (TBU) tier. Features on the register and tonal tiers are linked to a node on the TRN tier, and each TRN node is in turn linked to a mora on the TBU tier. This permits the specification of four level tones, which Snider labels Hi (= h, H), Mid2 (= h, L), Mid1 (= l, H), and Lo (= l, L). In a two-tone language (i.e. with H and L, as is frequently found in sub-Saharan Africa), the register feature associated with a particular TBU permits a register shift relative to the preceding TBU's register: h = higher than the previous register setting, l = lower than the previous register setting. Automatic downstep, then, is represented by the spread of the register feature l, which effects a downward shift, realizing the following high tone a step lower than on the preceding register setting.

Snider's tonal features H and L equate well with Yip's (1980) [±High], Pulleyblank's (1986), and Yip's (1989) [±Raised]. However, his h and l register features provide an advantage over Yip's and Pulleyblank's [±Upper], in that they are relative features, whereas [±Upper] is non-relative; it is either high or low. Both Snider's system and the Yip/Pulleyblank system, then, account well for phonemic tone levels, but the relative nature of Snider's register features permits description of the cumulative nature and the terracing associated with downstep.

3 Distributional characteristics of downstep

3.1 *Downstep type*

Non-automatic downstep (often equated with phonologically distinctive downstep) is usually found only in systems that also have automatic (or non-distinctive) downstep, though the two need not co-occur. Automatic downstep is not uncommon in the absence of non-automatic downstep; however, the reverse – i.e. cases of non-automatic downstep in the absence of automatic downstep – is rare.

Automatic downstep has been reported in languages such as Hausa (Chadic, Nigeria) by Leben (1984), Lindau (1986), Inkelas and Leben (1990), and Leben *et al.* (1989), and in Yoruba (Benue-Congo, Nigeria) by Connell and Ladd (1990), Laniran (1992), Akinlabi and Liberman (1995), and Laniran and Clements (2003). In neither of these languages is non-automatic downstep found, and downstep is neither lexically nor grammatically distinctive. Both automatic and non-automatic downstep occur in a great many languages, including not only the paradigm examples of Akan, Efik, and Igbo, but also languages such as Baule (Kwa, Ivory Coast; Ahoua 1996), Bimoba (Gur, Togo; Snider 1998), Chumburung (Kwa, Ghana; Snider 1999), Yala-Ikom (Benue-Congo, Nigeria; Armstrong 1968), and Zande (Adamawa-Ubangi, Democratic Republic of the Congo; Boyd 1981).

For only very few languages has non-automatic downstep been reported in the absence of automatic downstep. Three such languages are Dschang (Grassfields Bantu, Cameroon), Ikaan (Benue-Congo, Nigeria; Salffner 2009), and Kikuyu (Bantu, Kenya; Clements and Ford 1980), and each of these present analytic complexities for which consensus has yet to be reached.

3.2 *Geographical distribution*

All of the above mentioned languages are geographically located in sub-Saharan Africa, the region best known for downstep, and representative of several different language families and phyla. Downstep is also found in the Americas, the best-known examples being in Central America. Isthmus Zapotec (Oto-Manguean, Mexico; Mock 1981, cited in Yip 2002) shows downstep functioning in a manner expected from research on African languages, i.e. it is triggered by a floating L. Other languages of this region show both downstep and upstep; varieties of Mixtec (Oto-Manguean, Mexico) are discussed in §6 below.

Only very rarely has downstep been reported among Asian languages. One such language is Kuki-Thaadow (Tibeto-Burman; Hyman 2007), spoken in north-east India and Burma. Contrary to the well-reported differences between Asian and African tone languages, Kuki-Thaadow's tone system behaves very much like those found in Africa. Hyman analyzes Kuki-Thaadow as having three underlying tones: HL, H, and L. Downstep occurs when HL precedes H, with L being realized as a downstep on the following H, as shown in (2) (Hyman 2007: 6):

(2) /mêeŋ vóm thúm hí/ → méeŋ ꜜvóm thúm hí [¯ – – –]
'these three black cats'

According to Hyman's report, downstep in Kuki-Thaadow is realized phonetically by raising of the preceding H, with the amount of raising being determined by the number of downsteps to follow; though no instrumental data is presented, this is reminiscent of Rialland's (2001) findings for Dagara (see §6).

3.3 *Downstep in languages with more than two tones and with tones other than H*

The discussion thus far has centered on languages with just two tones, H and L, and downstepping of H tones. This is clearly the most commonly attested situation, though downstep does occur in languages with more than two tones, and with tones other than H, including in some languages with just two underlying tones.

The first language with more than a basic two-tone system recognized as having downstep, and as downstepping tones other than H, was Yala-Ikom (Benue-Congo, Nigeria; Armstrong 1968). Yala-Ikom has three contrastive tones, H, M, and L. H is lowered after both L and M, and M is lowered following L; this occurs regardless of whether the tone causing the lowering is underlying or surface (i.e. floating or associated), and terracing results in both situations. The example below (Armstrong 1968: 53) illustrates downstepping of M following a M (Armstrong used the diacritic ' to indicate downstep); note that the downstepped M is followed by H:

(3) ɔ́ tābɔ̄l↓ɔ̄nɛ̄ ní [¯ – – _ _ –] HMMMMH
'It did not begin in the evening.'

Downstep begins with the third M, a result of the underlying ("latent" in Armstrong's terms) floating L of /là/ 'in', which remains after vowel elision. Evidence for M triggering downstep of H is provided in examples such as the derived verbal noun, /òré↓ré/ 'eating'; the presence of a floating M is confirmed by cross-dialectal comparison, where M surfaces in Yala-Ogoja /òrɔ́ɔ̄ré/ 'eating'.

In Vute (Bantoid, Cameroon), also a three-tone language with H, M, and L, H apparently undergoes both automatic and non-automatic downstep (Guarisma 1978; Thwing and Watters 1987). Guarisma describes the second H of a HLH as being lowered, but does not comment on whether subsequent Hs are terraced, nor does she comment on the interesting situation of M, and the possibility of overlap of ↓H and M, or whether Ms and Ls lower correspondingly. However by Guarisma's examples, non-automatic downstep does extend beyond the first tone of the sequence and so terracing exists. Guarisma describes non-automatic downstep as marking associative constructions, but her examples of both non-automatic and automatic downstep are with associatives.

(4) ŋgwè sèhí → [¯ _ –] 'head (of) abscess'
ɓár jémi → [¯ – –] 'spots (of) leopard'

Bamileke-Dschang (Grassfields Bantu, Cameroon) is a language with two tones, H and L. Dschang has received considerable attention in the literature on downstep (Tadajeu 1974; Hyman 1985; Pulleyblank 1986; Clark 1993; Manfredi 1993; Stewart 1993; Bird and Stegen 1995; Snider 1999) as the first language (and one of very few languages) analyzed as having downstep affecting L as well as H; it has a four-way surface contrast, H, $^{\downarrow}$H, L, $^{\downarrow}$L. There is considerable divergence among the views of these authors as to the nature of downstep in Dschang; the downstepped H is attributable to a *following* floating L, with leftward spreading, and this seems largely agreed (Tadajeu 1974; Pulleyblank 1986; Snider 1999). Snider attributes the downstepped L to a floating H, which, when inserted between two Ls, results in downstepping of the second L. Clark (1993), however, prefers to see Dschang with a basic four-tone system and only relatively few occurrences of downstep.

So, while there are languages like Yala-Ikom with more than two tones in which both H and M may be downstepped, and others like Vute in which only H is affected, there are no languages reported where (non-automatic) downstep affects M (or L) but not H. Similarly, like Dschang, there are no languages reported where $^{\downarrow}$L occurs but not $^{\downarrow}$H.

Interestingly, for Yala-Ikom, discussed above, Armstrong (1968) reports that the effect of downstep triggered by M is indistinguishable from that triggered by L; i.e. $^{\downarrow}$H lowers the same degree regardless of whether L or M is the trigger. On the other hand, in Yala-Ikom $^{\downarrow}$H remains higher than M. This is contrary to reports for other three tone languages in which H is downstepped and for which it is claimed $^{\downarrow}$H is indistinguishable from M (e.g. Supyire, Gur, Mali; Carlson 1983; Moba, Gur, Togo; Russell 1996, cited in Snider 1999; Bimoba, Gur, Ghana; Snider 1998). Snider (1998) provides instrumental evidence for the phonetic equivalence of $^{\downarrow}$H and M in Bimoba.

3.4 *Downstep in "non-tonal" languages*

The possibility that downstep could account for pitch phenomena in non-tonal languages was first introduced in Pierrehumbert's (1980) work on English, in which it was proposed that declination could, largely, be accounted for as the successive lowering of pitch accents (CHAPTER 116: SENTENTIAL PROMINENCE IN ENGLISH). The term "catathesis" rather than downstep was adopted for a time (Poser 1984; Beckman and Pierrehumbert 1986), in order to avoid the terminological conflicts inherent in the use of downdrift *vs.* downstep and automatic *vs.* non-automatic downstep (e.g. as mentioned briefly in §2.3, and more on which in §7.1.3); usage has since reverted to, and settled on, downstep. Pierrehumbert's model has evolved considerably, both in her own work and that of others following, broadly speaking, the same tack. It has been applied to several other languages, e.g. Japanese (Japonic, Japan; Pierrehumbert and Beckman 1988; Kubozono 1989), and Dutch (Germanic, The Netherlands and Belgium; van den Berg *et al.* 1992), with discussion on the nature of downstep in these languages largely being separate from the debate on its functioning in African and other tone languages. One of the key issues has been the extent to which downstep is distinguishable from declination; in other words, can or does downstep account for all downward movement of pitch across a phrase or utterance? While there has been some effort to include both downstep and declination in models of intonation in such languages, resulting in a move away from the restrictive position in Pierrehumbert (1980), Ladd (2008) points out the methodological/empirical difficulty in separating the two. (In tone languages this is less problematic; see §7.1.2.) Ladd's general view of downstep as part of intonation (e.g. 1992, 1993, 2008) sees (intonational)

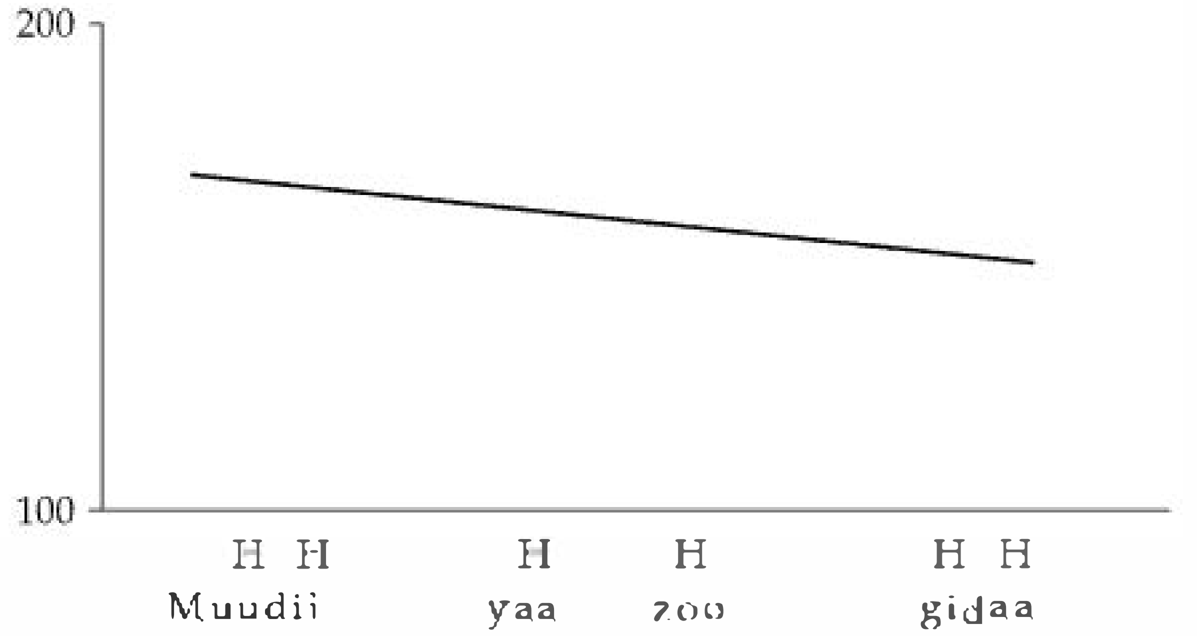

Figure 35.1 Declination illustrated in a sequence of Hausa High tones in the sentence *Muudii yaa zoo gidaa* 'Muudii came home', adapted from Lindau (1986)

7.1.2 Downdrift

Downdrift is somewhat more difficult to characterize, precisely because, as mentioned earlier, the term has been used in different senses. Most commonly, it has been used synonymously with Stewart's automatic downstep. Hombert (1974: 171), for example, describes downdrift as "the progressive lowering of a high tone after a low tone," and in a footnote explicitly equates it with automatic downstep. Similar views are expressed by a range of authors including, more recently, Snider and van der Hulst (1993) and Hyman (2001). However, Hombert also attributes an intonational element to downdrift, observing that Ls also descend, and then suggests that the term downdrift refer to "the lowering of like tones (consecutive or not)" (1974: 172, fn. 6). Given this proviso concerning like tones (or, when it applies to consecutive like tones), it appears to be the same phenomenon as that described earlier as declination; however as we have seen, declination is clearly something quite independent of automatic downstep. Both of these views of downdrift – i.e. that it involves a local assimilation between Ls and Hs, and that it is a phrase or sentence level effect – are found elsewhere in the literature, though it is most frequently characterized as being equivalent to automatic downstep. An illustration of downdrift of a presumably assimilatory nature, through the alternation of Hs and Ls, can again be taken from Lindau's (1986) study of Hausa (Chadic, Nigeria), and is shown in Figure 35.2. In this figure, as in Figure 35.1, a trend line for the H tone only is represented (in Lindau's representation, the second sentence also shows a downtrend affecting the Ls, and both map the actual F0 trace). What is important in comparing the two is that the slope in Figure 35.2 is steeper than that in Figure 35.1, with a decline of 33 percent per second; i.e. the slope shown in Figure 35.2 combines the declination of Figure 35.1 with the effect of downdrift, the local assimilation of Hs to Ls.[6]

7.1.3 Downstep

An important, indeed defining, feature of downstep, in addition to its lowering of a H relative to a preceding H (or lowering of other tones relative to preceding

[6] Gussenhoven (2004: 101) cites similar evidence for Japanese from Poser (1984).

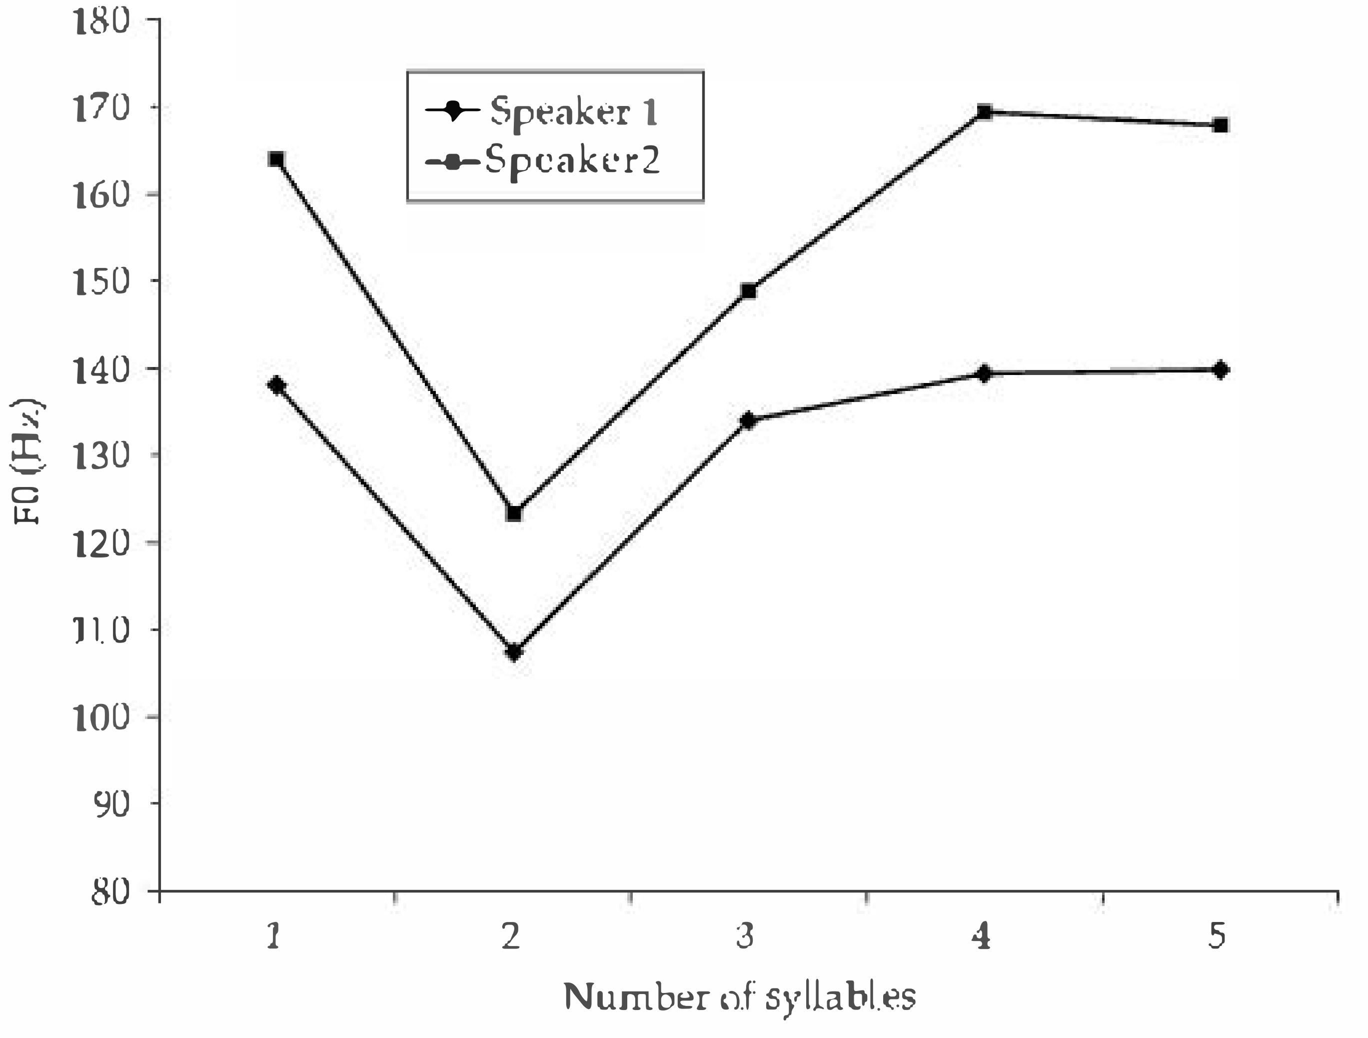

Figure 35.8 Pitch traces of T1T4T1T1T1 (HLHHH) for two Mambila speakers, showing the absence of automatic downstep

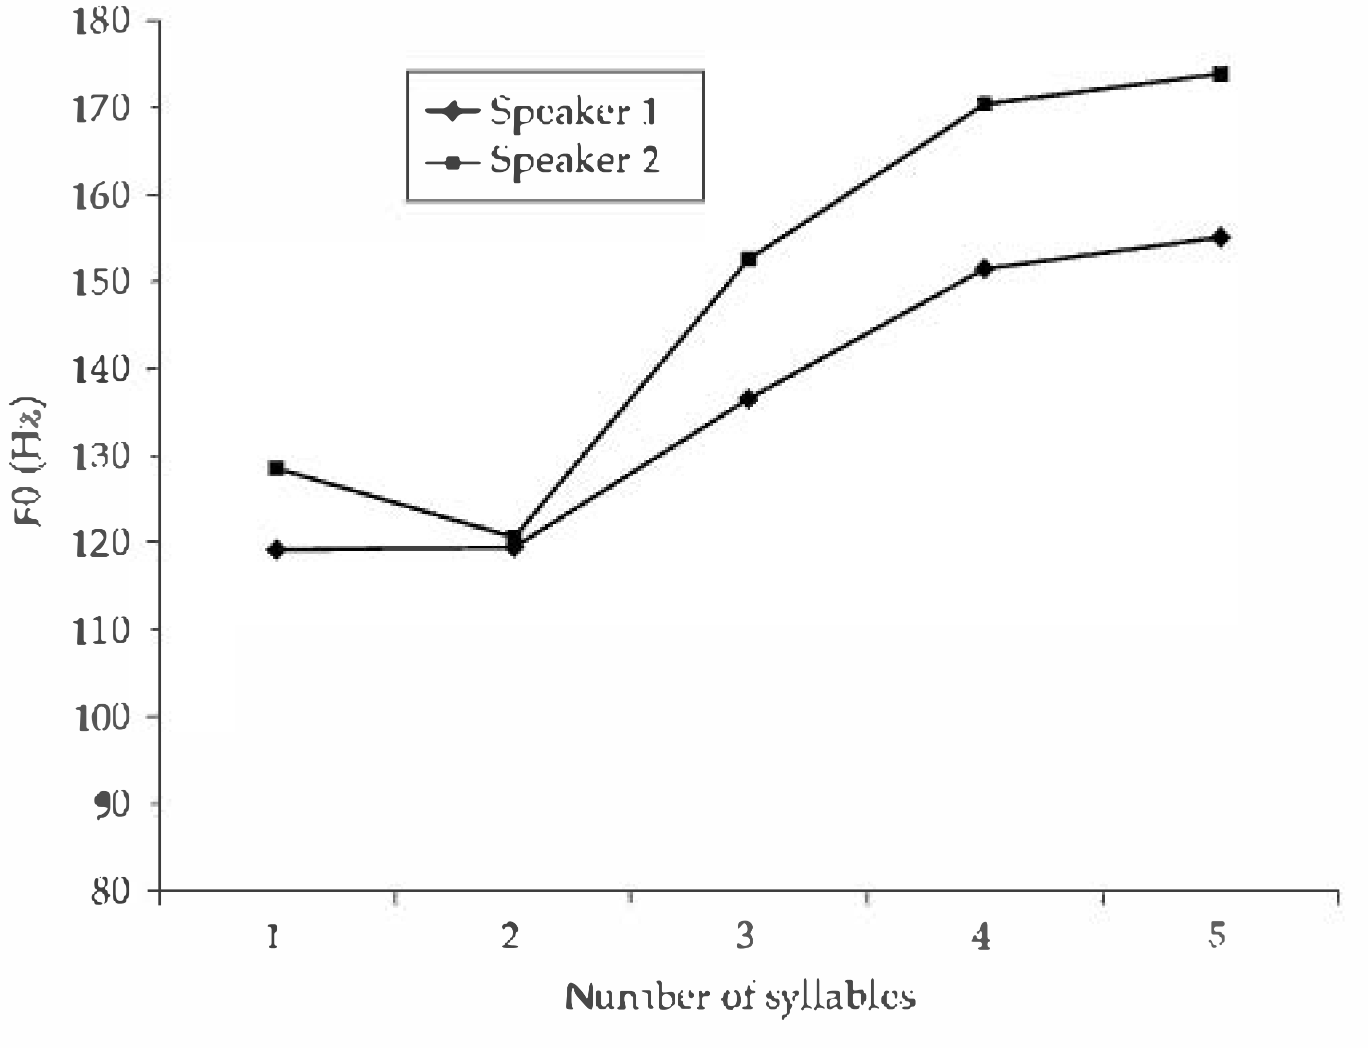

Figure 35.9 Pitch traces of T4T4T1T1T1 (LLHHH) for two Mambila speakers, showing the absence of automatic downstep

Rather than downstep, Mambila has a local interaction, a lowering of a high(er) tone following a low(er) tone, that appears to be simply a phonetic effect that is corrected once the low tone is not involved, allowing the H to regain its former height. That the effect of this interaction is cumulative, i.e. in a

36 Final Consonants

Marie-Hélène Côté

1 Introduction

Final consonants, in the stem, the word, or the phrase, often display properties that set them apart from consonants in other positions. Basic principles of syllabification predict that final consonants are codas (see also CHAPTER 33: SYLLABLE-INTERNAL STRUCTURE) and, as such, are expected to pattern like non-final codas. Final consonants thus pose an analytical challenge when this expectation is not fulfilled.

Languages in which final consonants simply mirror internal codas are referred to as "symmetrical." In Manam, only nasals appear in both positions, and stress is regularly attracted to closed syllables, internal and final (1a); default stress is penultimate in the absence of closed syllables (1b). So final consonants in Manam display the same segmental profile and stress-attracting power as internal codas (Buckley 1998; Piggott 1999).

(1) a. ['embegi] 'sacred flute'
[ʔu'laŋ] 'desire'
[ura'pundi] 'I waited for them'
b. [wa'bubu] 'night'

Spanish and Selayarese offer other illustrations of the correspondence between internal codas and final consonants. As shown by Harris's (1983: 14–15) list of word-medial and final rimes in Spanish, the set of permissible codas is the same in both positions and includes any consonantal category, possibly followed by [s]. Final syllables closed by consonants also attract stress, which is consistent with their contributing weight to the final syllable, as coda consonants regularly do cross-linguistically (CHAPTER 57: QUANTITY-SENSITIVITY). In Selayarese (Mithun and Basri 1986), medial codas are restricted to homorganic nasals, the first parts of geminates, and [ʔ]; final consonants are limited to [ʔ] and [ŋ]. Assuming that [ʔ] and [ŋ] lack place specification (e.g. Paradis and Prunet 1993; Lombardi 2002), all codas can be characterized by the absence of independent place features (CHAPTER 7: FEATURE SPECIFICATION AND UNDERSPECIFICATION; CHAPTER 22: CONSONANTAL PLACE OF ARTICULATION): they are placeless or acquire the place of the following onset.

In many other languages, final consonants pattern differently from internal codas. First, the right edge of constituents regularly hosts more consonants than internal codas may accommodate. Second, final consonants may be ignored in the application of metrical processes, while internal codas cannot be. These two tendencies, formulated in (2), define final consonant exceptionality.

(2) a. *Segmental immunity*
Final consonants escape segmental constraints that apply to internal codas.
b. *Metrical invisibility*
Final consonants are ignored in the application of metrical processes.

Both patterns occur in Cairene Arabic. While only one consonant is allowed in phrase-internal codas, two may appear phrase-finally (Wiltshire 2003); the additional final consonant is said to escape the coda conditions applicable elsewhere in the phrase. In addition, word stress is attracted to non-final CVC syllables and final CVCC/CVVC, as opposed to CV and final CVC, as if the final consonant were invisible to the stress assignment algorithm (Hayes 1995).

Final consonant exceptionality has attracted considerable attention in the development of modern phonological theory. Segmental immunity (2a), clearly the most widely discussed aspect of final exceptionality, is treated in §2–§4, starting in §2 with a review of various representative patterns (generalizations). Analyses of the special behavior of final consonants have almost exclusively relied on special accommodations to syllable structure in final position; different representational devices are examined and compared in §3 (representations). Representations, however, provide only part of the story: they offer a formal frame for the expression of the specificity of final consonants, but no explanation for it. §4 (motivations) is concerned with the formal, grammatical, or functional factors that have been called upon to account for the freedom of occurrence of right edge consonants. Metrical invisibility (2b) and its relationship to segmental immunity are addressed in §5.

Final consonants are also implicated in other processes, which are not reviewed in this chapter, since they fall under different topics. First, if final consonants appear with greater freedom, they are also regularly subject to deletion processes (CHAPTER 68: DELETION). Final clusters variably simplify in many languages. The factors that govern simplification, however, appear to be relevant to final and non-final clusters alike (e.g. Côté 2004), and I have chosen not to address this topic. Single final consonants also delete, giving rise to various types of C/Ø alternations. Examples include French liaison (see CHAPTER 112: FRENCH LIAISON), linking [r] in non-rhotic dialects of English (Hay and Sudbury 2005; among many others), and Maori verbal forms (Blevins 1994). Interestingly, such cases may involve a re-analysis of historically word-final consonants as epenthetic consonants (Vennemann 1972). Finally, final consonants are subject to resyllabification with a following initial segment. Both C/Ø alternations and resyllabification fall under the scope of external sandhi phenomena.

2 Segmental immunity: Generalizations

The immunity of final consonants emerges in static segmental distributions in the lexicon (§2.1) and in the asymmetrical application of segmental processes (§2.2).

More consonants are licensed in final than in internal coda position, allowing additional segmental slots (size effects) or a wider range of place, manner, or laryngeal contrasts (feature effects).

2.1 In the lexicon

Eastern Ojibwa (Piggott 1991, 1999) and Tojolabal (Supple and Douglass 1949; Lombardi 1995) exemplify increased licensing possibilities in final position in manner and laryngeal features. In Ojibwa, while nasals and fricatives are permissible codas in all positions in the word (3a), stops are only allowed word-finally (3b). In Tojolabal, the contrast between plain/aspirated and laryngeal stops and affricates is neutralized in word-internal codas, where only plain segments appear (4a), but remains active in onsets and word-finally (4b).

(3) a. [baŋgisin] 'it falls'
[moːʃkineː] 'it is full'
[wiːjaːs] 'meat'
b. [nindib] 'my head'
[ninik] 'my arm'

(4) a. [hutp'in-] 'to push'
[ʔatnija] 'you bathed'
b. [potot'] 'class of plant'
[k'ak] 'flea'

French illustrates the presence of additional consonantal slots word-finally. While it admits a large variety of final clusters of up to four consonants (5), all morpheme-internal clusters may be analyzed with codas limited to one consonant (Dell 1995). Final clusters include sequences of rising sonority, in violation of the Sonority Sequencing Principle (e.g. Clements 1990; CHAPTER 49: SONORITY). This can be taken as a further indication that final consonants are not regular codas: they exceed the possibilities offered by the syllable template applicable elsewhere in the word not only in terms of the number of segments, but also in their relative autonomy with respect to general syllabic principles.

(5) [adɔpt] 'adopt'
[sɛrkl] 'circle'
[ɑ̃bidɛkstr] 'ambidextrous'

English offers different kinds of final exceptionality effects. As in French, more consonants are found finally than in internal codas: up to three in monomorphemic words (e.g. *next*) and four with the addition of word-level suffixes (e.g. *thousandths*) *vs.* only one internally (exceptionally two, as in *empty*; see Borowsky 1986). Unlike French, however, English does not tolerate word-final sequences of an obstruent followed by a non-sonorant. In addition, English displays asymmetries in vowel + consonant combinations. Word-finally, long vowels are followed by any consonant (6a); morpheme-internally, long vowels in closed syllables appear in restricted contexts: before fricative + stop (6b) or a sonorant homorganic with the following onset (6c), often with additional combinatorial constraints. Coronal obstruents enjoy

(12)	a.	/siok-ta/	[siokta]	'our (INCL) chicken'
		/bantil-kon/	[bantilkon]	'inform (BENEFACTIVE)'
	b.	/laigan-ku/	[laiganku]	'my house'
		/wuruŋ-ta/	[wuruŋta]	'our (INCL) language'

Patterns so far have been described in terms of more consonants being *allowed* at the right edge. Another language type has been put forward, which *requires* constituents to end in a consonant. This possibility is instantiated in Yapese, the case most commonly discussed (Piggott 1991, 1999; Broselow 2003; Wiltshire 2003). This language has no internal codas, but a generalized final short vowel deletion process, which results in words ending in a consonant on the surface. (Final long vowels shorten but do not delete.) The status of Yapese as a distinct type is questionable. As in Kayardild (8), vowel deletion applies finally but not internally (at the word level rather than the phrase), leading to the same generalization as other cases of final consonant immunity: consonants are more easily tolerated in final position. The Yapese pattern may be interpreted as favoring vowel deletion to the extent that it results in phonotactically acceptable forms, rather than actively requiring words to end in a consonant. Menominee is another language in which words end in a consonant, lexically or as a result of final vowel deletion (Bloomfield 1962).[2]

3 Segmental immunity: Representations

If final consonants escape the conditions applying to codas in other positions, their identity as codas is called into question or must be qualified. At least four directions have been explored to account for the internal–final asymmetry. (i) One consists in admitting position-specific syllable well-formedness conditions, for example by defining different coda constraints for final and non-final syllables. This approach is often taken at a descriptive level but it has not been favored in analytical work. (ii) Uniform syllabic conditions may be maintained across positions but violated at edges under pressure from independent constraints. Recent Optimality Theory (OT) analyses have often relied on this type of reasoning; see §4 for a discussion of some relevant factors. (iii) Another line of research has explored the idea that syllabic structure is irrelevant in all or some of the final immunity effects, which arise through sequential generalizations. It has been argued, for instance, that final clusters in English and other languages are accounted for with a constraint limiting sequences of consonants to only one place of articulation (with coronals unspecified for place in English) (Iverson 1990; Yip 1991; Lamontagne 1993; see also Burzio 2007). Such a sequential generalization allows a unified account of consonant clusters in all positions in the word. Côté (2000) takes a more radically non-syllabic approach to consonant phonotactics in general, and final edge effects in particular, which are defined in terms of segment sequencing and adjacency to

2 If words may be required to end in a consonant, we should find cases of systematic final consonant epenthesis, instead of vowel deletion. Interestingly, I am aware of no such cases at the word level. However, many examples of *phrase*-final consonant epenthesis are reported (see some examples in Trigo 1988). This asymmetry between the word and the phrase needs to be investigated further, but it suggests that phrase-final epenthesis corresponds to an articulatory closure effect that is not relevant word-finally.

Appendix (13b): It has been argued that final consonants belong to a separate constituent that hosts consonants that do not fit into the coda. This constituent has been variably called "appendix"[4] (e.g. Halle and Vergnaud 1980; Mohanan 1982; Charette 1984; Borowsky 1986; Goldsmith 1990; Iverson 1990; Wiltshire 1994; Booij 1995; Kraehenmann 2001), "affix" (Fujimura and Lovins 1982), and "termination" (Fudge 1969). By stipulation, the appendix is available only in word-final position. This constituent is usually attached to the syllable node, as in (13b); it is alternatively part of the word structure, as a sister to the syllable. Two types of affixes may be distinguished, for non-suffixal and suffixal consonants (Goldsmith 1990; Duanmu 2008).

Defective syllables (13c): Final consonants are by default taken to be part of the syllable headed by the closest preceding vowel. This assumption is regularly challenged by claims that these consonants in fact belong to a separate syllable, one without a pronounced nucleus (e.g. McCarthy 1979; Selkirk 1981; Iverson 1990; Burzio 1994; Dell 1995; Bye and de Lacy 2000; Cho and King 2003). Representational and terminological details abound here. These special syllables have been termed "degenerate," "empty-headed," "minor," "defective," "semi-syllables," and "catalectic." They may or may not contain a nucleus position; the consonants may be onsets, rimes, or segments attached directly to the syllable node. Different types of degenerate syllables may even be distinguished, for example moraic *vs.* non-moraic (Nair 1999), or syllables whose nucleus position is empty *vs.* those whose nucleus is occupied by segmental material shared by the onset (Goad 2002; Goad and Brannen 2003). Final consonants have been considered to be universally onsets, notably in the model of Government Phonology (Kaye 1990; Harris and Gussmann 2002). Others advocate a mixed coda *vs.* onset approach to final consonants, depending on their segmental profile and behavior, and determined on a language-specific basis or even varying within the same language (Piggott 1991, 1999; Goad 2002; Rice 2003).

Attachment to higher prosodic constituents (13d): Final consonants may attach directly to prosodic constituents higher than the syllable, usually the prosodic word (PWd), but also phrasal constituents (e.g. Rubach and Booij 1990; Rialland 1994; Rubach 1997; Wiltshire 1998, 2003; Auger 2000; Spaelti 2002). As a variation on this theme, Piggott (1999) considers that final consonants are codas or onsets of empty-headed syllables *licensed* by, rather than attached to, the prosodic word. Attachment to higher prosodic constituents implies that the relevant domains for final consonant exceptionality are prosodic in nature. This proposal does not directly account for additional contrasts or slots at the end of morphosyntactic constituents, such as the stem (Broselow 2003).

Extraprosodicity (13e): The most prevalent approach to final consonant exceptionality involves the concept of extraprosodicity (or extrametricality; see CHAPTER 43: EXTRAMETRICALITY AND NON-FINALITY). Originally designed to exclude final syllables from stress assignment algorithms (Liberman and Prince 1977), extraprosodicity has been extended to final consonants by Hayes (1980 (citing a presentation by K. P. Mohanan 1982)) for stress and Steriade (1982) for syllabification. Designating final consonants extraprosodic makes them invisible for the

[4] The term "appendix" has also been used to refer to non-moraic "coda" consonants (13f) (Sherer 1994; Zec 2007) or consonants attached directly to the syllable or prosodic word nodes (13d) (Rosenthall and van der Hulst 1999).

purposes of syllabification, stress assignment, and other processes. The consonants are later adjoined to prosodic structure, in conformity with the principle of Prosodic Licensing (Itô 1986), at a stage in the derivation when syllabic constraints are no longer applicable and metrical structure has already been built. Extraprosodicity is subject to the Peripherality Condition, which restricts it to edges of constituents.

Here again, the theme of extraprosodicity allows for numerous variations, regarding its universality and the level at which it operates. Final consonants are claimed to be universally extraprosodic at the lexical level (Borowsky 1986; Itô 1986). At the word level, extraprosodicity is parametrized (Itô 1986) or universal (Piggott 1991). Itô argues that it is turned off post-lexically, but cases of final consonant exceptionality at the phrasal level motivate its possible extension to post-lexical phonology (Rice 1990).

Non-moraic "coda" consonants (13f): In languages with moraic codas, additional final consonants may be represented as non-moraic (Lamontagne 1993; Sherer 1994; Hall 2002; Kiparsky 2003).

The merits and disadvantages of each of these approaches depend in large part on theory-internal considerations. Each must give up on at least one established principle or generalization of phonological theory. The idea of enriching syllable structure with an appendix constituent has encountered some resistance, since it involves position-specific syllable architecture. Little evidence has been adduced to motivate the appendix as a constituent, which would be expected to act as a trigger or target of some phonological processes; the only case known to me is Mohanan's (1982) suggestion that [r] depalatalizes in the appendix position in Malayalam. Attachment to higher prosodic constituents violates the principle of exhaustive syllabification, as well as strict layering of prosodic constituents. Extraprosodicity requires multiple levels of syllabification, in itself a contentious issue, and may be interpreted as a weakening of the principles of prosodic phonology (Piggott 1999). On the other hand, it avoids syllabic constituents that are otherwise unnecessary (Steriade 1982). Degenerate syllables imply a higher level of abstractness; empty syllabic positions are either viewed as going against the "uncontroversial assumption that syllables must have nuclei" (Rubach 1997: 570–571) or, more positively, as a natural consequence of the phonological architecture in which the segmental and suprasegmental structures are independent of each other (Harris and Gussmann 2002).

Beyond conceptual considerations, at least three issues must be addressed by all approaches relying on specific representations for final consonants. One issue concerns the featural or combinatorial restrictions that additional consonants allowed at the right edge may themselves be subject to, and how these should be expressed. Final obstruent + sonorant sequences occur in French, but not in English. Germanic languages are also well known for allowing word-final strings of voiceless coronal obstruents. The representations in (13b)–(13f) do not make explicit predictions as to the range of consonants they may host, with the exception of the onset approach, according to which final consonants are expected to display onset-like properties. Final consonants or clusters in many languages do have an onset or coda-onset profile (e.g. French; Dell 1995). But many other patterns appear more challenging for the onset approach, as final consonants are regularly much more limited than onsets. In particular, the claim that final consonants are universally onsets is not readily compatible with languages in which

(20) a. No codas, no final empty nuclei Type (15c)
b. No codas, final empty nuclei Type (15a)
c. Codas, no final empty nuclei Type (15e)
d. Codas, final empty nuclei Type (15b)

Crucially, this typology excludes the other symmetrical pattern (15d), in which internal codas and final consonants obey the same constraints. This appears too restrictive, as argued by Piggott (1991). In response, Piggott (1999) proposes another parameter based on the notion of remote licensing. All segments must be licensed by a higher prosodic category, either directly by the syllable, or indirectly (remotely) by the PWd or a phrasal constituent. Piggott, unlike Kaye, allows final consonants to be either codas or onsets, depending on their segmental profile; final onsets, which escape coda restrictions, are always licensed remotely, final codas may be licensed by the syllable or a higher constituent, and vowels must be licensed directly by the syllable. Languages vary in whether remote licensing is excluded (all final segments are either vowels or codas), possible (final segments are vowels, codas, or onsets), or obligatory (final segments must be consonants). This last option, reminiscent of McCarthy's (1993) FinalC, derives Yapese generalized apocope. Unlike Coda Licensing, Piggott's parametric approach does not provide for languages of type (20c); it also predicts that final consonants that exceed the coda template display onset-like properties, which is not always the case, for example with final coronal obstruents in Germanic languages.

An OT account similar in spirit to that of Piggott has been proposed by Spaelti (2002). According to his WeakEdge family of constraints, the right edge of a constituent should contain as little prosodic structure as possible. These constraints favor the attachment of final segments to constituents higher than the syllable in the prosodic hierarchy. Since only consonants may be so attached, WeakEdge establishes consonants as the preferred segment type in final position.

Piggott's and Spaelti's proposals rely on the idea that constituents *should* end in a consonant, echoing the constraint Final-C mentioned above, and specifically in a non-coda consonant. Goad (2002) argues that final non-codas are indeed advantageous from a processing viewpoint. Final consonants that are not possible internal codas signal the right edge of words more clearly than final vowels or codas do, since they cannot appear syllable-finally inside words. Likewise, codas signal the right edge of syllables better than vowels do. This parsing argument needs to be tested; for now, two questions arise. First, if it is a desirable thing for words to end in onsets, one should expect to find more cases of generalized word-final vowel deletion or epenthesis of a non-coda consonant. As noted above, many languages actually require that words, but not syllables, end in a vowel. Second, if codas are the best indicators of the right edge of syllables, why are they considered marked in syllable typology?

4.4 Perception and adjacency to prosodic boundaries

The syllabic basis of consonant phonotactics has been questioned in the last decade or so (Steriade 1999a, 1999b; Blevins 2003), in particular by proponents of the "licensing by cue" approach, according to which the likelihood that a feature or segment occurs in a given context is a function of its relative perceptibility in that context (chapter 98: speech perception and phonology). Côté (2000) applies this idea to segmental immunity at the right edge, arguing that the additional licensing possibilities in peripheral positions are motivated by perceptual factors. More consonants are tolerated at edges, because their perceptibility is enhanced by a number of phonetic processes: lengthening, articulatory strengthening, and reduction of the amount of overlap with adjacent segments.

The formal architecture is based on two constraint families that require consonants to be followed by a vowel (21a) or adjacent to a vowel (21b), contexts where they benefit from optimal transitional cues. But consonants with stronger internal or contextual cues are less dependent on vocalic transitions and vowel adjacency. This includes final consonants, which are subject to the more specific constraints in (21c) and (21d), where *i* ranges over the set of prosodic boundaries at the word level and above, including Ø for word-internal consonants (which are not adjacent to any boundary).

(21) a. $C \rightarrow V$ A consonant is followed by a vowel.
b. $C \leftrightarrow V$ A consonant is adjacent to a vowel.
c. $C]_i \rightarrow V$ A consonant followed by a prosodic boundary i is followed by a vowel.
d. $C]_i \leftrightarrow V$ A consonant followed by a prosodic boundary i is adjacent to a vowel.

It is assumed that the higher the prosodic boundary a consonant is adjacent to, the more easily it surfaces without the support of an adjacent vowel; consonants not adjacent to any prosodic boundary are the weakest. This is expressed in the rankings in (22), which follows the three-way distinction between phrase-final, word-final, and (word-)internal consonants established in §2.2. Syllable well-formedness and extraprosodicity are irrelevant concepts in this framework, but $C \rightarrow V$ and $C \leftrightarrow V$ obviously bear similarity to, but are not equivalent to, NoCoda and NoComplexCoda/Onset, respectively.

(22) a. $C]_{\emptyset} \rightarrow V >> C]_{PW} \rightarrow V >> C]_{Ph} \rightarrow V$
b. $C]_{\emptyset} \leftrightarrow V >> C]_{PW} \leftrightarrow V >> C]_{Ph} \leftrightarrow V$

This approach derives the Kamaiurá and Cairene Arabic patterns. In Kamaiurá, NoDeletion is ranked between $C]_{\emptyset} \rightarrow V$ and $C]_{PW} \rightarrow V$; word-internal consonants have to be followed by a vowel, but word-final ones survive (23). It also directly accounts for cumulative immunity effects, as in Basque (10), with the rankings in (22). Note that C in these constraints may be restricted to specific categories or features (e.g. stops or [coronal] consonants).

(23)

o-mo-kon-mo-kon	$C]_{\emptyset} \rightarrow V$	NoDeletion	$C]_{PW} \rightarrow V$
a. omokonmokon	*!		*
b. omokomoko		**!	
☞ c. omokomokon		*	*

Broselow (2003) interprets the existence of exceptionality effects involving the stem – a morphosyntactic constituent – as contradicting the prosodic basis of the perceptual account. Moreover, enhancement effects are strongest at the phrase

4.6 *Summary and discussion*

The proposals in §4.1–§4.5 can be compared along two empirical dimensions: (i) do they adequately account for all types of final immunity?; (ii) are they compatible with other phonotactic patterns involving the internal–final relationship? Concerning the first question, alignment constraints, due to their variety, are capable of deriving the full range of immunity effects; parameters such as Coda Licensing and Remote Licensing also account for additional consonantal slots, but their onset status appears at odds with the limited range of final consonants often tolerated beyond syllabic possibilities. Positional faithfulness struggles with final consonant immunity obtained though final vowel deletion; ANCHOR-based analyses also fail to protect final clusters by targeting only the last segment. Prosodic approaches raise the issue of immunity effects at the end of morphosyntactic constituents. Finally, it remains to be seen how reasonably morphology can embrace all cases of final consonant immunity.

Beyond final immunity effects, Coda and Remote Licensing are integrated into parametric systems that claim to account for the full typology of internal–final phonotactic patterns, but the former fails to provide for symmetric languages of type (15d), where final consonants display a typical coda profile, and the latter ignores languages that require words to end in a vowel (15e). Alignment constraints probably offer the most flexible framework and derive the full range of patterns in (15). In fact, the flexibility of alignment constraints is such that final immunity effects enjoy no special status: consonant sequences are as likely to be more complex internally as to be more complex finally. This position might be argued to lack restrictiveness or explanatory power or, conversely, better reflect the range of formally possible patterns, depending in part on the status of type (15f), with complex codas productively allowed only inside constituents. Approaches based on positional faithfulness, perception, or morphology make no specific claims with regard to phonotactic patterns other than final immunity, especially those involving more complex internal codas, which need to be derived by independent constraints or factors. The requirement that words end in vowels might be interpreted as a morphological constraint, but type (15f) would seem to be more challenging. Progress in the analysis of final (and internal) immunity effects rests on a deeper understanding of the patterns in (15), how they arise diachronically, and what factors they are sensitive to.

5 Metrical invisibility

As noted in (2b), final exceptionality also manifests itself prosodically, final CVC syllables patterning like CV ones in stress assignment and vowel length alternations. While regularly noted, the metrical invisibility of final consonants has not given rise to the same analytical diversity as phonotactic immunity. Whether or not metrical invisibility and phonotactic immunity are amenable to a unified approach is also unclear: despite some attempts at a common analysis, there is evidence that the segmental and metrical manifestations of final exceptionality should be kept separate. §5.1 presents the relevant generalizations underlying metrical invisibility and its relationship with segmental immunity; §5.2 addresses its functional motivation.

5.1 Generalizations

In quantity-sensitive stress systems, syllable weight is normally determined by the segmental make-up of the rime. In some cases weight assignment also depends on the position of the rime in the word. Of interest here is the pattern where CVC syllables count as light in final position but as heavy elsewhere. See Hayes (1995: 57), Lunden (2006: 1), and Gordon *et al.* (2010: 142) for lists of languages in which final CVC patterns as light.

Various dialects of Arabic illustrate this effect, among them Cairene (Hayes 1995: 67–71; see also CHAPTER 124: WORD STRESS IN ARABIC). Cairene has three syllable types: light CV, heavy CVC and CVː, and superheavy CVCC and CVːC, found only in final position. Stress falls on final superheavy syllables (24a), otherwise on heavy penults (24b), otherwise on the penult or antepenult, according to a complex algorithm not described here. This pattern reveals an equivalence between final CVCC/CVːC and penultimate CVC/CVː, which regularly attract stress, and between final CVC and penultimate CV, which do not. This is straightforwardly accounted for if word-final consonants are ignored in the computation of weight and stress.

(24) a. [ka'tabt] 'I wrote'
[haʤ'ʤaːt] 'pilgrimages'
b. [ka'tabta] 'you (MASC SG) wrote'
[haː'ðaːni] 'these (MASC DUAL)'
[mu'darris] 'teacher'

As shown in (9) and (24), final consonants are simultaneously invisible to syllabic restrictions and stress assignment, which makes Cairene Arabic a textbook example of final consonant exceptionality, regularly discussed since Broselow (1976) and McCarthy (1979). Such data make it tempting to interpret segmental immunity and metrical invisibility as two effects of a single phenomenon. Yet the two must be distinguished. In Cairene, stress assignment applies at the word level, but the CVC syllable template is enforced at the phrasal level, after resyllabification of word-final consonants with a following vowel, as in (25a). Crucially, stress remains on the second syllable in [ʃi'ribt] and the first in ['katab] (25b), even though on the surface the second syllable is assumed to be CVC in both cases.

(25) a. /ʃiribt ahwa/ [ʃi.'rib.'tah.wa] 'you drank coffee' (Selkirk 1981: 222)
b. /katab lilmalik/ ['ka.tab.lil.'ma.lik] 'he wrote to the king' (Broselow 1976: 16)

Other evidence of the independence of segmental immunity and metrical invisibility can be found in the stress pattern of Hindi-Urdu (Hayes 1980; Hussain 1997). The relevant facts resemble those of Cairene Arabic, with stress falling on final superheavy syllables, otherwise on the rightmost heavy. Unlike Cairene, however, superheavy syllables are not restricted to the final position. Final consonants are metrically invisible, since CVC attracts stress only in non-final syllables. But segmental immunity is not involved, since complex codas occur in all positions.

Like stress, vowel length is sensitive to syllable shape, vowel shortening typically occurring in closed syllables and lengthening in open syllables. Again, final consonants appear to be ignored in some languages, with lengthening applying in final CVC syllables or shortening applying only in CVCC ones. Icelandic (Gussmann 2002) regularly stresses the initial syllable of the word. The stressed vowel lengthens in open syllables (26a) and in monosyllables closed by only one consonant (26b), but no lengthening is observed in non-final closed syllables (26c) and in monosyllables closed by two or more consonants (26d). This is a straightforward case of final consonant invisibility: final CVC patterns like non-final CV, and final CVCC like non-final CVC. Similar length alternations are observed in Swiss German (Spaelti 2002) and Menominee (Milligan 2005).

(26)	a.	['puː]	'estate'
		['staːra]	'stare'
	b.	['pruːn]	'edge'
		['θaːkʰ]	'roof'
	c.	['sɛnta]	'send'
		['flaska]	'bottle'
	d.	['tʰjalt]	'tent'
		['rixs]	'rich (GEN SG MASC)'

English shows both stress and length effects of final metrical invisibility. In verbs, final CVCC attracts stress (*u'surp, tor'ment*), but CVC does not (*'edit, de'velop*). The stress-attracting power of internal CVC is, however, visible in nouns (*a'genda, a'malgam*) (Hayes 1982). With respect to length, long vowels in final CVːC syllables regularly correspond to short vowels in final CVCC or non-final CVC, after the addition of a consonantal or syllable-size suffix (*keep–kept, wide–width, five–fifth–fifty, wise–wisdom, intervene–intervention*). This suggests that shortening applies in closed syllables (internal CVC and final CVCC) but spares final CVC, treated as open by virtue of final consonant invisibility.

The representations specific to final consonants discussed in §3 have also been used to derive their metrical invisibility, in particular extraprosodicity (13e) and non-moraic coda consonants (13f). The latter directly accounts for invisibility in the context of stress assignment, if stress depends on syllable weight and weight on moraic structure. Extraprosodicity for metrical purposes is generally kept distinct from phonotactically motivated extrametricality (e.g. Hayes 1995: 106), echoing the remarks above on the non-equivalence between metrically invisible and segmentally immune consonants. Iverson (1990) in fact argues that extraprosodicity should be restricted to stress and excluded from the segmental domain, with cases of segmental immunity and vowel length alternations re-analyzed as involving some of the other devices mentioned in §3: appendices, empty-headed syllables, and sequential cluster constraints (see also Lamontagne 1993).

5.2 *Motivation*

The lightness of final CVC syllables is motivated by the avoidance of final stress, embodied in OT by the constraint Non-Finality (Prince and Smolensky 2004), which excludes final stressed syllables or head feet (see CHAPTER 43: EXTRAMETRICALITY AND NON-FINALITY). Non-Finality, in conjunction with other constraints, correctly derives stresslessness on final CVC and stress on final CVCC and CVVC in Arabic dialects (Rosenthall and van der Hulst 1999).

If NON-FINALITY generates the facts, the question remains why final stress should be avoided or why final CVC is treated as light. A number of proposals functionally related to the special status of final CVC have recently been put forward. Ahn (2000), Lunden (2006), Hyde (2009), and Gordon *et al.* (2010) offer explanations that, although distinct, are all related to final lengthening.[10] Ahn suggests that the increased vowel duration resulting from final lengthening jeopardizes the contrast between short and long vowels by making final short vowels comparable in duration to non-final long vowels. Stressing the final vowel would weaken the length contrast even further. Lunden and Gordon *et al.* develop a duration-based account of syllable weight, according to which syllables count as heavy (and attract stress) if their rime is sufficiently longer than that of light syllables. The relative difference in duration between internal CVC and CV is sufficient for CVC to be categorized as heavy, but this may not be the case finally, where final lengthening reduces significantly the durational ratio of CVC to CV. Gordon *et al.* (2010) also reveal that the languages that asymmetrically treat final CVC as light lack vowel length contrasts in final syllables. It is proposed that phonetic final lengthening tends to be more pronounced when no length contrasts need to be maintained, making it more likely that CVC be interpreted as light.

Hyde (2009) focuses on certain properties of final lengthening rather than on duration itself. He notes that, unlike initial lengthening, final lengthening is typically associated with tempo deceleration and declining intensity. These characteristics make final position less compatible with stress, either because diminished intensity makes stress more difficult to perceive, or because the intensity that typically accompanies stress makes it more difficult to decelerate. See Hyman (1977) and Gordon (2001) for related ideas. Gordon invokes intonational factors, final stress being avoided because it would result in the high tone associated with stress and the low final boundary tone being realized on the same syllable. Note that these different factors – duration, final lengthening, length contrasts, tones, deceleration, and intensity – are potentially complementary rather than contradictory in explaining the distinction between final stressless CVC and stressed CVCC/CVVC.

6 Conclusions

Final consonants are implicated in a multiplicity of data and analytical approaches, involving a variety of representations, constraints, and parameters. Among the relevant empirical domains, consonant phonotactics has largely dominated the debates, and the stresslessness of final CVC has drawn some attention, while vowel length alternations have been relatively neglected. Analytically, no unified conception of final consonant exceptionality has really emerged, despite attempts based on extraprosodicity, which have been challenged by evidence for the independence of metrical invisibility and segmental immunity. In a changing theoretical landscape, discussions have tended to shift over time from issues of representation to motivations, ranging from abstract parameters (coda or remote

10 Final lengthening may also relate to length alternations that treat final CVC as open, as in Icelandic (26). I leave this issue open.

licensing) and OT constraints (alignment, positional faithfulness) to the role of morphology and functional explanations (perceptual factors, final lengthening). These approaches are probably to some extent complementary.

Focusing on phonotactic patterns, several issues remain to be clarified, concerning the typology of final immunity effects and their relationship to internal immunity effects, whereby more consonants are allowed in internal codas than in final position, and the prosodic or morphosyntactic nature of the constituents involved (phrases, words, stems). To what extent can patterns that require constituents to end in a consonant be analyzed along the same lines as those that merely allow additional consonants? What is the status of patterns displaying more complex codas inside constituents? Should internal and final immunity effects be accounted for in a unified and symmetrical fashion or do they involve distinct factors? One difficulty in answering such questions stems from the fact that positional asymmetries in the complexity of consonant sequences may relate to many factors other than the internal–final contrast, including stressed *vs.* unstressed syllables, initial *vs.* non-initial syllables, morpheme boundaries, and coda–onset linking.

37 Geminates

Stuart Davis

1 Introduction

The term "geminate" in phonology normally refers to a long or "doubled" consonant that contrasts phonemically with its shorter or "singleton" counterpart (see also CHAPTER 47: INITIAL GEMINATES). Such contrasts are found in languages like Japanese and Italian, as exemplified by the minimal pairs in (1) and (2), respectively.[1] Languages such as English and Spanish do not have geminates.

(1) *Japanese geminate contrast* (Tsujimura 2007)[2]

a. [saka] 'hill'
b. [sakka] 'author'

(2) *Italian geminate contrast*

a. [fato] 'fate'
b. [fatto] 'fact'

The issue of the phonological representation of geminates has engendered much controversy over the past thirty years. The main issue revolves around how to distinguish formally a geminate consonant from its singleton counterpart in a way that captures the cross-linguistic phonological patterning of geminate consonants. The featural representation of geminate consonants posited in Chomsky and Halle

[1] Languages with geminates vary considerably with respect to the durational difference between the geminate and its singleton counterpart. Idemaru and Guion (2008) report a 3:1 ratio in the duration of geminates to singletons in Japanese but only a 1.8:1 ratio for Italian. They further note that there may be other phonetic cues to geminates besides consonantal duration. These include pitch and intensity differences that may provide secondary acoustic cues to a geminate. However, this chapter will not focus on the phonetic properties of geminates, nor on the issue of which types of consonants are more likely to be geminated (but see Pycha 2007, 2009 and Kawahara 2007 for discussion on these issues). Instead, this article will focus on the phonological behavior of geminates and the matter of their representation in phonology.

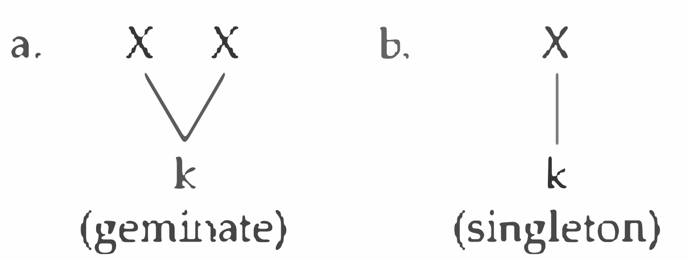
[2] In this chapter, geminate consonants are transcribed by a sequence of two identical letters; long vowels are represented either as a sequence of two identical vowel symbols or with the IPA length mark.

(1968) as being a single consonant possessing the distinctive feature [+long] has long been considered insufficient, since, as noted by researchers such as Leben (1980), long consonants can behave like a sequence of two consonants for certain phenomena. Leben posited an autosegmental representation of geminates in which a single phoneme is linked to two slots on a skeletal tier that encodes the prosody of the word. This skeletal tier is also referred to as a CV-tier, an X-tier, or a length tier, depending on the specific conception of the researcher. Important earlier works that incorporate a CV-tier include McCarthy (1979, 1981), Halle and Vergnaud (1980), Clements and Keyser (1983) and Hayes (1986), while Levin (1985) posited that the tier consisted of X-slots (see CHAPTER 54: THE SKELETON). Geminate representation on this view is exemplified by the geminate [kk] of the Japanese word in (1b), as is illustrated in (3).

(3) a. *CV-tier representation* b. *X-tier representation*

As seen in (3), a geminate consonant has one set of features indicated by the single consonant "k" on the phoneme (or melody) tier, whereas it is linked to two slots on a prosodic tier. In (4), we make clear the distinction between a geminate and a singleton using an X-tier that encodes prosody.

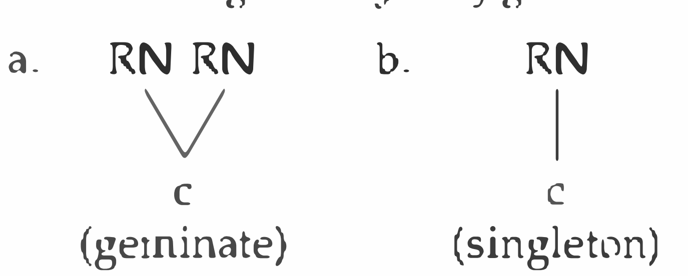
(4) *Prosodic length analysis of geminates*



While the proposals for the representation of geminates in (4) go back thirty years, this representation is specifically argued for by Ringen and Vago (2010), who refer to (4) as the segmental length analysis of geminates.

A different representation of geminates from that in (4) is the two-root node analysis of geminates posited by Selkirk (1990) shown in (5). The root node in a feature-geometric framework indicates the major class features of a sound (McCarthy 1988) and it dominates the rest of the specified features. Every phoneme has a root node, but a geminate under this view has two root nodes (RN = root node, c = consonant).

(5) *Prosodic length analysis of geminates*



There are at least two main differences between the two-root node analysis of geminates in (5) and the segmental length analysis in (4). First, unlike the X-slots epenthesis pattern. On the other hand, if a geminate is represented as moraic, as in (6a) and (7d), epenthesis might not be predicted to occur with a word ending in a geminate, since the consonantal length of a geminate is not segmentally encoded. That is, there would not be two C-slots or two consonantal elements at the end of the word to trigger the epenthesis. Ringen and Vago point out that the Hungarian epenthesis pattern poses a problem for the moraic view. Further, given the weight analysis of geminates in (7d), geminate consonants are predicted to play a role in processes that are sensitive to syllable weight even when singleton (coda) consonants do not. Much of the recent research on geminates has focused on whether geminates display weight properties that are independent of other consonants. This will be discussed shortly.

Over the past twenty years, a wide variety of phonological evidence has been brought to bear on the correct representation of geminates. The issue is still controversial.[3] All three views of geminate representation presented in this section, namely the prosodic length view in (4), the two-root node view in (5) and the moraic weight view in (6), have been argued for on the basis of the phonological patterning of geminates. Some composite views have even been proposed that combine aspects of the above representations, such as those of Schmidt (1992), Hume *et al.* (1997) and Curtis (2003). In §2 we will present specific evidence from a variety of phenomena to argue for the inherent weight representation of geminates. In §3, we will examine the behavior of geminates with respect to stress processes, cross-linguistically. In these sections, we will try to maintain a consistent view for the weight analysis in (6a) even when the data presented seem problematic for such a view. In §4 we will reconsider the representational issue and suggest that a composite view of the representation of geminates under a constraint-based approach can account for the patterning of geminates in the world's languages.

2 The weight analysis of geminates

The underlying weight analysis of geminate consonants, as proposed in Hayes (1989), views a geminate consonant as being underlyingly moraic, as shown in (6a), whereas a non-geminate consonant is underlyingly non-moraic, as in (6b). The weight representation of geminates in (6a) has a number of implications, which will be discussed in this section. One such implication is that if geminates are inherently moraic, they should count as moraic in considering minimal word effects: that is, the cross-linguistically common requirement that content words be at least bimoraic. In §2.1 we show that this is the case for Trukese. A specific structural aspect of the weight representation in (6a) is that geminates do not entail a double linking to two C-slots as in the length representation. This implies that there should be cases in which geminates do not pattern with a sequence of consonants. §2.2 discusses cases of the asymmetrical patterning of geminates and consonant

[3] The controversy over geminates has fostered a number of dissertations with a focus on the phonology of geminates. Some of the important ones include Sherer (1994), Ham (1998), Keer (1999), Morén (1999), Kraehenmann (2001), Muller (2001), Curtis (2003), and Topintzi (2006). Although space does not allow me to discuss the wide variety of interesting issues and proposals that are raised in these dissertations and the different positions that are taken, some issues raised in these dissertations will be brought up in the course of this chapter.

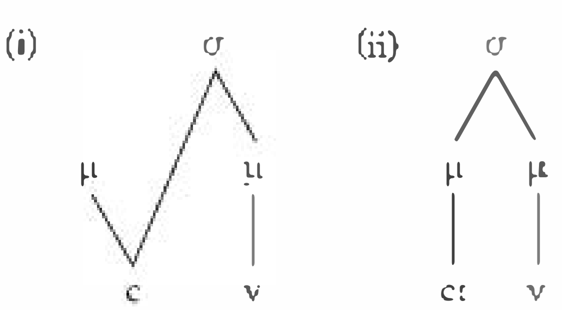
sequences. A third implication that emerges from the weight representation in (6a) is the prediction that there should be languages that treat syllables closed by a geminate (CVG) as heavy but do not otherwise treat syllables closed by a (coda) consonant (CVC) as heavy. In §2.3, we will provide evidence for this prediction by discussing languages that avoid long vowels in syllables closed by a geminate (CVVG), but do not generally avoid long vowels in closed syllables (CVVC). We hold off until §3 the discussion of geminate behavior in weight-sensitive stress systems.

2.1 *Trukese initial geminates*

One type of evidence for the underlying moraic nature of geminates as in (7d) comes from the bimoraic minimal word requirement in Trukese (also called Chuukese) and the behavior of word-initial geminates with respect to it. Although word-initial geminates are rare, they are attested in a number of languages. (Indeed, the dissertations of Muller 2001 and Topintzi 2006, 2010 are exclusively on initial geminates; see also CHAPTER 47: INITIAL GEMINATES.)[4] Muller (2001), whose study incorporates acoustic analyses of word-initial geminates in a variety of languages, including Trukese, concludes that initial geminates are moraic in some languages but not in others, while Topintzi (2006, 2008, 2010), focusing on languages where initial geminates pattern as moraic, argues that such geminates constitute moraic onsets, thus providing examples in which onsets carry weight.[5] Trukese provides a clear example of a language where a word-initial geminate patterns as moraic. Consider the data in (8) and (9), which reflect a minimal word constraint on Trukese nouns. The data here are cited from Davis (1999b) and Davis and Torretta (1998), and are mainly taken from Dyen (1965) and Goodenough and Sugita (1980). The relevance of Trukese geminates for moraic phonology has previously been observed by Hart (1991) and Churchyard (1991).

[4] It is clear from typological surveys of geminate consonants such as Thurgood (1993) and from the discussion in Pajak (2009) that geminates are most commonly found in intervocalic position and least commonly found when not adjacent to any vowel (e.g. between two consonants). Languages that allow for geminates that are only adjacent to one vowel (e.g. word-initial or word-final geminates), although not common, are not as rare as languages that allow for geminates to occur not adjacent to any vowel. As noted by Pajak (2009), the typological facts correspond to perceptual saliency in that the contrast between a singleton and a geminate consonant is most perceptually salient in intervocalic position and least salient in a position not adjacent to any vowel.

[5] Following a suggestion in Hayes (1989), Davis (1999b) proposes that word-initial geminates are moraic but that the mora is not part of the syllable onset. His representation is in (i), while Topintzi's moraic onset representation is given in (ii) (where the vowel of the syllable is also shown).



One difference between (i) and (ii) is that the latter predicts that onset geminates could occur word-internally, not just at the beginning of the word. In support of (ii), Topintzi (2008) provides interesting evidence from Marshallese that word-internal geminates are syllabified as onsets and are not heterosyllabic as commonly assumed in Moraic Theory.

2.3 *Avoidance of CVVG syllables*

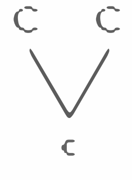
Hayes's theory of underlying moraic representation was presented in (7): geminate consonants (7d) differ from singleton consonants (7c) in being underlyingly moraic. Furthermore, Hayes distinguishes long vowels from short vowels by representing the former as underlyingly bimoraic and the latter as monomoraic. Moraic Theory has an implication for the patterning of geminates with respect to weight-sensitive processes – an implication not discussed by Hayes (1989), but taken up by other researchers such as Selkirk (1990), Tranel (1991), and Davis (1999a, 2003). That is, there should be languages in which syllables with a long vowel (CVV) and those closed by a geminate consonant (CVG) count as heavy since they would be bimoraic, while CV syllables and CVC syllables (i.e. syllable closed by a non-geminate consonant) would be considered light or monomoraic. This weight distinction is shown in (11) (G = geminate consonant, C = non-geminate consonant).

(11) *Syllable weight distinction based on geminates being underlyingly moraic*

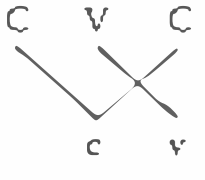
heavy	*light*
CVV	CV
CVG	CVC

The system in (11) is predicted to occur under Hayes's theory in any language with long vowels and geminate consonants that do not regard coda consonants as moraic. The moraic representation for syllables with the structure of (11) is given in (12).

(i) *Geminate in UR: length representation*



(ii) *Epenthesis into a geminate*



Geminate inalterability effects were handled by a condition on interpretation in segmental rules that association lines in structural description of rules had to be interpreted as exhaustive. A rule like spirantization in Tiberian Hebrew, which only applied to singleton consonants and not to geminates, would include in its rule environment a single C-slot linked to the phoneme. Since the rule environment did not explicitly show double linking as in (i), the rule would fail to apply to geminates. Kenstowicz (1994: 410–416) summarizes important criticisms of the CV account of both geminate integrity and inalterability. He points out that geminate integrity could be called into question if epenthesis is viewed as a two-stage process of inserting a V-slot followed by a late default spell-out rule. However, it is worth noting that geminate integrity effects follow automatically from the weight representation of geminates as in (10a). With respect to geminate inalterability, Kenstowicz specifically calls attention to work by Selkirk (1991), who noted that rules of inalterability tended to always involve spirantization processes, thus suggesting a more general explanation that does not involve the length representation of geminates. Along these lines, Kirchner (2000) approaches the issue of geminate inalterability from a general theory of lenition within a functionally based optimality-theoretic framework.

epenthesis apply between the two consonants to create open syllables, thereby avoiding any trimoraic syllable.

In the Arabic dialects, the rule (or constraint) of Weight-by-Position applies, resulting in a moraic coda. However, if we consider the weight division in (11) in which Weight-by-Position does not apply, we would expect to find a language where CVVG syllables but not CVVC syllables are avoided. A potential CVVG syllable would not surface, since it is trimoraic, while a CVVC could still occur, as it would only be bimoraic. Kiparsky (2008a) discusses Swedish dialects where vowel shortening occurs before a geminate but not before a single coda consonant. For example in West Swedish (Kiparsky 2008a: 191) /ruu-dde/ 'rowed' surfaces as [rudde], with its underlying long vowel shortened, but no shortening occurs when a long vowel is before a singleton coda consonant. The shortening before a geminate changes the potential trimoraic CVVG syllable to bimoraic CVG. There is no need for shortening in a CVVC syllable since it would be bimoraic, given that Weight-by-Position does not apply. Kiparsky specifically uses the Swedish data to argue for the moraic representation of geminate consonants.

Another language displaying this pattern of shortening is the Dravidian language Koya, brought up by Sherer (1994), based on Tyler (1969), and discussed in Davis (1999a, forthcoming). Koya has long vowels, coda consonants and geminate consonants. Sherer notes that there are words in Koya like those in (14a)–(14c), with a long vowel before a coda consonant. Crucially, as Tyler (1969: 6) observes, there are no words that contain a long vowel before a geminate. They are always short, as in (14d). All Koya data are cited from Tyler (1969), with the page numbers provided. (The transcription of the vowel quality is phonemicized and does not reflect the precise allophonic variant.)

(14)	a.	leːŋga	'calf' (p. 11)	b.	aːɳɖa	'female' (p. 8)
	c.	neːrs	'learn' (p. 76)	d.	ett	'lift' (p. 76)

Sherer additionally notes cases where a stem-final long vowel shortens before a geminate-initial suffix, as the examples in (15) show.

(15)	a.	keː + tt + oːɳɖu	[kettoːɳɖu]	'he told' (p. 39)
	b.	oː + tt + oːɳɖu	[ottoːɳɖu]	'he bought' (p. 38)

This shortening can be viewed as a way of avoiding trimoraic syllables. Shortening does not occur before a non-geminate consonant, as the examples in (16) illustrate.

(16)	a.	naːl + ke	[naːlke]	'tongue' (p. 47)
	b.	tuŋg + anaː + n + ki	[tuŋganaːŋki]	'for the doing' (p. 90)

In (16), a long vowel surfaces before a syllable-final singleton coda consonant. Since vowel shortening occurs before a geminate in (15), the Koya data in (14)–(16) are consistent with the weight system in (11), in which CVV and CVG syllables are bimoraic whereas CVC syllables are light.[8]

[8] Curtis (2003: 169–170) suggests that the lack of word-internal CVVG syllables in Koya may be due to a shortening effect that geminate consonants have on preceding vowels, since the perceptual cues for vowel length can be blurred in CVVG syllables; thus, Curtis maintains that vowel shortening before geminates is independent of the issue of the moraic status of geminates. However, this does not explain cases like Fula in (19) where avoidance of CVVG is achieved by degemination rather than vowel shortening.

While the above examples of Koya and Swedish are cases where vowel shortening occurs in syllables closed by a geminate, there are other languages where vowel-lengthening processes are prevented in CVG syllables but not in CVC syllables. This suggests that in such languages geminates are underlyingly moraic, although coda consonants in general are not. Vowel lengthening then does not apply before a geminate, since that would create a trimoraic syllable. This is illustrated by Seto (Southeastern Estonian), discussed by Kiparsky (2008b). According to Kiparsky, Seto has feet that are required to be trimoraic and such a restriction is normally implemented by foot-final vowel lengthening. As a result, a foot with the underlying sequence CV.CVC surfaces as CV.CVVC. However, given an input structure where the final consonant of the foot is part of a geminate, i.e. CV.CVG, no vowel lengthening occurs. This provides evidence that the geminate is underlyingly moraic: that is, foot-final vowel lengthening need not occur in CV.CVG since the foot is already trimoraic.

A different case that avoids the surfacing of CVVG syllables can be found in the West African language Fula as discussed by Paradis (1988) and Sherer (1994). Fula avoids CVVG syllables by degemination of the consonant but, importantly, it allows for CVVC syllables, as seen in (17).

(17) CVVC *syllables in Fula* (Sherer 1994: 176)

a. kaakt-ɛ 'spittle' b. caak-ri 'couscous'

This language has a suffixation process that triggers the gemination of a root-final consonant. Consider the singular/plural alternations in (18). Because of an active constraint that requires geminates to be [−continuant] in Fula, a root-final continuant segment changes to a stop when it geminates. (I thank Abbie Hantgan for help with the Fula data.)

(18) *Fula morphological gemination* (Paradis 1988: 78)

	stem (SG)	*suffixed form* (PL)	
a.	lɛw	lebb-i	'month'
b.	lɛf	lepp-i	'ribbon'

Of relevance here is that when a long vowel precedes the stem-final consonant, gemination fails to occur, but the stem-final consonant nonetheless is realized as a stop. This is illustrated by the singular/plural alternations in (19).

(19) *Lack of gemination after a long vowel* (Paradis 1988: 80)

	stem (SG)	*suffixed form* (PL)	*expected form*	
a.	laaw	laab-i	*laabb-i	'road'
b.	lɛɛs	lɛɛc-ɛ	*lɛɛcc-ɛ	'bed'

Given that gemination is part of this suffixing process, we note that the expected forms in (19), where the initial syllable would be CVVG, fail to surface as such. Rather, the nature of the occurring suffixed forms in (19) makes it appear that degemination has occurred. This can be understood as the avoidance of a trimoraic CVVG syllable. Since CVVC syllables are allowed as in (17), Fula seems to instantiate a language with the weight system of (11), where CVG syllables are heavy but not other CVC syllables. Thus, we see that a variety of languages have strategies to avoid CVVG syllables but not CVVC syllables. These languages can be understood as providing support for the inherent weight analysis of geminates.

3 The patterning of geminates in stress systems

One of the criticisms of the weight analysis of geminates proposed by Hayes (1989), discussed by Tranel (1991), comes from the observation that there do not seem to be quantity-sensitive stress systems that support the weight division in (11), repeated below as (20), where stress would be attracted onto a syllable with a long vowel or closed by a geminate consonant, but not on a syllable closed by a non-geminate.

(20) *Syllable weight distinction based on geminates being underlyingly moraic*

heavy	*light*
CVV	CV
CVG	CVC

The system in (20) is predicted to occur under Hayes's theory in any language that allows long vowels and geminate consonants, but in which Weight-by-Position does not generally apply to coda consonants. According to the division in (20), CVV and CVG syllables would syllabify as bimoraic, while CV and CVC syllables would syllabify as monomoraic, as was shown in (12). Since quantity-sensitive stress systems single out bimoraic syllables, it would be expected that at least some quantity-sensitive stress systems would reflect the weight division in (20) if the moraic representation of geminates were correct. Tranel suggests that weight systems like (20) do not exist and instead proposes a principle of equal weight for codas. Specifically, in languages in which codas pattern as moraic, geminates will be moraic; but in languages in which codas are not moraic, geminates would not be moraic. While our observation in §2.3 above – that in a variety of languages CVVG syllables are avoided but CVVC are not – can be taken as evidence for the weight division in (20), Tranel's observation is of importance. In this section, we will overview the behavior of geminates in quantity-sensitive stress systems. In §3.1, we will provide stress data from various languages which indeed support the division in (20) whereby CVV and CVG syllables pattern together, thus supporting the moraic weight analysis of geminates. These are languages whose stress patterns Tranel predicts not to occur. In §3.2, I will review the type of case mentioned by Tranel in which quantity-sensitive stress treats all closed syllables in the same manner whether they be CVG or CVC. These are the languages that motivated Tranel's principle of equal weight for codas and can be considered somewhat problematic for the weight analysis of geminates. In §3.3, I will present the case of the Australian language Ngalakgan (variably spelled Ngalagkan and Ngalakan; Baker 1997, 2008), in which CVC syllables can attract stress but apparently not CVG syllables. This seems to suggest that somehow geminates are resistant to carrying a mora. Thus, this section will identify three different types of geminate behavior with respect to quantity-sensitive language that requires exhaustive footing. The data item in (21e) is similar to the last two syllables in (21d) in that the syllable with a long vowel forms a foot on its own and the syllable immediately after it is at the beginning of a new trochaic foot, thereby receiving stress. We see then that bimoraic CVV syllables in Cahuilla are distinguished from monomoraic syllables, not only in bearing stress, but also by the presence of stress on the syllable immediately after them. CV and CVC syllables lack these two characteristics and function as monomoraic. It is interesting in this light to observe the patterning of syllables closed by a geminate, as in (21f), where the first syllable is CVG. This CVG syllable functions as bimoraic. It has stress, as would be expected of any initial syllable, but crucially it patterns exactly like a CVV syllable in that the syllable immediately after it also carries stress. This provides evidence that the CVG syllable comprises a bimoraic (trochaic) foot on its own. This constrasts with the initial CVC syllable in (21c) that forms a trochaic foot with the following syllable, suggesting the monomoraic nature of the CVC syllable. Cahuilla thus serves as a clear illustration for the weight distinction in (20) in which stress treats syllables with long vowels and those closed by geminates as bimoraic but not other types of syllables, be they CV or CVC.

San'ani Arabic (Yemen) presents a very interesting case, in which CVV and CVG syllables pattern together with respect to stress. Watson (2002: 81–82) specifically notes that they pattern together as opposed to CVC syllables (see also CHAPTER 135: WORD STRESS IN ARABIC). Consider the data in (22), which illustrate the stress pattern in words without geminates.

(22) *San'ani Arabic* (Watson 2002: 81–82)

a.	mak.'tu:b	'office'
b.	da.'rast	'I/you (MASC SG) learnt'
c.	'sa:.fa.rat	'she travelled'
d.	mak.'sa:.lih	'launderette'
e.	mi.'gam.bar	'sitting'
f.	'mad.ra.sih	'school'
g.	mak.'ta.ba.ti:	'my library'
h.	'li.bi.sat	'she wore/put on'
i.	'ka.tab	'he wrote'
j.	'ra.ga.ba.tih	'his neck'

Stress normally falls on one of the last three syllables of the word: it falls on a final superheavy syllable (CVVC or CVCC) if there is one, as in (22a)–(22b); it falls on the rightmost non-final heavy syllable (CVC or CVV) up to the antepenultimate, as in (22c)–(22f); otherwise, stress falls on the leftmost CV syllable, as in (22g)–(22j). The data in general show that the word-final segment does not play a role in the computation of weight so that the final syllable can only be stressed if it is superheavy. The word in (22g) illustrates two important aspects of the stress system. It shows that a word-final syllable ending in a long vowel does not attract the stress; it also indicates that a CVC syllable in pre-antepenultimate position fails to attract stress. The latter point is significant, since it suggests that Weight-by-Position, which assigns a mora to a coda consonant, is restricted to one of the last three syllables of the word. Now let us consider the data in (23) with words possessing geminate consonants.

(23) *San'ani Arabic* (Watson 2002: 81–82): *stress on words with geminate consonants*

a. ji.'ħib.bu 'they (MASC) love/like'
b. mit.'ʔax.xi.raːt 'late (FEM PL)'
c. mu.'sadʒ.dʒi.la.ti 'my recorder'
d. 'haː.ka.ða.haː 'like this'
e. 'daw.wart 'I/you (MASC SG) looked for'
f. 'sa.far.t 'I/you (MASC SG) travelled'

The comparison between (22) and (23) indicates the priority of CVG and CVV syllables for stress assignment, in that CVG and (non-final) CVV syllables always attract stress even when in pre-antepenultimate position as in (23c) and (22d). The word in (22g), in contrast, shows that a CVC syllable does not receive stress in pre-antepenultimate position. The difference between CVG and CVC syllables can be readily understood on the inherent weight analysis of geminates. If a geminate is underlyingly moraic, it contributes weight to the syllable regardless of its location in the word. Recall that Weight-by-Position does not apply here, because it is restricted to one of the last three syllables in San'ani Arabic. In pre-antepenultimate position, only CVV and CVG act as bimoraic. Moreover, (23e) shows that CVG syllables have a priority of stress over a final superheavy syllable and should be compared with (22a) where a regular CVC syllable is devoid of such priority. It could be argued that Weight-by-Position in San'ani Arabic only applies to words that would not otherwise have bimoraic syllables (CVV or CVG). That is, there is no necessity for Weight-by-Position to apply in (23e) or (23f). While we do not pursue a full analysis here (but see Watson 2002), the priority given to both CVV and CVG syllables in stress assignment, especially as seen by the comparison of (23c) and (23d) with (22g), provides an interesting argument for the underlying moraic weight analysis of geminates, and, in turn, against Tranel's (1991) claim of equal weight for codas.

We have detailed above two cases where CVV and CVG syllables pattern together with respect to stress systems as predicted by the inherent weight analysis of geminates. Further support for the weight analysis of geminates is found in other languages. For example, Gupta (1987) discusses a Hindi dialect in which stress is attracted to the leftmost heaviest syllable in the word. The dialect treats both CVV and CVG syllables as bimoraic, while CVC syllables behave as light, although, as noted by Curtis (2003), such a pattern appears unusual among Hindi dialects. Additional support may come from the stress system of Pattani Malay, discussed by Topintzi (2006, 2008, 2010) and references cited therein. Pattani Malay has geminates that are restricted to word-initial position and the language lacks long vowels. Although primary stress typically falls on the final syllable of a word, stress occurs on the initial syllable in words that begin with a geminate consonant. This can be taken as evidence for the moraification in (10a) where a geminate is underlyingly moraic. That is, stress is attracted onto a syllable that is bimoraic.

Despite the range of examples presented in this section, it remains rare to see languages that display the weight system in (20), grouping CVV and CVG syllables together as heavy. It is possible, on the other hand, that the rarity is due to the infrequent occurrence of the specific set of properties that is required for CVV and CVG to pattern together in stress assignment; namely, the language would have to have quantity-sensitive stress, long vowels, coda consonants, and geminates. Perhaps when such languages, San'ani Arabic for one, are examined closely, more instances of the special properties of CVG syllables will emerge. In this connection, it is worth noting that in most Arabic dialects CVG syllables are special: they always attract stress when in word-final position. This property separates them from other CVC syllables, which do not attract stress in word-final position. The difference thus finds a logical explanation in the underlying weight analysis of geminate consonants (especially in those dialects, such as Hadhrami Arabic, discussed earlier, which disallow final consonant clusters).[10]

3.2 *Languages in which stress treats all codas equally*

There are two types of languages in which stress assignment treats all codas equally. In the first type, stress is quantity-sensitive and is attracted to a heavy syllable, be it CVV, CVC, or CVG. Latin belongs to this group: any coda consonant makes a syllable heavy, so both CVC and CVG syllables are bimoraic. In the second type, which is more relevant for the representation of geminate consonants, both CVC and CVG syllables behave as light in a quantity-sensitive stress system. In such a language, stress is attracted to a CVV syllable, but both CVC and CVG syllables seem to pattern as monomoraic, treating CVG as light, just like other CVC syllables. As an illustration, consider the stress data from the Uralic language Selkup in (24). The data in (24a)–(24f) come from Halle and Clements (1983). The data items in (24g)–(24h) are reported in Ringen and Vago (2010) from the Selkup language scholar Eugene Helimski, and reflect the Taz Selkup dialect, which seems to have the same stress pattern as that in Halle and Clements (1983).

(24) *Selkup stress*

a.	qu'moːqi	'two human beings'
b.	'uːciqo	'to work'
c.	uː'cɔːmɨt	'we work'
d.	'quminɨk	'human being (DAT)'
e.	'amɨrna	'eats'
f.	'uːcikkak	'I am working'
g.	'ɛsykka	'(it) happens (occasionally)'
h.	ɛs'sɪːqo	'to happen (already)'

[10] In many Arabic dialects, word-final CVC syllables behave as extrametrical. Ham (1998) puts forward the very intriguing observation that final CVC syllables are always extrametrical in languages that possess word-final geminates. This is because a word-final geminate is moraic and would need to be distinguished in final position from a potential moraic coda. With the underlying moraic weight representation of geminates as in (10a), final extrametricality of CVC syllables is able to preserve the contrast between an underlying final geminate and the corresponding final singleton consonant. The geminate of a final CVG syllable would surface as moraic while the singleton coda of the final CVC would be non-moraic. This difference is found in Arabic dialects where a final CVG syllable attracts stress, making it distinct from a final CVC syllable (i.e. bimoraic), which is light (monomoraic) and does not attract the stress. In a variety of other languages having word-final geminates examined by Ham (1998), the same distinction is made between final CVG and CVC syllables. If Ham's observation holds up to further scrutiny, it constitutes an interesting argument for the underlying moraification of geminate consonants. (See also Topintzi 2008: 175 for discussion on this point.)

In Selkup, primary stress falls on the rightmost syllable with a long vowel (24a)–(24c) or on the initial syllable if there are no long vowels (24d). A CVC syllable does not count as heavy (24e), even if the CVC syllable is closed by a geminate, as seen in (24f) and (24g). As noted by Tranel (1991), if stress targets bimoraic syllables and geminates are underlyingly moraic, the second syllable in (24f) and (24g) would be the rightmost bimoraic syllable. Both the vowel and the geminate would contribute a mora to the second syllable. The fact that (24f) and (24g) do not receive stress on the second syllable, however, seems to provide evidence against geminates being underlying moraic, favoring a representation of geminates that is different from that in (10a).

The stress pattern of Selkup does not appear to be unique in ignoring geminate consonants. Davis (1999a: 41) notes the Altaic language Chuvash (Krueger 1961), which exhibits an almost identical stress pattern to that of Selkup: stress is attracted to the rightmost syllable with a full vowel (interpreted as being bimoraic), but CVC syllables are ignored. Thus, in both Chuvash and Selkup, CVC syllables do not function as bimoraic CVV syllables but instead act like monomoraic CV and CVC syllables.

Data from languages like Selkup have been used by Tranel (1991) and Ringen and Vago (2010) to argue against the underlying moraic weight representation of geminates. Ringen and Vago note that such languages are consistent with the length analysis of geminates as in (10b). In these languages, stress is sensitive to the presence of a long vowel, and ignores a coda consonant, whether the coda is part of a geminate or not. However, it is not that proponents of the weight representation are unaware of languages like Selkup. Topintzi (2008, 2010), who for the most part maintains the underlying moraic weight view of geminates, suggests that weightless geminates are represented by double consonants with two root nodes rather than as a single root node linked to a mora like (10a). But such a comment implies that there is language-specific variation in the representation of geminate consonants. On the other hand, Davis (2003) suggests that the stress pattern of languages like Selkup does not necessarily argue against the underlying moraic representation of geminates; viewed from an optimality-theoretic perspective, the pattern can be a consequence of certain high-ranking stress constraints that have the effect of ignoring the bimoraicity of any CVC syllable. As suggested by Steriade (1990: 275), there may be reasons in some languages to restrict the set of stress-bearing segments to those that are also tone-bearing, "for reasons that are clearly related to the fact that pitch is one of the main realizations of metrical prominence." Steriade's suggestion can be incorporated into an optimality-theoretic approach as a constraint that restricts pitch realization to vocalic elements: the constraint prefers to place stress on any CVV syllable over any syllable closed by a consonant, even if that consonant is part of a geminate. Thus, the lack of second syllable stress in (24f) and (24g) of the Selkup data need not reflect on the underlying moraicity of geminate consonants.

3.3 *Languages in which geminates repel stress*

A third type of geminate behavior is witnessed in languages where stress is attracted to a closed syllable, but not to one with a geminate. The Australian language Ngalakgan, discussed by Baker (1997, 2008), serves as a major example. Consider the pattern of primary stress in (25), taken from Baker (2008) who notes that other geographically proximate languages have a similar stress pattern.

(25) *Ngalakgan*

a.	pu'ruʈci	'water python'	k.	'calapir	'red ant (species)'
b.	ki'piʈkuluc	'frogmouth (bird)'	l.	'kupuj	'sweat (N)'
c.	mi'ɽarppuʔ	'crab'	m.	kaɳ'ʈalppuru	'plains kangaroo'
d.	pu'ʈolkoʔ	'brolga (bird)'	n.	'cakanta	'macropod sp.'
e.	ˌmaca'purka	'plant sp.'	o.	'ŋuɽuɳʈuc	'emu'
f.	'ɭaɽkurca	'vine sp.'	p.	'ŋoɭoŋkoʔ	'eucalyptus'
g.	'calpurkic	'fish sp.'	q.	'ŋamucˌculo	'subsection term'
h.	'ciwi	'liver'	r.	'capatta	'tortoise sp.'
i.	'ceraʈa	'women's ceremony'	s.	'moloppoɭ	'catfish sp.'
j.	'paɽaˌmunu	'sand goanna'	t.	'ŋanaʔpaj	'and moreover'

(25a)–(25l) show that primary stress in Ngalakgan falls on the leftmost (non-final) heavy syllable; if there is no heavy syllable, it falls on the initial syllable. From these data, it can be surmised that a coda consonant is moraic in making a syllable heavy, be it an obstruent (as in (25a) and (25b), or a sonorant (as in (25c)–(25g)). The data in (25m)–(25t) show that the leftmost closed syllable (underlined) fails to attract primary stress. Note that the coda in the leftmost closed syllable in (25m)–(25t) belongs to one of three types: in (25m)–(25p) the coda is a nasal homorganic with the following onset, in (25q)–(25s) it is the first part of a geminate consonant, and in (25t) the coda is a glottal stop. Key to our discussion is the fact that CVG syllables in (25q)–(25s) resist stress. However, the comparison of the stress-resistant nature of CVG syllables with the other instances of stress-resistant closed syllables in (25m)–(25p) and (25t) points to the fact that a common property these syllables have is that they do not possess their own place features: either the place features are shared with the following onset, or, in the case of the glottal stop in (25t), there is a lack of place features altogether. Thus, Ngalakgan seems to divide closed syllables into two types: those in (25a)–(25l), in which the coda has independent place features and attracts stress, and those in which the coda does not have its own independent place features and fails to attract stress. This suggests that Ngalakgan is best analyzed as having a requirement that moraic elements have independent place features (i.e. not shared with a following onset), as advocated in Baker (1997). It follows that the stressed closed syllables in (25a)–(25l) would be bimoraic and attract stress, whereas the CVG syllables in (25m)–(25p) would be monomoraic and not attract stress.

Languages like Ngalakgan seem to present a challenge for the underlying weight representation of geminates in (10a), since not only do syllables with geminates not attract stress, but they are not even equal in weight to CVC syllables, as in (25a)–(25l), which do attract stress. Baker (2008) offers an articulatory gestural analysis of the difference. He observes that the apparent CVC syllable attracts stress only if the postvocalic coda consonant has an articulatory gesture distinct from that of the following onset. That is, in a CVCCV sequence, the first syllable counts as heavy only if the two intervocalic consonants have distinct articulatory gestures. When the intervocalic sequence involves a geminate or a nasal that is homorganic with a following consonant (or a glottal stop, which does not have a distinct articulatory gesture) there is only one articulatory gesture, and stress is not attracted onto CVG (or CVN where N is homorganic with a following consonant). Baker (2009) adopts a composite view of geminate representation that incorporates a gestural tier along with root nodes and moras. Under this view, stress in Ngalakgan is characterized as sensitive to the gestural tier. Ringen and Vago (2010), in contrast, take the Ngalakgan data as supporting the length representation of geminates where the stress rule treats linked structures like those in (10b) as light. Davis (2003), who maintains the underlying weight representation of geminates, suggests that the Ngalakgan stress pattern in (25) does not necessarily argue against the underlying moraic representation of geminates as in (10a); rather, the language has a high-ranked constraint that requires moraic elements to have their own place features. Thus, while geminates may be underlyingly moraic, they do not surface as moraic.[11]

To conclude this section, we have surveyed languages demonstrating three types of behavior of CVG syllables in stress systems: (i) cases where CVG and CVV pattern together; (ii) cases where CVG patterns with other CVC syllables; and (iii) cases where CVG syllables are specifically resistant to stress. We have tried to maintain the underlying moraic weight representation of geminates despite apparent evidence to the contrary. In the concluding section we will further discuss representational issues.

4 Representational issues and conclusion

In this overview, we have focused on the cross-linguistic patterning of geminate consonants while trying to maintain the representational view of geminates in (10a), in which geminates are marked as being underlyingly moraic, over the length representation in (10b). In §2, we provided evidence for the underlying moraic representation of geminate consonants by considering a variety of phonological patterning pertinent to geminates. This included the moraic analysis of initial geminates in Trukese in §2.1 and the cross-linguistic avoidance of CVVG syllables in §2.3. We made it clear in §2.2 that geminates do not always behave like a sequence of two C-slots in prosodic patterning, thereby contradicting the length representation of geminates in (10b). In §3, we surveyed geminate patterning in stress systems identifying three types of behavior. Despite the differences, we still argued for the underlying moraic view of geminate consonants.

The issue of the representation of geminate consonants has been a controversial matter and will most likely remain so in future investigations. This is because geminates do not display uniform behavior, as we have illustrated. It seems that the very nature of the data under examination determines what type of representation must be appropriate. For example, the parallel patterning between final CC sequences and final geminates in Hungarian seems to be supportive of the length representation, while the difference between final CC sequences and final

[11] It should be noted that Baker (2008) actually considers the intervocalic geminates in (25q)–(25s) and the intervocalic homorganic nasal clusters in (25m)–(25p) to be syllabified completely as onsets rather than as heterosyllabic. This differs from his earlier work, Baker (1997), where a heterosyllabic parse of geminates and homorganic nasal clusters is maintained. One shortcoming of Baker's (2008) onset analysis is that geminates and homorganic nasal clusters do not occur word-initially. Nonetheless, even if geminates could be analyzed as syllabifying as onsets, they would not add weight to a syllable and thus would be different from the initial geminates of Trukese discussed earlier.

to different aspects of the representation. For example, in Trukese, the moraic aspect of the geminate representation is crucial, while it may or may not surface with two X-slots, depending on the constraints. In Hungarian, given the parallel behavior of word-final clusters and geminates, the X-tier representation is effective, while the geminate may or may not surface as moraic, depending on the constraints. In Ngalakgan, the behavior of geminates with respect to stress can be understood through the gestural tier, as proposed by Baker (2008, 2009). Geminates and homorganic nasal + consonant clusters have a single gesture. Consequently, they can pattern as single consonants despite having two X-slots, as long as there is a high-ranked constraint that requires a moraic element not to share place features. This would provide an explanation for the repulsion of geminates to stress. It follows that while geminates may have one underlying universal representation (as in (26)), its surface realization may vary cross-linguistically, e.g. as non-moraic in Ngalakgan, but moraic in Trukese.

The composite view, or some version of it, may ultimately be the best universal representation for an underlying geminate. For example, one criticism of a purely weight account of geminates is that it cannot distinguish between a geminate that syllabifies entirely in a coda from a single coda consonant in a language in which Weight-by-Position applies. This matter comes up in the Palestinian Arabic dialect described by Abu-Salim (1980) and mentioned in Rose (2000), where a coda singleton in a word like [bit.na] 'our house' is representationally indistinguishable from a coda geminate in a word like [sitt.na] 'our grandmother' on a strictly moraic view of geminates as in (10a). Unless a length tier (or two root nodes) is assumed, there is no obvious way to distinguish the two cases. Although such examples are probably rare, the occurrence of this type of contrast indeed favors a composite analysis, especially given the language-specific evidence for Arabic moraic structure presented in various parts of this chapter. That said, it may still be possible to argue for the underlying moraic weight representation as universal, but with the understanding that the surface realization of geminates may vary across languages because of the interaction of relevant constraints.

In conclusion, there is much about the phonology of geminates that remains to be investigated. Geminates do not all pattern the same way across languages. Consequently, geminate phonology will remain an area of theoretical controversy for the foreseeable future.

ACKNOWLEDGMENTS

I thank Brett Baker, Ken de Jong, Daniel Dinnsen, Tracy Alan Hall, Abbie Hantgan, Brian José, Michael Marlo, Paul Newman, Anne Pycha, Nathan Sanders, Robert Vago and Islam Youssef for discussion on various aspects of this paper. I especially thank Natsuko Tsujimura for her detailed comments. The usual disclaimers apply.

38 The Representation of sC Clusters

Heather Goad

1 Introduction

Clusters of the shape *s* + consonant (sC), exemplified by *stack*, have posed a challenge for theories of syllabification, as they defy many of the constraints holding of true branching onsets, as found in, for example, *track*. Accordingly, some researchers have proposed that *s* is organized outside the onset constituent that contains the following consonant. Others have proposed that this sort of analysis holds only for a subset of sC clusters; those that rise in sonority, for example in *slack*, are represented in the same fashion as branching onsets. Yet others have argued that some sC clusters, those of the shape s + stop, form complex segments.

This chapter will critique each of these proposals. An element shared by all of them is that phonological units are highly articulated: the burden of explanation is placed precisely on the structural relationships that adjacent segments enter into. Although this approach captures many peculiarities of sC clusters, there is little attempt to explain why the consonant that displays unorthodox behavior is typically *s*. Under the view that segments are ordered to maximize their perceptibility, the behavior of *s* becomes less puzzling: strident fricatives have robust internal cues, ensuring their perceptibility even in non-optimal contexts.

If the acoustic properties of *s* are of central importance, it behoves us to ask whether the differences between sC clusters and branching onsets can be explained solely by perceptual considerations. This, of course, would challenge the view that a structural approach to cluster well-formedness is necessary. In the final section of the paper I will argue that this position is too strong. I will conclude that an adequate understanding of sC clusters requires consideration of both perceptual and structural factors.

Much of the paper compares sC clusters with branching onsets. We will observe that they differ in several respects: phonotactic constraints, word-internal syllabification, allomorph selection, patterns of reduplication, options for cluster repair, etc. Although the general observations we will detail are likely to be accepted by most phonologists, there is little agreement on how these differences should be formally represented. In this context, there are three topics that will be addressed.

The first involves critical assessment of various proposals in the literature concerning the representation of sC clusters – as a single class – in contrast to obstruent + sonorant clusters. Henceforth, I will use the term "obstruent" to refer to obstruents other than *s*. "*s*" is itself a cover term for the sibilant(s) appearing in sC clusters; although this sibilant is usually /s/, in some languages, other sibilants pattern as *s* (e.g. German *s* is usually /ʃ/; in Russian, /s z ʃ ʒ/ all pattern as *s*).

Concerning obstruent + sonorant clusters, there will be nothing particularly special to say about their representation; they form branching onsets, and there is little controversy on this matter among those who accept a hierarchically organized syllable. For sC clusters, in contrast, several options will be considered. Most of these share the idea that *s* is an appendix, a segment which is not organized by any sub-syllabic constituent; one views *s* as a coda. We will see, in addition, that some researchers propose a single representation for sC in all languages; others argue for different representations across languages.

The second topic that must be addressed is whether, in a given language, all sC clusters are represented in the same fashion. *s* + sonorant clusters are phonotactically ambiguous: like obstruent + sonorant clusters, they rise in sonority, yet like *s* + obstruent clusters, they do not respect the place constraints holding of obstruent + sonorant clusters. Depending on the weight assigned to each of these, different conclusions will be arrived at concerning the analysis of *s* + sonorant. For those researchers who place most weight on sonority profile, *s* + sonorant clusters form branching onsets. This research itself falls into two categories. One body of work aims to show that s + sonorant patterns with branching onsets while *s* + obstruent patterns differently, and is organized with some type of appendix. Another body of work considers *s* + sonorant clusters to be branching onsets, but focuses on arguing that *s* + stop clusters form complex segments.

The proposals sketched above assume that the syllable is hierarchically organized. However, there is a growing literature that de-emphasizes the role of constituency and aims to provide phonetically grounded explanations for phonological behavior. The third topic therefore considers whether differences in the behavior of obstruent + sonorant, *s* + sonorant, and *s* + obstruent can be explained by perceptual considerations alone. This topic will be the focus of the final section of the paper. Until then, a structural approach will be assumed.

2 Cluster phonotactics

We begin by detailing the phonotactic constraints most commonly held of obstruent + sonorant clusters on the place and sonority dimensions, in turn, examining sC clusters on these same dimensions (see also CHAPTER 33: SYLLABLE-INTERNAL STRUCTURE; CHAPTER 55: ONSETS). Our focus will be on the left word edge; other types of phonological behavior will be discussed in later sections, when we examine alternative representations for sC clusters.

Consider the inventories of two-member clusters found in word-initial position in English and Dutch in (1) and (2).[1] The data are organized by the place and manner values of C_1 for obstruent + sonorant clusters and of C_2 for sC clusters. (On cluster phonotactics for English, see Fudge 1969; Selkirk 1982; Clements and

[1] We restrict discussion of obstruents in clusters to those that are voiceless; some languages display fewer options for voiced obstruents (e.g. */vl vr/ in English). We avoid consonant+ glide clusters altogether, as there are more representational options available for glides than we have space to consider.

Keyser 1983; Goldsmith 1990; Harris 1994; for Dutch, see Trommelen 1984; van der Hulst 1984; Fikkert 1994; Booij 1995; van der Torre 2003.)

We first consider place identity, which forbids the consonants in obstruent + sonorant clusters from having the same place (CHAPTER 22: CONSONANTAL PLACE OF ARTICULATION). This captures the ill-formedness of */tl θl ʃl/ in English (1a), and */tn tl/ in Dutch (2a).[2] Turning to (1b) and (2b), the well-formedness of /st sn sl/ indicates that sC clusters do not respect place identity, suggesting that sC clusters do not have the same representation as obstruent + sonorant clusters. However, before we can conclude this with certainty, we must consider place-sharing */sr/, which is ill-formed in English and Dutch.[3] Importantly, */sr/ is illicit even in Dutch dialects with dorsal /r/, suggesting that the ill-formedness of this cluster has nothing to do with place identity. We return to */sr/ later in the chapter.

A second, less commonly discussed, constraint on place concerns asymmetries that hold between C_1 and C_2 in obstruent + sonorant clusters (when $C_2 \neq$ glide). English is not very revealing, because C_2 is restricted to liquids, which are coronal. Dutch is potentially more illuminating, because it contains stop + nasal clusters, and nasals contrast for place.[4] As (2a) shows, when a nasal is in C_2 in an obstruent + sonorant cluster, it must be coronal: /kn/ is well-formed; */km/ is out. The broader generalization is thus that when C_2 is a contoid, it must be coronal (except /r/; see note 2).

[2] Place identity is not respected with /r/. In English and Dutch dialects with coronal /r/, coronal + /r/ clusters are well-formed, as are dorsal + /r/ clusters in Dutch dialects with dorsal /r/. Even in languages where /t/ and /r/ are articulated near-identically, the constraint is not respected (see Arvaniti 2007 on Greek). This may suggest that /r/ permanently lacks place (Rice 1992; Goad and Rose 2004; see also CHAPTER 30: THE REPRESENTATION OF RHOTICS).

[3] Concerning Dutch */sr/, some speakers realize /sχr/ as [sr] (Waals 1999). If this represents a re-analysis of /sχr/ (van der Torre 2003), then /sr/ is well-formed for these speakers. Concerning English /ʃr/, we have placed this cluster in the obstruent + sonorant category (Goad and Rose 2004), rather than treating it as an assimilated form of /sr/ (Clements and Keyser 1983; Goldsmith 1990).

[4] I say "potentially," because, as is undoubtedly evident, obstruent + sonorant clusters will be analyzed as branching onsets below. There is, however, dispute about the status of /kn/ in Dutch, as branching onset (Fikkert 1994; Booij 1995) or appendix-initial (van der Hulst 1984; Trommelen 1984; Kager and Zonneveld 1986). Notably, intervocalic /kn/ is syllabified as coda + onset, *contra* the branching onset analysis.

C_2 in sC clusters has a different profile: it can have any place of articulation. Indeed, in s + obstruent and s + nasal clusters, C_2 displays the same range of place contrasts attested for singleton onsets (e.g. /sp st sk/ alongside /p t k/ in English). Directly comparing nasal-final clusters in Dutch, we find the following: */km/, /kn/; /sm/, /sn/. The absence of */km/ alongside the presence of /sm/ is unexpected, if these clusters are represented identically.

Because of the disputed status of Dutch /kn/ (note 4), we turn to Modern Greek to better examine differences in place profile between C_2 in obstruent + sonorant *vs.* sC clusters. (On Modern Greek cluster phonotactics, see Joseph and Philippaki-Warburton 1987; Drachman 1990; Klepousniotou 1998; Morelli 1999; Tzakosta and Vis 2009; on Attic Greek, see Steriade 1982.) The data in (3) reveal that, although C_2 in an obstruent + sonorant cluster can have any manner, leading to a wider range of cluster profiles than in Dutch or English, C_2 must still be coronal (Klepousniotou 1998).[5] (3b) shows that sC clusters are more restricted on the manner dimension than they are in Dutch, but among clusters with obstruents in C_2, it can nevertheless be seen that C_2 can have any place.

In sum, we have observed that C_2 in an obstruent + sonorant cluster does not parallel C_2 in an sC cluster on the place dimension. On the contrary, a closer parallel is observed between C_1 in an obstruent + sonorant cluster and C_2 in an sC cluster, which we return to below.

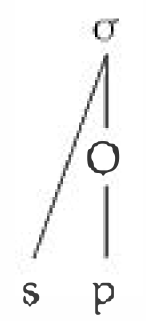
We consider finally the sonority constraints that hold between C_1 and C_2 in initial clusters.[6] Greek is not very revealing here, as both obstruent + sonorant and sC clusters can have a falling, flat, or rising sonority profile (although (3b) indicates that the productivity of the latter for sC clusters is questionable; we return to this below). We therefore focus on English and Dutch. (1) and (2) show that sC clusters need not rise in sonority, in contrast to obstruent + sonorant clusters. Although C_1 in an sC cluster is an obstruent and so the potential exists for these

[5] Stop + stop and fricative + stop are often considered to be archaic in spoken Modern Greek (Joseph and Philippaki-Warburton 1987; Morelli 1999). They do occur in higher registers, which is why they are included here. /ps ts ks/ are absent from (3a); I assume they are complex segments (following Tzakosta and Vis 2009). Clusters in parentheses (as well as /tm/) are not productive, although the number of /sm/-initial roots is somewhat larger than for the others.

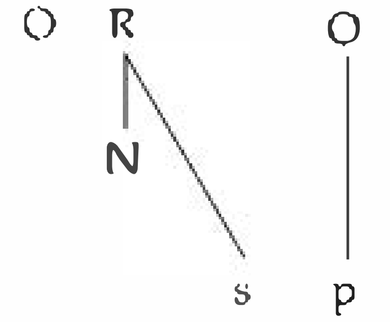
Thanks to Jenny Dalalakis and Katerina Klepousniotou for help with the Greek data.

[6] I assume the following sonority scale, which is roughly based on relative intensity: stop < fricative < nasal < liquid < vocoid. See also CHAPTER 49: SONORITY.

c. *Licensed by σ* (e.g. van der Hulst 1984)



d. *Coda* (e.g. Kaye 1992)



In (5a), *s* is extraprosodic. I am using this term in its narrowest sense, to refer only to the situation where an element is licensed but not organized into higher structure; compare (5b) and (5c). These two share with (5a) the idea that *s* is an appendix: *s* is not organized by any sub-syllabic constituent, in contrast to (5d), where *s* is a coda (technically in Kaye's model a rhymal dependent).

Two predictions follow from the difference in representation and headedness in (4) *vs.* (5). First, there should be languages that permit dependents in branching onsets but not sC clusters, and vice versa. This prediction holds true. Spanish is a language with branching onsets, but lacking initial sC clusters (Harris 1983). Acoma, spoken in New Mexico, has the opposite profile: initial clusters are restricted to sC (Miller 1965). Relatedly, Fikkert's (1994) study on the acquisition of Dutch reveals that some children acquire branching onsets first, parallel to Spanish, while others acquire sC clusters first, parallel to Acoma. Second, languages permitting both types of structures should not prevent them from being combined. To my knowledge, this prediction always holds. In languages that have branching onsets and sC clusters, three-member clusters of the shape *s* + branching onset are also well-formed. However, these clusters may be restricted to a subset of what would be expected from a free combination of sC clusters and branching onsets in the particular language (e.g. Greek /sx/, /xr/, */sxr/; English /sk/, /kl/, */skl/ (loans aside)).

Further, an explanation emerges under (5) for why the constraints against place identity and for rising sonority do not hold of sC clusters. It is not enough for two consonants to be adjacent; they must be sisters, as in (4).

Finally, we demonstrate that the difference in headedness between branching onsets and sC clusters can account for a commonly attested pattern of cluster reduction in acquisition, illustrated in (6) from two learners of German and English respectively, Annalena (Elsen 1991) and Amahl (Smith 1973).[7]

(6) a. *Annalena* (age 1;4–1;9)

	output	*target*	
obs + son	[daɯbɛ]	[tr]*aube*	'grape'
	[fɪkə]	[fl]*iege*	'fly'
s + obs	[pɪgəl]	[ʃp]*iegel*	'mirror'
	[daɪnə]	[ʃt]*ein*	'stone'
s + son	[mɪsən]	[ʃm]*eißen*	'to throw'
	[lɑːfə]	[ʃl]*afen*	'to sleep'

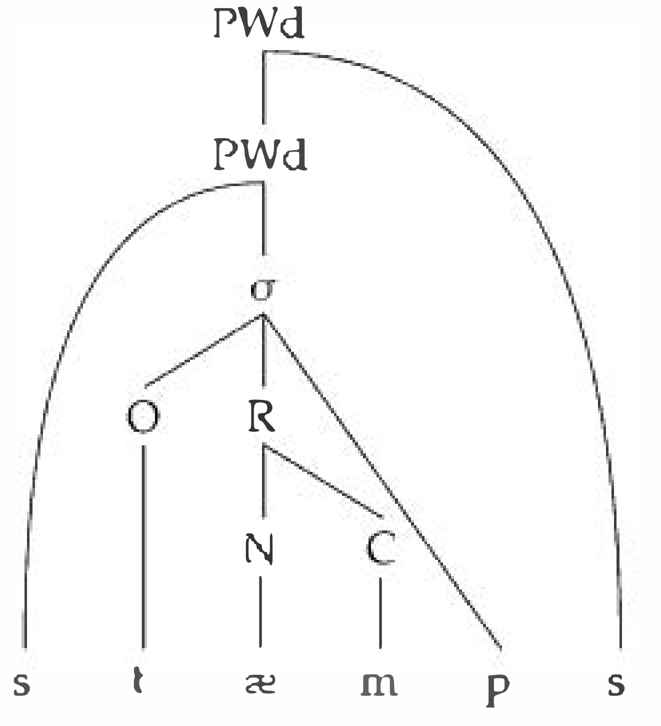
[7] [b̥ d̥ g̊] indicate voiceless unaspirated lenis stops in Amahl's data (Smith 1973).

The alternative that is typically adopted, therefore, is that these two types of extraprosodic segments are extraprosodic at different points in the derivation. Extraprosodic /s/ in *taxed* and /p/ in *tramps* are incorporated as codas in the post-lexical phonology before inflectional /t/ and /s/ are added (cf. Borowsky 1986). Initial /s/ in (7a) similarly loses extraprosodic status in the post-lexical phonology, where lexical constraints on sonority profile are no longer assumed to hold. The problem with this approach, however, is that it fails to show that extraprosodic elements ever function as members of the constituents that ultimately come to organize them, the onset in (7a) and the coda in (7b) (Piggott 1991).

This problem is resolved once the Strict Layer Hypothesis is abandoned – the requirement that elements be dominated by the immediately higher category in the prosodic hierarchy (Nespor and Vogel 1986). Extraprosodic segments on this view are technically not *extra*prosodic (unaffiliated); instead, they are organized by some higher constituent in the prosodic hierarchy.

One possible representation for /<s>tæm<p><s>/, consistent with this approach, is in (8): initial /s/ is organized by the PWd, extrarhymal /p/ is organized by the syllable, and inflectional /s/ is adjoined to the PWd. This representation is consistent with the Peripherality Condition: extrarhymal /p/ and inflectional /s/ are each at the right edge of a separate PWd (Goad and White 2006).

(8)



Returning specifically to sC clusters, the representation for /st/ in (8) involves s linking directly to the PWd (see e.g. Goldsmith 1990, drawing on evidence from English; Trommelen 1984 and Fikkert 1994 from Dutch; Goad and Rose 2004 from German). An alternative involves s linking directly to the syllable, the inverse of extrarhymal /p/ in (8) (see e.g. van der Hulst 1984 with evidence from Dutch; Levin 1985 and Kenstowicz 1994 from English; Barlow 1997 and Gierut 1999 from English in phonologically delayed children; Drachman 1990 and Tzakosta and Vis 2009 from Greek; Tzakosta 2009 from child Greek).[10] These two proposals were provided earlier as (5b) and (5c).[11]

[10] Note that Levin (1985) adjoins, rather than directly links, *s* to the syllable. To the list in the text we can add Giegerich (1992), Hall (1992), and Booij (1995), who analyze s as an onset-internal appendix, using data from English, German, and Dutch, respectively; and Ewen and Botma (2009), who organize *s* into the specifier position of the onset for Germanic.

[11] Other less commonly proposed licensers for *s* will not be considered due to space constraints: e.g. the Foot (Green 2003 on Munster Irish) and the Phonological Phrase (Vaux 1998 on Armenian).

The alternatives in (5b) and (5c) make different predictions concerning the distribution of sC clusters. I show that both options (or their equivalents) are needed, indicating that sC clusters cannot be represented identically across languages (Goad and Rose 2004; Vaux 2004; Ewen and Botma 2009). In languages with (5b), sC is only licensed PWd-initially. German has this profile (Goad and Rose 2004). (9) shows that sC clusters only occur stem-initially; word-internal tautosyllabic sC clusters are actually stem-initial, (9b). If stem-initial corresponds to PWd-initial, this restriction on sC distribution can be captured through (5b).

(9) *German*

a.	[ʃpɪnə]$_{PWd}$	'spider'
	[ʃteːən]$_{PWd}$	'to stand'
b.	[bə[ʃteːən]$_{PWd}$]$_{PWd}$	'to insist'
	[gə[ʃteːən]$_{PWd}$]$_{PWd}$	'to confess'
	*[CV.ʃCV]$_{PWd}$	

Hall (1992) argues against (5b) for German on grounds that it incorrectly predicts aspiration in s + stop clusters, as the stop is syllable-initial in this representation. However, Iverson and Salmons (1995), following Kim (1970), offer an explanation for the absence of aspiration in *s* + stop that holds independently of how *s* is organized: because *s* is voiceless, the peak of glottal width that characterizes aspiration is internal to *s*, not the following stop. Thus, we do not see the absence of aspiration in s + stop as reason to reject (5b).

In contrast to German, sC clusters in Dutch and English have a wider distribution, requiring (5c). Both languages contain monomorphemic examples where the rhyme preceding sC appears unable to accommodate *s* (e.g. Dutch [ɛkstər] 'magpie', English [ɛkstrə] *extra* (van der Hulst 1984; Levin 1985)). (5c), however, freely permits violations of the Peripherality Condition. Accordingly, before we definitively conclude that it is required for morpheme-internal sC, we must examine the following alternative: PWd-initial sC clusters involve appendices organized as in (5b); in word-medial clusters, *s* is a coda. If this analysis could be supported, we could dispense with (5c).

To show that (5c) is truly needed, we examine word-medial sC clusters in English in detail. Harris (1994) discusses the constraints governing three-position rhymes shaped VVC in this language. As (10a) reveals, coda sonorants in these superheavy syllables are confined to coronals which share place with the following onset (*[ʃowlbər], *[mawmpən]). PWd-internal VCC rhymes are not considered by Harris (they are not well-formed in Government Phonology, the framework in which he works). (10b) reveals that the onset is similarly constrained to coronal and the preceding consonants must be homorganic nasal + stop (*[vɪltnər], *[ʤʌlkʃən]).

(10) *English*

a.	VVC *rhymes*		b.	VCC *rhymes*	
	[ʃowldər]	*shoulder*		[æntlər]	*antler*
	[mawntən]	*mountain*		[vɪntnər]	*vintner*
	[kawnsəl]	*council*		[ʤʌŋ(k)ʃən]	*junction*

With these constraints in mind, we turn to cases where the consonant following VV/VC is s. Parallel to (10a), (11a) shows that only coronal s is permitted after VV (*[iːftər]) and the following consonant must be coronal (*[iːspər]).[12] This leads Harris to conclude that *s* in (11a) is syllabified as the coda of a three-position rhyme. The forms in (11b) are similarly parallel to those in (10b), seemingly leading to the same conclusion.

(11) a.	VVs *rhymes*		b. VCs *rhymes*	
	[iːstər]	*Easter*	[mɑnstər]	*monster*
	[ɔjstər]	*oyster*	[mɪnstrəl]	*minstrel*

Problems arise, however, in (12). (12a) shows that VCs does not always respect the constraints holding of (11b): the consonant preceding *s* is not restricted to place-sharing sonorants. (12b) reveals that the onset following *s* can be other than coronal, in contrast to (11a) and (11b). One could object on grounds that, *extra* aside, the words in (12) involve Latinate prefixes. However, these prefixes are not synchronically productive: they fall within the stress domain, and must therefore be contained inside the lower PWd (['ɑbstəkəl]$_{PWd}$, *['ɑb[stəkəl]$_{PWd}$]$_{PWd}$).

(12) *Appendix* s

a. *Non-coronal codas*
['ɛkstrə] *extra*
['ɑbstəkəl] *obstacle*

b. *Non-coronal onsets*
[ˌɛkspə'zɪʃən] *exposition*
['kɑnskrɪpt] *conscript*

If the forms in (12) truly involve appendixal s, we expect to find s occurring after three-position rhymes of the shape in (10). (13) shows that such words are well-formed, albeit rare. *Bolster* and *holster* are monomorphemic, and while *-ster* in *upholster* is historically a class 2 suffix (seventeenth-century *uphold-ster* 'small furniture dealer'), this analysis no longer holds, as revealed by the fact that *upholster* is now a verb and *-y* can attach outside (*upholstery*).[13]

(13) VVC *rhymes followed by* s

[bowlstər] *bolster*
[howlstər] *holster*
[ʌp(h)owlstər] *upholster*

In short, while some instances of medial sC in English may involve *s* as coda, appendixal s is required to capture the data in (12) and (13). This thereby supports the postulation of (5c), where *s* is licensed by the syllable.

Although languages like English appear to require (5c), this analysis cannot straightforwardly capture the fact that these same languages syllabify *s* as a coda

[12] Neither constraint holds in dialects with lengthened [ɑː]/[æː] in e.g. *after*, *basket* (Harris 1994).

[13] Hayes (2009: 210–211) considers the vowel in such words to be monophthongized (so presumably short) in some dialects. However, this does not hold of all dialects; witness, for example, RP [bəwlstə].

after short stressed vowels. If the appendix representation is available word-medially, why do native speakers judge sC as heterosyllabic ('*pes.ter*) rather than as appendix + onset ('*pe.ster*)? It cannot be due to sonority profile, as will be seen shortly for Dutch. Heterosyllabicity of medial sC is handled more elegantly in Kaye's (1992) Government Phonology approach to sC clusters, which we consider now.

Kaye (1992) proposes that sC clusters are syllabified as coda + onset sequences, shown earlier in (5d).[14] He provides support from Italian, Ancient Greek, European Portuguese, and British English; see also Brockhaus (1999) on German and Cyran and Gussmann (1999) on Polish. We consider first Italian, where the coda + onset pattern observed for '*pester*-type words is illustrated more concretely. In Italian, rhymes of stressed syllables must branch (Chierchia 1986). When a stressed syllable lacks a coda, the vowel lengthens; see (14a) and (14b). (14c) shows that sC clusters do not trigger lengthening as do branching onsets; instead, they pattern with coda + onset sequences (14d), revealing that medial *s* is a coda.

(14) *Medial* sC *in Italian*

a. ['faːto] 'fate'
b. ['kaːpra] 'goat'
c. ['pasta] 'pasta'
d. ['parko] 'park'

Turning to word-initial position, Kaye proposes that s in this position is also a coda; the difference between the initial and medial environments is that, in the former, *s* is the coda of an empty-headed syllable. Word-initial coda *s* follows from the Uniformity Principle in Government Phonology, which requires syllabification to be constant for a given string of segments, within and across languages. Kaye provides empirical support for Uniformity from Italian masculine definite article allomorphy and *raddoppiamento sintattico*. In the former, vowel- and sC-initial words pattern together, in contrast to words beginning with (branching) onsets; compare (15a) and (15b) with (15c). Since the representation for s in an sC cluster in (5d) includes a preceding nucleus, there is a structural parallel with vowel-initial words.

(15) *Masculine definite article allomorphy* (Davis 1990)

a. *l'est* /lo est/ 'the east'
b. *lo studente* 'the student'
c. *il burro* 'the butter'
il clima 'the climate'

In *raddoppiamento sintattico*, the first consonant in an onset geminates when the preceding word ends in a stressed vowel, while the first consonant in an sC cluster resists gemination; see (16). The pattern in (16b) follows directly from the view that s is a coda: as coda + onset, sC already has precisely the structure that holds of geminates.

[14] A precursor to this appears in Vennemann (1988). Vennemann proposes that initial *s* is "quasi-nuclear" in some languages, a type of degenerate syllable. He argues that this analysis of Latin *s* explains its development into a regular Vs syllable in some Romance languages, notably Spanish.

(16) *Raddoppiamento sintattico* (Chierchia 1986)

a.	*palto pulito*	[pal'toppu'lito]	'clean coat'
	citta triste	[ʧit'tat'triste]	'sad city'
b.	*citta straniera*	[ʧit'tastra'niera]	'foreign city'
		*[ʧit'tasstra'niera]	

Although it is evident from (15) and (16) that sC clusters in Italian cannot be analyzed in the same fashion as branching onsets, the proposal that they contain an initial appendix can also handle these data (see Chierchia 1986; Davis 1990). Of the cases Kaye considers, the construction that poses a particular challenge for appendixal *s* is European Portuguese vowel nasalization. We turn to this case now.

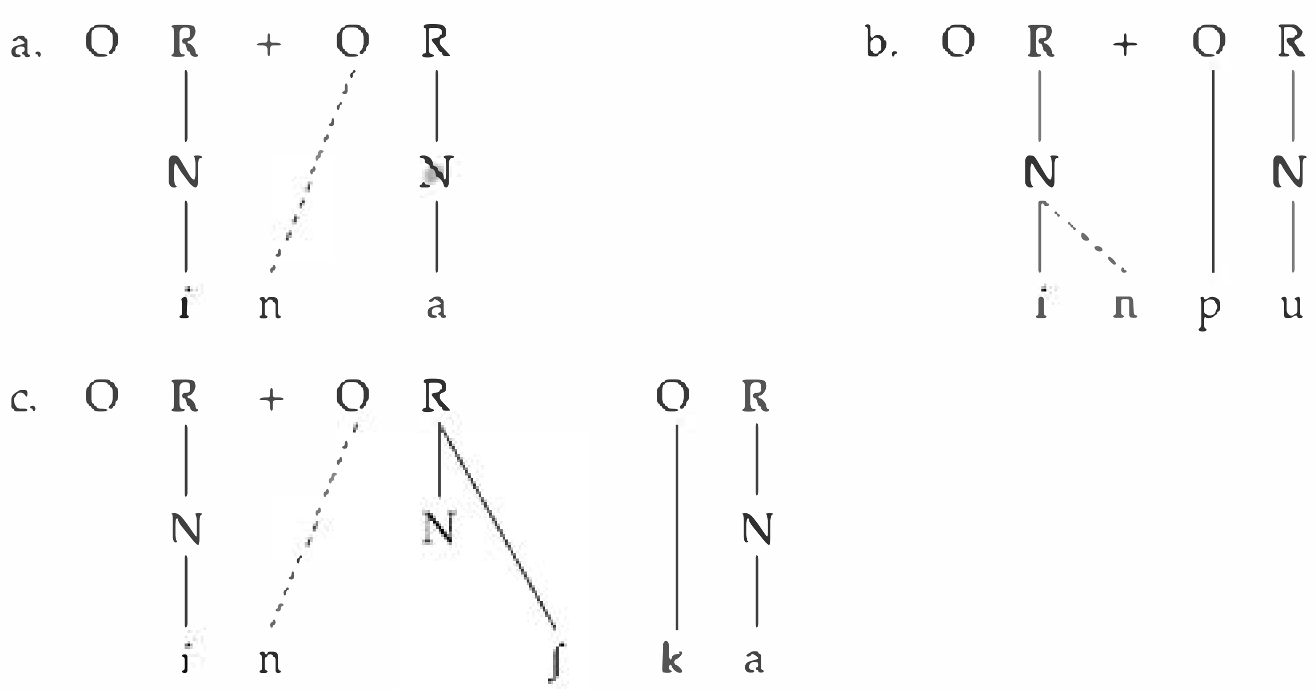
In European Portuguese, nasal consonants cannot close syllables. While /n/ is realized intact before vowel-initial bases (17a), before onset-initial bases, nasality surfaces on the preceding vowel (17b), (17c). Interestingly, sC-initial bases pattern as vowel-initial (17d).

(17) *European Portuguese*

a.	[in]*admissivel*	'inadmissable'
b.	[ĩ]*pureza*	'impurity'
	[ĩ]*satisfeito*	'dissatisfied'
c.	[ĩ]*tratavel*	'unsociable'
d.	[inʃk]*apavel*	'inescapable'

(17d) can be straightforwardly expressed under Kaye's view that sC clusters are coda + onset, because, for independent reasons, all syllables in Government Phonology contain an onset constituent. Consider the representations below.[15] In (18a), /n/ associates to the onset of the first syllable in the base. In (18b), this position is occupied, so nasality is preserved on the preceding vowel. The right result obtains in (18c) precisely because the syllable containing *s* includes an empty onset.

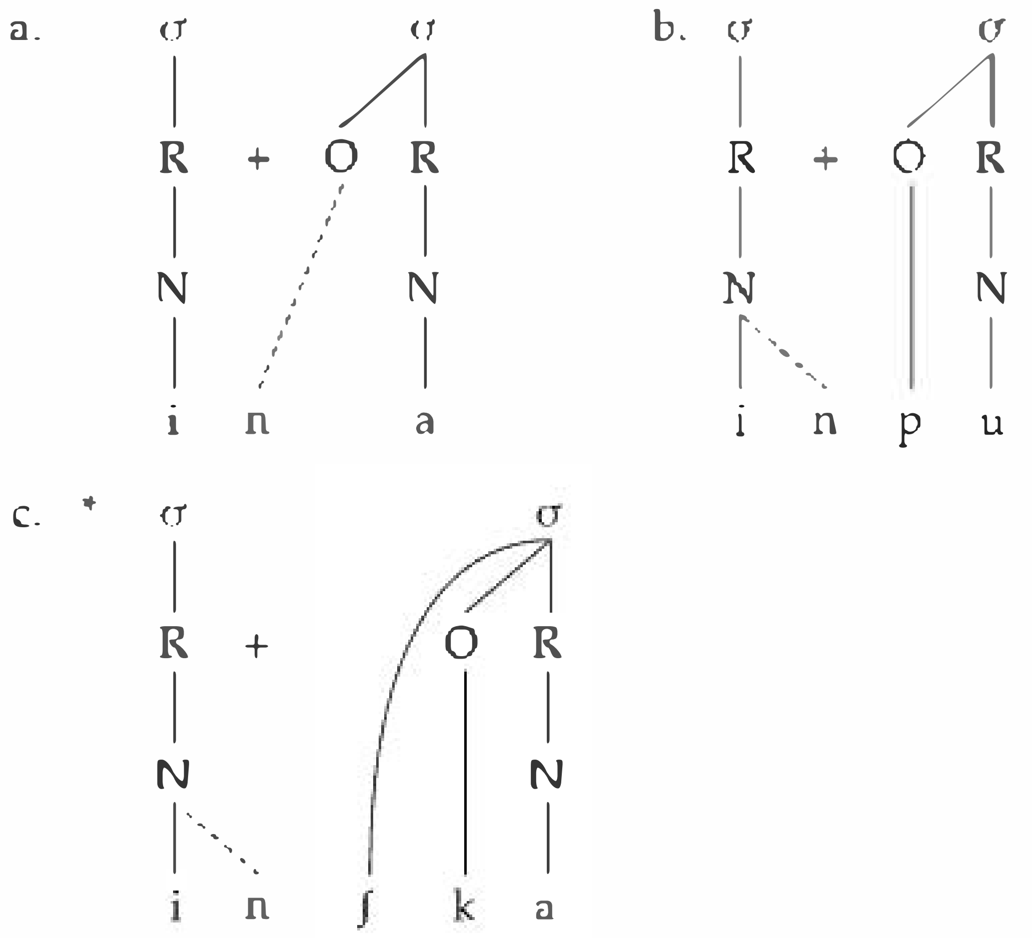
(18) *Coda analysis*



15 No representations are provided by Kaye. (18) reflects my best guess (minus X-slots), based on his discussion.

An appendix analysis of *s*, it seems, cannot formally capture (17d). See (19c), where bases with initial sC are incorrectly predicted to pattern with onset-initial bases because there is no empty constituent to host /n/.

(19) *Appendix analysis*



Kaye's paper compares the coda + onset analysis of sC clusters to the alternative that they form branching onsets; the option that *s* is analyzed as an appendix is not discussed. We have seen that appendixal *s* cannot straightforwardly capture European Portuguese. It also goes against the Uniformity Principle: Italian s is an appendix in *stra'niera* but a coda in *'pasta*; this would likely be considered a weakness by proponents of Government Phonology. However, there are contexts where word-internal s maintains its appendix status, in contrast to the pattern observed for Italian; sC can follow a rhyme that is already full, so *s* cannot be accommodated as an ordinary coda. We have already observed this for English, but we have also seen that English permits word-internal three-position rhymes under limited circumstances and most of the problematic sC data are in words that historically involve prefixes. To ensure that there is nothing unusual about English concerning the distribution of sC clusters, let us turn to Acoma (Miller 1965).

Two-position rhymes in Acoma are limited to VV and seemingly Vs (loans aside); see (20a) and (20b). If word-internal *s* were always a regular coda, as it appears to be in (20b), we would expect it to be restricted to occurring after short vowels, as in Italian. (20c) reveals that this is not the case.

(20) *Acoma*

a.	[spúuná]	'pottery'
	[jaˀái]	'sand'
b.	[sust'á]	'I took water'
	[ˀéská]	'rawhide'

Table 38.1 Jarmo's cluster development

Stage	*Pattern*		*Examples*		*Age*
1	stop	/'vlɪndər/	['kɪnʉ]	'butterflly'	2;2.6
		/'slaːpə(n)/	['taːpə]	'to sleep'	2;0.28
2	liquid	/'vlɪndər/	['lɪŋʉ]	'butterfly'	2;2.27
		/'slaːpə(n)/	['laːpə]	'to sleep'	2;3.9
3	fricative	/'χlɛiˌbaːn/	['χɛiχaːn]	'slide'	2;4.1
		/'slaːpə(n)/	['saːpə]	'to sleep'	2;3.9
4	stop + liquid	(skipped by Jarmo)			
5	fricative/s + liquid	/'flɛsjə/	['slɛsjə]	'bottle (DIM)'	2;4.1
		/slak/	[flak]~[slak]	'snail'	2;4.1

study: all follow the same developmental path for fricative + liquid and s + lateral clusters. The stages through which learners pass are exemplified in Table 38.1 with data from Jarmo.

Further, all children in Fikkert's study master *s* + stop clusters at a different point in time from rising sonority clusters. As all rising sonority clusters pattern together in Dutch acquisition, in contrast to s + obstruent, Fikkert concludes that *s* + sonorant clusters are represented in the same manner as branching onsets. For her, *s* + obstruent clusters involve *s* licensed by the PWd, as in (5b) above.

While sonority plays a decisive role in Fikkert's data, this is not the case for all children. Indeed, we observed in (6) that when only one member of a cluster is produced by Annalena and Amahl, it is the cluster head that survives, regardless of its relative sonority. To show that this pattern extends past the deletion stage, consider the developmental path for Amahl in Table 38.2.

Table 38.2 Amahl's cluster development

Stage	*obstruent + liquid*	*/sl/*	*/sm sn/*	*/sp sk/*	*/st/*	*Age*
1–8	reduction to head	reduction to head	reduction to head	reduction to head	reduction to head	2.60–2.175
13–14	branching onset acquired					2.233–2.256
15–19		fusion	fusion	vacuous fusion	vacuous fusion	2.261–2.333

26–29				appendix acquired	appendix acquired	3.133–3.355

approach to cluster behavior. The epenthesis site, in particular, is chosen to maximize perceptual similarity between the target (non-epenthesized) form and the output. In view of this, we consider in this section whether the differences that hold between sC clusters and true branching onsets can be explained by perceptual considerations alone; this, of course, would challenge the claim that a structural approach to cluster behavior is necessary.

We do not have space to examine Fleischhacker's proposal in detail, but the predictions she motivates are as follows: (i) anaptyxis is preferred to prothesis in stop + sonorant; (ii) prothesis is preferred to anaptyxis in s + stop; (iii) among s + sonorant, more anaptyxis is expected as C_2 increases in sonority; and (iv) more anaptyxis is expected in stop + sonorant than in fricative + sonorant. Concerning (iv), note that Fleischhacker's account does not distinguish s from other fricatives; that is, no explanation is provided for the observation that fricatives other than *s* pattern with stops in preferring anaptyxis to prothesis ((24) above). We return to this shortly. First, let us examine the role of perception in sC well-formedness in more detail (CHAPTER 98: SPEECH PERCEPTION AND PHONOLOGY).

As alluded to earlier, the acoustic properties of *s*, unlike other obstruents, enable it to appear in positions where it is not followed by a sonorant: strident fricatives have robust internal cues for both place and manner, ensuring their perceptibility in all contexts, even before stops (Wright 1996, 2004). Clearly, then, the view that segments are ordered to yield a rise in sonority toward the peak does not extend to s. Indeed, in spite of the sonority reversal, (strident) fricative + stop is superior to both stop + stop and stop + fricative,[20] even though the latter two contain a sonority plateau and minimal rise respectively, because (strident) fricatives are less dependent on formant transitions for their identification than stops (Wright 1996, 2004).[21]

However, while the acoustic properties of s explain why appendices are so often limited to *s* on the one hand and why these segments can be followed by stops on the other, they cannot, as far as I can tell, explain cross-linguistic preferences on sC profile. Table 38.3 shows that sC clusters have a rather unusual distribution across languages when viewed from the perspective of perceptual robustness. We focus on word-initial position. Since the perceptibility of all consonants in C_2 position in an initial sC cluster will be partly compromised by the preceding s,

Table 38.3 sC cluster profiles across languages

	Spanish	*French, Acoma*	*Greek*	*English*	*Dutch*	*German*	*Russian*
s + stop	*	✓	✓	✓	✓	✓	✓
s + fricative	*	*	✓	*	✓	*	✓
s + nasal	*	*	(*)	✓	✓	✓	✓
s + lateral	*	*	*	✓	✓	✓	✓
s + rhotic	*	*	*	*	(*)	✓	✓

20 Evidence that this observation is not restricted to *strident* fricative + stop comes from Greek: the stop + stop clusters in (3a) are often replaced by fricative + stop.

21 See Morelli (1999) for an alternative explanation of obstruent cluster well-formedness that appeals to markedness constraints on segment sequencing.

we would expect consonants that are most perceptible to be positioned after s. Masking should not be too severe in this context; as mentioned earlier, Byrd (1994) observes that #sk clusters involve less overlap than s#k and sk#. The problem may rather be one of duration: Byrd finds that /s/ is longer in #sk than in both s#k and sk#, while /k/ is shorter in #sk than in both s#k and sk#. If the relatively short duration of C_2 can be generalized to other #sC clusters, we would expect segments with robust internal cues to be favored in this position. Liquids should be optimal, since they have clear formant structure throughout. Nasals should be favored over stops, since their manner (and to a lesser extent their place) properties are present in the nasal spectrum. Stops, which have weak internal cues, should be the least optimal.

What we observe in Table 38.3, by contrast, is that s + stop is favored. French and Acoma do not permit s + sonorant clusters at all (French has s + sonorant in loanwords), and depending on the status of marginal s + nasal clusters, Greek may fall into this category as well. Otherwise, it permits s + sonorant clusters of lower sonority than those of higher sonority.

Although a larger typology of languages is required before firm conclusions can be drawn, Table 38.3 suggests that s + stop > s + nasal > s + lateral > s + rhotic (> = is more harmonic than). The favored profile in sC clusters is thus the opposite of that observed for branching onsets. This is not unexpected on a structural account if all sC clusters are head-final, in contrast to branching onsets. In sC clusters, C_2 is the onset head; thus it should respect the preferences holding of singleton onsets. Since obstruents are the optimal onsets (e.g. Clements 1990), a parallel should be observed between obstruents in C_1 position in branching onsets and stops in C_2 position in sC clusters (not fricatives more generally, because of the preceding s; see Wright 2004: 51).

While the C_1C_2 asymmetry in branching onsets *vs.* sC clusters follows from the status of s as an appendix, it is best captured, I suggest, under Kaye's proposal that s is a coda. Recall from (14) and (21) that medial sC clusters in Italian and Dutch are heterosyllabic. If sC clusters are *always* syllabified as coda + onset clusters, then their profile should respect cross-linguistic preferences for optimal syllable contact. Syllable contact will favor C_2 with lower sonority: Vs.TV > Vs.NV> Vs.lV > Vs.rV. As C_2 increases in sonority, the cluster prefers to be syllabified as a branching onset, but if this option is never available for sC clusters, then higher-sonority sC clusters will be forbidden, regardless of their position in the word.

The profile in Table 38.3 closely parallels Fleischhacker's typology in (25) for preferred epenthesis sites, in sC clusters. Prothesis occurs more commonly when C_2 has lower sonority. As the sonority of C_2 increases, prothesis will result in poor syllable contact. Note as well that the proposed syllable contact account of sC well-formedness leads to a distinction between s + sonorant and fricative + sonorant, as only the latter can form branching onsets. Thus, the fact that fricative + sonorant patterns with stop + sonorant in epenthesis follows, in contrast to under Fleischhacker's account (see (iv) above).

In sum, I contend that both perceptual and structural considerations must be factored into our understanding of cluster well-formedness. While perceptual considerations can explain why appendices are so often limited to s and why s + stop is well-formed in spite of its sonority profile, it is the structural differences between sC clusters and branching onsets that explain the preference for sC profile on the sonority dimension as well as some observed differences in epenthesis site.

7 Conclusion

In this chapter, we have examined several alternative analyses for sC clusters. On the empirical front, we have seen that s + stop clusters reliably pattern differently from true branching onsets. Not surprisingly, then, the proposals we have examined for s + stop all share an important property: s + stop clusters are head-final, whether *s* is unaffiliated, an appendix organized by some prosodic constituent above the onset, the coda, or the first member of a complex segment. Branching onsets, by contrast, are head-initial. This difference in headedness helps to explain parallels on the place dimension between C_2 in an s + stop cluster and C_1 in a branching onset, as well as syllabification preferences in word-medial contexts.

Beyond that, however, details of the proposals differ, and, following on this, each proposal is both supported and challenged by the available evidence. There are languages like Acoma, English, and Dutch where *s* can appear medially after rhymes that are "full," thereby providing support for the analysis that s is linked to the syllable and potentially challenging the coda analysis. However, in some of these same languages, namely English and Dutch, as well as in languages like Italian, the observation that sC clusters are heterosyllabic after stressed vowels supports the coda analysis and thereby questions the proposal that s is licensed by the syllable or that s + stop form a complex segment. The complex segment analysis, in turn, is supported by the reduplication pattern in Gothic which both the appendix and coda analyses fail to elegantly capture.

At present, then, it seems that multiple representations for sC clusters may be required. If the number of parametric options is limited and there is robust evidence available for learners to determine the appropriate representation for the language being acquired, this is far from problematic. For example, the fact that sC clusters have a more limited distribution in some languages (German) than in others (English, Dutch) can be captured if licensing by the PWd represents the least marked option and therefore the starting point for learners. There will then be positive evidence available to signal learners of some languages that sC clusters are licensed lower down, by the syllable. However, we have also seen that this type of scenario may not always work. If Dutch learners initially assume that s + sonorant clusters form branching onsets, the evidence available to undo this analysis in favor of one where all sC clusters pattern as a class is far from robust and may present a learnability challenge.

The problem with s + sonorant clusters more generally is that they are phonotactically ambiguous and, following from this, they pattern ambiguously across languages. While one could fail to be surprised by this, on the grounds that these clusters are both s-initial and rise in sonority, exactly how their ambiguous behavior should be formally expressed is far from clear. They appear to be analyzed as branching onsets in some languages (e.g. Jarmo's Dutch grammar) and as appendix/coda-initial in others (e.g. Amahl's English grammar), but in this particular case, this finding is surprising, in view of the otherwise high degree of similarity between the two target languages.

The solution that languages employ different analyses for s + sonorant is far from optimal and may lead some researchers to abandon a structural approach to the syllable altogether in favor of a perceptually grounded account of segmental contact. Indeed, the latter may find support in the observation that even within the class of *s* + sonorant, languages show different patterns of behavior; we have seen that the division between prothesis and anaptyxis can be drawn anywhere internal to this class. At the same time, however, a purely perceptually based account seems to be challenged by the finding that preferences for sC cluster profile are virtually the inverse of those observed for obstruent + sonorant clusters. While an appeal to syllable contact was made to capture both of these observations, the analysis follows most straightforwardly from the proposal that sC clusters are always syllabified as coda + onset strings. We have already seen that this proposal may be challenged by languages such as English, Dutch, and Acoma.

In spite of the quantity of research that has been undertaken on sC clusters, it is perhaps most evident that more needs to be done before the issue of their representation can be resolved (if ever). A sampling of questions at the two extremes includes the following. At one end of the spectrum, can a more detailed examination of perceptual factors capture differences in the behavior of fricative + sonorant and *s* + sonorant clusters, thereby further questioning the need for a structurally based approach to segmental contact and syllabification behavior? At the other end, if a structural account of behavior based on syllable contact proves fruitful to pursue, with judicious use of abstract representations, can the coda + onset analysis be motivated for all languages? I leave these and many other questions in between to future research.

39 Stress: Phonotactic and Phonetic Evidence

MATTHEW GORDON

1 Introduction

Stress can be signaled through a number of different acoustic properties, including increased duration, greater intensity, and higher fundamental frequency. Stress may also affect segmental and syllable structure. Typically, stressed syllables trigger qualitative fortition and/or lengthening, whereas unstressed syllables are associated with lenition and/or shortening. To take an example of a stress-driven fortition process affecting syllable structure, Dutch (Booij 1995) inserts an intervocalic glottal stop as an onset to stressed vowels; epenthesis does not interrupt vowel sequences in which the second vowel is unstressed. We thus have pairs such as ['xa.ɔs] 'chaos' and [a.'ʔɔr.ta] 'aorta', in which the presence of glottal stop is predictable from stress. American English provides well-described cases of lenition in unstressed syllables. For example, post-vocalic coronal stops weaken to taps before unstressed syllabic sounds, e.g. /sɪti/ → ['sɪɾi] 'city'. Furthermore, most unstressed vowels reduce to schwa, e.g. ['kanˌtɛkst] *context vs.* [kən'tɛkstʃuəl] *contextual*, or may delete in certain contexts delete, e.g. ['tmeɪɾoʊ] ~ ['təmeɪɾoʊ] *tomato*, ['ksændɹə] ~ [kə'sændɹə] *Cassandra*.

While most segmental effects of metrical structure can be transparently linked to stress, there are others that are not predictable from stress, despite displaying properties typically associated with stress-induced alternations. For example, Nganasan, a Uralic language (Tereshchenko 1979; Helimski 1998; Vaysman 2009), has an alternation between strong and weak intervocalic consonants, termed "consonant gradation," whereby strong consonants, generally voiceless or prenasalized obstruents, alternate with weak consonants, typically voiced or not prenasalized. The appearance of strong and weak consonants is predictable from syllable count (1). In the onset of even-numbered non-initial syllables, the strong grade appears, while the weak grade appears in the onset of odd-numbered non-initial syllables. Long vowels interrupt the alternating syllable count and, as long as they are not word-initial, are always preceded by weak consonants.

(1) *Nganasan consonant gradation* (Vaysman 2009: 43)

ˌjamaˈða-tu	'his/her/its animal'
ˌŋoruˈmu-tu	'his/her/its copper'
suːˈðəː-ðu	'his/her/its lung'
ŋuˈhu-ðu	'his/her/its mitten'

As Vaysman shows, this pattern is explained if one assumes that words are parsed into binary feet starting at the left edge of words with long vowels forming monosyllabic feet and degenerate feet allowed word finally. Strong consonants occur foot medially and weak consonants occur in foot-initial syllables that are not also word-initial (2).

(2) *Nganasan consonant gradation as a reflex of foot structure* (Vaysman 2009: 43)

(ˌjama)(ˈða-tu)	'his/her/its animal'
(ˌŋoru)(ˈmu-tu)	'his/her/its copper'
(suː)(ˈðəː)-(ðu)	'his/her/its lung'
(ŋuˈhu)-(ðu)	'his/her/its mitten'

The interesting feature of the Nganasan data is that stress does not always fall on syllables predicted to be stressed by the metrical structure diagnosed by consonant gradation. Primary stress in Nganasan falls on the penultimate syllable in all the words in (2), with a secondary stress occurring on initial syllables that are not adjacent to the primary stress. The monosyllabic foot in the last two words is thus completely unstressed, as is the first foot in the penultimate word.

This chapter provides a typological overview of the phonetic correlates of stress and the various types of effects of stress and metrical structure on segment-level features, exploring how these effects can offer insight into the nature of stress and metrical structure and their formal representation (see CHAPTER 40: THE FOOT, CHAPTER 41: THE REPRESENTATION OF WORD STRESS and CHAPTER 57: QUANTITY-SENSITIVITY for related issues). The structure of the chapter is as follows. §2 examines supra-segmental correlates of stress including the phonetic parameters of duration, fundamental frequency, and intensity. §3 examines segmental alternations conditioned directly by the presence or absence of stress. §4 focuses on the role of foot structure in predicting fortition and lenition of vowels and consonants. §5 addresses segmental changes triggered by foot structures that conflict with metrical constituency as diagnosed by the stress system. §6 explores the role of history in shaping these mismatches between stress and the foot structure relevant for segmental alternations. Finally, §7 summarizes the chapter.

2 Suprasegmental phonetic correlates of stress

Fry (1955, 1958) pioneered research on the acoustic correlates of stress in his examination of the effect of stress in English on duration, intensity, and fundamental frequency. Focusing on the vowels in noun–verb minimal pairs such as *ˈconvert* (noun) *vs. conˈvert* (verb) and *ˈimport* (noun) *vs. imˈport* (verb), Fry found that stressed vowels were associated with greater duration, greater intensity, and higher fundamental frequency than their unstressed counterparts, with the last of these properties being most reliable as a cue to stress.

Since Fry's work, phoneticians have considerably broadened the typological database on stress correlates by examining other potential correlates of stress and by targeting a diverse set of languages for phonetic study. This research program has yielded many important results. For example, beyond the acoustic domain, stress is also associated with hyperarticulation of segments, which has ramifications for the segmental alternations discussed in §3. Furthermore, other potential acoustic correlates of stress have come to light, such as measurements of stress that are sensitive to spectral tilt (Sluijter and van Heuven 1996a, 1996b) or that integrate intensity over time (Lieberman 1960; M. Beckman 1986). Finally, typological study has shown that many languages are similar to English in using duration, intensity, and/or fundamental frequency to signal stress, e.g. Polish (Jassem *et al.* 1968), Tagalog (Gonzalez 1970), Mari (Baitschura 1976), Indonesian (Adisasmito-Smith and Cohn 1996), Pirahã (Everett 1998), Aleut (Taff *et al.* 2001), Chickasaw (Gordon 2004), Turkish (Levi 2005), and Kabardian (Gordon and Applebaum 2010). It has also become increasingly clear that the phonetic study of stress is a complicated matter for several reasons.

Languages differ in their relative reliance on different cues to stress where the relevance of certain properties is functionally constrained in many languages by the extent to which potential stress correlates are used to mark phonemic contrasts other than stress. For example, lexical tone languages – e.g. Thai (Potisuk *et al.* 1996) and Pirahã (Everett 1998) – are less reliant on fundamental frequency to cue stress, and languages with phonemic length contrasts, e.g. Finnish, may have phonetically longer unstressed vowels than stressed vowels.

There are also languages in which potential phonetic markers of stress do not converge on a single syllable but rather are shared between multiple, often, though not always, adjacent syllables. For example, in Welsh (Williams 1985) an unstressed final syllable often has higher fundamental frequency and longer vowel duration than an unstressed penultimate syllable in the same word. In such cases, lengthening of the consonant immediately following the stressed vowel seems to be the most reliable correlate of stress. A similar situation arises in Estonian, where the primary stressed initial syllable, if it contains a phonemic short vowel, will be shorter than the immediately following syllable and often have less intensity and lower fundamental frequency (Lehiste 1965; Eek 1975; Gordon 1995). Lengthening of the consonant in the onset of the stressed syllable serves as the most reliable cue to stress in Estonian (Lehiste 1966; Gordon 1997). Hyman (1989) discusses cases in Bantu of different diagnostics leading to different conclusions about the location of stress. For example, certain Eastern and Southern Bantu languages display evidence for metrical prominence on the penultimate syllable, such as vowel lengthening, attraction of high tone, and even phonetic stress. However, these properties may conflict with other properties that suggest stress on another syllable, e.g. high tone on the antepenult in Zulu, even though the penult conditions vowel lengthening. A similar pattern of high tone on the antepenult preceding a stressed penult is found in the Northern Iroquoian language Onondaga (Chafe 1970, 1977; Michelson 1988), the Polynesian language Tongan (Schütz 1985), and several Micronesian languages (Rehg 1993). In "split-cue" stress systems such as those described in this paragraph, determining the location of stress is potentially problematic.

3 The taxonomy of segmental correlates of metrical structure

Fortition and lenition effects associated with metrical structure may be broadly classified into three groups according to the property triggering these segmental alternations. The first type of segmental effect is well documented and involves stress (or lack thereof) directly as a trigger of fortition and/or lenition. A second type of segmental effect is predictable from constituent structure rather than stress, but the constituent structure motivating the segmental change accords with the metrical parse evinced by the stress system. A third type of segmental alternation, exemplified by Nganasan, is linked to metrical constituency, where the foot structure diagnosed by the segmental change is at odds with that suggested by the stress system. In the following sections we take a closer look at examples of each of these types of relationships between segmental properties and metrical structure.

3.1 Stress-driven segmental phenomena: Fortition and lenition

Many languages display segmental changes that are conditioned by stress or lack of stress. The typical pattern is for sounds to strengthen in stressed contexts and to weaken in unstressed positions. Fortition and lenition can target either consonants or vowels. In the case of consonants, unstressed position is usually associated with decreased resistance to coarticulatory effects and hypo-articulation (de Jong 1995), resulting in reduced constriction either temporally or in magnitude. Kirchner (2001), Lavoie (2001), Bye and de Lacy (2008), and Vaysman (2009) summarize a number of segmental alternations conditioned by stress, of which I mention a few here (see CHAPTER 66: LENITION for an overview of the typology of lenition). Post-vocalic coronal stops in American English reduce to flaps before an unstressed syllabic sound, and stops become aspirated in the onset of stressed syllables. In Kupia (Christmas and Christmas 1975), the stops /p ʈ/ have lenited variants in the onset of unstressed syllables: /p/ is realized as a fricative and /ʈ/ as a tap. West Tarangan (Nivens 1992) displays fortition in the onset of stressed syllables: /j/ affricates to /ʤ/, and /w/ occlusivizes to /g/, a change that also applies to word-initial consonants. In the development from Proto-Samurian to pre-Lezgian (Topuria 1974; Giginejshvili 1977; Yu 2004), voiced stops devoiced, a type of fortition, and geminated in the onset of stressed syllables.

Stress often also triggers lengthening of consonants. Thus, in Urubu Kaapor (Kakumasu 1986) and optionally in Tukang Besi (Donohue 1999) oral stops lengthen in the onset of primary stressed syllables. Lengthening is also employed as a strategy to beef up the rime of stressed syllables. Hayes (1995: 83) discusses several cases of lengthening in order to enhance the weight of stressed syllables. For example, in Munsee (Goddard 1979), a consonant geminates after metrically prominent short vowels, thereby converting the stressed syllable from light (CV) to heavy (CVC).

Vowels are also subject to fortition and lenition processes conditioned by stress. As in the case of consonantal alternations, vowels may be affected either qualitatively or quantitatively by the presence or absence of stress. Cross-linguistically, it is very common for vowels to lengthen in stressed syllables. Hayes (1995: 83) initial syllable in non-derived words containing only reduced vowels underlyingly (3b). (We abstract away from cases where an underlying schwa alternates with a full vowel on the surface.)

(3) *Eastern Mari stress* (Vaysman 2009: 62–64)

a.	koŋ'ga	'oven'
	ʃer'ge	'comb'
	køgør'ʧen	'dove'
	'teŋgəz	'sea'
	'olək	'meadow'
	'joŋaləʃ	'mistake'
	pu'ʃaŋgə	'tree'
b.	'βəɲər	'canvas'
	'əʃkəl	'step'
	'ləβə	'butterfly'

Rounding harmony is propagated rightward from the stressed vowel in a word. Thus, the 3rd person possessive suffix surfaces as [ʃe] when the stressed vowel is unrounded (4a) but as [ʃø] or [ʃo] when the stressed vowel is a rounded vowel (4b). (The backness of the rounded vowel is conditioned by a process of front–back harmony.)

(4) *Eastern Mari rounding harmony* (Vaysman 2009: 92)

a.	'ergəʃe	'his/her/its boy'
	y'reməʃe	'his/her/its street'
	pykʃer'ɯne-ʃe	'his/her/its walnut tree'
b.	'ʃyrə-ʃø	'his/her/its soup'
	kəʎ'mo-ʃø	'his/her/its shovel'
	'ʃoʃə-ʃo	'his/her/its spring'

Another type of harmony that is sensitive to stress involves the propagation of a feature from an unstressed syllable up through a stressed syllable, which blocks further spreading of the harmonizing feature. Tudanca Spanish (Penny 1978) instantiates this type of harmony. In Tudanca, underlying final high vowels, which surface as more centralized than their non-final counterparts, induce centralization (in the front/back and/or height dimension depending on the vowel) of preceding vowels up to and including the stressed vowel (5). (Centralized vowels are marked by the ˟ diacritic.) Stress is lexically governed and may fall on either the penultimate or antepenultimate syllable.

(5) *Tudanca laxness harmony* (Penny 1978: 54–55)

'pintu̽	'male calf'	cf. 'pinta	'female calf'
'se̽ku̽	'dry (MASC)'	cf. 'seka	'dry (FEM)'
'po̽rti̽ku̽	'portico'		
'pu̽lpi̽tu̽	'pulpit'		
anti'gwi̽si̽mu̽	'very old'		
o're̽ga̽nu̽	'oregano'		

Walker (2004, 2005) discusses several cases of metaphony in Romance languages involving harmonizing in height of a stressed vowel to a posttonic one (see also CHAPTER 110: METAPHONY IN ROMANCE for an overview of similar processes in Italian dialects). In some language varieties, as in Tudanca Spanish, harmony propagates left-wards from the triggering vowel to the stressed vowel through any intervening unstressed vowels. In other varieties, e.g. Asturian Lena Bable (Hualde 1989, 1998), the stressed vowel is transparent to the harmonizing feature, which propagates past the stressed vowel leftward to the pre-tonic vowel.

3.3 *Exceptional lenition in prominent syllables*

Despite the cross-linguistic tendency for stressed syllables to be associated with increased segmental strength, this pattern is not universal. Mokša Mordvin (Vaysman 2009) optionally lenites consonants in the onset of stressed syllables that are not word initial. Stress in Mokša is sensitive to a distinction between the low-sonority vowels [i u ə] and the high-sonority vowels [a æ o e]. In words containing vowels belonging to the same sonority class, stress falls on the first syllable of a word (6a). In words consisting vowels of different sonority classes, stress falls on the leftmost vowel belonging to the higher-sonority group (6b).

(6) *Mokša Mordvin stress* (Vaysman 2009: 135–137)

a.	'bʲanəʧ	'boat'
	'məkur	'buttocks'
	'kuʃin	'jug'
	'juʒə	'skin'
	'aka	'older sister, aunt'
	'lopæ	'leaf'
	'pango	'mushroom'
	'sʲeja	'goat'
b.	tsʲə'ræ	'son'
	vi'na	'alcohol'
	az'na	'older sister's husband'
	sʲi̥rək-'ka	'elm (PROLATIVE)'

Lenition in stressed onsets entails voicing of underlying voiceless obstruents, liquids, and glides, the spirantization of underlying voiced stops, the conversion of /m/ to /w/ and the deletion of /n/, with concomitant nasalization of the stressed vowel. Crucially, lenition does not target word-initial consonants, as the examples in (7) indicate.

(7) *Mokša Mordvin lenition in stressed onsets* (Vaysman 2009: 142–143)

kur'ka	~ kur'ga	'turkey'
sʲər'pe	~ 'sʲər'be	'heart'
bʲanʲə'ʧ-oze	~ bʲanʲə'ʤ-oze	'my boat'
pəjə'l̥ʲ-oze	~ pəjə'lʲoze	'my knife'
bu'jæ-ze	~ bu'jæ-ze	'my end'
tʲə̥'bʲe-ze	~ tʲe'βʲe-ze	'my work'
pin'gæ-ze	~ pin'ɣæ-ze	'my period of time'
pʲi'ma	~ pʲi'wa	'large cup, mug'
kə'nak-oze	~ kə'ãk-oze	'my guest'

This constraint interaction can be illustrated by considering the analysis of Guaraní vowel harmony developed in J. Beckman (1998). In Guaraní (Gregores and Suárez 1967), nasalized and oral vowels contrast in stressed syllables, but in unstressed syllables nasalized vowels may only surface before a nasal consonant. The [nasal] feature also spreads leftward from a prenasalized stop and from a phonemic nasalized vowel up to but not including a stressed vowel (8). Nasalization additionally spreads rightward (as the examples below indicate) although its phonetic properties are different, which has led certain researchers, e.g. Flemming (1994), to analyze it as phonetic rather than phonological. Beckman thus does not develop an analysis of rightward spreading of nasality.

(8) *Guaraní nasal harmony* (Gregores and Suárez 1967: 69)

/amaa'porõre'ju/	→	ʔãᵐbaʔa'porõrẽju	'if I work you come'
/je' intena/	→	je'intẽnã	'just once more!'
/ija,kāra'ku/	→	ʔĩnã,kãrã'ku	'is hot-headed'
/rojotopa'pamarõro'xova,rã/	→	rojotopa'pamãr̃õr̃õ'xoṽã,r̃ã	
		'if now we meet all of us, we will have to go'	

Two faithfulness constraints play a pivotal role in Beckman's analysis. First, a generic faithfulness constraint, IDENT(nasal), requires that segments underlyingly associated with a [nasal] feature preserve that feature on the surface. The second constraint is the positionally defined analog to IDENT(nasal), IDENT-σ́(nasal), which requires that surface segments in stressed syllables preserve their underlying [nasal] specification. The existence of contrastive nasality on stressed vowels but not on unstressed vowels follows from the ranking of a markedness constraint banning nasalized vowels, $*V_{nasal}$, above generic IDENT(nasal) but below position-specific IDENT-σ́(nasal). This ranking ensures that any underlyingly nasalized vowel will lose its nasality if it surfaces in an unstressed position. Critical to the analysis of nasal harmony in Beckman's analysis is an alignment constraint, ALIGN-L(nasal), requiring that all instances of the feature [nasal] be aligned with the left edge of a word. This constraint is honored in forms in which nasality either is underlyingly associated with a segment in the first syllable or has propagated to the first syllable through nasal spreading. One violation is incurred for each segment intervening between a nasal feature and the left edge of the word. By sandwiching ALIGN-L(nasal) above IDENT (nasal) but below IDENT-σ́(nasal), nasality is correctly predicted to spread as far leftward as the stressed syllable, where it is blocked from spreading any further (9).

(9)

/je'intenã/ 'just once more'	IDENT-σ́(nas)	ALIGN-L(nas)	IDENT(nas)
☞ a. je'ɨntẽnã		***	*
b. nẽ'ɨ̃ntẽna	*!		***
c. je'ɨntenã		***, *!*****	

Lenition in unstressed syllables can be handled similarly in the positional faithfulness approach. A constraint banning non-lenited segments is ranked above a generic faithfulness constraint, but below a positional faithfulness constraint

(1990) as a foot, in recited Japanese verse. Finally, foot-final lengthening may be viewed as the foot-level manifestation of the well-attested phenomenon of final lengthening observed at levels above the foot, such as the word and phrase (Wightman *et al.* 1992). Foot-final lengthening has also been appealed to by Revithiadou (2004) as a factor in promoting the cross-linguistically pervasive phenomenon of iambic lengthening discussed in the next section.

4.3 Iambic/trochaic length asymmetries

Certain asymmetries in quantitative alternations are also best explained with reference to foot structure rather than directly to stress. In particular, stressed syllables in iambic and trochaic feet appear to display fundamentally different length characteristics (see Hayes 1985, 1995 and CHAPTER 44: THE IAMBIC–TROCHAIC LAW). Stressed syllables in languages employing an iambic parse are often lengthened cross-linguistically, whereas those with trochaic feet characteristically either fail to lengthen the stressed syllable, or, in some cases, even shorten the stressed syllable. Chickasaw (Munro and Ulrich 1984; Munro and Willmond 1994, 2005; Munro 1996, 2005; Gordon *et al.* 2000; Gordon 2003, 2004; Gordon and Munro 2007) is an iambic language in which closed syllables and syllables containing long vowels are heavy, i.e. are parsed as monosyllabic feet word-initially or following a stressed syllable. The final syllable is also parsed as a foot even if it is light (CV). The rightmost stress, i.e. the one on the final syllable, is the primary one, except that a long (or lengthened) vowel in pre-final position attracts the primary stress from a final CV(C). As shown in (11), stressed vowels in open non-final syllables substantially lengthen, where the output of lengthening is a vowel that is either nearly neutralized or completely neutralized in length with a phonemic long vowel depending on the vowel and the speaker (see Gordon *et al.* 2000 for phonetic duration results).

(11) *Iambic lengthening in Chickasaw* (lengthened vowels indicated by ˑ)

(ʧiˌpiˑ)(saˈliˑ)(ˌtok)	'I looked at you.'
	cf. (piˈsaˑ)(liˌtok) 'He looked at you.'
(ʧiˌʧoˑ)(ˌkoʃ)(koˈmoˑ)(ˌʧi)	'He makes you play.'
	cf. (ʧoˌkoʃ)(koˈmoˑ)(ˌtok) 'He played.'
(ʧiˌkiˑ)(siˈliˑ)(ˌtok)	'He bit you.'
	cf. (kiˈsiˑ)(liˌtok) 'He bit it.'
(aˌsaˑ)(biˈkaˑ)(ˌtok)	'I was sick.'
	cf. (aˈbiˑ)(kaˌtok) 'He was sick.'

The process of iambic lengthening has an intuitive purpose, in that it enhances the prominence of the stressed syllable. In some languages, the beefing up of the stressed syllable in an iambic foot is achieved by lengthening a consonant rather than a vowel (see Hayes 1995: 82–83 for a survey of iambic lengthening; but see Bye and de Lacy 2008 for re-analyses of iambic consonant lengthening). This consonant can either be the coda consonant in a stressed CVC syllable, as in the Chevak dialect of Central Alaskan Yupik (Woodbury 1981) or the onset of the following syllable, the first half of which ends up closing the stressed syllable, as in Delaware (Goddard 1979, 1982).

(13) *Nganasan consonant alternation and foot structure* (Vaysman 2009: 43, 52)

(ˌjama)('ða-tu)	'his/her/its animal'
(ˌŋoru)('mu-tu)	'his/her/its copper'
(sɯː)('ðəː)-(ðu)	'his/her/its lung'
(ŋu'hu)-(ðu)	'his/her/its mitten'
(baːr)('pə-ⁿtə)(nu)	'master, chief (LOC SG NON-POSS)'
(hɨa)('ʧə-ⁿtə)(nu)	'thumb (LOC SG NON-POSS)'
(ku'bu)(tənu)	'skin, fur (LOC SG NON-POSS)'
('hʷaː)(tənu)	'tree (LOC SG NON-POSS)'

As these examples show, the strong variant of the 3rd person possessive suffix (beginning with [t]) and the locative singular non-possessive suffix (beginning with a prenasalized [ⁿt]) surface foot medially, whereas the weak allophone (beginning with [ð] and plain [t] in the two suffixes, respectively) occurs foot initially. The strong grade and the weak grade both occur in the onset of unstressed syllables, meaning that stress does not predict the alternation. Furthermore, the foot structure diagnosed by the consonant alternations does not accord with the foot structure that would be required to predict primary stress.

It is not the case, however, that stress assignment in Nganasan is completely blind to foot structure. Secondary stress falls on odd-numbered syllables counting from the left edge of a word in keeping with the footing predicted by consonant gradation (14a). Two provisions to this generalization, however, make the relationship even between secondary stress and foot structure opaque. First, secondary stress may not clash with an immediately following stress (14b) and, second, secondary stress skips over a light (CV) syllable in favor of a heavy (CVV) syllable (14c). In both situations, a final syllable is potentially footed but unstressed, and a word may display a mix of iambic and trochaic feet.

(14) *Nganasan secondary stress* (Vaysman 2009: 24)

a.	(ˌbaku)(ˌnumə)('numə)	'my salmon (PROLATIVE)'
	(ˌtiri)(ˌmɨmə)('numə)	'my caviar (PROLATIVE)'
b.	(ˌkaðar)(mə'nu)(mə)	'my light (PROLATIVE)'
	(ˌʧemɲi)(mə'nu)(mə)	'my salary (PROLATIVE)'
c.	(ky)(ˌmaː)(mə'nu)(mə)	'my knife (PROLATIVE)'
	(le)(ˌhua)(mə'nu)(mə)	'my board (PROLATIVE)'

A further context in which foot structure is relevant to stress arises in words in which both the penult and the antepenult contain a central vowel. We abstract away from cases in which the penult and antepenult contain different central vowels, a situation that gives rise to variability in the location of stress, and consider here only cases in which both the penultimate and antepenultimate syllables contain the same central vowel. In words of this profile, the penult attracts stress if it is foot-initial (15a) but the antepenult carries the stress if the penult is foot-final (15b).

(15) *Nganasan stress in words with the same central vowel in the penult and antepenult* (Vaysman 2009: 36)

a.	(ˌbiðɨ)('tɨrə)	'you (SG) are drinking (INTR)'
	(ˌɲilɨ)('tɨrə)	'you (SG) are living'

7 Summary

Stress or lack of stress is associated with both suprasegmental and segmental properties. On a suprasegmental level, stress typically triggers lengthening, higher fundamental frequency, and greater intensity, although there are many languages in which these properties do not converge on a single syllable but rather are distributed over multiple syllables. On a segmental level, stress characteristically, although not always, triggers consonant fortition or blocks lenition targeting unstressed syllables. Some metrically conditioned segmental alternations, on the other hand, are better explained with reference to foot structure. For example, boundary-driven processes such as foot-initial fortition and foot-final lengthening are plausibly the foot-level analogs of well-documented phenomena applying at the word level. Furthermore, stressed vowel lengthening in many languages is explicable in terms of stress, but its cross-linguistic bias toward applying in iambic stress systems suggests that it is sensitive to foot structure. A final type of segmental alternation cannot be accounted for with reference to stress but rather suggests the relevance of foot structure that is orthogonal to the stress system in certain languages. Examination of historical data potentially provides insight into these mismatches between foot structure diagnosed by fortition and lenition and foot structure diagnosed by stress by showing that the segmental changes became entrenched at a chronologically earlier stage, when stress and foot structure coincided.

40 The Foot

Michael Hammond

1 Overview

The metrical foot organizes the syllables of words into higher-order units built around stressed syllables.

In this chapter, we review the evidence for, and structure of, the foot. Along the way, we treat some of the major issues that have arisen in the development of this notion.

The organization of this chapter is as follows. First, we review the background against which the foot was proposed: linear generative phonology and then early footless metrical phonology. We then turn to the earliest foot proposals and the arguments advanced at the time, including arguments from stress theory and prosodic morphology. We then go on to consider how the theory of the foot has changed in Optimality Theory (OT). (For a more general discussion of stress, see CHAPTER 39: STRESS: PHONOTACTIC AND PHONETIC EVIDENCE.)

2 Background

In this section, we lay out the necessary background for understanding the earliest proposals about the foot. First and foremost is the background of generative phonology generally and Chomsky and Halle (1968) specifically. We then go on to consider the foundation for the foot laid in early metrical theory.

2.1 *Generative phonology and* SPE

Here we discuss Chomsky and Halle (1968; henceforth *SPE*) as the foundation for the foot.[1] The main contribution of *SPE* for our purposes is an explicit treatment of the regularities of stress in English. The analysis is comprised of a number of

[1] Some of the issues in this section are developed further in CHAPTER 51: THE PHONOLOGICAL WORD, CHAPTER 116: SENTENTIAL PROMINENCE IN ENGLISH and CHAPTER 41: THE REPRESENTATION OF WORD STRESS.

rules written in the specific formalism proposed there. Their full rule for main stress in English is given in (1) (*SPE*: 240).

(1)

$$V \rightarrow [1\ \text{stress}] \ / \left[X \_\_ C_0 \left(\begin{bmatrix} -\text{tense} \\ \gamma\text{stress} \\ V \end{bmatrix} C_0^1 \left(\begin{bmatrix} \alpha\text{voc} \\ \alpha\text{cons} \\ -\text{ant} \end{bmatrix} \right) \right) \right.$$

$$\left. / \_\_ \left\langle \left(\begin{Bmatrix} (_{\text{c}}fik)At \\ [+D]C_0 \end{Bmatrix} \right) \begin{Bmatrix} \langle_1 + C_0 \rangle_1 \begin{bmatrix} -\text{stress} \\ -\text{tense} \\ -\text{cons} \end{bmatrix} [+\text{cons}]_0 \\ \langle_1 \begin{bmatrix} -\text{seg} \\ \langle_2 -\text{FB} \rangle_2 \end{bmatrix} \rangle_1 C_0[\beta\text{stress}]C_0 \langle_2 V_0 C_0 \rangle_2 \end{Bmatrix} \right\rangle \right]_{\langle \text{NSP} \langle_1 \text{VA} \rangle_1 \rangle}$$

Conditions: $\beta = \begin{Bmatrix} 2 \\ 1 \end{Bmatrix}$

$\gamma \leq 2$

X contains no internal #

Setting aside morphological and diacritic variables, and focusing on nouns in particular, the main stress rule assigns main stress and secondary stress to nouns in the following way. First, a [+tense] vowel in a final syllable gets primary or secondary stress, e.g. *kangaroo* [ˌkæŋgə'ru] or *chickadee* ['ʧɪkəˌdi]. If the final syllable does not have a stress, and the penultimate vowel is followed by appropriate consonants, then it gets stress, e.g. *agenda* [ə'ʤɛndə]. Likewise, if the penultimate vowel is [+tense], it gets stress as well, e.g. *aroma* [ə'romə]. Finally, in other cases, the antepenult receives stress, e.g. *America* [ə'mɛrəkə] or *remedy* ['rɛmədi].

Abstracting away from the formalism of the time, what we see is a restriction of the primary stress to the last three syllables of the word and a pressure to stress syllables of appropriate weight.

The alternating stress rule in (2) (*SPE*: 240) is responsible for stresses further to the left, e.g. the first stress in *kangaroo* [ˌkæŋgə'ru]. Like the main stress rule, it places stress subject to a basically alternating pattern.

(2) $V \rightarrow [1\ \text{stress}] \ / \_\_ C_0 \ (=) \ C_0 V C_0 [1\ \text{stress}] C_0]_{NAV}$

Both rules alternate in a similar way; both rules assign stress with respect to a following landmark. The fact that both rules exhibit similar patterns and the fact that this kind of alternation is ubiquitous in other languages was a missed generalization in *SPE*, and one that found an explanation in the development of the metrical foot.

A second important aspect of the analysis proposed in *SPE* is that, unlike other phonological features, the feature [stress] exhibited more than two levels in the phonology. Thus, while a feature like [high] could have the values [+high] or [−high] in the phonology, the feature stress could have an *infinite* number of values: [0stress], [1stress], [2stress], [3stress], etc. These different numerical values corresponded to degrees of stress that were held to be contrastive. Moreover, the values had a rather odd interpretation, where [0stress] is the least stressed element and [1stress] has the most stress. Since the values can increase without bound, as the integer value increases, the degree of stress gets smaller, but never quite reaches [0stress].

Rischel (1972) was the earliest proposal to replace aspects of the *SPE* stress system with a hierarchical tree. Specifically, Rischel proposes that compound stress in Danish does not require a cycle and that degrees of stress can be easily read off the morphosyntactic tree.

Compare the following two compounds in Danish:

(6)	*fædrelandssang*	'patriotic song'	[father-land]song
	perlehalsbånd	'pearl necklace'	pearl[neck-band]

In the first case, the compound is left-branching and has the stress values 132. In the second case, the compound is right-branching and has the stress pattern 123. The *SPE* rules given for English here would actually accommodate these directly, as shown in the derivations below.

(7) $[_N [_N$ fædre lands $]_N$ sang $]_N$

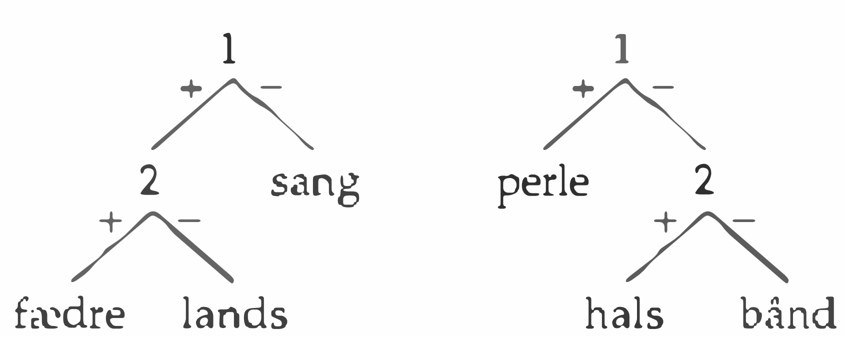
fædre	lands	sang	
1	1	1	NSR
1	2	–	CSR
1	3	2	CSR

(8) $[_N$ perle $[_N$ hals bånd $]_N]_N$

perle	hals	bånd	
1	1	1	NSR
–	1	2	CSR
1	2	3	CSR

Rischel proposes that cyclic effects can be gotten by reading stress levels directly off of trees. He gives trees like the following for the examples above. The pluses and minuses reflect the relative strength of left and right branches and the numbers on nodes reflect the relative effects of those strengths at different levels of the tree.

(9)



Rischel does not propose a specific algorithm for reading stress values off trees like these, but it is easy to see that various interpretations will produce what appear to be reasonable values. The gist is that reapplication of stress rules per se is not required to get the same kind of cyclic effects cited above from *SPE*.[2]

Liberman and Prince (1977) made a similar proposal a few years later, proposing a fairly complete analysis of English stress along similar lines. Basically, they propose that [stress] be treated as a binary feature, with the values [+stress] and

[2] Ultimately, Kiparsky (1979) argued that cyclicity is still necessary in a metrical theory of stress. The debate resurfaced again a few years later. See Hammond (1989), Halle and Kenstowicz (1991), and Cole and Coleman (1992) for more discussion.

As noted above, the labeling of the lower-level trees is unambiguous, because of a general constraint against [+stress] in weak position. The higher-level trees are labeled in accord with the Lexical Category Prominence Rule (LCPR; 1977: 270).

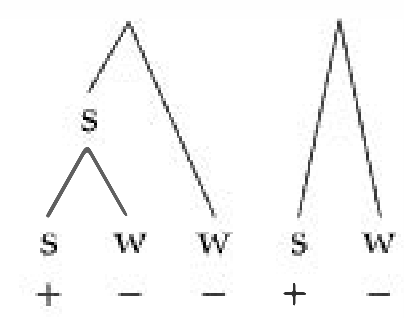
(18) In the configuration $[N_1N_2]$, N_2 is strong *iff* it branches.

Let us take a look at an example: *Winnepesaukee* [ˌwɪnapəˈsɔki]. First, [+stress] values are assigned by the ESR, producing:

(19) + − − + −
Winnepesaukee

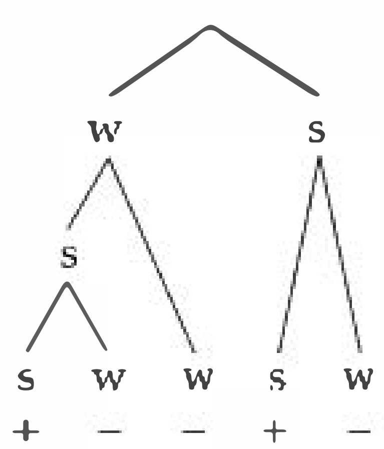
Syllables are gathered into feet as below:

(20)



Finally, the feet are gathered into a tree, the right node of which is labeled strong, since it is branching.

(21)



What is important about this entire tree-construction and tree-labeling procedure is that it explicitly recognizes two levels: a *foot* level and a higher *word* level. This is the first step toward an explicit theory of the foot. Liberman and Prince showed how the foot could be employed in a reanalysis of the basic stress facts of English that *SPE* introduced.

3 Why we need feet

The next step was the parametric elaboration of the foot. At around the same time as Liberman and Prince (1977), Hyman (1977) offered the first typological treatment of stress. While he was not able to go very far in terms of the technical analysis offered, this paper was an important catalyst in forcing phonologists interested in stress to look at the broader typological implications of their work.

The first parametric approaches to the metrical foot showed up in Halle and Vergnaud (1978) and McCarthy (1979), but the most influential early proposal was that of Hayes (1980). Let us look at the Hayes proposal in some depth.

Hayes offered a theory of the foot based on the trees proposed in Liberman and Prince. In particular, feet were parameterized for the following:

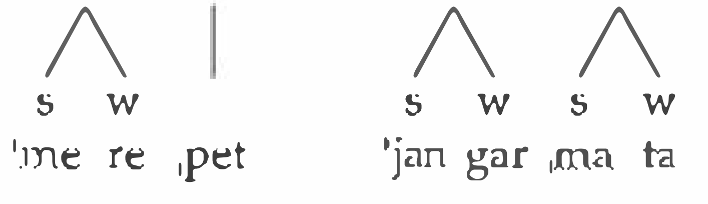
(22) a. *Headedness*
Is the designated terminal element – the strongest element of the foot – on the left edge or the right?
b. *Boundedness*
Are feet binary or unbounded? Do feet contain only two syllables or as many as possible?
c. *Directionality*
Are feet built left-to-right or right-to-left?
d. *Iterativity*
Are feet constructed iteratively or not? That is, is only a single foot built on some edge or are as many feet built as possible?
e. *Quantity-sensitivity*
There are three choices here. First, feet can be quantity-sensitive (QS): weak nodes cannot dominate heavy syllables. Second, feet can be quantity-insensitive (QI): syllable weight is irrelevant. Last, feet can be obligatory-branching (OB): in OB feet, strong nodes must dominate heavy syllables and weak nodes may not.
f. *Syllable weight*
If feet are sensitive to syllable weight, are they sensitive to the weight of the syllable nucleus or the syllable rhyme?

Let us go through some of the examples Hayes cites in support of this theory. Maranungku (Tryon 1970) is cited as an example of left-headed binary left-to-right QI feet. Here, main stress falls on the first syllable of the word and secondary stresses fall on alternating syllables to the right.

(23)	ˈtiralk	'saliva'
	ˈmereˌpet	'beard'
	ˈjangarˌmata	'the Pleiades'
	ˈlangkaˌrateˌti	'prawn'
	ˈweleˌpeneˌmanta	'kind of duck'

Here are two examples:

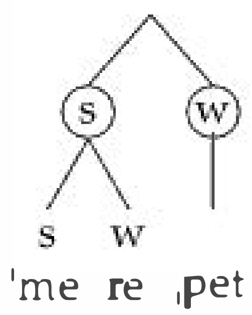
(24)



Notice how the left-to-right construction of feet is apparent from the fact that in words with an odd number of syllables, a monosyllabic, or *degenerate*, foot is built on the right.

The difference between primary and secondary stress is captured by positing a higher level of structure: the *word tree*. These are left- or right-headed unbounded trees built on the roots of feet (see CHAPTER 41: THE REPRESENTATION OF WORD STRESS). In Maranungku, the word tree is left headed.

(25)



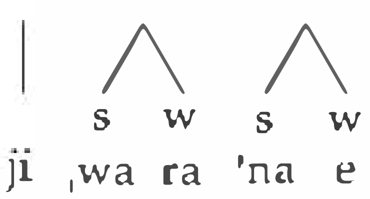
Note that in this and in subsequent diagrams we circle the roots of feet when the word tree is represented.[3]

Warao (Osborn 1966) provides an example of right-to-left footing with left-headed binary feet.

(26)	ˌjapuˌrukiˌtane'hase	'verily to climb'
	ˌnahoˌroaˌhaku'tai	'the one who ate'
	jiˌwara'nae	'he finished it'
	eˌnahoˌroaˌhaku'tai	'the one who caused him to eat'

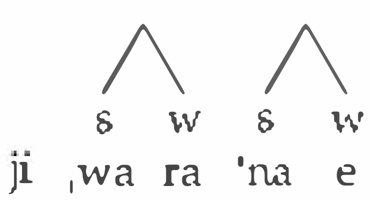
Warao differs from Maranungku in that, in words with an odd number of syllables, there is no initial degenerate foot; rather that foot is removed by an additional *destressing rule*. For example, [jiˌwara'nae] is first footed as follows:

(27)



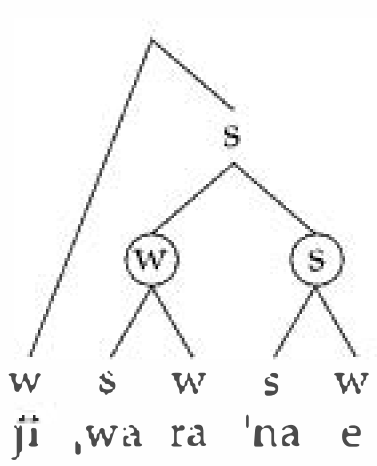
This intermediate representation is then converted to:

(28)



The word tree in Warao is right headed. Hayes assumes that unfooted syllables are adjoined as weak nodes to the word tree. For example:

(29)



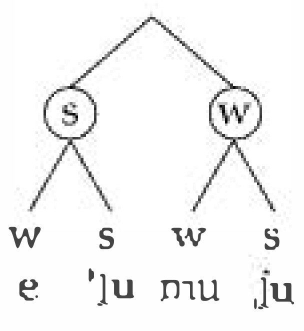
Hayes cites Weri (Boxwell and Boxwell 1966) as an example of binary right-headed feet constructed from right to left with a right-headed word tree.

[3] Hayes (1980) uses underlining, rather than circles.

(34) wu'le 'tomorrow'
ţi'panto 'year'
e'lumu,ju 'give us'
e'lua,enew 'he will give me'
ki'mufa,luwu,laj 'he pretended not to know'

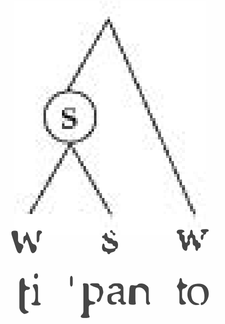
The analysis here is binary right-headed feet built left to right.

(35)



Monosyllabic feet are generally disallowed (or removed) in odd-syllabled cases:

(36)

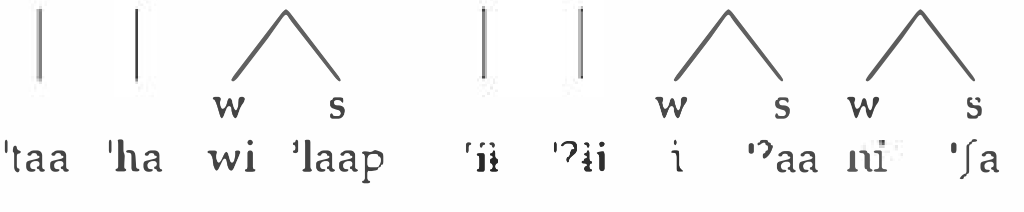


Let us now consider quantity-sensitivity (QS; see CHAPTER 57: QUANTITY-SENSITIVITY). This parameter allows heavy syllables to attract stress. Hayes cites Tübatulabal (Voegelin 1935) as an example of right-to-left right-headed QS bounded feet. The generalization is that stress falls on (a) the final syllable, (b) any long vowel, and (c) any vowel that is two syllables to the left of a stress. Since stresses are unranked, there is no word tree.

(37) 'taa'hawi'laap 'in the summer'
pɨ'tipɨ'tɨɨdi'nat 'he is turning it over repeatedly'
'ɨɨ'ʔɨɨi'ʔaani'ʃa 'he will meat-fast'
'pɔnih'wɨn 'of his own skunk'

Here are two examples of the footings produced by these parameter settings.

(38)



Notice that long vowels count as heavy in Tübatulabal; thus QS refers to the nucleus, not the rhyme.[5]

Hayes' theory of feet also allows for unbounded feet. When these are quantity-insensitive, they simply position stress on the first or last syllable of the word. No actual examples are cited, but we would expect trees like the following for a language with initial stress and QI left-headed unbounded feet:

[5] The data cited by Hayes do not establish unequivocally that codas do not contribute to weight.

We have only exemplified some of the combinations of parameter settings that this theory allows. The claim of the theory is that all settings can be freely combined and that the set of possible stress languages is fully defined by these settings.

The argument for feet per se comes from their role in this parametric system. If the set of possible stress languages is best defined in terms of a theory that adopts the foot as a central descriptive device, then the typology of stress is an argument for the foot.

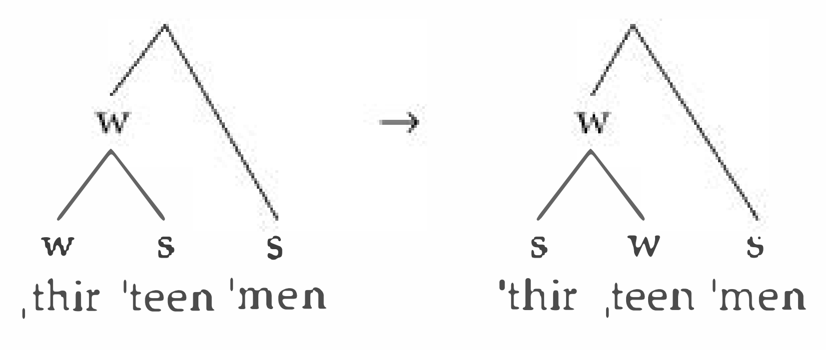
4 Do we need constituency?

One could argue that while the foot is a central computational device in the system Hayes develops, the full predictive power of the foot in that system is not exploited; specifically, while the foot is a *constituent* in metrical trees, its constituency plays no specific role in the system.

Prince (1983) takes this observation to its logical conclusion, proposing an alternative metrical theory without constituency and without feet. To understand this proposal, let us return to Liberman and Prince (1977) and their theory of the *metrical grid.*

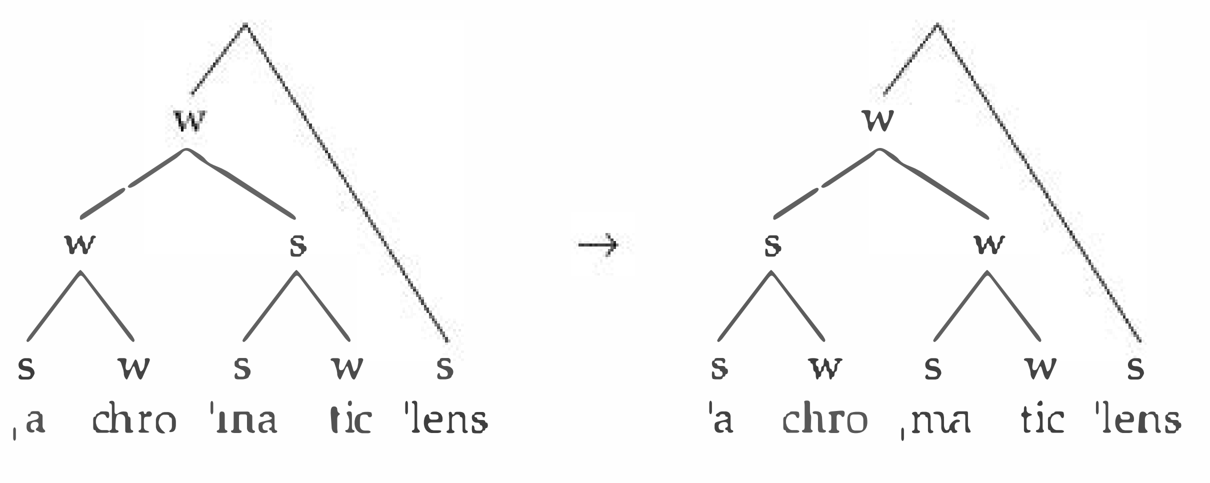
Liberman and Prince propose the metrical grid as a mechanism for identifying the environment for the *rhythm rule*, the phenomenon whereby stress is shifted in certain contexts. Thus, when a word like *ˌthir'teen* is combined with *'men*, we get a shift of stress in the former: *'thirˌteen 'men*. The effect of this shift can be diagrammed as follows:

(46)



Interestingly, the shift also happens with phrases like *'achroˌmatic 'lens*, but not with phrases like *ˌMon'tana 'cowˌboy*. Why this should be the case is not apparent from the metrical trees.

(47)



```
(54)  Feet          Halle and Vergnaud (1987)   Hayes (1995)

      degenerate              x
                             (x)                    (x)
                              σ                      σ

      binary                x
                           (x  x)                  (x  .)
                            σ  σ                    σ  σ
```

The other proposal in response to parallel tree and grid representations of stress was that of Prince (1983). Specifically, Prince proposed a grid-only theory of stress *without* the foot. The basic idea behind the proposal as far as feet are concerned is that binary patterns of iteration are replaced by appeal to the *perfect grid*. This device allows for a binary pattern of stress to be assigned in one of four ways, depending on whether the assignment is from left to right or from right to left and on whether one begins with a stressed syllable or a stressless syllable.

```
(55)  Feet          Left-to-right (LR)     Right-to-left (RL)

      peak first    x   x   x                   x   x   x
                    x x x x x                   x x x x x
                    σ σ σ σ σ ...           ... σ σ σ σ σ

      trough first    x   x                       x   x
                    x x x x x                   x x x x x
                    σ σ σ σ σ ...           ... σ σ σ σ σ
```

Notice how this pattern is achieved with no appeal to binary constituents.

To get the effect of word trees and unbounded foot construction, Prince proposes the *End Rule*. This device assigns a grid mark to the leftmost or rightmost element of the highest level of the grid present. If no stresses have already been assigned, the effect of the End Rule is to assign a stress to the first or last syllable of the word.

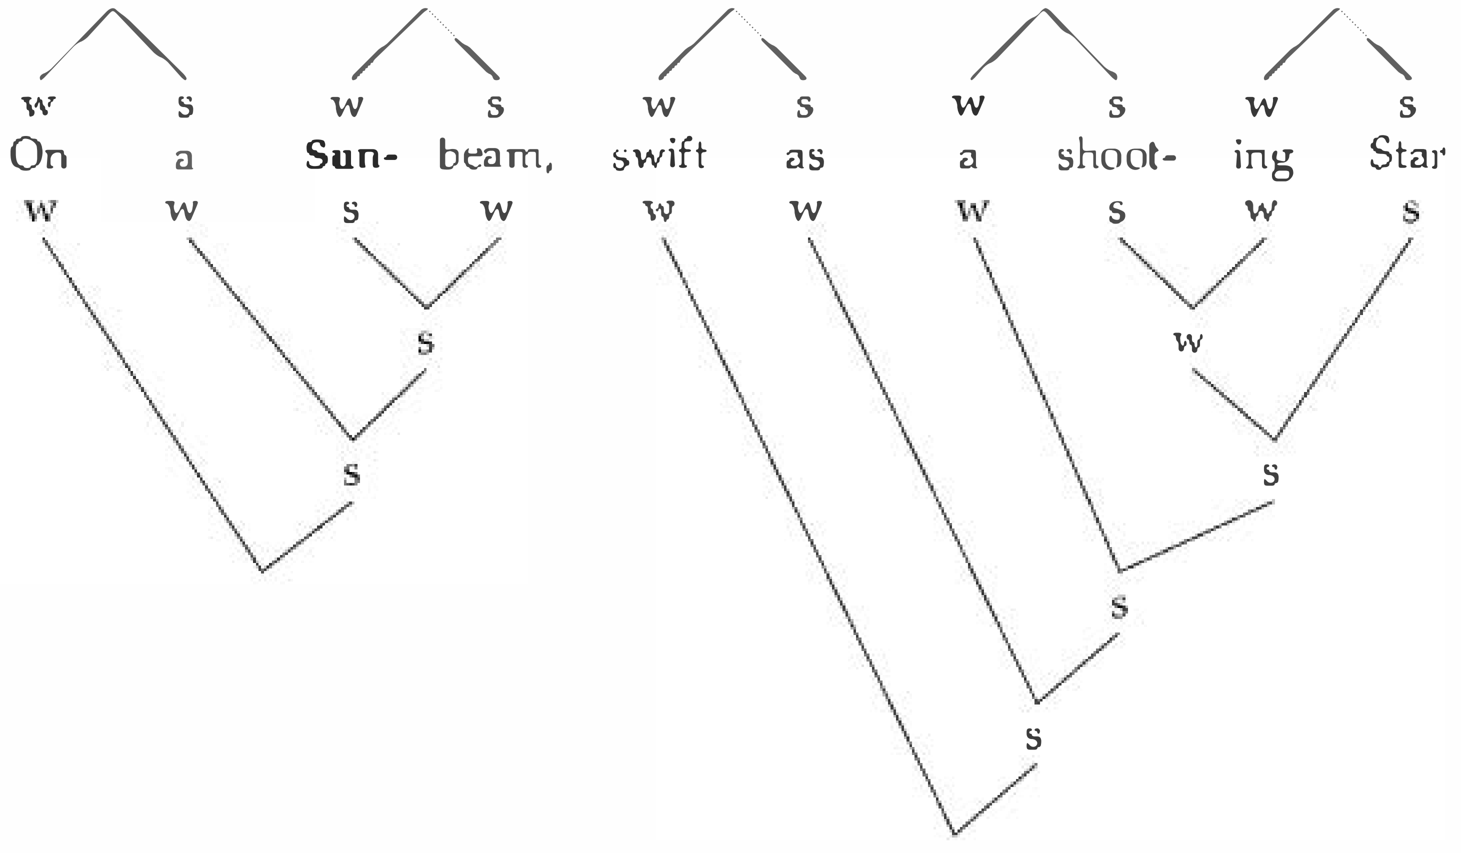
```
(56)  End Rule Left                    x
                        x x x x        x x x x
                        σ σ σ σ   →    σ σ σ σ

      End Rule Right                         x
                        x x x x        x x x x
                        σ σ σ σ   →    σ σ σ σ
```

If stresses are already present, however, then the effect of the End Rule is to promote the leftmost or rightmost stress to primary stress:

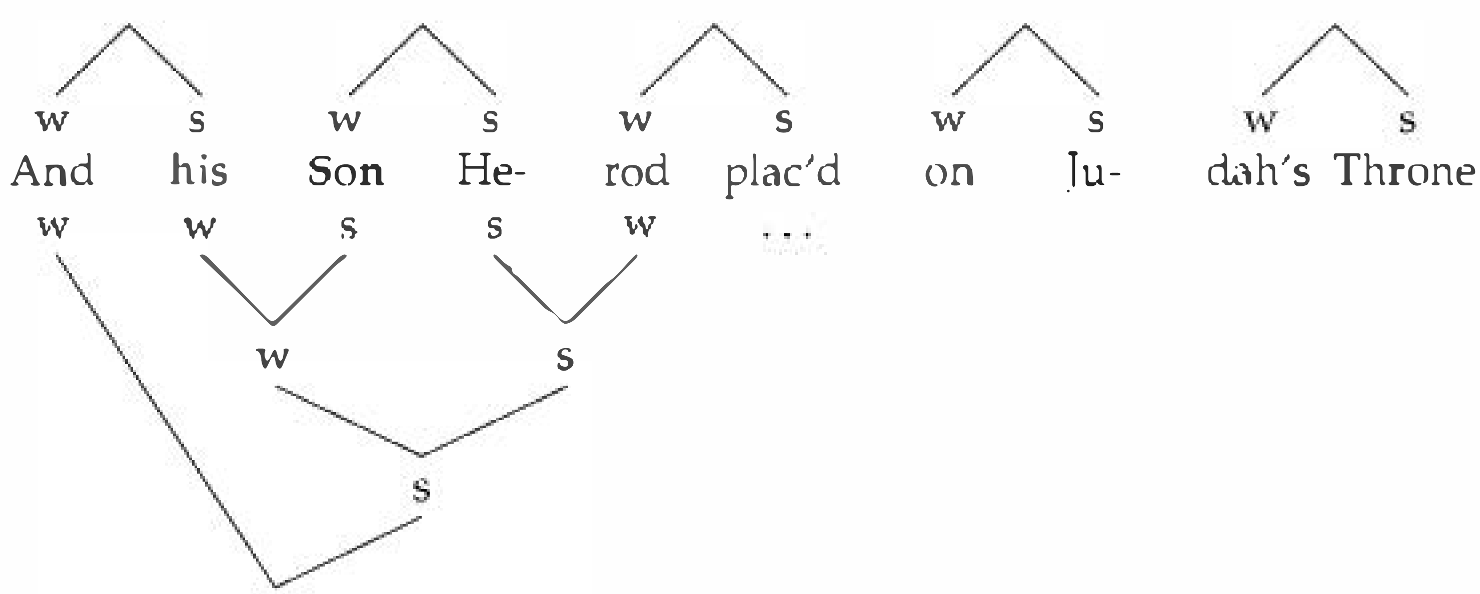
```
(57)  End Rule Left                    x
                        x   x          x   x
                        x x x x        x x x x
                        σ σ σ σ   →    σ σ σ σ
```

(69)



Finally, examples like the following show that the element must be the strongest element of the phrase, and that the bracketing restrictions do not suffice of themselves (Paradise Regained 2.424).

(70)



Hayes (1983) argues that references to foot constituency can be done away with if we define stress peaks over metrical grids and refer to higher-level prosodic constituency. His version of Milton I looks like this:

(71) *Milton I* (grid version)
*Peak / [. . . __]$_{phrase}$

A peak is defined in terms of the grid as a grid column that is higher than at least one of its neighbors.

Let us now look at how this constraint separates the cases we have considered so far. Hayes represents grids in terms of a single symbol "x," rather than numbers. In addition, he represents the line template as a simple single-level grid, rather than with nodes labeled "s" and "w." For the line in (68), we would have this template:

(72) . x . x . x . x . x
Resembling strong youth in his middle age

(79)	*Word*	*Legal*	*Illegal*
	[ˌMinne]['sota]	Minne-fuckin'-sota	Mi-fuckin'-nnesota Minneso-fuckin'-ta
	[ˌTim][ˌbuk]['tu]	Tim-fuckin'-buktu Timbuk-fuckin'-tu	–
	[ˌHali][ˌcar]['nassus]	Hali-fuckin'-carnassus Halicar-fuckin'-nassus	Ha-fuckin'-licarnassus Halicarna-fuckin'-ssus
	[ˌApa][ˌlachi]['cola]	Apa-fuckin'-lachicola Apalachi-fuckin'-cola	A-fuckin'-palachicola Apala-fuckin'-chicola Apalachico-fuckin'-la

Strikingly, there are multiple infixation possibilities just in case we find two medial stressless syllables in a row. This follows directly from the claim that feet in English are binary.

(80)	*Word*	*Legal*	*Illegal*
	[ˌWinne]pe['saukee]	Winne-fuckin'-pesaukee Winnepe-fuckin'-saukee	Wi-fuckin'-nnepesaukee Winnepesau-fuckin'-kee
	[ˌKala]ma['zoo]	Kala-fuckin'-mazoo Kalama-fuckin'-zoo	Ka-fuckin'-lamazoo

The second stressless syllable is affiliated with neither of the adjacent feet allowing the infix to be positioned to either side of it, still satisfying the requirement that there be feet to each side and that the primary stress follows.

There are additional complications to the system (Hammond 1997, 1999). First, the main stress cannot precede the infix. Thus *ˌKalama-fuckin'-'zoo* is decidedly better than *'catama-fuckin'-ˌran*. In addition, if the syllable preceding the infix is stressed, it must be at least bimoraic. Hence, *mun-fuckin'-dane* [ˌmʌnˌfʌkən'den] is better than *ra-fuckin'-ccoon* [ˌræˌfʌkən'kun].

Those complications notwithstanding, the locus of infixation provides additional evidence for foot constituency.

5.5 *Minimum word size*

Lardil (Wilkinson 1988) provides a nice example of a minimum word constraint based on the foot: words in Lardil must have at least two vowels. If they do not, then they are augmented to meet this target with an epenthetic [a]. This provides for alternations in the shape of the stem depending on whether it is suffixed or not; an unsuffixed sub-minimal stem is augmented. Verbs with at least two syllables are inflected as follows:

(81)		'tree'	'dugong'	'beach'	'inside'
	underlying	/ṯuŋal/	/kentapal/	/kela/	/wiṯe/
	uninflected	ṯuŋal	kentapal	kela	wiṯe
	non-future	ṯuŋalin	kentapalin	kelan	wiṯen
	future	ṯuŋaluɽ	kentapaluɽ	kelaɽ	wiṯeɽ

Monosyllabic consonant-final roots with long vowels behave in similar fashion.

(82)

	'ti-tree sp.'	'spear gen.'
underlying	/peeɾ/	/maaɳ/
uninflected	peeɾ	maaɳ
non-future	peeɾin	maaɳin
future	peeɾuɽ	maaɳkuɽ

However, nouns with only a single vowel get augmented when uninflected.

(83)

	'thigh'	'shade'
underlying	/teɾ/	/wik/
uninflected	teɾa	wika
non-future	teɾin	wikin
future	teɾuɽ	wikuɽ

The two-vowel target can be seen as foot based if we treat Lardil as Hayes (1980) treated Southern Paiute: each vowel element is a potential terminal element for footing. Alternatively, if we view vowels as the sole bearers of moras in Lardil, we can view this as a bimoraic target, which was later proposed to be a foot.[15]

5.6 *Language games*

Hammond (1990) discusses a language game in English that provides further evidence for the foot. The game is played by substituting names into the following rhyme.

(84)

Jack, Jack bo back	—, —, bo b —
[ʤæk ʤæk bo bæk]	
banana fana fo fack	banana fana fo f —
[bənænə fæ nə fo fæk]	
me my mo mack	me my mo m —
[mi maj mo mæk]	
Ja–ack	—
[ʤæ–æk]	

The onset of the name undergoes various substitutions not relevant here. The relevant point here is that the name must fit a particular prosodic template: from one to three syllables, where the first syllable is stressed and any subsequent syllables are stressless.

This corresponds to a single left-headed binary foot plus an optional extrametrical syllable. Marking feet with square brackets and the extrametrical syllable with angled brackets, we get a clear difference between names that are acceptable and those that are not.

(85)

Permissible	*Impermissible*
['Jack]	A[n'nette]
['To]<ny>	[ˌIsa]['do]<ra>
['Jenni]<fer>	['Mira][ˌbeil]
['Gwendo]<lyn>	O['livi]<a>

15 Garrett (1999) argues, though, that word minimality is not connected to foot structure.

41 The Representation of Word Stress

Ben Hermans

1 Introduction

Since the publication of Hayes (1985), the asymmetries between iambs and trochees have been a central theme in the literature on stress. Two types of asymmetries can be distinguished. One has to do with quantity. It has frequently been claimed that iambs do not allow a heavy syllable in the weak position, and require a heavy syllable in the strong position. Kager (1993) deals with asymmetries of this type on the basis of a theory whose central hypothesis is that feet are built over moras, rather than syllables. The recent literature, however, has shown that these "quantitative asymmetries" are not supported empirically. It is simply not true, for instance, that iambs invariably constrain the occurrence of heavy and light syllables in the way just described. A particularly convincing argument to this effect is given in Altshuler (2009), with respect to Osage. (See also CHAPTER 44: THE IAMBIC–TROCHAIC LAW and CHAPTER 57: QUANTITY-SENSITIVITY.)

There is a second class of asymmetries, however, which remains valid. These are "parsing asymmetries," which have to do with the direction of foot construction in a word. Two authors have argued that such parsing asymmetries can only be explained if the representation of word stress is fundamentally changed. Interestingly, however, they disagree as to *how* it should be changed. While Gordon (2002) proposes to *simplify* the representation of word stress by eliminating foot structure completely, Hyde (2001, 2002, 2008) recognizes not only foot structure but, in addition, a new type of structure, the "overlapping foot," thus *complicating* the representation of stress in order to account for the asymmetries.

In this chapter I consider the ongoing debate about the representation of word stress from the perspective of parsing asymmetries. In §2, after presenting some of the most important asymmetries, I briefly sketch Gordon's account, which is as simple as it is radical. In his view, asymmetries can be accounted for if foot structure is abolished. Word stress representations contain only gridmarks, as in Prince (1983) and Selkirk (1984).

In the spirit of Gordon, then, we might say that feet are superfluous if we want to account for the *distribution* of stress in the words of the world's languages. This raises the question of whether feet are necessary at all. Interestingly, if we broaden our scope to include other phenomena as well, the evidence for foot structure becomes overwhelming. In §3 I present some cases from the recent literature which support the existence of feet, thus suggesting that representations with only gridmarks are too impoverished.

If foot structure does exist, then how do we account for the *distribution* of stress in the words of the world's languages? Is it still reasonable to formulate the relevant constraints in terms of the grid only? Or must they be stated in terms of foot construction, with gridmarks playing only a marginal role? In §4 I present an overview of Hyde's work, in which the claim is made that the distribution of stress can best be explained in terms of constraints regulating foot construction. Gridmarks only read off some of the basic properties of a word's foot structure. This is a continuation of the tradition initiated by Liberman and Prince (1977). Other authoritative studies, such as Hayes (1984, 1995), have argued for the same idea, which also led to development of the "bracketed grid" notation (Halle and Vergnaud 1987). There are some important differences between the various "tree-cum-grid" theories, however. In §5 I give a brief overview of one issue where theories seem to differ. This concerns the status of headedness in foot structure. Is a foot inherently headed, even if it is not accompanied by a gridmark? Or is it the case that a foot is inherently headless unless there is a gridmark accompanying it, marking one syllable as the head? In the first approach, some or all of the properties of foot structure can simply be read off the grid. In this view foot structure is primary and the grid secondary. In the second approach, in which the grid is imposed on foot structure, the grid is primary and foot structure secondary.

2 Explaining parsing asymmetries without foot structure

Hyde (2001, 2002) shows that some non-existing systems can easily be derived with generally accepted foot inventories (see CHAPTER 40: THE FOOT). Let us consider three of these cases. The first one is the Australian language Garawa, which can be compared with what Hyde (2002: 329) calls "Anti-Garawa," an unattested system.

(1) *Garawa* *Anti-Garawa*

```
 x   x   x           x   x   x
(1 2)(3 4)(5 6)     (1 2)(3 4)(5 6)
 x      x   x        x   x       x
(1 2) 3 (4 5)(6 7)  (1 2)(3 4) 5 (6 7)
```

In these representations foot structure is indicated by round brackets and headedness is represented by gridmarks. Garawa can be derived with the following rules. One trochee is built at the left edge. Then trochees are built from right to left. Furthermore, degenerate feet are not allowed. In odd-parity words this creates a lapse following the stressed initial syllable. If we change just two ingredients of this system we derive a non-existing pattern. One *iamb* is built at the *right* edge, and then a series of iambs from left to right. We then derive a system in which odd-parity words contain a lapse before the final (stressed) syllable.

The second example is a pair consisting of the Australian language Pintupi, which can easily be derived by the rules of the theory, and Anti-Pintupi, which can be derived just as easily but does not exist.

```
(2) Pintupi              Anti-Pintupi

     x   x   x             x   x   x
    (1 2)(3 4)(5 6)       (1 2)(3 4)(5 6)
     x   x   x                 x   x   x
    (1 2)(3 4)(5 6) 7     1 (2 3)(4 5)(6 7)
```

In Pintupi, trochees are built from left to right. Degenerate feet are not allowed. In odd-parity words this creates a lapse at the right edge of a word. Anti-Pintupi can be derived just as easily, by constructing iambs from right to left, so that the lapse is located at the left edge.

Finally, consider Piro, spoken in Brazil and Peru, and Anti-Piro, an impossible system.

```
(3) Piro                 Anti-Piro

     x   x   x               x   x   x
    (1 2)(3 4)(5 6)       (1 2)(3 4)(5 6)
     x   x     x             x     x   x
    (1 2)(3 4) 5 (6 7)    (1 2) 3 (4 5)(6 7)
```

In Piro, one trochee is built at the right edge. Remaining trochees are built from left to right; degenerate feet are not allowed. In odd-parity words this creates a lapse before the stressed penultimate syllable. Anti-Piro can be derived by changing just two ingredients. One iamb is built at the left edge; remaining iambs are built from right to left. In odd-parity words this creates a lapse after the peninitial syllable.

The three non-existent cases have in common that iambic structure refers to the right edge. In Anti-Carawa one iamb is constructed at the right edge, while in Anti-Pintupi and Anti-Piro foot construction starts at the right edge. One might suppose, then, that iambs cannot refer to a word's right edge. This, however, is not true; languages where iambs are constructed from right to left do exist. One example is Suruwaha, spoken in Brazil (Hyde 2002: 320), which is the mirror image of Araucanian, spoken in Chile and Argentina (Hyde 2002: 320). In this language iambs are constructed from left to right. These systems are illustrated in (4):

```
(4) Araucanian           Suruwaha

       x   x   x           x   x   x
    (1 2)(3 4)(5 6)       (1 2)(3 4)(5 6)
       x   x   x          x   x   x   x
    (1 2)(3 4)(5 6) 7     (1)(2 3)(4 5)(6 7)
```

In Araucanian the final syllable is unparsed in odd-parity words. In Suruwaha the first syllable of odd-parity words is assigned a degenerate foot.

(12) *Anti-Garawa resolved (Suruwaha)*

```
  x   x   x
1 2 3 4 5 6

x   x   x   x
1 2 3 4 5 6 7
```

Insertion of the initial gridmark creates a system with a binary rhythm. This is a possible system, which is exemplified by Suruwaha.

The same reasoning applies to Anti-Piro, whose pattern is given again in (13), without foot structure.

(13) *Anti-Piro*

```
  x   x   x
1 2 3 4 5 6

  x     x   x
1 2 3 4 5 6 7
```

The presence of stress on the final syllable indicates that ALIGNEDGES is high-ranked, as in Suruwaha. To ensure that in even-parity words the final syllable is stressed, ALIGN(x_1,R) must dominate ALIGN(x_1,L). With these rankings, it is impossible to derive the stress pattern of odd-parity words in (13). Again, this pattern has a lapse, and violates ALIGNEDGES. Both violations can be eliminated by inserting a gridmark over the first syllable, and by moving the gridmark of the second syllable to the third, as shown in (14).

(14) *Anti-Piro resolved (Suruwaha)*

```
  x   x   x
1 2 3 4 5 6

x   x   x   x
1 2 3 4 5 6 7
```

Again this pattern is actually attested, and is exemplified by Suruwaha.

I have shown in this section that grid-only frameworks can easily explain the asymmetries occurring in binary rhythmic patterns. They do so in a way that is as simple as it is radical. Foot structure is eliminated, and only stresses are preserved, represented as gridmarks. As far as the *distribution* of stress is concerned, grid-only approaches do rather well. Surely this explains why the grid-only approach is still adopted (see for recent applications Karvonen 2005, 2008; also Gordon 2003: 179, note 4, where he confidently states that "a grid-based theory of stress offers a closer fit to the typology of stress than foot-based metrical theories"). It seems, then, that grid-only approaches are sufficient, and that foot structure is therefore superfluous.

Interestingly, however, if we go beyond the *distribution* of stress, and broaden our scope to other phenomena, we find abundant evidence for feet. In the next section I will present a few arguments in favor of foot structure. Then, in §4, I will investigate what this means for the theory of stress.

tone receives word stress, because it is the head of a trochee. With a grid-only approach it is difficult to explain these facts. It seems as if an unstressed syllable with a low tone behaves differently from an unstressed syllable with a high tone; the former but not the latter seems to avoid a lapse. By its very nature, the grid structure of an unstressed syllable with a low tone is identical to the grid structure of an unstressed syllable with a high tone. This indicates that a grid-only framework cannot account for these facts.[3]

I now turn to the second type of evidence for foot structure: the proper characterization of domains.

3.2 *The characterization of domains*

A stressed syllable and a neighboring unstressed syllable often form a domain within which a phenomenon applies. A grid-only approach is notoriously bad at defining domains of this type, as it can only define a primary stressed position, secondary stressed positions, and unstressed positions. It is impossible to express the fact that some unit creates a bond with another unit.[4]

An example showing this is provided by Guugu Yimidhirr, a language spoken in Australia (Zoll 2004; Elías-Ulloa 2006). In this language long vowels can only occur in the first and/or the second syllable of a word, but nowhere else. Some illustrative examples, from Elías-Ulloa (2006: 231–232), are given in (18):

(18)	a.	ˈguːgu	'language-ASS'
		ˈbuːraˌjaj	'water-LOC'
		ˈdaːbaˌŋahŋaˌla	'ask-RED-IMP'
	b.	maˈgiːl	'branch-ABS'
		maˈjiːŋu	'food-PURP'
		maˈgiːlnajˌgu	'branch-PL-EMPH'
	c.	ˈbuːraːj	'water-ABS'
		ˈdjiːraːlˌgal	'wife-ADESS'
		ˈbuːraːjˌbigu	'water-LOC-EMPH'

In a theory that recognizes feet, it is easy to characterize the domain within which the long vowels can occur; it is the initial foot, which is also the head of the word. This foot can either be a trochee or an iamb, depending on the presence and location of a long vowel. On the other hand, in a grid-only account it is difficult to understand why long vowels are restricted to the first two syllables of the word. This is a consequence of the fact that in this approach the first two syllables cannot be characterized as a domain. The facts illustrated in (18) are therefore

[3] Other phenomena showing that not all syllables behave in the same way in a lapse are high vowel deletion in Old English (Dresher and Lahiri 1991) and vowel balance effects in Scandinavian (Bye 1996) and Old Frisian (Smith 2004; Smith and van Leyden 2007). Unfortunately, due to lack of space I cannot discuss these phenomena here.

[4] The domain-defining character of the foot is the oldest evidence in favor of its existence (Selkirk 1980). It turns out to be very difficult to find cases where it is absolutely impossible to define a domain with grids only. An interesting example is provided by Pearce (2006), who argues that feet in Kera create the domains for tone association. I suspect, however, that an alternative is possible with grid marks only, such that (certain) tones tend to anchor to strong positions on the grid. The role of the foot as a domain delineator is systematically eliminated in Majors (1998). She argues that feet do not play a role in stress-dependent harmony.

problematic for a grid-only framework. Let us now turn to the third type of evidence: syllable weight.

3.3 *Evidence from syllable weight*

Prince (1983) shows that the grid-only framework can explain the relationship between syllable weight and the position of stress. This seems to suggest that the effect which weight has on the position of stress can be described without making use of foot structure. However, once we broaden our view beyond the distribution of stress in the strict sense, it becomes obvious that weight does provide us with convincing evidence for foot structure. Here I present one case: allomorph selection in Shipibo, spoken in Brazil and Peru.[5]

Shipibo has two allomorphs meaning 'again': /ribiː/ and /riːba/. The allomorph /ribiː/ has a long vowel in the second syllable, /riːba/ in the first syllable. Elías-Ulloa (2006) shows that allomorph selection is determined by foot structure. The language has two different feet: moraic trochees and iambs. The former is preferred; iambs are only built if the construction of moraic trochees is not possible. Furthermore, both moraic trochees and iambs must be bisyllabic. Two other high-ranking constraints are relevant here. The constraint Weight-to-Stress is inviolable, so a heavy syllable cannot be left unparsed. There is also one Alignment constraint that is high-ranked: the left edge of a word must be aligned with the left edge of a foot. Consider the following forms (from Elías-Ulloa 2006: 7), where the relevant allomorphs are underlined:

(19) *Allomorph selection in Shipibo*

a.	(pi-'riː)(ba-kɨ)	'eat-again-PAST'
b.	('puta)(riˌbiː)-kɨ	'throw-again-PAST'
c.	('puta)(-ma-ˌriː)(ba-kɨ)	'throw-CAUS-again-PAST'
d.	('puta)(-ˌjama)(-riˌbiː)-kɨ	'throw-NEG-again-PAST'

In (19a), /riːba/ is selected, allowing all syllables of the word to be parsed into feet. If the other allomorph had been selected, the form /pi-ribiː-kɨ/ would have been created. This form cannot be correctly parsed into foot structure. One possible parse is ('pi-ri)(ˌbiː-kɨ), but this representation contains an uneven trochee, which is not allowed in Shipibo. Another realization might be pi-(ri'biː)-ki. But this structure violates the Alignment constraint, which is not possible either.

In (19b), /ribiː/ is selected; this is again explained by foot structure. If the other allomorph had been selected, a form would have been created that could not be properly parsed, viz. /puta-riːba-kɨ/. The parse ('puta)(-ˌriːba)-kɨ is unacceptable, because it contains an uneven trochee. The alternative ('puta)(-ˌriː)(ˌba-kɨ) is also bad, because it contains a monosyllabic iamb, a type of foot that is non-existent in this language. Yet another alternative would be pu(ta-'riː)(ˌba-kɨ), but this representation violates the requirement that a word should begin with the left edge of a foot. This constraint is very highly ranked in Shipibo. The form that is actually realized, (19b), does not suffer from any of these problems. It is parsed

5 Other cases are reduplication in Kosraean (Kennedy 2005) and tonal spread in Capanahua (Hagberg 1993).

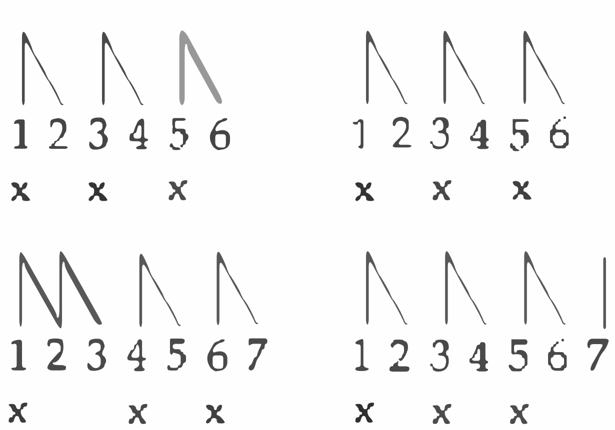
(28) *Excluded by stipulation*

The implication of this stipulation is that if PRWD-L, which requires a trochee at the left edge, is high-ranked, then the other feet cannot be iambic, even though iambs better satisfy right-alignment. The mirror image is also true, of course; if PRWD-R, which requires an iamb at the right edge, is high-ranked, then the other feet cannot be trochaic, even though trochees better satisfy left-alignment.

Maranungku has the ranking PRWD-L >> HDS-R, which derives the representation on the left in (27). This is an instance of maximization, because, in an odd-parity word, as many gridmarks are present as there are feet. Suruwaha has the ranking PRWD-R >> HDS-L, deriving the pattern on the right in (27). Again, in the odd-parity words the number of stresses equals the number of feet. Maranungku has traditionally been analyzed as a language with trochees built from left to right, with a degenerate foot at the right. Suruwaha has been described as its mirror image, with iambs built from right to left and a degenerate foot at the left (cf. (4)).

In principle, every foot receives a gridmark, although, due to overlapping feet, this does not necessarily mean that there are as many gridmarks as there are feet. At the right edge, NON-FINALITY might exclude the presence of a gridmark over the last syllable. Furthermore, at the left edge, the first syllable can be subject to a constraint called INITIALGRIDMARK (Hyde 2002: 320), which requires the presence of a gridmark on the first syllable of a word. If these constraints are high-ranked, this can lead to a situation where a foot is not accompanied by a gridmark. Pintupi has high-ranking NON-FINALITY, while Garawa has high-ranking INITIALGRIDMARK, as illustrated in (29).

(29) *Garawa* *Pintupi*



Garawa is like Nengone (cf. (25)) in the sense that feet are attracted to the left by high-ranking HDS-L. There are also two differences. In Garawa, INITIALGRIDMARK is high-ranked, so the initial syllable must have stress. The constraint against clashing gridmarks is also high-ranked, excluding an immediately following gridmark in the domain of the second foot. With these two constraints dominating GRIDMARKMAPPING, the first foot of the two overlapping feet is stressed, whereas the second foot is not. We thus get a stressless trochee. This is a foot with a head, but without a gridmark. The absence of a gridmark in the second foot creates a lapse immediately after the initial stress.

Pintupi is similar to Maranungku (cf. (27)), but has high-ranking Non-finality. If the final syllable is a foot-head, then it may not receive a gridmark. This creates a lapse at the right edge.

With the system described here it is very easy to explain all the asymmetries mentioned in §2, which are listed again in (30).

(30) *Anti-Garawa* *Anti-Pintupi* *Anti-Piro*

```
  x    x    x          x    x    x          x    x    x
(1 2)(3 4)(5 6)      (1 2)(3 4)(5 6)      (1 2)(3 4)(5 6)
  x    x       x        x    x    x         x       x    x
(1 2)(3 4) 5 (6 7)   1 (2 3)(4 5)(6 7)    (1 2) 3 (4 5)(6 7)
```

In Anti-Garawa, one iamb is built at the right edge, and the other iambs are built from left to right, so that, in odd-parity words, a lapse is created before the final stress. In Hyde's theory it is impossible to derive such a pattern. There are two ways to stress the final syllable of a word: either Hds-R or PrWd-R is high-ranked. With these two systems, it is impossible to create a lapse before the final stress. With high-ranking Hds-R, we derive Araucanian, as already shown in (25). This is a language with a minimization pattern, where in odd-parity words stresses are economically placed, so as to avoid a lapse. With high-ranking PrWd-R we get a system like Suruwaha, whose basic structure is given in (27). This is a maximization pattern, where an extra stress is created so as to avoid a lapse. Anti-Garawa, then, is ruled out, because it cannot be derived.

There is also no place for Anti-Pintupi. The particular property of this imaginary system is that there is no stress on the *initial* syllable. There is only one way to block a stress on a peripheral syllable, Non-finality, which, however, can only block stress on a final syllable. Since there is no equivalent Non-initiality preventing stress from the initial syllable, Anti-Pintupi cannot be derived.

Anti-Piro is also impossible. In this imaginary system, one iamb is built at the left edge, creating a fixed stress on the peninitial syllable. To place a fixed stress at the left periphery two constraints are available. Either Hds-L or PrWd-L must be high-ranked. In the former case we derive Nengone, whose basic configurations are shown in (25). Nengone is a minimization pattern, where the minimal number of stresses is economically placed so as to avoid a lapse. With high-ranking PrWd-L Maranungku is derived, as shown in (27). Maranungku displays a maximization pattern, where an additional stress is inserted so as to avoid a lapse. Thus there is no way to generate a system like Anti-Piro.

Hyde's system is similar to Gordon's in one sense. Neither uses the classical alignment constraints that refer to *feet*. In particular, AllFeet-L/R and PrWd-L/R (McCarthy and Prince 1993) are eliminated.

(31) a. AllFeet-L/R
The left/right edge of every foot is aligned with the left/right edge of some prosodic word.

b. PrWd-L/R
The left/right edge of every prosodic word is aligned with the left/right edge of some foot.

In these constraints, Hyde replaces the argument *foot* by *foot-head*, as shown in (21) and (26), whereas Gordon replaces it by *gridmark*. These two changes are almost identical, since a foot-head normally has exactly the same distribution as a gridmark.

The crucial difference, of course, is the notion of overlapping feet. We might say that, where Gordon eliminates foot structure entirely, Hyde introduces a new type of structure. Of course, Hyde is aware of the fact that this concept must be motivated on independent grounds, a task which he undertakes in Hyde (2008).

Optimality Theory struggles with what Hyde calls the "odd-parity problem." This problem can be divided into two sub-problems: the "even-only problem" and the "odd-heavy problem." The introduction of overlapping feet provides a solution which is not available in standard approaches. For reasons of space I will only discuss the first instance of the odd-parity problem.

The even-only problem is caused by the fact that, in odd-parity words, Faithfulness constraints are in conflict with two other constraints: FootBinarity (the constraint that penalizes degenerate feet) and Parse-σ (the constraint requiring that syllables be dominated by feet). Suppose that the Faithfulness constraints are ranked below FootBinarity and Parse-σ. Under this ranking it is better to insert or delete a syllable than to create a violation of either FootBinarity or Parse-σ, as shown in the following tableau:

(32)

1 2 3 4 5 6 7	Parse-σ	FootBinarity	Max	Dep
a. (1 2)(3 4)(5 6) 7	*!			
b. (1 2)(3 4)(5 6)(7)		*!		
☞ c. (1 2)(3 4)(5 6)(7 8)				*
☞ d. (1 2)(3 4)(5 6)			*	

This tableau shows what happens to a word with an uneven number of syllables. The first candidate, (32a), contains an unparsed syllable, violating Parse-σ. (32b) has a final, monosyllabic foot, violating FootBinarity. In (32c), a vowel is inserted. In this way an extra syllable is created, so that at the right edge a binary foot is built. FootBinarity and Parse-σ are therefore satisfied, although Dep is violated. Finally, in (32d) a vowel is removed, so that both Parse-σ and FootBinarity are again satisfied, although Max is violated.

We can see, then, that in an odd-parity word Parse-σ and FootBinarity can be satisfied if a syllable is inserted or deleted. From this it follows that there should be languages in which all words contain an even number of syllables. These languages would have the ranking Parse-σ, FootBinarity >>Max, Dep. However, no language like this has ever been attested. This illustrates the phenomenon referred to as the even-only problem.

Hyde (2008) shows that the even-only problem does not arise in a theory with overlapping feet. In such a theory, it is possible to satisfy FootBinarity and Parse-σ without violating Faithfulness. In other words, with overlapping feet, no conflict arises between FootBinarity and Parse-σ on the one hand and the two Faithfulness constraints on the other. This is shown in (33):

Nengone has overlapping trochees, with a stressed syllable in the middle. Araucanian has overlapping iambs, also with stress in the middle (cf. (25)). Finally, Garawa has overlapping trochees, with a stress in initial position, as shown in (29).[6]

These representations indicate that headedness is not expressed by gridmarks. In Hyde's framework a foot can be an iamb, even though it does not have a gridmark in its final syllable, as in Araucanian; similarly, a foot can be a trochee, even without a gridmark in its initial syllable, as in Nengone and Garawa.

This is a unique aspect of Hyde's theory. Most recent theories claim that headedness is expressed on the grid. Some theories claim that feet *must have heads*, so that for each foot there must be a gridmark accompanying it. Theories of this type invoke a principle like the Faithfulness Condition, originally formulated in Halle and Vergnaud (1987: 15–16).[7]

Meanwhile, another theory on the relation between foot structure and headedness has been developed. In this theory, headedness is disconnected from foot structure. In these theories there are two foot types; headed feet, which are accompanied by a gridmark, and headless feet, which are not accompanied by a gridmark. The loose connection between headedness and foot structure is expressed by the Separability Hypothesis (Crowhurst and Hewitt 1995b: 39), which states that feet can be headed or headless. Normally, a foot does have a head, but under the pressure of certain constraints, it can happen that a foot is not able to acquire a head. Proponents of the Separability Hypothesis are Hagberg (1993), Crowhurst and Hewitt (1995a, 1995b), Bye (1996), and Crowhurst (1996). Bye occupies a special position among them, because he assumes that feet can sometimes have two heads; when this happens there are two gridmarks in a single foot.[8]

It is clear that Hyde's theory differs from both views just mentioned. On the one hand, it (implicitly) uses the Faithfulness Condition, because all feet are inherently headed. (Heads are not expressed on the grid, but by line structure, as we have already seen; a head has a vertical line, whereas a dependent has a slanted line.) Yet the theory also recognizes the Separability Hypothesis, in the sense that there is a separate mode of representation, the grid, where a gridmark may or may not accompany a foot. Hyde's theory, therefore, does not recognize headless feet, but it does recognize stressed (headed) feet and unstressed (headed) feet. In this sense, Hyde's theory is certainly representationally richer than all other recent theories.

There is some evidence from Vogul, a language of Siberia, that feet can be headed, even if they are not stressed. In Vogul, stress does not seem to be quantity-sensitive (Vaysman 2009). The main stress is realized on the initial syllable, and there are secondary stresses on every other syllable thereafter. If, however, the final syllable is a target for secondary stress, this stress is not realized. Syllable quantity is irrelevant for this distribution. Only syllables with long vowels are heavy: words with a heavy syllable have exactly the same stress patterns as words with only light syllables. These regularities are illustrated in (35).

[6] The mirror image of Garawa (overlapping iambs with stress on the final syllable) does not exist. This system could only arise with a constraint requiring stress on the final syllable, together with high-ranking *Clash. However, in Hyde's system there is no constraint requiring stress on the final syllable. Therefore, two overlapping iambs at the right edge will always have stress in the middle (the minimization pattern).

[7] Halle and Vergnaud's Faithfulness Condition should not be confused with the Faithfulness constraints of OT. The former is a condition on the relation between a foot and its head.

[8] Level stress in Scandinavian dialects necessitates this representation, according to Bye (1996).

words. Overlapping feet can be motivated on independent grounds: overlapping feet solve the odd-parity problem.

In Hyde's theory, the grid is mostly subservient to foot structure. Feet are always inherently headed, with or without a gridmark.

42 Pitch Accent Systems

Harry van der Hulst

1 Introduction

This chapter deals with the typology of *word prosodic systems* and, specifically, discusses the notion of "pitch accent (language)," asking whether there is such a class of pitch accent languages distinct from "stress languages" and "tone languages." Several issues will turn out to be crucial. Firstly, there is the issue of recognizing (or not) a notion of *accent* which could be said to underlie both pitch accent and "stress" (or indeed stress accent), and perhaps other phenomena which are not frequently referred to as accentual (such as phonotactic asymmetries). Secondly, there is the question as to whether we wish to distinguish between pitch as a *non-distinctive* and thus perhaps strictly phonetic property (found in phonetic implementation) and pitch as the exponent of a phonological category (namely *tone*). Thirdly, there is the possibility of having tone, stress, and accent (in various combinations) "side by side" within the same language, which raises the question of how these notions interact in any given language.

The structure of this chapter is as follows. In §2 I will introduce the basic notions and definitions. §3 will briefly discuss examples of languages that have been referred to as pitch accent languages, where accent is apparently realized in terms of *non-distinctive* pitch. In §4, I examine cases in which tone realization or tone distribution has been said to depend on accent (or stress), a class of languages that is also often included in the pitch accent type. §5 and §6 focus on the different ways in which alleged pitch accent languages have been analyzed, with or without using the notion "accent." In §7, I define the notions accent and stress as distinct phonological entities and suggest that stress languages may or may not be accentual. In §8 I offer some conclusions.

2 Accent, tone, and stress: Definitions and usage

2.1 *Accent and stress*

For many languages, researchers have reported word-level "prominence," associated with a specific syllable in the word, which is called "stress" (an English term) or "accent" (the term used in, for example, French or German) (see also CHAPTER 41: THE REPRESENTATION OF WORD STRESS). In literature in English on the subject, both "stress" and "accent" have been used for word-level prominence, which has lead to a good deal of confusion, in particular because there are writers who use the terms for different things. Cutler (1984), for example, regards "stress" as a property of words and "accent" as a property of sentences. There is thus a need for clarity on how these two terms are used.

2.2 *Accent and its cues*

On closer scrutiny, the informal notion of "prominence" can be divided into two distinct phenomena. On the one hand, we have the *location* of the prominent syllable (e.g. penultimate; final if the final syllable has a long vowel, otherwise penultimate; etc.) and on the other hand, there are phonetic (and phonotactic) *cues* that signal the location of the prominent syllable (CHAPTER 39: STRESS: PHONOTACTIC AND PHONETIC EVIDENCE). In one (fairly old) terminological tradition, the locational aspect of prominence is referred to as *accent*. The characterization of the accent (location) is essentially sequential (or *syntagmatic*); only one syllable within the relevant domain can have this property. This is what Martinet (1960) and Garde (1968) refer to as the *contrastive* or *culminative* function of "accent," a term mainly used by Trubetzkoy (1939). The realizational aspect of prominence is, in a sense, paradigmatic (cf. van Coetsem 1996): there are various (not necessarily incompatible) phonetic and phonotactic means for cueing the accent. Some languages may favor one specific cue (e.g. pitch or duration), but several cues may conspire to manifest the accent. This division of "prominence" correlates with traditional terminological systems such as *musical accent vs. dynamic accent* or (with much the same meaning) *pitch accent* (systems) *vs. stress accent* (systems) (see Fox 2000: ch. 3 for an excellent general review of the notion *accent*; also van Coetsem 1996; van der Hulst 1999b, 2010b). In each case, the modifier of the head noun ("accent") says something about the way in which the accent is "manifested" or "realized." In this chapter I will focus on relationships that involve accent and pitch, whether used distinctively (in terms of contrastive tones) or non-distinctively. However, I will also consider the relationship between accent and stress.

2.3 *Word prosodic types*

While in some languages pitch is a property of words, all languages use pitch features within an *intonational system*, a system that aligns "sentences" with a melody that can be defined in terms of pitch events that mark boundaries of (syntactic or prosodic) units as well as the informational packaging of the utterance with reference to the notion "focus" (Bolinger 1982; Gussenhoven 2004; CHAPTER 32: THE REPRESENTATION OF INTONATION). At the same time there are languages in which pitch is a property of "words." Within this group of languages we commonly find the labels in (1b) and (1c). The label "stress" in (1a) is reserved for languages that need no specification of pitch at the word level, although, like all other languages, they use pitch for intonation purposes.

(1) a. Stress (or stress accent)
    b. Pitch accent
    c. Tone

There is, however, a great deal of controversy concerning the use of the terms tone and pitch accent, and, for that matter, the term stress.[1]

Hyman (2001, 2006, 2009) makes a case for treating systems that we label stress and tone as "prototypes," meaning that languages that belong to one or the other (or both) type(s) display one or more specific defining properties.[2] "Pitch accent," according to Hyman, is not a prototype, but rather a label for a large class of hybrid systems that mix "tone" and "stress" properties in various ways, or systems that are clearly tonal, although displaying various restrictions on the distribution of tones. In effect, Hyman regards the notion accent as unnecessary, whether as a formal mechanism in analysis or as a prosodic type. Other researchers (such as Gussenhoven, e.g. 2004) who also reject the idea of "pitch accent languages" nonetheless recognize the notion of accent as an analytic device. In this chapter these views will be discussed and compared to views that attribute a fundamental role to the notion accent.

2.4 *Definitions and use of tone*

A traditional way of defining the notion tone is in terms of "*distinctive* use of pitch." Thus, if a language uses pitch to distinguish different otherwise identical morphemes, pitch has a phonological or contrastive (distinctive) status. The following frequently quoted definition captures what is perhaps the canonical use of distinctive pitch:

> A tone language may be defined as a language having lexically significant, contrastive, but relative pitch on each syllable (Pike 1948: 3).

If tones are distinctive on all syllables (possibly like properties such as frontness, height, or roundness) we can say that the distribution of tones is *unrestricted*. Most researchers, however, agree that there is no reason to limit the term tonal language to cases in which the distribution of tones is *entirely* unrestricted (see CHAPTER 45: THE REPRESENTATION OF TONE). Presumably, all tonal systems show restrictions resulting from tonal spreading or assimilation (Schuh 1977; Hyman 2007), from using a limited set of tonal melodies which are properties of morphemes rather than of syllables (Leben 1971; Goldsmith 1976b; Halle and Vergnaud 1982), from the avoidance of sequences of identical tones (dissimilatory or OCP effects), or indeed from relations between tone distribution and accent (or "stress") (see §4). Also, it is not uncommon to find that the full range of contrasts is not found in affixes (as opposed to roots or stems) (CHAPTER 104: ROOT–AFFIX ASYMMETRIES). Finally, initial or final syllables may fail to bear tonal contrast (sometimes to leave room for intonational tones or for other, perhaps "perceptual," reasons; CHAPTER 98: SPEECH PERCEPTION AND PHONOLOGY).[3] Since it would be unwise

[1] Typological studies of word prosodic systems are numerous: e.g. Trubetzkoy (1939); Hockett (1955); Garde (1968); Meeussen (1972); Goldsmith (1976a, 1988); Greenberg and Kaschube (1976); Hyman (1977, 1978, 1981, 2006, 2009); Lockwood (1982); Clements and Goldsmith (1984); Beckman (1986); Clark (1987, 1988); Haraguchi (1988); Hollenbach (1988); van der Hulst and Smith (1988); Mock (1988); Wright (1988); Hayes (1995); van der Hulst (1999a, 2010c); de Lacy (2002); Duanmu (2004).

[2] Here Hyman avoids the term "stress accent," presumably because he no longer (cf. Hyman 1977) recognizes the label "pitch accent" as a useful one and thus essentially wants to eliminate the notion accent altogether.

[3] Suárez (1983: 52) observes that in Huichol and Mazahua there is no tone contrast on the last two syllables or the last syllable, respectively. In these languages, inherent lexical tones are removed to free up space for intonational tones.

to maintain the strictness of Pike's definition (according to which perhaps there is not a single tonal language), van der Hulst and Smith (1988) quote the much more liberal definition of Welmers (1973: 2):

> A tone language is a language in which both pitch phonemes and segmental phonemes enter into the composition of at least some morphemes.[4]

Note the use of the term *pitch phoneme* (CHAPTER 11: THE PHONEME), which suggests that Welmers requires that pitch is used contrastively, a crucial point to which I return below. This definition includes languages in which there are tonal contrasts in certain positions, or even in only one position, in some morphemes.

With this broader definition, tonal languages can be ranked on a scale of *tonal density* (Gussenhoven 2004), which indicates how many word positions have how much tonal contrast. In a sense, such a scale indicates the relative *functional load* of tone properties. Stretching Gussenhoven's notion, we could say that relative density arises not only in the syntagmatic dimension (depending on how many positions display tonal restrictions), but also in the paradigmatic dimensions (depending on the number of contrastive options per position):

(2) *Tonal density matrix*

T1	+	+	+	+	+	+	
T2	+	+	+	+	+	+	
T3	+	+	+	+	+	+	
	x	x	x	x	x	x	(tone bearing-units)

Each potential minus would indicate a restriction on the distribution of a distinctive tone. However, no matter how dramatic the restrictions, as long as there is tonal contrast (i.e. distinctive use of pitch), phonological tones *must* be specified in the lexical entries. The smallest tonal system would have two tones, H and L. More extensive systems would add an M tone, or possibly two different M tones (high mid and low mid). In addition, systems can have contour tones (rise, fall, etc.) (CHAPTER 45: THE REPRESENTATION OF TONE).

2.5 Culminativity and obligatoriness

Another frequently cited term in this context is "restricted tone language," introduced by Schadeberg (1973) and Voorhoeve (1973). This term, too, would seem to indicate a scale of restrictiveness, although Voorhoeve introduced it in the context of Bantu languages whose tonal system is so severely restricted (up to one H per word in a H/L system) that he suggested that an accentual analysis might be considered (CHAPTER 114: BANTU TONE). Indeed, adding syntagmatic and paradigmatic restrictions on the distribution of tone together, one could see that a language, despite having a H/L contrast, while allowing at most one H tone per word could easily permit an accentual analysis in which the H "tone" is regarded as the predictable pitch cue of an accent, even in a case where there is no indication of any additional independent cues for this accent.

[4] Strictly speaking this excludes cases in which a language has tonal affixes without having affixes or other morphemes that combine tone and segmental properties.

But what is "accent," and how is it formally represented? Hyman (2009) formulates two necessary properties of what he calls stress, which I will take as a point of departure for establishing what might be seen as characteristics of accent, if these notions are going to be distinguished. One "property" is that each "word" can have stress or accent *at most once* (only one syllable can be stressed or accented) and, additionally, each word must have it *at least once*. These two properties, following Hyman (2006, 2009) can be referred to as:

(3) a. Culminativity (at most one)
 b. Obligatoriness (at least one)

Let us now ask whether the two properties in (3) *must* be regarded as necessary properties of accent. An issue that goes to the heart of what is often seen as problematic for the notion "pitch accent" is that languages which allegedly have a pitch accent system, and thus accent, sometimes have (lexical) words that appear to be unaccented (see the discussion of Tokyo Japanese in §6). This, however, is only problematic if obligatoriness is stipulated to be a *necessary* property of accent. We could investigate a more liberal interpretation of accent, in which unaccented words are permitted in an accentual language. This, of course, has important consequences, because it opens the door to using the presence *vs.* absence of accent as a contrastive option and thus to analyzing alleged tonal languages that have a H–L contrast as fully accentual languages, with H as the exponent of accent and L as the lack of accent.

We might then also question whether culminativity is a necessary requirement for describing accent. If culminativity is not required, even "H/L" languages that allow multiple H "tones" *could* be analyzed as fully accentual. Allowing words to have multiple accents separates the notions stress and accent even more dramatically than just giving up obligatoriness for accent. Still, if accent is not the same thing as stress, there is no a priori reason for believing that any properties of the latter need to be true of the former. I return to these issues in §5.3.

2.6 Representational issues

Answers to the question of whether or not the properties in (3) are definitional of accent have repercussions for, or are implicit in, the manner in which accents are formally represented. In one type of approach the relevant syllables are marked with an "accent mark," as is common in dictionaries and in autosegmental theory (e.g. the "star" of Goldsmith 1976a), or in terms of a segmental feature, as in the phonological theory of Chomsky and Halle (1968). In this "lexicographic" approach there is no commitment to culminativity or obligatoriness.

A different formal approach is to provide the string of syllables with a headed tree structure, as proposed in various versions of metrical theory (Liberman and Prince 1977) and dependency phonology (Anderson and Ewen 1987) (see also CHAPTER 40: THE FOOT). Metrical structures have one designated terminal unit, the head of the word, which counts as the (primary) "stress." This notation (assuming that all syllables must be grouped in one structure) implies culminativity, but not necessarily obligatoriness, because it does not follow from the notation that each word must be provided with a metrical tree.

However, rather than seeing asterisks and trees as competing mechanisms, we should entertain the idea that they are complementary, in that the former represent accents, while the latter represent stress. This point is acknowledged by Anderson and Ewen (1987), who, in addition to headed tree structures, also use asterisks to indicate what we might call "potential heads."[5] I will return to this point in §7.

2.7 *Problems with the notion "pitch accent"*

We have been considering a use of the term accent as an abstract mark of a position that can be cued by various phonetic properties, "stress" being one of them. Beckman (1986) refers to languages that are *not* stress accent languages, as "non-stress accent" languages (thus avoiding the term "pitch accent language"). This, of course, is compatible with the idea that in many non-stress languages pitch is the most salient property of accent. Van der Hulst (1999a, 2010b) points out that if we maintain the term "pitch accent language" we might also expect to find languages that can be labeled as "duration accent" languages (if duration is the only cue). On this view, pitch accent languages are languages in which accent is (mainly) cued by phonetic pitch.

There are, in fact, various factors that make the use of this term problematic. One factor is, obviously, that people may simply define the term differently. For example, as we will see in §4, tonal contrast is often limited to specific syllables in the word; cases of this sort have been analyzed by identifying a notion "accent," with association of tones being dependent on this accent. While in this case, the *presence* of tone can be said to function as a cue of accent, the cue is not a phonetic, but rather a phonological, fact (namely the phonotactic distribution of tones). The fact that the possibility of tonal contrast may signal the accent location is part of a much more general pattern, found in many languages, where accented syllables display contrastive or structural options that are exclusive to a particular syllable (see Downing 2010; van der Hulst 2010b).[6] Pursuing the terminological path that we started out on above, we might refer to such cases in which tonal contrast is limited to the accented syllable as *tone accent* (or *tonal accent*) languages, rather than pitch accent languages. It is apparently the case that accented syllables can be referred to by the phonology as well as by the phonetic implementation system. In fact, accents can be referred to by other grammatical modules as well, e.g. the intonation system. Does this mean that we can refer to English as an "intonation accent" language? Languages cannot be put in a single box as far as cues for accent are concerned.

Tonal accent systems, then, differ from pitch accent systems if we agree that in the latter pitch is not used distinctively. However, some writers (e.g. Downing 2010) use the term "pitch accent" for *any* system in which pitch properties (whether distinctive or not) enter into a relationship with accent or stress. This would include not only what is referred to here as a pitch accent or tone accent language, but also another class of languages which have both tone and accent, in which accent (or "stress") is assigned with reference to tone. Downing's use of the term pitch accent is thus much broader than the one considered above.

[5] Another formal notation (also proposed in Liberman and Prince 1977) is the metrical grid, which does not imply culminativity. See CHAPTER 41: THE REPRESENTATION OF WORD STRESS for extensive discussion.

[6] This relates to the notion of positional faithfulness; cf. Beckman (1998).

3.2.1 *Basque*

The dialects of Basque present a great diversity of word prosodic systems (see Hualde 1999). Gussenhoven (2004: ch. 9) presents an analysis of Northern Bizkaian Basque with reference to the Gernika and Lekeito dialects. Both have accented and unaccented roots, the former being in the minority. There are inflectional and derivational suffixes that are accented or pre-accenting. In Lekeito, if a word has an accent, this accent always ends up on the penultimate syllable. In Gernika, the leftmost (non-final) accent prevails; this is the more common case in Basque dialects. In Lekeito, unaccented words are grouped with an accented word to their left or right, whereas sequences of unaccented words together form a single domain. Each such domain either has an accent (if it contains an accented word) or is unaccented. Unaccented domains receive a default final accent in certain syntactic positions, namely at the end of the sentence or before the finite verb. Each accent, whether lexical or default, is associated with a HL pitch accent. The left edge of the accentual domain is marked by a LH boundary sequence; a high plateau is found between the boundary H and the H of the pitch accent. Systems of this sort seem obvious candidates for accentual analyses, which of course begs the question of whether they *must* be analyzed accentually. One argument that could be made for an accentual approach is that in the various dialects we note a variety of accent locations (ranging from lexical to rule-governed) which is very reminiscent of the distribution of stress in "stress accent languages." The second argument again involves the fact that pitch is non-distinctive in Basque dialects. Note that in Basque, unaccented words are provided with default accent, at least in some cases.

3.2.2 *Japanese*

We also find a broad array of word prosodic systems among the dialects of Japanese (cf. Haraguchi 1977). An overarching property of all systems is the relevance of pitch at the level of the "word," or, as some researchers prefer to put it, the "accentual domain." An interesting overview in the context of autosegmental theory of dialectal differences is offered by Haraguchi (1977, 1988), who divides Japanese dialects into two broad categories: pitch accent systems and unaccented systems. Cross-classifying with this dichotomy, he suggests a "universal" inventory of melodies (H, L, HL, LH, and LHL), from which a system may select at most one or two. In addition to the choice of one or more melodies, the differences among dialects depend on:

(4) a. The location of accent/H: fixed or free.[11]
b. The spreading of H: no spreading, rightward or leftward.

Thus, in Tokyo Japanese, the H tone spreads leftwards (leaving an initial mora low, possibly due to a boundary L tone that comes with the left). We will focus on the pitch aspect of Tokyo Japanese in §6. The system of Tokyo Japanese is such that the constituents of words (stems, affixes) can be accented or unaccented (or, in the case of affixes, pre-accented). When more than one accent is present in the accentual domain (which can be larger than the word and therefore needs careful definition; Gussenhoven (2004) calls it the α-domain), the first (or leftmost

[11] In §6 we will discuss the way accents are distributed in Tokyo Japanese, which is partly lexical and partly rule-based.

accent) predominates, i.e. will attract the high pitch/tone. If no accent is present, the high pitch occurs on the last (rightmost) syllable (and spreads from there). This "First/Last" pattern constitutes a system that is reminiscent of so-called *unbounded stress systems* (Hayes 1995). In fact, Haraguchi (1988) notes that three of the possible unbounded patterns occur in Japanese dialects (see also CHAPTER 120: JAPANESE PITCH ACCENT).

(5) a. *Systems with unaccented words*

First/First[12]	Kumi
First/Last	Tokyo, Osaka
Last/First	—
Last/Last	Hirosaki

b. *Systems without unaccented words*

First	Fukuoka
Last	—

Note that systems without unaccented words have no default clause.

Haraguchi (1977, 1988) also recognizes *unaccented systems*, i.e. systems in which no word is accented. He mentions Sendai, Miyakonojo, and Kagoshima. In such systems the tonal melody is associated either from left to right or from right to left in his analysis:

(6) *Systems with only unaccented words*

First
Last

For these systems, tones are associated to words in terms of association conventions that make no reference to accents, but rather the word edges. These same conventions are invoked for unaccented words in accentual languages (as in (5a)), which implies that in such systems tones are associated partly to accents and partly *directly* (i.e. without "intervening" accents).

In all dialects that use just one melody, the question can again be raised whether this "melody" is a phonological entity or entirely due to phonetic interpretation. Haraguchi (1988) does not consider this issue, but it could be argued, as before, that only dialects that have more than one word melody are truly tonal.

3.3 Bantu languages

Many Bantu languages are commonly described as having both tone and accentual properties, while a few (such as Swahili) have lost tone, and retain only "stress" (CHAPTER 114: BANTU TONE). Bantu word prosodic systems have always been of special interest in the debate regarding the appropriate analysis for languages that have both significant word-level pitch movement and indications that accent plays a role as well; see Schadeberg (1973), Voorhoeve (1973), Goldsmith (1976a, 1988), Hyman (1978, 1981, 1982, 1989), Clements and Goldsmith (1984), Odden (1988), and especially Downing (2010). The accentual analysis of Bantu languages was promoted by Goldsmith (1976b, 1988), although the approach has a long history (see the introduction in Clements and Goldsmith 1984 for a historical perspective).

[12] This can be glossed as: "Associate a tone with the first accented syllable, or, if no accent is present, with the first syllable."

tonal accent system. A question that arises in these cases is whether the accented syllable is cued merely by its attraction of tonal contrast, or, additionally, by other "stress-like" cues. I will consider this issue in §5. I consider here some examples from Suárez (1983), as well as from Yip (2002), in their surveys of Meso/Middle American languages. Isthmus Zapotec has two tones which associate to the accented syllable and from there spread rightwards. "Pre-stress" syllables are low-toned. Suárez also mentions Northern Pame and Yaitepec Chatino as languages that have a tonal contrast only in the syllable that is said to be "stressed" (in both cases the "final" syllable, presumably of the stem). This can be compared to Huautla Mazatec, where every syllable can have contrastive tone. In between, we find cases where the contrast on certain non-accented syllables is limited. In Palantla Chinantec, for example, there is no tonal contrast on post-stress syllables.

Van der Hulst and Smith (1988) cite the case of San Juan Copola Trique, which illustrates how restricted tonal distribution can arise historically (cf. Hollenbach 1988; Yip 2002). In the Otomanguean family in general, we find a continuum of reduction of tonal contrast and, interestingly, an *increase* in tonal contrasts on the accented syllable. A case where accent has only mildly influenced tonal contrast is found in Cajonos Zapotec (Nellis and Hollenbach 1980). Of the four underlying tones H, L, HL, and M, only M is disallowed in unaccented syllables. In this case, then, we do not have a tone accent system, but simply a tone *and* accent system, with accent-driven reduction.

Among the languages in which the distribution of tone is dependent on accent, there is a subclass of cases in which tonal contrast is only found on or near accented syllables, not because tones have been neutralized in other positions, but simply because a tonal contrast historically developed only in this position. In these cases, the accented syllable, in addition to being an attractor for tonal association, has clear stress-like cues. Hence languages of this kind are both stress accent and tonal accent languages, with the proviso that the tone does not always associate directly to the accented syllable, but sometimes on a syllable near it (although this also depends on the details of the analysis). Two well-known cases of this sort are some of the Scandinavian languages and Serbo-Croatian. For discussions of the Scandinavian type I refer to Bruce (1999) and Gussenhoven (2004) (see also CHAPTER 97: TONOGENESIS). For Serbo-Croatian, see e.g. Inkelas and Zec (1988).[13]

We must note that the co-occurrence of stress accent and a lexical pitch contrast enforces a tonal analysis of the latter. If the accent was not manifested in any other way than forming an anchor for lexical pitch, it could be argued that the opposition is one between accented words and unaccented words.

5 The accent debate

5.1 *Accents or no accents*

We have so far discussed two possible interactions between accent and pitch or tone:

[13] In his chapter on central Franconian tones, Gussenhoven (2004: ch. 12) discusses the emergence and representation of a tonal distinction that is very similar to the Scandinavian distinction; see also Gussenhoven and Bruce (1999) and Hermans (1994). We also find a similar contrast (due again to different historical factors) in Scottish Gaelic; see MacAulay (1992: 234–236).

(8) a. Pitch is dependent on accent (pitch accent systems; §3).
b. Tone is dependent on accent (accent-dependent reduction and distribution; §4).

The dividing line between the two types is distinctivity. If pitch is non-distinctive, i.e. if there is no tonal contrast, the system uses pitch to cue accent. But if there is tonal contrast, tones are involved.

The Bantu systems mentioned in the preceding section have been analyzed as involving accent and tone. However, the question of whether the occurrence of tone contrast on one specific syllable requires a notion of accent cannot be taken for granted, even when tonal association seems to be limited to an "accent-like" position. Consider the case in which the alleged accented syllable has no independent property apart from being the locus of tonal contrast. One could then say that there really is no accent at all, and instead assume that the tones, being specified as a property of morphemes, associate to their specific locus *directly*, without first assigning an accent that attracts the tones. In this case we would accept that accent rules and tone association rules fall under the umbrella of a general theory of *positional identification*, and that the principles for positional identification are similar, if not the same, for both accent placement and tone association.

(9) a. *Indirect (accentual) approach*
Step one: Accent goes to position X.
Step two: Tones go to accent.
b. *Direct approach*
Step one: Tones go to position X.

If the direct approach is taken, the category of tonal *accent* systems reduces to tonal systems which are then further differentiated in terms of different principles of association (LR, RL, positional). Below we will see that the direct tonal approach can also be applied in systems that have unpredictable (i.e. lexically specified) loci for accents.

To what degree should tone placement and accent placement be allowed to overlap? If, for example, a tonal contrast occurs on the final syllable if it is closed, and otherwise on the penultimate syllable, should we say that there is a quantity-sensitive accent rule and that tones are attracted to the accent, or should we make the tonal association rules quantity-sensitive? The earlier literature on systems in which tone contrast is limited to specific syllables reflects the view that the theory of accent placement should *not* be duplicated in a theory of tone placement, so that in these cases accent is usually seen as placing a role in tonal association.

On the other hand, Haraguchi (1977, 1988, 1991), as we saw in §3.2, makes a sharp distinction between tones that associate to accents and tones that associate directly to tone-bearing units at edges. The latter case involves only strict directional association in his analysis (from right to left, or from left to right). But, if peripheral tone-bearing units can be "extra-tonal," we can expand the set of cases in which tonal association can be direct. However, we do not expect direct tonal association to be dependent on syllable weight distinctions. Hence, if tones are attracted to positions that reflect weight criteria one would be inclined to associate tones to accent which are assigned in a weight-sensitive fashion.

Given the inevitable overlap between accent placement and direct tonal association, Pulleyblank (1986) launched an attack on the use of accents and suggested replacing accents by tones. This approach, discussed in the next section, has since become dominant.

5.2 *Giving up accents*

The direct tone approach was promoted by Pulleyblank (1986) mainly for various African tonal systems and by Poser (1984) for Tokyo Japanese in particular. The most important of Pulleyblank's arguments against the use of stars (cf. Blevins 1993: 238) are as follows. Firstly, using stars and tone makes the system overly rich, in that we now predict rules referring to stars and to tones, and to both at the same time. Secondly, the inherent culminative nature of stars can also be found in systems that are arguably tonal and non-accentual, i.e. the asymmetry between accent and non-accent finds a counterpart in systems in which H tone contrasts with zero (ending up as default L). Another argument that could be mentioned is that accent (if equated with stress) is a property of syllable, whereas stars sometimes need to be assigned to moras. Finally, as we have already mentioned, the existence of unaccented words in accentual systems, or indeed of words with multiple accents which all surface, can be regarded as problematic.

Pulleyblank applied the direct tone approach to a variety of cases, not only cases in which the position of the tone is predictable, but also those where the former accent location is lexically specified; it was subsequently adopted in much other work (Clark 1988; Hyman 1989). We note again that this move entailed the use of phonological features for non-distinctive, i.e. predictable properties. Even though the location of the alleged tone could be a lexical, unpredictable property, the phonetic nature of the entity (high pitch) would nonetheless be predictable.[14]

The abandonment of stars implies, firstly that the systems discussed in §4, where H tone is restricted (perhaps up to the point of being culminative), but not obligatory, are now analyzed as tonal. However, a further-reaching conclusion is that "straightforward" pitch accent systems (discussed in §3), where high pitch is both obligatory and culminative, are also analyzed as tonal, despite the fact that pitch is not distinctive. This may or may not be considered a (conceptual) problem (cf. Clements 2001, 2009). Another issue is of course that we have rules for tonal association which duplicate the theory of accent which is independently needed for non-tonal accent systems.

Abandoning accent cannot make the Scandinavian (and Serbo-Croatian) case purely tonal, since, as mentioned, in these cases we need the notion of stress (accent), independently of the tonal specifications.

5.3 *In defense of accents*

If accents are rejected for pitch accent and restricted tone languages, the term "accent" can simply be abandoned in favor of the term "stress" (for stress accent languages). Hyman (2007) adopts this position, reducing the typology of word

[14] This might suggest a "compromise" position in which "accents" are regarded as unspecified tonal "root nodes." In an approach which adopts a wider use of accents as possible ingredients of stress accent systems, this idea could not be maintained.

prosodic systems to tone languages and stress languages. In this section I will focus on the use of accents in "tonal" systems and suggest a different approach, one which maximizes the use of accents at the expense not just of non-contrastive "tones," but also of (allegedly) contrastive tones.

The issue here does not revolve around languages that have obligatory and culminative high pitch such as Nubi. Here, the case for accent could be considered uncontroversial, if we believe that culminativity and obligatoriness are necessary for an analysis using accent (which essentially means that accent and stress are the same thing). Rather, let us focus on languages in which H tones violate one or both of these two constraints. I will argue that languages of this sort can also be analyzed as accentual (and thus non-tonal), if obligatoriness and culminativity, while perhaps being typical or even necessary for stress, are not required for accent. These points were anticipated in §2.5.

Let us first consider the type of case in which one syllable per word is either H or L, meaning that H is culminative, but *not* obligatory. In an accent-cum-tone analysis we would postulate an accent, and from there we have several options, depending on how we characterize the tonal contrast (H/L, H/zero, zero/L). But there is also another option. We can also analyze the contrast as accent *vs.* no accent (with accent giving rise to phonetic high pitch and low pitch as default). This means that we can analyze these alleged H/L systems as pitch accent systems as long as we "allow" that accentual languages have a class of unaccented words.

Secondly, even when a "H/L" system allows multiple (non-adjacent) "H tones," this does not necessarily enforce a tonal analysis. If neither criterion proposed by Hyman (2007) for stress applies to accent, there is no reason why a word could not have more than one accent.

Concluding, if we push the use of accents to its limits (at the expense of using tones), this implies allowing unaccented words (violating obligatoriness) and multiple accents (violating culminativity). In this liberal view on accent, only languages that have more than a binary pitch contrast are *necessarily* tonal; in addition, we find languages in which culminativity and obligatoriness of accent is independently required (as in the case discussed in §4).

One could say that "H/L" systems are the real pivotal cases, where, as linguists (or as language learners), we have a choice between an accentual and a tonal analysis. There may be certain diagnostics that will tip the balance to either an accentual or a tonal analysis, and these need to be made explicit. More work is called for in this area.

An accentual approach is favored when the distribution of accent falls squarely within a theory of accent placement that is independently needed for stress accent and other types of accentual languages. This, perhaps, makes an accentual analysis of those languages in which the alleged accents need to be assigned to moras undesirable (cf. the case of Somali; Biber 1981; Hyman 1981; Banti 1988). Another diagnostic pointing to tones is the need to refer to *floating tones*, on the assumption that the notion "floating accent" is suspect. Thirdly, it could be argued that tonal spreading processes might suggest tone, but implementational mechanisms can also be held responsible for pitch extending over several syllables. A fourth potential way to discriminate between accent and /H/ tone would be to look at the details of phonetic implementation. One could conceivably argue that the phonetic pitch target of phonological categories like /H/ is more specifically defined than the pitch target of accents. Lastly, an accentual analysis could account for cases in which we need rules that delete apparent accents in clash, or other rules that refer to accents, irrespective of their pitch or "tonal" correlates.

McCawley (1978) suggested that in some cases one might want to say that a system is accentual first, and then becomes tonal in the course of the derivation. The question is, however, whether the tonal end of the derivation is still part of the phonology or part of the phonetic implementation.

In this section I have suggested that accentual systems should be "allowed" to have unaccented words or multiple accented words, or even both. This seems to imply that obligatoriness and culminativity are not necessary properties of accent and that the case in which accents are both obligatory and culminative is just one of four possibilities; see §7.

6 The case of Tokyo Japanese

Tokyo Japanese is a language that is often mentioned as a prime example of a pitch accent system, but differs from both Nubi and Somali, while apparently sharing properties with each. Every word is said to have high pitch, but, at the same time, some words are accented and others are non-accented. Let us first consider the basic facts; references to various types of analyses are offered below.

In Tokyo Japanese, nouns have a specific pitch contour, which in some but not all cases involves LHL. In those words that have the full LHL pattern, the L occurs on the initial mora. This mora is followed by a high plateau, which may drop to low at some point. After the drop, remaining syllables are low. In some words the initial L is missing, and in other words the final L. Thus we find the following patterns, taking trisyllabic nouns to illustrate the possibilities:

(10)	a.	HLL	b.	LHL	c.	LHHL	d.	LHHH
		σσσ		σσσ		σσσ(-σ)		σσσ(-σ)
		inoti		kokoro		atama		sakana
		'life'		'heart'		'head'		'fish'

This system can be and has been analyzed in many different ways; here we will specifically focus on accounting for the difference between (10c) and (10d). For (10a)–(10c) we have three options; depending on which one is chosen, various approaches can be suggested for class (10d):

(11)	(10a)–(10c)	(10d)		
		(i)	(ii)	(iii)
a.	Accent → /H/ → [H]	default accent	/H/ to last σ	implementation
b.	/H/		/H/ to last σ	implementation
c.	Accent → [H]			implementation

In (11a), the accent-cum-tone analysis, the (10d) case would be lexically unaccented. Since such words surface with an apparent H tone throughout (except for the initial mora), one could consider assigning a default final accent (11.i), which then triggers an H tone. This analysis encounters a problem, however. Words that have no lexical accent must be identifiable as such in the phonetic interpretation because there is a phonetic difference between (10c) and (10d). Roughly speaking, (10c) is LHH and (10d) is LHM, with the stem-final "H" in the latter not quite as high as the other Hs in both examples. The two types of words also have different effects on following words (or "accentual phrases") inside the Intermediate Phrase: (10c) causes downstep, (10d) does not; cf. Haraguchi (1988); Pierrehumbert and Beckman (1988); Gussenhoven (2004). Alternative (ii), which would use the H tone assignment rule in (12), resolves this issue, because it can be argued that a H tone on an accented syllable and a H tone on an unaccented syllable are interpreted differently (cf. (5a)):

(12) Assign /H/ to the first accent or, if there is no accent, to the final syllable.[15]

The difference between (10c) and (10d) could also be described if the pitch properties of the latter class are entirely accounted for in terms of phonetic implementation (11.iii), since this system could respond to the presence *vs.* absence of an accent.

In the second (tone-only) approach, (10d) should be accounted for by method (iii), since method (ii), available in principle, would wrongly conflate (10c) and (10d), as there is no longer an accent to differentiate between them. Finally, in the third method, (11c) (accent only), both classes *must* be differentiated in the phonetic implementation: accent is interpreted as high pitch, while lack of accent is interpreted differently, although also in terms of elevated pitch.

I have briefly discussed three different approaches to a system such as that of Tokyo Japanese nouns, namely those mentioned in (11). All three approaches have been defended in the literature in one form or another. The tone accent approach (although often *called* "pitch accent approach"), (11a), comes closest to the analysis offered in McCawley (1968). Lexically, the language is accentual, but in the course of the derivation (presumably at the word level) tone is added, and from that point on the language is tonal. This approach was adopted as part of the autosegmental analysis of languages like Japanese and other monomelodic systems (cf. Goldsmith 1976b; Haraguchi 1977, 1988). The tone-only approach, (11b), has been advocated by Meeussen (1972), Poser (1984), Pulleyblank (1986), Clark (1987), and Pierrehumbert and Beckman (1988). Lockwood (1983) is a clear representative of (11c), the pitch accent analysis.

To what extent do these linguists recognize the possibilities in (11), other than the one that they propose for Japanese, as valid for other languages? Clark (1988) rejects (11a) as a theoretical option, but claims that (11c) represents an independent possibility, alongside (11b). She makes a distinction between restricted tonal systems, i.e. (11b), and metrical pitch accent systems, i.e. (11c). The difference between the two types is claimed to be that only metrical pitch accent systems have the characteristics that we also find in non-tonal accent languages with respect to accent location (e.g. influence of syllable weight) and other phonetic cues that occur as the manifestation of accent. In her restricted tonal languages, the alleged accent is simply a tone at every level of representation (Clark 1988: 52). An argument for analyzing Tokyo Japanese as tonal would be the fact that we have words like (10d), distinct from (10c). In a tonal analysis, this difference is expected, since words do not have to have a tone. But in an accentual analysis,

15 Here I have added "first" to the rule because, if a word ends up having more than one accent, it is always the leftmost accent that attracts the H tone.

prosodic boundaries. We can, if accents have high pitch, first assign [H] to accent and then do the actual implementation. The same applies to boundaries; we can assign a [H] to the left boundary of a certain type of prosodic phrase. Strictly speaking, we only do this in order to make the implementation rules refer to only one type of entity (namely tonal entities, whether phonetic or phonological) instead of to three different types of entities (tones, accents, and boundaries). In any event, it would seem that the pitch profiles of Tokyo Japanese words do not require reference to word-level tones.

7 Accent and stress

A discussion of pitch accent systems forms part of the broader discussion of word prosodic systems. However, having made reference in the preceding sections to a view that recognizes both accent and stress as independent notions, this section will briefly discuss their properties and interaction.

We might entertain the idea that the alleged accents in Tokyo Japanese are simply "marks" which are to be compared to syllable weight. If this comparison holds, we might refer to the accents as "diacritic weight marks" and in that case there is no reason for every word to have one such mark, just as languages that have a contrast between CV (light) and CVX (heavy) syllables typically do not necessarily demand that each word has a "heavy syllable." Nor, for that matter, do we expect words to have only one "accent," since words also can have more than one heavy syllable. This interpretation of "accents" explains the occurrence of unaccented words and multiple accented words in specific systems.

A problem with this approach is that weight diacritics have characteristics that are more reminiscent of "stress" than of heavy syllables, notably predictability. This can be illustrated by taking a closer look at the accentual system of Tokyo Japanese. See CHAPTER 120: JAPANESE PITCH ACCENT, where it is shown that the Tokyo Japanese accent rule is very similar to the Latin-style English accent rule.

We now have a new problem. If the Tokyo Japanese accents are like weight, (a) why is their distribution predictable by rule, and (b) why is the rule so similar to the typical "stress" placement rules? And why are there accentual systems in which accent is culminative and/or obligatory? To resolve these issues, van der Hulst (2009, 2010c) proposes to account for accent and "rhythm," which traditional metrical theories conflate in one representation, in two different modules. The accentual module accounts for the location of so-called primary accent or primary "stress" in systems where this location shows influence of lexical factors (exceptions, morphological classes, etc.), while the rhythmic module associates words with metrical structures. This separation of tasks allows a simpler version of the metrical system, which, as van der Hulst shows, cannot handle all varieties of primary accent locations in bounded systems and is simply not designed to deal with accent locations in unbounded systems.

The theory of accent that has been suggested is "liberal," in that accent is required neither to be culminative nor obligatory. While this allows four different kinds of pitch accentual systems, it might be argued that we now predict four kinds of *any* sort of accent system, whatever the cues for accent. Focusing on the specific case of stress accent languages, Hyman (2009) argues that in such systems "stress" is always culminative and obligatory.

of accent) if, at the same time, cases in which accent is cued by non-distinctive duration or vowel quality are *not* analyzed as involving lexical specification of length or of non-distinctive vowel features?

ACKNOWLEDGMENTS

I would like to thank Carlos Gussenhoven, Marc van Oostendorp, Keren Rice, and two anonymous reviewers for valuable comments on earlier drafts of this chapter.

43 Extrametricality and Non-finality

Brett Hyde

1 Introduction

Extrametricality and *non-finality* are often treated as two terms that refer to the same principle of final stress avoidance, the former being implemented in a rule-based framework and the latter being implemented in a constraint-based framework. The labels and native frameworks of the two approaches, however, do not constitute the full extent of their differences. As Prince and Smolensky (1993) explain, extrametricality focuses on the parsability of prosodic constituents, while non-finality focuses on the position of stress peaks. Extrametricality is concerned primarily with dominance relations, and non-finality is concerned primarily with prominence relations.

Liberman and Prince (1977) introduced extrametricality in their foundational work on metrical stress theory to capture the apparent exclusion of certain English suffixes from the domain of stress rules.[1] Recognizing the potentially wide range of applications, Hayes (1980) proposed the general formulation for extrametricality rules in (1), where the initial or final constituent of a particular domain is designated as extrametrical.

(1)

$$C \rightarrow [+\text{extrametrical}] \; / \; \left\{ \begin{array}{l} \_\_\_\,]_D \\ {}_D[\, \_\_\_ \end{array} \right\}$$

The result of extrametricality is essentially invisibility to the application of subsequent rules. When a constituent is designated as extrametrical, it is excluded from the domain of rules that might incorporate it into higher levels of prosodic structure. An extrametrical segment cannot be associated with a mora; for example, an extrametrical syllable cannot be footed, and an extrametrical foot cannot be included in a prosodic word.

[1] Liberman and Prince introduce the notion of extrametricality to account for the apparent invisibility to stress rules of final *-y* in English: "From our point of view, *-y* functions as a kind of 'extrametrical' syllable; it simply does not take part in the metrical calculation" (Liberman and Prince 1977: 293). Later in the same paragraph: "*-y* is effectually *hors de combat* in the basic determination of metrical structure."

As part of his general approach, Hayes proposed four restrictions on extrametricality. The first, *constituency*, ensures that only constituents – segments, syllables, feet, affixes, and so on – can be designated as extrametrical. *Peripherality* restricts extrametrical constituents to the edges of a domain, while *edge markedness* prefers that they occur at the right edge. Finally, *non-exhaustivity* ensures that extrametricality cannot exhaust the domain of a rule, preventing it from applying altogether.

Prince and Smolensky (1993) incorporated similar restrictions into non-finality when they presented it as a replacement for extrametricality as part of their initial work on Optimality Theory. As (2) indicates, non-finality only applies at the edge of a domain (peripherality), and it only applies at the right edge in particular (edge markedness). The stress peaks that must avoid the right edge are prosodic categories (constituency) that are the heads of larger categories.

(2) *Head-based non-finality*

No head *Cat1* of a *Cat2* occurs in final position in *Cat3* (where *Cat1*, *Cat2*, and *Cat3* are prosodic categories).

The effect of non-finality constraints is to prevent prominent categories – the heads that represent stress peaks – from occurring at the right edge of a domain. Non-finality might prevent the head moras of syllables from occurring at the right edges of feet, for example, or head syllables of feet from occurring at the right edge of a prosodic word.

Although it is usually a simple matter to distinguish non-finality from extrametricality, some approaches do exhibit characteristics of both. This is especially true of approaches that target relationships between final constituents and entries on the metrical grid, the classical device for representing stress patterns (see CHAPTER 41: THE REPRESENTATION OF WORD STRESS). As (3) indicates, the non-finality constraints of Hyde (2003) prohibit stress peaks – grid entries – in final position, but they specify a particular final constituent that stress must avoid.

(3) *Grid-based non-finality*

No *Cat1*-level grid entry occurs over the final *Cat2* of *Cat3* (where *Cat1*, *Cat2*, and *Cat3* are prosodic categories).

Under the grid-based approach, a non-finality constraint might prevent foot-level grid entries (secondary stress) from occurring over the final mora of a foot, for example, or prosodic word-level entries (primary stress) from occurring over the final foot of a prosodic word.

The grid-based non-finality approach is like the head-based approach, then, in that it focuses on stress peaks, but it is similar to an extrametricality approach in that it excludes a particular final element from associating with some structure (in this case, certain levels of the metrical grid). A similar mixture of characteristics can be found in approaches that are typically considered extrametricality approaches. Since the grid-based account of Prince (1983) lacked feet, for example, the effect of extrametricality was to prevent syllables from mapping to the metrical grid – in other words, from associating with a stress peak – rather than to prevent them from being footed.

from left to right. With the final syllable extrametrical, the last two syllables in an even-parity form cannot form an iambic foot, so the expected final stress fails to appear. The difference between the two languages would be that Aguaruna tolerates degenerate feet – and can parse the penult as a degenerate foot after iambic footing is no longer possible – but Choctaw does not. Since Aguaruna can parse the penultimate syllable as a degenerate foot, as (6) illustrates, the expected final stress shifts to the penult.

(6) *Aguaruna extrametricality analysis*

		extrametricality		parsing
i.ʧi.na.ka	→	i.ʧi.na⟨ka⟩	→	(i.ˈʧi)(ˌna)⟨ka⟩

Since Choctaw cannot parse the penult as a degenerate foot, however, as (7) illustrates, the expected final stress is absent altogether.

(7) *Choctaw extrametricality analysis*

		extrametricality		parsing
ʧi.pi.sa.li	→	ʧi.pi.sa⟨li⟩	→	(ʧi.ˈpi)sa⟨li⟩

For additional, and more detailed, extrametricality analyses of final stress avoidance, see Halle and Vergnaud (1987) and Hayes (1995).

A non-finality approach produces the same patterns, although a bit more directly, simply by prohibiting stress at the right edge of the word. Head-based non-finality, where heads represent stress, prohibits the head syllable of a foot from occurring in final position. Grid-based non-finality, where grid entries represent stress, prohibits a foot-level gridmark from occurring over the final syllable. In either case, prohibiting final stress effectively prohibits a final iambic foot.

The difference between Aguaruna and Choctaw is in the options that they employ to avoid a final iamb. As (8) illustrates, Aguaruna employs a final trochaic foot, shifting the expected final stress to the penult. Notice that the non-finality analysis does not necessarily require underparsing like the extrametricality analysis. (In (8) and examples throughout, the expression "X >> Y" indicates that X is more harmonic than Y or that some constraint, in this case non-finality, prefers X to Y.)

(8) *Aguaruna non-finality analysis*

	non-finality	
(i.ˈʧi)(ˌna.ka)	>>	(i.ˈʧi)(na.ˌka)

In contrast, as (9) illustrates, Choctaw prefers to leave its final two syllables unparsed in order to avoid a final iamb.[3]

(9) *Choctaw non-finality analysis*

	non-finality	
(ʧi.ˈpi)sa.li	>>	(ʧi.ˈpi)(sa.ˈli)

[3] An alternative to leaving the final two syllables unparsed is to parse them into a stressless foot: (ʧi.ˈpi)(sa.li). See Hyde (2002) for discussion.

See Hyde (2002, 2003) for more detailed grid-based non-finality analyses of final stress avoidance, and McCarthy and Prince (1993) and Kenstowicz (1995) for more detailed head-based non-finality analyses.

In this section, then, we have seen that extrametricality and non-finality provide equally effective analyses for the avoidance of stress on final syllables. Both approaches account for cases where a binary stress pattern is perturbed at the right edge, whether the final stress arrives early or is absent altogether.

3 Final feet

Another important use of extrametricality and non-finality has been to prevent primary stress from occurring over a word-final foot. In the clearest examples of the phenomenon, the primary stress is the penultimate stress, the presence of a secondary stress further to the right being the clearest indication that there is a final foot that primary stress might have occupied.

Consider Banawá (Buller *et al.* 1993; Everett 1996, 1997) and Paumari (Everett 2003). In Banawá, consonant-initial words have a trochaic pattern, and vowel-initial words have an iambic pattern. In both the trochaic pattern and the iambic pattern, however, the primary stress is the penultimate stress. The secondary stress that follows indicates that there is a final foot that primary stress might have occupied if it had been drawn as far to the right as possible.

(10) *Primary stress in Banawá*

a.	aˈbariˌko	'moon'
b.	ˌmetuˈwasiˌma	'find them'
c.	ˌtinaˈrifaˌbune	'you are going to work'

The primary stress is also the penultimate stress in the consistently iambic Paumari, indicating the presence of a final foot that primary stress has avoided.

(11) *Primary stress in Paumari*

a.	kaˈbahaˌki	'to get rained on'
b.	ˌahaˈkabaˌra	'dew'
c.	aˌtʰanaˈrariˌki	'sticky consistency'
d.	biˌkanaˌtʰaraˈraviˌni	'to cave in, to fall apart quickly'

It is a relatively simple matter to produce the Banawá and Paumari patterns with either extrametricality or non-finality. In the extrametricality approach, a word-final foot is designated as extrametrical, excluding it from the prosodic word. As (12) illustrates, when a right-headed prosodic word is constructed, it positions the primary stress over the penultimate foot, rather than the final.

(12) *extrametricality* *word layer*

( x   )( x   )( x    ) → ( x   )( x   )⟨( x    )⟩ → ( x   )( x   )⟨(x     )⟩
 ti na  ri fa  bu ne      ti na  ri fa   bu ne       ti na  ri fa   bu ne
```

The non-finality approach produces a similar result, although it does not require that final feet be excluded from the prosodic word. Head-based non-finality avoids primary stress on final feet by prohibiting head feet from occurring in final position. Grid-based non-finality prohibits a prosodic word-level gridmark from occupying the final foot.

(13) *non-finality*

```
(       x          )    (             x    )
( x   )( x   )( x    )   ( x   )( x   )( x    )
 ti na  ri fa  bu ne >>  ti na  ri fa  bu ne
```

In either case, the primary stress and the foot associated with it are pushed back from the right edge. As a result the primary stress is the penultimate stress, and the associated foot the penultimate foot.

It should be noted at this point that many of the examples cited in the literature on primary stress avoiding final feet are not as compelling as those discussed above. Hayes (1995) presents several languages as potential examples of foot extrametricality: Bedouin Arabic (Blanc 1970), Cayuga (Chafe 1977; Foster 1982; Michelson 1988), Delaware (Goddard 1979, 1982), Eastern Ojibwa (Piggott 1980, 1983), and Palestinian Arabic (Kenstowicz and Abdul-Karim 1980; Kenstowicz 1983). McCarthy (2003) points out, however, that these are not especially clear cases, because no secondary stress has been reported in a position associated with the supposed extrametrical foot. While McCarthy's point overreaches a bit – Piggott (1983) reports post-tonic secondary stresses in Ojibwa, and patterns of reduction and non-reduction suggest post-tonic feet in Delaware – it is true of many of the traditional examples. As Banawá and Paumari demonstrate, however, the avoidance of stress on final feet is still one of the important functions performed by extrametricality and non-finality.

4 Final moras

The avoidance of final moras can make stress sensitive to the weight of syllables generally or to the weight of domain-final syllables (see CHAPTER 57: QUANTITY-SENSITIVITY). As we shall see below, non-finality offers a relatively straightforward analysis in such cases. §4.1 demonstrates how avoidance of syllable-final moras promotes general weight-sensitivity, §4.2 how avoidance of prosodic word-final moras promotes sensitivity to the weight of prosodic word-final syllables, and §4.3 how avoidance of foot-final moras promotes rhythmic lengthening. §4.4 examines the difficulties confronting extrametricality analyses.

4.1 General weight-sensitivity

A fairly common type of weight-sensitivity is the type where stress avoids light syllables. It has been addressed, for example, using the Obligatory Branching Parameter (Hayes 1980) of classical metrical theory and the PEAK-PROMINENCE (Prince and Smolensky 1993) and STRESS-TO-WEIGHT (Hammond and Dupoux 1996; Lorentz 1996) constraints of Optimality Theory. As Hyde (2006, 2007b) demonstrates, Similarly, the Aguacatec pattern would emerge when non-finality in the syllable takes precedence over rightward orientation.

Moraic non-finality constraints applied to the syllable domain, then, have the same effect as Obligatory Branching, PEAK-PROMINENCE and STRESS-TO-WEIGHT. One point that favors the non-finality approach over the others is that non-finality constraints are motivated by their usefulness in a much wider range of contexts – the avoidance of stress on final syllables (§2) and feet (§3), for example – many of which have nothing to do with syllable weight.

4.2 *Weight-sensitivity in word-final syllables*

In this section, we examine the situation where stress is sensitive to the weight of prosodic word-final syllables only. To make stress sensitive to the weight of prosodic word-final syllables, all that is necessary is to require that prosodic word-final moras be stressless. When word-final moras cannot be stressed, stress can occupy a heavy final syllable, but it cannot occupy a light final syllable.

One situation where stress is sensitive to the weight of prosodic word-final syllables only arises in syllabic trochee systems. Consider the case of Wergaia (Hercus 1986), where heavy syllables are syllables with long vowels (typically limited to initial position), syllables with diphthongs (limited to initial or final position), and closed syllables. As (17) illustrates, Wergaia stress is largely weight-insensitive. It falls automatically on every odd-numbered syllable counting from the left, except the final syllable. Stress falls on final syllables only if they are odd-numbered and heavy, as in (17f) and (17g). It avoids final syllables if they are light, as in (17d) and (17e).

(17) *Avoidance of final light syllables in Wergaia*

a.	ˈLL	ˈwuru	'mouth'
b.	ˈHL	ˈŋaːri	'oak tree'
c.	ˈLH	ˈŋarau	'wild turkey'
d.	ˈHLL	ˈmaːbila	'to tell lies'
e.	ˈLHL	ˈdaguŋga	'to punch someone'
f.	ˈLLˌH	ˈbunaˌɖug	'broad-leaved mallee'
g.	ˈLLˌH	ˈwaɲaˌgai	'catfish'
h.	ˈLLˌLL	ˈbunaˌmala	'fine-leaved mallee'
i.	ˈLLˌLH	ˈwuregˌwuraŋ	'speaking together, gabbing'

In Hyde's (2007b) grid-based non-finality approach, the Wergaia pattern emerges when it is more important that foot-level gridmarks avoid prosodic word-final moras than it is that feet contain a stressed syllable. When the final syllable of an odd-parity form is light, stress cannot occur on the final syllable without occurring on the final mora, so the final foot emerges without a stress, as in (18).

(18) *Moraic non-finality preferences in the prosodic word*

```
( x      )( )     ( x      )(x)
  μμ   μ  μ  >>    μμ   μ  μ
 maa . bi . la    maa . bi . la
```

When the final syllable is heavy, however, stress can occupy the final syllable without occupying the final mora, so the final foot emerges with a stress, as in (19).

(19)
```
( x      )( x )
  μ   μ   μμ
 wa . ɲa . gai
```

The same result can be produced in a more standard structural framework when non-finality in the prosodic word takes precedence over the constraints that require syllables to be parsed into feet. Odd-parity forms with a light final syllable would emerge with the final syllable unparsed and stressless. Odd-parity forms with a heavy final syllable would emerge with the final syllable parsed and stressed. The result can also be produced with head-based non-finality by prohibiting the head mora of a foot from being final in the prosodic word.[5]

4.3 *Rhythmic lengthening*

Non-finality can be used not only as a simple detector of syllable weight – the use focused on in §4.1 and §4.2 – but also as a trigger to increment syllable weight. When stress would fall on an underlyingly light syllable, non-finality can force the syllable to become heavy on the surface. Rhythmic lengthening is an example of this effect. It results from avoidance of stress on foot-final moras or syllable-final moras.

There are two types of rhythmic lengthening: iambic lengthening and trochaic lengthening. The former adds a mora to the stressed syllable of an iamb; the latter adds a mora to the stressed syllable of a trochee. The iambic type appears to occur more frequently than the trochaic type (Hayes 1985, 1987, 1995; Kager 1993; CHAPTER 44: THE IAMBIC–TROCHAIC LAW), but both are well attested. Iambic lengthening can be found in Carib (Hoff 1968), for example. As (20) illustrates, Carib lengthens even-numbered syllables counting from the left, but not the final syllable, producing a fairly typical iambic pattern.

(20) *Iambic lengthening in Carib*

a.	tonoro	→ tono:ro	'large bird'
b.	kurijara	→ kuri:jara	'canoe'
c.	woturoporo	→ wotu:ropo:ro	'cause to ask'
d.	woturopotake	→ wotu:ropo:take	'I shall ask'

Trochaic lengthening can be found in Chimalapa Zoque (Knudson 1975), a dual stress language based on trochaic footing. In Chimalapa Zoque, stress occurs on the initial syllable and the penult, with the stress on the penult being primary. As (21) illustrates, every stressed syllable must be heavy on the surface. When an underlyingly light syllable is stressed, the syllable is made heavy by lengthening its vowel.

[5] An alternative approach is to rely on a foot minimality requirement to distinguish between light and heavy final syllables. This is essentially the approach adopted by Hayes (1995). As Hyde (2007b) points out, however, such an approach produces the same type of weight-sensitivity in non-final syllables, as well, where it is, unfortunately, unattested.

(25) a. *Final* CV

i. *Preceding consonant stray*

```
( x        )
  μ     μ   ⟨μ⟩
[CV] [CV] CV
```

ii. *Preceding consonant as coda*

```
( x          )
  μ      μ   ⟨μ⟩
[CV] [CVC] V
```

b. *Final* CVC

```
( x         )(  x)
  μ      μ      μ ⟨μ⟩
[CV] [CV] [CV] C
```

Hayes does not actually consider this second option and, therefore, does not reject it explicitly. Its rejection is implied, however, by his assumption that extrametricality never prevents syllabification. Unfortunately, he only justifies the assumption as it relates to extrametrical consonants, but there do seem to be good reasons for applying it to extrametrical moras as well.

The analysis presents some fairly obvious problems in CV-final words. When the final mora and its associated vowel remain unsyllabified, there are essentially two options for dealing with any consonants that would otherwise be part of the final vowel's onset. First, they might be left stray, as in (25a.i), in which case they would be subject to Stray Erasure and deleted (see §6.3). The result would be a language where final CVC and CVV sequences are preserved and their vowels stressed but final CV sequences have their consonants deleted and their vowels left stressless. To my knowledge, such an outcome is unattested. Second, preceding consonants might be incorporated into the preceding syllable as a coda, as in (25a.ii). The result would be a language where final CVV and CVC sequences always have their consonants syllabified as onsets and their vowels stressed but final CV sequences always have their consonants syllabified as codas and their vowels left stressless. To my knowledge, this outcome is also unattested.[6]

There is an additional, primarily theoretical, reason for rejecting extrasyllabic moras, not only in the particular situation under consideration, but in all situations. Moras are unique in that the primary motivation for including them in the prosodic hierarchy in the first place is to provide an effective representation of syllable weight, a function that cannot be performed outside the syllable.

Neither of the options that might be used to achieve the desired results under an extrametricality approach, then, appears to be viable.

5 Final consonants

Evolved from proposals by Mohanan (1979) and Hayes (1980), traditional consonant extrametricality rules prevent word-final consonants from having moraic status and, therefore, from contributing to the weight of final syllables. The result is that final syllables that end in a consonant are lighter than we would otherwise

[6] Similar arguments can be made against proposals that involve extrasyllabic moras acting as a sort of prosodic licenser for otherwise stray segments in order to protect them from deletion through Stray Erasure (Downing 1993; Everett 1996). Although such licensing has only been employed at the left edge, there would seem to be nothing to prevent it applying at the right edge, as well, leading to the results illustrated in (25).

expect. As (26) illustrates, final CV and CVV are unaffected. Final CVC, CVVC, and CVCC, however, are all lighter than they would be otherwise. Final CVC, normally bimoraic, emerges as monomoraic and counts as light. Final CVVC and CVCC, normally trimoraic, emerge as bimoraic and count as heavy.

(26) *Weight contrasts under consonant extrametricality*

a. *Light syllables*

i.	μ CV	ii.	μ CV⟨C⟩

b. *Heavy syllables*

i.	μμ CVV	ii.	μμ CVV⟨C⟩	iii.	μμ CVC⟨C⟩

Among the languages that have been argued to exhibit consonant extrametricality are English (Hayes 1982), various dialects of Arabic (McCarthy 1979; Hayes 1995), Ancient Greek (Steriade 1988), Spanish (Harris 1983), and Estonian (Hint 1973; Prince 1980). Examples from Estonian are provided in (27).

(27) *Final syllables in Estonian*

a. ˈkavaˌlatt 'cunning'
b. ˈpaheˌmait 'worse (PART PL)'
c. ˈpimestav 'blinding'
d. ˈpimesˌtavale 'blinding (ILL SG)'

Like Wergaia, Estonian automatically stresses every odd-numbered syllable except the final syllable. Final syllables are stressed only if they are heavy, as in (27a) and (27b). When a final syllable is light, as in (27c) and (27d), it is unstressed. Since final CVV, CVVC, and CVCC are always stressed, they must pattern together in counting as heavy. Since final CV and CVC are always stressless, they must pattern together in counting as light. This is exactly the division predicted by consonant extrametricality.

Since moras are not stress peaks, non-finality cannot directly prohibit moras from associating with final consonants. Non-finality can only affect a final consonant's moraic status by referring to a stress peak that coincides with moras. The success of a non-finality approach, however, depends crucially on the representation of stress peaks. Under head-based non-finality, no stress peak coincides with moras generally. A mora coincides with a stress peak only if it is a head mora, and banning head moras from final position does not ban all moras.[7] In contrast,

[7] As an anonymous reviewer points out, the claim that head-based non-finality cannot prevent final consonants from being moraic depends on the assumption that moras – unlike the higher prosodic categories – do not have heads. If moras have head segments, as argued by de Lacy (1997), then final consonants might be prevented from being moraic by prohibiting head segments from being final in the prosodic word. There are several arguments against this approach, however, one of which is that segments are not constituents of moras in the usual sense. It is often the case that multiple moras are associated with single segments. In such cases, not only would each mora have exactly the same single constituent, but it would also have exactly the same head. Neither situation is tolerated at higher prosodic levels, even in fairly permissive theories, like Hyde (2002), that allow prosodic categories to share constituents.

assuming that moras map to the base-level of the grid, there are stress peaks that coincide with moras generally under grid-based non-finality. By prohibiting base-level gridmarks from occurring over prosodic-word final consonants, non-finality can prevent final consonants from associating with moras.

To illustrate, when it is more important for final consonants to avoid associating with base-level gridmarks than it is for coda consonants to be moraic, final consonants will give up their moraic status to avoid associating with base-level gridmarks. Final CVC syllables emerge as monomoraic and light, and final CVVC and CVCC syllables emerge as bimoraic and heavy, resulting in the same weight distinctions among final syllables as those created by consonant extrametricality.

(28) *Consonantal non-finality preferences*

```
a.   x            x x
     μ     >>     μ μ
    CVC           CVC

b.   x x          x x x
     μ μ   >>     μ μ μ
    CVVC          CVVC

c.   x x          x x x
     μ μ   >>     μ μ μ
    CVCC          CVCC
```

Given its parsability focus, then, the extrametricality analysis is the most straightforward for cases like Estonian. Since it makes final consonants invisible to the process of mora assignment, consonant extrametricality produces the desired weight distinctions in a fairly direct fashion. While it is also possible to provide a non-finality analysis, it is only possible to do so with a grid-based approach.

For additional discussion of this and other issues concerning final consonants, see CHAPTER 36: FINAL CONSONANTS.

6 The classic arguments

We turn now to some of the classic arguments marshaled in support of extrametricality and briefly consider whether or not they also provide support for non-finality. Below we consider three of extrametricality's traditional uses: establishing trisyllabic stress windows, helping to capture generalizations about the stress patterns of different lexical classes, and helping to provide a general account of the deletion of unsyllabifiable segments.

6.1 *Eliminating ternary foot templates*

In many languages, a word's final three syllables form a domain that is crucial in creating the appropriate stress pattern. The most direct option for creating such a domain – establishing it with a trisyllabic foot – has the disadvantage of making it necessary to expand the foot inventory beyond the well-motivated binary templates to include less well-motivated ternary templates. As Hayes (1980) demonstrates, a less direct extrametricality approach allows us to maintain the smaller inventory. It allows the theory to create trisyllabic windows using a binary foot followed by an unparsed syllable.

Consider the stress pattern of Latin. In Latin words of at least three syllables, stress falls on either the antepenult or penult, depending on the weight of the latter. If the penult is heavy, it is stressed; otherwise, the antepenult is stressed.

(29) *Trisyllabic stress window in Latin*

a.	L'HH	a'miːkus	'friend (NOM SG MASC)'
b.	LH'HH	moneː'baːmus	'warn (1PL IMPERF INDIC ACT)'
c.	L'LLH	ko'mitium	'the election site in the forum (NOM SG)'
d.	L'HLH	do'mestikus	'domestic (NOM SG MASC)'

Without extrametricality, the Latin pattern requires the quantity-sensitive ternary template (σ́ L σ) to establish the appropriate trisyllabic domain at the right edge. When the penult is light, the template is used to construct a ternary foot at the right edge of the word, resulting in antepenultimate stress. When the penult is heavy, however, the template allows only a binary foot, resulting in penultimate stress.

(30) *Ternary foot analysis*

			parsing
a.	do.mes.ti.kus	→	do('mes.ti.kus)
b.	mo.neː.baː.mus	→	mo.neː('baː.mus)

Extrametricality makes the ternary template unnecessary, allowing the trisyllabic domain to be formed with an unparsed syllable and a maximally disyllabic foot. The unparsed syllable is the result of syllable extrametricality. The maximally disyllabic foot is produced with the quantity-sensitive template (σ́ L). If the penult is light, as in (31a), the template allows for a disyllabic foot at the right edge. In combination with the extrametrical syllable, the result is stress on the antepenult. If the penult is heavy, however, as in (31b), the template only allows for a monosyllabic foot, resulting in stress on the penult.

(31) *Extrametricality analysis*

			extrametricality		*parsing*
a.	do.mes.ti.kus	→	do.mes.ti⟨kus⟩	→	do('mes.ti)⟨kus⟩
b.	mo.neː.baː.mus	→	mo.neː.baː⟨mus⟩	→	mo.neː('baː)⟨mus⟩

As Prince and Smolensky (1993) demonstrate, a head-based non-finality approach can also construct trisyllabic domains from a binary foot and an unparsed syllable. When it is more important for the head foot to avoid final position than it is for the head foot to occur as far to the right as possible, the desired pattern emerges.

(32) *Head-based non-finality analysis*

		non-finality	
a.	do('mes.ti)kus	>>	do.mes('ti.kus)
b.	mo.neː('baː)mus	>>	mo.neː.baː('mus)

With the head foot pushed back from the right edge by non-finality, a disyllabic foot positions stress on the antepenult when the penult is light, and a monosyllabic foot positions it on the penult when the penult is heavy.

In the case of Latin, extrametricality and head-based non-finality have a very similar effect. They both result in the final syllable being left unparsed. The similarity arises because the stress peak that must avoid final position in the non-finality analysis happens to be a foot, the head foot of the prosodic word. If the head foot must be the rightmost foot but cannot be final, then the final syllable must remain unfooted, the very situation demanded when a final syllable is made extrametrical.

Two points should be kept in mind, however. The first is that grid-based non-finality is unable to produce this same result. Since stress peaks do not double as prosodic constituents, grid-based non-finality cannot require that final syllables remain unfooted.[8] Second, as Hyde (2008) points out, even head-based non-finality does not offer a general approach to trisyllabic stress windows. It is unable to produce the stress window of Macedonian (Comrie 1976), for example. An alignment-based analysis actually provides a more successful general approach.

For a discussion of ternary stress intervals more generally, not just those limited to word edges, see CHAPTER 52: TERNARY RHYTHM.

6.2 *Similarities between lexical classes*

In many languages, one class of lexical items exhibits one stress pattern, while a different class exhibits a slightly different pattern. In many cases, the difference can be reduced to an extrametricality effect that one class exhibits and the other does not. Once the extrametricality effect is recognized, the similarities between the patterns become apparent, and it is possible to address both with a more unified approach. English (Hayes 1982), Spanish (Harris 1983), and Yawelmani (Archangeli 1984) are among the languages where extrametricality has played an important role in this context. English is used to illustrate below.

At first glance, English verbs and nouns seem to have very different stress patterns. In verbs, the position of stress depends on the shape of the final syllable. If the ultima is CVV, CVVC, or CVCC, the ultima is stressed. If the ultima is CV or CVC, the penult is stressed.

[8] As an anonymous reviewer points out, whether or not grid-based non-finality can prevent the final syllable from being footed depends on the particular structures that are assumed to be the constituents of feet. If feet are actually built on base-level gridmarks, rather than syllables, preventing the final syllable from mapping to a base-level gridmark would also prevent it from being footed. The grid-based non-finality approach presented here, however, assumes that metrical structure and prosodic structure are independent, so that feet are built on syllables. Under this approach, the failure of a final syllable to map to the grid would not prevent it from being footed.

(33) *English verbs*

o'bey	de'velop
a'tone	as'tonish
tor'ment	

In nouns, the position of stress depends on the weight of the penult. If the penult is heavy, stress appears on the penult. Otherwise, it appears on the antepenult.[9]

(34) *English nouns*

a'genda	A'merica
e'litist	'discipline
Ari'zona	'labyrinth

As Hayes (1982) demonstrates, the difference between verbs and nouns is that they show the effects of two different types of extrametricality. The verb pattern is influenced by consonant extrametricality, the evidence being the characteristic weight distinctions among final syllables (see §5). The noun pattern is influenced by syllable extrametricality, the evidence being the presence of a trisyllabic stress window (see §6.1).

Once we allow for the two different types of extrametricality, the correct patterns emerge for both verbs and nouns when we use the quantity-sensitive binary template (σ́ L) to construct a foot at the right edge. In verbs, the (σ́ L) template positions stress on the penult when the ultima emerges as light, once the effects of consonant extrametricality have been taken into account. It positions stress on the ultima when the ultima emerges as heavy.

(35) *English verbs and consonant extrametricality*

```
a.                              ( x        )
      μ    μ    μ       →     μ    μ    μ
      de . ve . lo⟨p⟩         de . ve . lo⟨p⟩

b.                               ( x    )
      μμ    μμ          →     μμ    μμ
      tor . men⟨t⟩            tor . men⟨t⟩
```

Once syllable extrametricality excludes final syllables from the foot layer in nouns, the same (σ́ L) template positions stress on the antepenult when the penult is light. It positions stress on the penult when the penult is heavy.

(36) *English nouns and syllable extrametricality*

```
a.                        →     ( x     )
      A . me . ri ⟨ca⟩          A . me . ri ⟨ca⟩

b.                        →     ( x )
      a . gen ⟨da⟩              a . gen ⟨da⟩
```

[9] This generalization applies to English nouns with a stressless final syllable. Nouns with final stress must be treated differently.

Extrametricality, then, allows us to extract the aspects of the English verb and noun patterns that differ, in order to capture the similarities in a single general stress rule. The analysis consists of two independently motivated extrametricality rules, the source of the differences, and a single, general stress rule, the source of the similarities. If extrametricality were unavailable, we would be forced to incorporate its effects directly into separate stress rules for verbs and nouns, making both that much more complicated and obscuring the similarities between the patterns.

It is not a straightforward matter to reproduce the extrametricality analysis in this case with a non-finality analysis. As mentioned in §6.1, head-based non-finality can produce the type of stress window found in Latin and in English nouns, but grid-based non-finality cannot. As mentioned in §5, however, grid-based non-finality can reproduce the consonant extrametricality effect seen in English verbs, but head-based non-finality cannot. Although non-finality could, in principle, help to capture similarities between the stress patterns of different lexical classes, then, its success depends very much on the facts of the particular case.

6.3 Licensing segments

Itô (1986) puts extrametricality to a use that is quite different from those discussed thus far. In the types of effects discussed above, extrametricality makes a domain-final constituent invisible to rules that create prosodic structure. Itô, however, uses extrametricality to make domain-final segments invisible to Stray Erasure (Harris 1983), a rule that deletes unsyllabified segments. The result is a theory of syllabification that relies on general, rather than idiosyncratic, deletion rules.

As a simple illustration, consider deletions that occur as part of the syllabification process in Diola Fogny (Sapir 1965). Diola prefers not to syllabify obstruents as codas. As seen in (37a)–(37c), a medial obstruent that would otherwise be syllabified as a coda ends up being deleted instead. The preference to avoid obstruent codas seems to be thwarted at the right edge of the word, however, as seen in (37d). Final obstruents are not deleted, even though they cannot be syllabified as anything other than a coda.

(37) *Obstruent deletion in Diola Fogny*

a.	letkuɟaw	→	lekuɟaw	'they won't go'
b.	uɟukɟa	→	uɟuɟa	'if you see'
c.	kobkoben	→	kokoben	'yearn, long for'
d.	kuɲilak	→	kuɲilak	'the children'

Extrametricality accounts for the different treatment of final and medial obstruents. In the lexical phonology, Diola's coda condition prevents obstruents from being syllabified if they would syllabify as codas. Stray Erasure then deletes any segment that remains unsyllabified and has not been designated as extrametrical. Since medial consonants cannot be designated as extrametrical – due to the Peripherality restriction – medial obstruents that fail to syllabify are always deleted, as in (38a). Since final consonants can be designated as extrametrical, however, final obstruents are invisible to Stray Erasure and escape deletion, as in (38b), even syllables often have a longer rhyme might make them seem more compatible with final lengthening. The fact that intensity declines in the rhyme under phonetic final lengthening but increases under stress, however, suggests that this is really not the case. The increased intensity in the rhyme and the strengthening of the onset makes stress more compatible with initial lengthening.

Based on a parallel phenomenon in music (Gabrielsson 1987, 1993), Hyde (2009) suggests that different types of tempo changes at prosodic boundaries might account for the different characteristics of initial and final lengthening. Initial lengthening is the result of a strong attack and acceleration to medial tempo, while final lengthening is the result of a deceleration from medial tempo. An initial acceleration results in strengthening of initial segments and increased intensity in initial syllables, characteristics consistent with stress. A final deceleration results in declining intensity in final rhymes, a characteristic consistent with stresslessness.

7.2 *Stress typologies*

The second line of evidence against initial extrametricality and "non-initiality" is that they result in a decline in the accuracy of typological predictions (Hyde 2002; Altshuler 2009). Consider, for example, the iambic patterns of Aguaruna and Choctaw, discussed in §2. They emerge when rightward binary alternation of unstressed and stressed syllables is perturbed at the right edge of even-parity forms in order to avoid final stress. Aguaruna avoids final stress by shifting it one syllable to the left, and Choctaw avoids it simply by not assigning it.

σσ́σσ́σσ
σσ́σσ́σσ́σ

Although the trochaic mirror images of these patterns are both unattested, they would be predicted to occur if leftward binary alternation of unstressed and stressed syllables could be perturbed at the left edge in order to avoid initial stress.

Among the attested binary patterns in general, final stress avoidance is often a reason to perturb binary alternation, but initial stress avoidance is not. Including a principle of initial stress avoidance in the grammar, then, would only result in the prediction of unattested patterns.

The only requirement for initial syllables that produces attested patterns is a requirement that initial syllables be stressed. For example, in the trochaic Passamaquoddy (LeSourd 1993) and Garawa (Furby 1974) patterns, an initial stress requirement perturbs leftward binary alternation at the left edge.

(40) a. *Passamaquoddy*
σ́σσ́σσ́σ
σ́σ́σσ́σσ́σ

b. *Unattested*
σσ́σσ́σσ́
σσ́σσ́σσ́σ́

c. *Garawa*
σ́σσ́σσ́σ
σ́σσσ́σσ́σ

d. *Unattested*
σσ́σσ́σσ́
σσ́σσ́σσσ́

Not coincidentally, given the repulsion of stress by final syllables, the iambic mirror images of these patterns are both unattested.

Both final stresslessness and initial stress, then – the two aspects of the asymmetry suggested by the phonetic and rhythmic considerations discussed above – are confirmed by the typology of binary stress patterns.

7.3 *Potential counterexamples*

While the vast majority of extrametricality and non-finality effects have been found at the right edges of prosodic domains, a few languages have been argued to exhibit extrametricality effects at the left edge. In most such cases, however, alternative analyses are readily available.

Halle and Vergnaud (1987), for example, attribute the unstressability of initial vowels in Western Aranda to initial segment extrametricality. Subsequent research, however, has resulted in a number of alternative analyses of Western Aranda and similar languages, analyses that do not require initial extrametricality or non-initiality. Typically, they require the left edge of an appropriate prosodic structure to align with a consonant, preventing initial vowels from being included in that structure and, therefore, from being stressed. In Goedemans (1996), for example, the left edges of feet must align with a consonant. This prevents the initial vowel from being footed and, therefore, from being stressed. In Hyde (2007a), it is the left edges of head syllables that must align with a consonant; in Downing (1998), it is the left edges of prosodic words. Smith's (2002) approach simply requires stressed syllables to have onsets.

As a second example, in the stress patterns of Winnebago (Miner 1979; Hale and White Eagle 1980) and Kashaya (Oswalt 1961, 1988; Buckley 1992) the primary stress in a form is the leftmost stress, but it typically does not appear until the third syllable. Since this ternary interval is characteristic of both even- and odd-parity forms, the most straightforward analysis is to establish a trisyllabic stress window at the left edge of the word. An initial extrametricality approach could establish the stress window by making the initial syllable extrametrical and then constructing a maximally disyllabic foot just to the right of the initial syllable. This is not necessarily strong evidence for initial extrametricality, however. As mentioned in §6.1, there are alternative approaches to trisyllabic stress windows in the literature, some of them addressing a greater variety of windows than is possible with extrametricality.

8 Summary

Extrametricality and non-finality have much in common. Both deal with peripheral positions in a domain, both deal primarily with the right edge of the domain, and both often result in final stresslessness. An important difference, however, is that extrametricality focuses on constituent parsability, while non-finality focuses on the position of stress peaks. Extrametricality rules typically prevent some domain-final constituent from being parsed into higher prosodic structure; non-finality constraints typically prevent a stress peak from occurring in some domain-final position. While they have been used to address many of the same phenomena, the difference in focus ensures that they do not address all types with equal success.

In §2 and §3, we saw that extrametricality and non-finality provide equally effective analyses of situations where stress avoids larger final constituents like syllables and feet. In situations where stress is avoided on final syllables, an expected final stress either arrives early or is absent altogether. An extrametricality analysis achieves the desired effect by excluding the final syllable from the foot layer, a non-finality analysis by prohibiting head syllables in final position or by prohibiting foot-level gridmarks over final syllables. In situations where primary stress avoids final feet, the primary stress emerges as the penultimate stress. An extrametricality analysis excludes the final foot from the prosodic word; non-finality either prohibits head feet in final position or prohibits prosodic-word level gridmarks over final feet.

In contrast, extrametricality and non-finality do not perform equally well in accounting for phenomena involving smaller final constituents. In §4, we saw how the avoidance of stress on word-final moras makes stress sensitive to the weight of word-final syllables, how the avoidance of stress on foot-final moras results in iambic lengthening, and how the avoidance of stress on syllable-final moras results in general weight-sensitivity, iambic lengthening, and trochaic lengthening. In these cases, a non-finality analysis is much more straightforward than an extrametricality analysis. With its stress peaks focus, non-finality can prohibit stress on domain-final moras directly. With its parsability focus, however, extrametricality can only prohibit stress on domain-final moras by excluding them from some higher prosodic structure, a requirement that seems impossible to implement without either violating syllable integrity or requiring moras to remain unsyllabified.

In §5, we saw how the failure of final consonants to contribute to syllable weight affects the stressability of final syllables. Extrametricality achieves the desired result directly by making final consonants invisible to mora assignment. A grid-based non-finality approach achieves the desired result indirectly by prohibiting mora-level gridmarks – and, thus, the moras associated with them – from occurring over final consonants. A head-based non-finality approach, however, appears to be unable to capture the effect at all.

In §6, we examined some of the classic arguments for extrametricality, focusing on trisyllabic stress windows and segmental licensing, and we considered the possibility of non-finality approaches. While head-based non-finality offers analyses for some types of trisyllabic windows, grid-based non-finality does not. Recent alternative proposals for a general approach to stress windows, however, make non-finality's limitations in this area less problematic. With respect to segmental licensing, it is not clear that a non-finality approach is even possible.

Finally, §7 outlined the evidence for the edge asymmetry in extrametricality and non-finality formulations. First, the types of effects analyzable in terms of extrametricality or non-finality occur almost exclusively at right edges. Second, phonetic and rhythmic considerations motivate stresslessness in final positions, but they actually motivate stress in initial position. Third, the inclusion of initial extrametricality or non-initiality in the grammar negatively impacts the accuracy of typological predictions.

44 The Iambic–Trochaic Law

Brett Hyde

1 Introduction

In the development of metrical stress theory, several influential approaches (Hayes 1985, 1987, 1995; McCarthy and Prince 1986; Prince 1990) have employed the Iambic–Trochaic Law (ITL) to provide extralinguistic grounding for an account of the differences between iambic and trochaic stress systems (see also CHAPTER 39: STRESS: PHONOTACTIC AND PHONETIC EVIDENCE; CHAPTER 40: THE FOOT; CHAPTER 41: THE REPRESENTATION OF WORD STRESS). The ITL, given in (1), is a statement about the naturalness of two types of rhythmic groupings in two different contexts. According to the ITL, sequences of elements that contrast in intensity most naturally divide into groups with trochaic prominence, and sequences of elements that contrast in duration most naturally divide into groups with iambic prominence.

(1) *The Iambic–Trochaic Law* (Hayes 1985, 1987)

a. Elements contrasting in intensity naturally form groupings with initial prominence.
b. Elements contrasting in duration naturally form groupings with final prominence.

For approaches to metrical stress based on the ITL, this difference in naturalness is responsible for the duration-related differences found in iambic and trochaic stress patterns.

The ITL is based on a long tradition of experimental investigation into the perception of rhythmic grouping (Bolton 1894; Woodrow 1909). In the typical experiment, participants are asked to group a sequence of artificially created alternating sounds. The sounds alternate either in intensity, as in (2a), or in duration, as in (2b).

(2) a. . . . o O o O o O o O o O o O o O o O o O o . . .
b. . . . – — – — – — – — – — – — – — – — – — – . . .

The outcome, under certain circumstances, is that participants tend to divide intensity alternations into groups where the more intense element appears first, as in (3a), and they tend to divide duration alternations into groups where the longer element appears second, as in (3b).[1] The ITL is essentially a statement of these results.

(3) a. *Intensity contrasts: Left-prominent groupings*
. . . [O o][O o][O o][O o][O o][O o][O o][O o][O o] . . .

b. *Duration contrasts: Right-prominent groupings*
. . . [– —][– —][– —][– —][– —][– —][– —][– —] . . .

Though the ITL is an extralinguistic principle, it seems to be reflected in the stress patterns of numerous languages, suggesting, at least initially, that it plays an important role in shaping them. For example, many trochaic languages are like Cahuilla (Seiler 1965, 1967, 1977; Seiler and Hioki 1979). They exclude heavy syllables from disyllabic feet, ensuring that durational contrasts never arise in a foot with trochaic prominence. In Cahuilla, heavy syllables are CVV and CVʔ.

(4) *Exclusion of H from disyllabic feet in Cahuilla*

('LL)(ˌL)	('taxmu)(ˌʔat)	'song'
('LL)(ˌLL)	('taka)(ˌliʧem)	'one-eyed ones'
('H)(ˌL)	('paʔ)(ˌli)	'the water (OBJ)'
('H)(ˌLL)	('qaː)(ˌniʧem)	'palo verde (PL)'
('L)(ˌH)(ˌL)	('su)(ˌkaʔ)(ˌti)	'the deer (OBJ)'
('L)(ˌH)(ˌLL)	(ˌnesun) ('ka)(ˌviː)(ˌʧi-wen)	'I was surprised'

Many iambic languages are like Hixkaryana (Derbyshire 1985). They lengthen the vowel of stressed syllables, if necessary, to ensure that feet with iambic prominence always contain durational contrasts. In Hixkaryana, heavy syllables are CVV and CVC.

(5) *Iambic lengthening in Hixkaryana*

a.	(L'L)('H)L	→	(L'H)('H)L	
	(khæ'næ)('nɯh)nɔ	→	(khæ'næː)('nɯh)nɔ	'I taught you'
b.	(L'L)(L'H)L	→	(L'H)(L'H)L	
	(mɯ'hæ)(næ'nɯh)nɔ	→	(mɯ'hæː)(næ'nɯh)nɔ	'you taught him'
c.	('H)(L'L)L	→	('H)(L'H)L	
	('ɔw)(tɔ'hɔ)næ	→	('ɔw)(tɔ'hɔː)næ	'to the village'
d.	('H)(L'L)LL	→	('H)(L'H)LL	
	('tɔh)(ku'rʲi)hɔnæ	→	('tɔh)(ku'rʲiː)hɔnæ	'to Tohkurye'

This chapter reviews the strengths and weaknesses of ITL approaches to metrical stress, and examines some of the most promising alternatives. We shall see that the ITL does not actually offer an adequate foundation for an account

[1] The effect emerges in the range of one half to five beats per second. (The syllable rate of "ordinary conversational speech" is typically toward the upper limits of this range; Bell 1977.) Hayes (1995) states that the right-prominent effect illustrated in (3b) requires a durational contrast where the longer elements are 1.5 to 2 times as long as the shorter elements, noting that Woodrow (1909) found that smaller durational contrasts actually result in left-prominent groupings.

of stress systems in general, but it may provide an adequate foundation for an account of quantity-sensitive stress systems in particular (see CHAPTER 57: QUANTITY-SENSITIVITY). This is not to say that it provides the best foundation. There is a clear sense in which the superficial and descriptive ITL is itself an observation in need of an explanation, much like the stress patterns found in natural language. Part of the appeal of the most promising alternatives is that they have the potential to account not only for the stress patterns of natural language, but also for the ITL itself.

Before reviewing the various proposals, we should note the results of more recent investigations into the perception of rhythmic grouping. In some cases, more recent studies have confirmed the grouping preferences found in the earlier studies on which the ITL was based. In other cases, they have challenged their universality. The studies of Rice (1992), Vos (1977), and Hay and Diehl (2007), for example, found grouping preferences among English, French, and Dutch speakers similar to those found in the earlier studies of Bolton (1894) and Woodrow (1909).[2] The studies of Kusumoto and Moreton (1997) and Iversen *et al.* (2008), however, found significant differences between speakers of English and Japanese. Iversen *et al.*, for example, found that English speakers had a fairly strong preference (68 percent) for dividing sequences of amplitude contrasts into trochaic (loud–soft) groups, but Japanese speakers had a much stronger preference (91 percent) for trochaic grouping. English speakers showed a very strong preference (89 percent) to divide duration contrasts into iambic (short–long) groups, but Japanese speakers showed no preference. While the challenge to universality may be troubling to those particularly concerned with extralinguistic grounding, and it certainly presents an interesting problem in this connection, it does not necessarily tell us anything about the ITL's ability to predict differences between iambic and trochaic stress patterns in language. Having noted the problem with respect to extralinguistic grounding, then, I will not address the issue further.

2 Interpretations of the ITL

The most recent ITL accounts (McCarthy and Prince 1986; Hayes 1987, 1995; Prince 1990) reflect two distinct interpretations. The stronger of the two, given in (6), takes the ITL to be concerned with the actual presence or absence of durational contrasts within rhythmic groupings.

(6) *Strong interpretation of the ITL*

a. If a foot contains a durational contrast, it is iambic.
b. If a foot lacks a durational contrast, it is trochaic.

The weaker interpretation, given in (7), takes the ITL to be concerned with sensitivity to the positions of the heavy syllables that might help to create durational contrasts.

[2] Rice's study also found a preference for iambic grouping when elements contrasted in pitch, a result not found in previous studies.

(7) *Weak interpretation of the ITL* (Hayes 1985)

a. If parsing is sensitive to the position of heavy syllables, it is iambic.
b. If parsing is insensitive to the position of heavy syllables, it is trochaic.

Even at the point at which the ITL was introduced to metrical stress theory, it was clear that the strong interpretation in (6) was unsustainable, at least when applied to stress systems generally. Under the strong interpretation, iambic footing and the presence of durational contrasts are intimately connected: only iambs contain durational contrasts; durational contrasts arise only in iambic feet; and only iambic systems employ rules that create durational contrasts. Similarly, trochaic footing and the absence of durational contrasts are intimately connected: only trochees lack durational contrasts; durational contrasts are absent only in trochaic feet; and only trochaic systems employ rules that destroy durational contrasts.

Even a cursory look at the general typology of attested stress patterns reveals that the strong interpretation misses the mark by a wide margin. As mentioned above, many iambic languages are like Hixkaryana, lengthening the vowel of stressed syllables, if necessary, to ensure that surface iambs contain durational contrasts. Many other iambic languages are like Araucanian (Echeverria and Contreras 1965), however. They tolerate surface iambs that have no durational contrasts.

(8) *Even iambs in Araucanian*

(L'L)	(wu'le)	'tomorrow'
(L'L)L	(ti'pan)to	'year'
(L'L)(L,L)	(e'lu)(mu,ju)	'give us'
(L'L)(L,L)L	(e'lu)(a,e)new	'he will give me'

A similar situation obtains with trochaic languages. As mentioned above, several are like Cahuilla in prohibiting foot-internal durational contrasts. Several others, however, are like Chimalapa Zoque (Knudson 1975). They tolerate foot-internal durational contrasts and even have rules that create them. In Chimalapa Zoque, heavy syllables are CVV and CVC.

(9) *Trochaic lengthening in Chimalapa Zoque*

a.	('LH)	→	('HH)	
	('kosaʔ)	→	('koːsaʔ)	'scold (IMP)'
b.	(,L)('LL)	→	(,H)('HL)	
	(,hu)('kuti)	→	(,huː)('kuːti)	'fire'
c.	(,LL)L('LL)	→	(,HL)L('HL)	
	(,witi) hu('kuti)	→	(,wiːti) hu('kuːti)	'big fire'
d.	(,LH)H('HL)	→	(,HH)H('HL)	
	(,wituʔ)paj('niksɨ)	→	(,wiːtuʔ)paj('niksi)	'he is coming and going'

There appears to be no close connection between iambs and the presence of durational contrasts, then, or between trochees and the absence of durational contrasts, at least in the general case.

Given the shortcomings of the strong interpretation, Hayes (1985) introduced the ITL to metrical stress theory under the weak interpretation in (7). Under the weak interpretation, the crucial connections are between iambic footing and quantity-sensitivity and trochaic footing and quantity-insensitivity. While iambic feet and trochaic feet might both contain durational contrasts, parsing is iambic if and only if it is sensitive to the positions of heavy syllables. Parsing is trochaic if and only if it is insensitive to the positions of heavy syllables.

There are three problems with the weak interpretation. The first is conceptual. The ITL is plainly a generalization about the appropriateness of durational contrasts within two different types of feet. Since its requirements concerning durational contrasts affect both types, the ITL does not countenance situations where either type is quantity-insensitive (where either type simply ignores the differences in syllable weight that help to create durational contrasts). In viewing the primary concern of the ITL to be the appropriateness of quantity-sensitivity for different types of feet, the weak interpretation seems really to be a misinterpretation.

The second problem is a loss of empirical coverage. Since it only addresses quantity-sensitivity, the weak interpretation tells us nothing about the status of lengthening and shortening rules addressed by the strong interpretation.

The final problem is that the weak interpretation is false. A significant number of trochaic systems are quantity-sensitive, falsifying (7a), and a significant number of iambic systems are quantity-insensitive, falsifying (7b). In (4), for example, we saw that heavy syllables consistently perturb the basic stress pattern of the trochaic Cahuilla, indicating that it is quantity-sensitive. In (10), we see that heavy syllables consistently fail to perturb the basic pattern of the iambic Paumari (Everett 2003), indicating that it is quantity-insensitive. In the basic pattern, stress appears on every odd-numbered syllable from the right. CVV syllables are heavy.

(10) *Quantity-insensitive iambs in Paumari*

(ˌL)(LˈL)	(ˌma)(siˈko)	'moon'
(LˌL)(LˈL)	(kaˌʤo)(wiˈri)	'island'
(ˌH)(HˈL)	(ˌkai)(haiˈhi)	'type of medicine'
(HˌL)(LˈL)	(waiˌʧa)(naˈwa)	'little ones'

Additional quantity-sensitive trochaic languages include Palestinian Arabic (Brame 1973, 1974; Kenstowicz and Abdul-Karim 1980; Kenstowicz 1983) and Fijian (Schütz 1978, 1985; Dixon 1988). Additional quantity-insensitive iambic languages include Araucanian, Osage (Altshuler 2009), Suruwaha (Everett 1996), and Weri (Boxwell and Boxwell 1966).

As we shall see in §3, parts of both interpretations, (6a) of the strong interpretation and (7b) of the weak interpretation, are brought together to form the basis for two subsequent ITL accounts, those of Hayes (1987, 1995) and of McCarthy and Prince (1986). This marriage between the halves of two very different interpretations often makes the connection between the ITL and the phenomena that these approaches attempt to account for less than clear. This is part of the reason, perhaps, that some have concluded that there is actually little of the ITL left in ITL-based approaches (see van der Hulst 1999, for example). A third ITL approach, that of Prince (1990), employs only the strong interpretation, but seeks to avoid the problems discussed above by employing it only in the context of quantity-sensitive systems and only as a relative "preference" rather than an absolute "law."

Though I will point out the aspects of the more recent ITL accounts that derive from the weak interpretation, it should be clear at this point that the weak

The reason is simply that the foot that is constructed immediately after the heavy syllable is parsed, rather than the foot that is constructed to parse the heavy syllable itself, determines how the basic alternation resumes. Whether heavy syllables are included in disyllabic feet or parsed as monosyllabic feet, the basic alternations of both iambic and trochaic systems would resume with an unstressed syllable (the underlined syllable in the examples below).

(12) *Parsing directionality matches headedness*

a. *Left-to-right iambic*

```
i. Iamb                     ii. Monosyllable
     (   x)(   x)                (x)(   x)
   ...L  H  L  L...            ...H  L  L...
   ---------------->           ---------------->
```

b. *Right-to-left trochaic*

```
i. Trochee                  ii. Monosyllable
     (x   )(x   )                (x   )(x)
   ...L  L  H  L...            ...L  L  H...
   <----------------           <----------------
```

In left-to-right iambic systems, the heavy syllable must occur at the right edge of a foot whether the foot is an iamb, as in (12a.i), or a monosyllable, as in (12a.ii). Since the next foot constructed would be iambic in either case, the alternation resumes with an unstressed syllable. In right-to-left trochaic systems, the heavy syllable would be parsed at the left edge of a foot whether the foot is a trochee, as in (12b.i), or a monosyllable, as in (12b.ii). Since the next foot constructed would be trochaic in either case, the alternation again resumes with an unstressed syllable.

A difference in the resumption of basic alternations emerges only in situations where parsing directionality and the headedness of the foot do not match. In right-to-left iambic languages like Tübatulabal (Voegelin 1935), as (13) illustrates, heavy syllables are always preceded by stressless syllables. In Tübatulabal, heavy syllables are CVV(C).

(13) *Resumption with a stressless syllable in Tübatulabal*

'LL'L	'ʧiŋi'jal	'the red thistle'
L'LL'H	ti'ŋija'laap	'on the red thistle'
L'LL'L	wi'taŋha'tal	'the Tejon Indians'
'LL'LL'HL'L	'witaŋ'hata'laaba'tsu	'away from the Tejon Indians'
'H'LL'L	'taa'hawi'la	'the summer'
'H'LL'H	'taa'hawi'laap	'in the summer'

In left-to-right trochaic languages like Cahuilla, however, as illustrated in (4), heavy syllables are always followed by stressed syllables. The difference between right-to-left iambic systems and left-to-right trochaic systems, then, is that the former resume their basic alternations with stressless syllables while the latter resume them with stressed syllables.

The reason that a difference emerges when headedness and parsing directionality do not match is that the resumption of basic alternations depends directly on how the heavy syllable itself is footed.

existence of several quantity-insensitive iambic languages. While Hayes argues that the quantity-insensitivity of such systems is only apparent, as they do not actually contain heavy syllables to perturb the basic pattern, the argument is plausible only in the cases of Araucanian and Weri. It is not plausible in the cases of Osage, Paumari, and Suruwaha, each of which has long vowels, diphthongs, or both.

Given that both iambic and trochaic systems can be quantity-sensitive, clause (6a) of the strong interpretation, "if a foot contains a durational contrast, it is iambic," motivates a disparity in precisely how the two types can be quantity-sensitive. As (15b) indicates, Hayes's account requires trochaic systems to deal with heavy syllables differently than iambic systems. Iambs allow heavy syllables in strong position in disyllabic feet, where they can create durational contrasts. They exclude them only from weak position. Trochees, however, exclude heavy syllables from disyllabic feet entirely. Trochaic systems must parse heavy syllables into monosyllabic feet, where no durational contrast is possible.

The disparity in how the two types of feet can be quantity-sensitive predicts the difference, discussed above, in how right-to-left iambic languages and left-to-right trochaic languages resume basic stress alternations after encountering a heavy syllable. The fact that iambic systems parse heavy syllables into disyllabic feet in Hayes's account correctly predicts that right-to-left iambic languages will resume their basic alternation with a stressless syllable, as in (14a.i). The fact that trochaic systems must parse heavy syllables into monosyllabic feet correctly predicts that left-to-right trochaic languages will resume their basic alternation with a stressed syllable, as in (14b.ii).

McCarthy and Prince (1986) arrive at a foot inventory similar to Hayes's, but they arrive at it through a slightly different route and in service of a different purpose. They posit one type of quantity-insensitive foot: the balanced [σ σ] template, and two types of quantity-sensitive feet: the balanced [μ μ] template and the unbalanced [σ_μ $\sigma_{\mu\mu}$] template.

(16) a. *Quantity-insensitive*
   Balanced [σ σ]

b. *Quantity-sensitive*
   i. Balanced [μ μ]
   ii. Unbalanced [σ_μ $\sigma_{\mu\mu}$]

The ITL contributes to McCarthy and Prince's account in two ways. First, clause (6a) of the strong interpretation, "if a foot contains a durational contrast, it is iambic," motivates the iambic configuration of the quantitatively unbalanced foot. To guarantee that quantitatively iambic feet are also iambic with respect to stress, they posit the Quantity/Prominence Homology principle. It ensures that the heavier syllable in feet with a quantity contrast – in effect, the heavy syllable in a [σ_μ $\sigma_{\mu\mu}$] foot, given the limited possibilities in (16) – bears the stress.

(17) *Quantity/Prominence Homology*

For a, b ∈ F, if a > b quantitatively, then a > b stresswise.

Prominence in unbalanced feet is determined by the Trochaic Default principle, which ensures that [σ σ] and [μ μ] feet both stress their initial syllable.

(22)	*satisfy:*	IQ/TQ, Binarity		Binarity only		neither
a.	Iambic	[L H]	>	[L L], [H]	>	[L]
b.	Trochaic	[L L], [H]	>	[H L]	>	[L]

The asymmetry in this case arises in how the iambic and trochaic hierarchies order balanced and unbalanced feet. Iambs prefer unbalanced [L H] to balanced [L L] and [H], but trochees prefer balanced [L L] and [H] to unbalanced [H L].

The main difference between the inventory of quantity-sensitive feet in Prince's and Hayes's accounts is the possibility of unbalanced [H L] trochees. As Prince notes, however, with their lesser status, there are limited situations in which unbalanced trochees might arise. First, consider the result of Harmonic Parsing in a left-to-right trochaic system. Since feet are constructed serially, and parsing the next syllable in line is the overriding concern, Harmonic Parsing would parse the H of an HL sequence as monosyllabic foot, just like Hayes's moraic trochees. If the following L could not combine with another L to form a disyllabic foot, giving [H][LL], it might be parsed as a monosyllable, giving [H][L], or left unparsed, giving [H]L, depending on whether or not degenerate feet are tolerated. These are the same options available under Hayes's moraic trochees. The results are rather different in right-to-left systems. Harmonic Parsing would always parse an HL sequence into an [HL] foot, but Hayes's moraic trochees would yield either [H][L] or [H]L, depending on whether or not degenerate feet are tolerated. The latter option results in the same stress pattern, but the former does not. I am not aware, however, of a right-to-left trochaic language that would allow us to distinguish between the two approaches.

3.2 *A symmetric foot inventory*

As discussed above, the evidence for a difference between iambic and trochaic quantity-sensitivity comes from systems where parsing directionality is opposite the headedness of the foot. After left-to-right trochaic parsing encounters a heavy syllable, binary alternation resumes with a stressed syllable. In contrast, after right-to-left iambic parsing encounters a heavy syllable, binary alternation resumes with a stressless syllable. Where ITL approaches posit an asymmetric foot inventory to account for this difference, Kager (1993) proposes a symmetric foot inventory, arguing that the difference is best explained in terms of the metrical principles of clash and lapse avoidance.

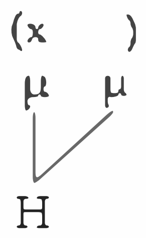
Kager distinguishes between parsing feet and the surface feet that can be formed later through adjunction of unparsed syllables. The inventory of parsing feet is symmetric. The quantity-insensitive syllabic trochee corresponds to a mirror-image syllabic iamb. The quantity-sensitive moraic trochee corresponds to a mirror-image moraic iamb. Iambic quantity-sensitivity and trochaic quantity-sensitivity are identical, then, in that both exclude heavy syllables from disyllabic feet.

(23) *Parsing feet*

	trochaic	*iambic*
	(x)	(x)
Syllabic (quantity-insensitive)	σ σ	σ σ
	(x)	(x)
Moraic (quantity-sensitive)	μ μ	μ μ

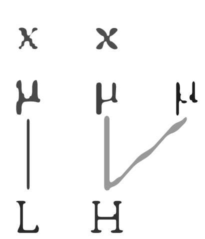
Crucial to Kager's account is the claim that heavy syllables contain an internal prominence contrast corresponding to a decline in sonority between the first and second mora. According to Kager, the internal contrast is the characteristic of heavy syllables responsible for their attraction of stress (Prince's 1990 Weight-to-Stress principle). The decline in sonority ensures that stress occurs over the first mora and that the second mora is stressless, as in (24).

(24)

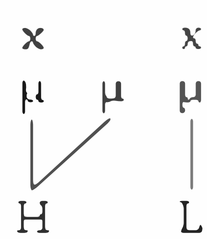


A heavy syllable's strong–weak contour translates into different results with respect to clash at the mora level. When a stressed heavy syllable immediately follows another stressed syllable, as in (25a), the result is a clash. When the order is reversed, as in (25b), there is no clash.

(25) a. *Clash*

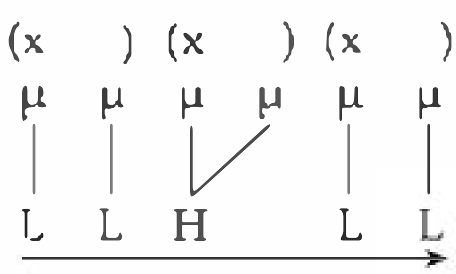


b. *No clash*



Assuming that clash is never tolerated at the point the basic alternation is resumed, the internal prominence contrast accounts for the different modes of resumption after a heavy syllable.[4] In left-to-right trochaic systems, a trochaic foot can immediately follow the heavy syllable without creating clash, so the pattern resumes with a stressed syllable.

(26) *Left-to-right trochees: No clash*



In right-to-left iambic systems, however, an iambic foot cannot immediately precede the heavy syllable without creating clash. This being the case, the parsing algorithm must skip a syllable before constructing an iambic foot, and the pattern resumes with an unstressed syllable.

[4] More precisely, Kager assumes that the construction of a foot cannot introduce clash within the parsing window. The parsing window consists of the syllables being parsed in the current iteration plus the string of syllables encountered by the parsing algorithm in previous iterations. It does not include syllables that the algorithm has not yet encountered.

pattern. Rhythmic lengthening appears to be based solely on the alternation of strong and weak positions, affecting only the former. In contrast, rhythmic shortening can affect both strong and weak positions and seems in many cases to be motivated, at least partially, by a preference for exhaustive parsing.

Rhythmic lengthening increases the duration of stressed syllables either through vowel lengthening (CHAPTER 20: THE REPRESENTATION OF VOWEL LENGTH) or gemination of an adjacent consonant (CHAPTER 37: GEMINATES), the former method being more common than the latter. It can be found in both iambic and trochaic languages. In (5), for example, we saw that the stressed vowels of underlyingly light syllables lengthen in the iambic Hixkaryana, making them heavy on the surface. Other iambic lengthening languages include Carib, Choctaw, and several varieties of Yupik (Woodbury 1981, 1987; Jacobson 1984, 1985; Krauss 1985a; Leer 1985; among others). In (9), we saw that the stressed vowels of underlyingly light syllables lengthen in the trochaic Chimalapa Zoque. Other trochaic lengthening languages include Chamorro (Topping and Dungca 1973; Chung 1983), Icelandic (Árnason 1980, 1985), Mohawk (Michelson 1988), and Selayarese (Mithun and Basri 1986).

An interesting difference between iambic and trochaic lengthening is that lengthening occurs in iambic systems only when they are quantity-sensitive, and in trochaic systems only when they are quantity-insensitive.[5] When it is seen as shaping the possibilities of stress patterns generally, then, the existence of trochaic lengthening in quantity-insensitive systems clearly undermines the ITL. If we restrict the ITL's scope to quantity-sensitive systems, however, the distribution of lengthening gives it considerable support. The presence of lengthening in iambic languages, where durational contrasts are encouraged, is consistent with the ITL, as is the absence of lengthening in trochaic languages, where durational contrasts are prohibited.

Another important generalization concerning rhythmic lengthening is the correlation between what I will refer to as *regular lengthening* and certain types of minimal words. *Regular lengthening* is the exceptionless lengthening in non-minimal forms characteristic of many lengthening languages: vowels lengthen in underlyingly light syllables whenever they receive the appropriate degree of stress.[6] As (32) indicates, languages with regular lengthening allow only three types of minimal word: H, LL, and HL.

(32) *Minimal words associated with regular lengthening*

a. *Monosyllabic*		b. *Disyllabic*	
L	*unattested*	LL	Choctaw verbs (iambic)
H	Chimalapa Zoque (trochaic)	HL	Carib (iambic)
	Choctaw nouns (iambic)		Hixkaryana (iambic)
	Icelandic (trochaic)		Selayarese (trochaic)
	Yupik varieties (iambic)		
		LH	*unattested*

[5] The clearest cases of quantity-insensitive iambs – Osage, Paumarí, and Suruwaha – do not exhibit lengthening. The less clear cases – Weri and Araucanian – also do not exhibit lengthening.

[6] Lengthening is not "regular" when it is prohibited in various positions in non-minimal forms, especially in final position. Syllables with primary stress in Italian, for example, lengthen if they are penultimate but not if they are antepenultimate or final. Languages like Unami and Munsee Delaware (Goddard 1979), which make stressed syllables heavy through consonant gemination, also fall outside the generalization.

Iambic lengthening languages and trochaic lengthening languages can both insist on H or HL minimal words, but only iambic lengthening languages can insist on an LL minimal word. There appear to be no regular lengthening languages with L minimal words, and none with LH minimal words.

If we exclude alternations better described as vowel reduction (see below), rhythmic shortening is a marginal phenomenon. It occurs in only a few trochaic systems, and, as Mellander (2003) points out, each of these few is quantity-sensitive. Trochaic shortening can affect either a stressed syllable or an unstressed syllable. In Fijian, for example, stressed syllables shorten, converting HL sequences into LL sequences.

(33) *Trochaic shortening in Fijian*

ŋbuː-rŋu	→	ˈmbu-rŋu	'my grandmother'
θaː-j-a	→	ˈta-j-a	'chop-TRANS-3 SG OBJ'
nreː-ta	→	ˈnre-ta	'pull-TRANS'

In Pre-Classical Latin (Allen 1973; Mester 1994), stressless syllables shorten, converting LH sequences into LL sequences.[7]

(34) *Trochaic shortening in Latin*

egoː	→	ˈego	'I'
maleː	→	ˈmale	'bad'
amiːkitiam	→	ˌamiˈkitiam	'friendship'

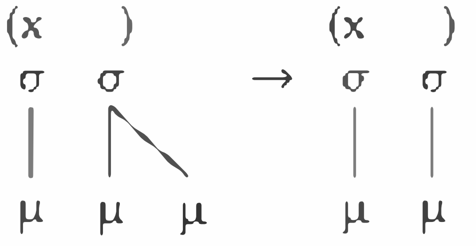
Rhythmic shortening, though marginally attested, is consistent with the ITL. Among quantity-sensitive languages, it occurs only in trochaic systems, destroying the durational contrasts that the ITL prohibits. It does not occur in iambic systems, where it would destroy durational contrasts that the ITL requires. Quantity-insensitive languages, of either type, apparently do not exhibit rhythmic shortening.

Before we proceed, it should be noted at this point that there are at least two languages with shortening phenomena that are potential counterexamples to the generalizations presented in the preceding paragraph: Central Slovak (Dvonč 1955; Bethin 1998; Mellander 2003) and Gidabal (Geytenbeek and Geytenbeek 1971; Rice 1992; Mellander 2003). The stress patterns of both languages are fairly complex, however, and their analyses are not at all straightforward. It is not clear whether they are examples of shortening in trochaic feet (resulting in unbalanced HL trochees), shortening in iambic feet, or both, or whether they are simply examples of shortening in non-head syllables generally. Since it is unclear exactly how such examples are relevant, I have set them aside here.

I have also set aside phenomena involving vowel strengthening in stressed syllables and vowel reduction and deletion in unstressed syllables. Some of the alternatives to an ITL approach draw to a significant extent on such phenomena as evidence that the difference between iambs and trochees with respect to rhythmic lengthening and shortening is not as great as previously thought (Revithiadou and van de Vijver 1997; van de Vijver 1998; Revithiadou 2004). Strengthening, reduction, and deletion phenomena are fairly common in both iambic and trochaic systems.

[7] The Latin-type shortening is often referred to as *iambic shortening*, because it affects the second syllable in a two-syllable sequence rather than the first.

b. *Latin-type*



The effect of the Latin-type shortening rule in (36b) is to convert an ill-formed (LH) trochee to a well-formed (LL) trochee. An ill-formed (LH) trochee might be created inadvertently, for example, when an extrametrical H syllable is adjoined to a degenerate (L) foot, and (36b) repairs the defect.

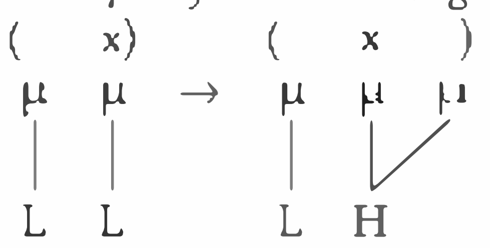
Though the ITL account captures the distribution of rhythmic lengthening and shortening in quantity-sensitive systems, it falls short in two ways. First, it fails to allow for trochaic lengthening in quantity-insensitive systems (a phenomenon whose existence Hayes denies). Second, it does not account for the correlation between regular lengthening and the group of minimal words in (32). Based on the ITL, lengthening rules might be employed to create durational contrasts in iambic feet (or, possibly, to destroy them in trochaic feet), but there is nothing in the law entailing that lengthening languages should prefer H, HL, and LL minimal words above L and LH minimal words. If the ITL is actually the motivation for lengthening, then the correlation of regular lengthening with these particular minimal words is a mystery.

4.2 *Lapse avoidance and non-finality*

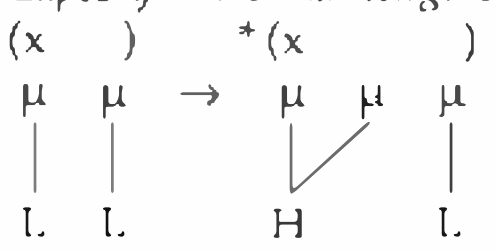
Kager's (1993) approach to the asymmetries in rhythmic lengthening and shortening is based on the same principles that governed his approach to quantity-sensitivity (see §3.2). In conjunction with a prohibition against foot-internal lapse, the internal prominence contrast in heavy syllables restricts the occurrence of lengthening. Kager views lengthening of stressed syllables in general as phonetically motivated, but the restriction against foot-internal lapse ensures that such lengthening is more common in iambs than in trochees. As (37) illustrates, the grammar tolerates lengthening that creates (LH) iambs, because they contain no foot-internal lapse, but it does not tolerate lengthening that creates (HL) trochees, because they do contain a foot-internal lapse.

(37) *Lengthening asymmetry through lapse avoidance*

a. *No lapse after iambic lengthening*



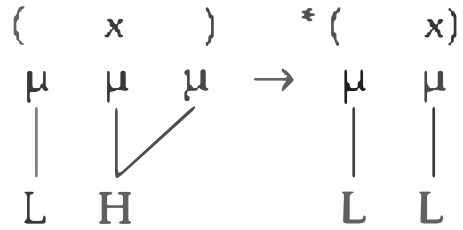
b. *Lapse after trochaic lengthening*



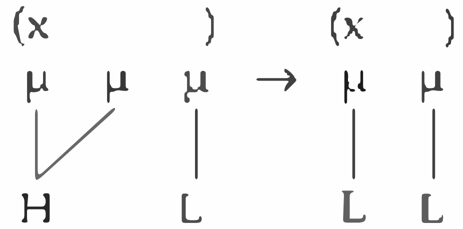
The prohibition against foot-internal lapse also accounts for the shortening asymmetry, but in this case it acts as a trigger. In Kager's view, the purpose of trochaic shortening is to eliminate foot-internal lapses like those found in (HL) trochees. Since there is no foot-internal lapse in (LH) iambs, the motivation for shortening never arises in iambic systems.

(38) *Lapse avoidance predicts shortening asymmetry*

a. *No lapse in iambs to trigger shortening*



b. *Lapse in trochees triggers shortening*



Although foot-internal lapse avoidance effectively addresses the lesser frequency of lengthening in trochaic systems, it does not address the actual phonological triggers for lengthening. Hyde's (2007) non-finality approach addresses the lesser frequency of lengthening in trochaic systems, but it also provides phonological triggers for rhythmic lengthening and addresses its correlation with certain types of minimal words (CHAPTER 43: EXTRAMETRICALITY AND NON-FINALITY).

Under the non-finality approach, rhythmic lengthening is a special case of the type of weight-sensitivity where stress avoids light syllables. To avoid stressing a light syllable, the syllable is lengthened to make it heavy. Non-finality produces this type of weight-sensitivity by prohibiting stress on domain-final moras. Following Kager (1995), Hyde applies non-finality to the foot domain to promote iambic lengthening. Going a step further, he also applies non-finality to the syllable domain. This gives the approach a second mechanism for promoting iambic lengthening but it also gives it a mechanism for promoting trochaic lengthening.

(39) a. NON-FINALITY(Ft)
No stress occurs over the final mora of a foot.

b. NON-FINALITY(σ)
No stress occurs over the final mora of a syllable.

NON-FINALITY(Ft) effectively prohibits stress on light foot-final syllables. Since it bans foot-level gridmarks from foot-final moras, foot-final syllables must be at least bimoraic to support stress. NON-FINALITY(σ) effectively prohibits stress on light syllables generally. Since it bans foot-level gridmarks from syllable-final moras, syllables generally must be at least bimoraic to support stress.

To produce lengthening, one of the non-finality constraints must dominate DEP-μ, the faithfulness constraint that prevents mora insertion. Under such rankings, when stress would otherwise occupy a light syllable, a mora can be added to make the syllable heavy on the surface. The two non-finality constraints do not, however, have equal ability to promote lengthening in every type of foot. Since NON-FINALITY(Ft) prohibits stress over light foot-final syllables in particular, it can lengthen the stressed syllable of an iamb but not the stressed syllable of a trochee. In contrast, since NON-FINALITY(σ) prohibits stress over light syllables in general, it can lengthen the stressed syllables of both.

Consider first the situation where the stressed syllable occurs in an iamb. When NON-FINALITY(Ft) dominates DEP-μ, a second mora is added to underlyingly light syllables to avoid stress on foot-final moras.

(40)

LLLL		NON-FIN(Ft)	DEP-μ
☞ a.			**
b.		*!*	

The result is similar when NON-FINALITY(σ) dominates DEP-μ: a second mora is added to the underlyingly light syllables to avoid stress on syllable-final moras.

(41)

LLLL		NON-FIN(σ)	DEP-μ
☞ a.			**
b.		*!*	

Now consider the situation where the stressed syllable occurs in a trochee. When NON-FINALITY(Ft) dominates DEP-μ, as in (42), there is no lengthening. Because stress does not occupy the foot-final syllables in either candidate, there is no danger that it will occupy the foot-final moras, and NON-FINALITY(Ft) cannot distinguish between them. The lower ranked DEP-μ settles on the faithful (42b) candidate.

(42)

LLLL		NON-FIN(Ft)	DEP-μ
a.			*!*
☞ b.			

When NON-FINALITY(σ) dominates DEP-μ, however, as in (43), the lengthening candidate emerges as the winner. The stressed syllables become heavy, to allow stress to avoid syllable-final moras.

(43)

LLLL		NON-FIN(σ)	DEP-μ
☞ a.			**
b.		*!*	

One advantage of the non-finality approach is that it has a built-in explanation for the lesser frequency of lengthening among trochaic systems. Non-finality in the syllable and non-finality in the foot both produce iambic lengthening, but only non-finality in the syllable produces trochaic lengthening. Every ranking that produces trochaic lengthening, then, also produces iambic lengthening, but some rankings that produce iambic lengthening do not produce trochaic lengthening. Since the percentage of possible rankings that produce iambic lengthening is greater than the percentage of possible rankings that produce trochaic lengthening, we would expect lengthening to occur with greater frequency in iambic systems than it does in trochaic systems, all else being equal.

A second advantage of the non-finality approach is that it helps to account for the particular group of minimal words associated with regular lengthening. As discussed above, languages that automatically lengthen appropriately stressed vowels only allow three types of minimal word: H, LL, and HL. They never allow L or LH minimal words. Using the same non-finality constraints to produce rhythmic lengthening and the minimal word restrictions predicts this situation.

L minimal words are absent, because the lengthening constraints themselves both establish H minimal words. NON-FINALITY(σ) has the same effect in monosyllabic feet that it has in disyllabic feet, and NON-FINALITY(Ft) has the same effect that it has in iambs. They both force the stressed syllable to lengthen. As (44) indicates, if either of the lengthening constraints ranks highly enough to produce lengthening in the disyllabic feet of longer forms, then it also ranks highly enough to produce lengthening in the monosyllabic feet of monosyllabic forms.

(44) a. NON-FINALITY(σ) >> DEP-μ
Iambic or trochaic lengthening + H minimal word
b. NON-FINALITY(Ft) >> DEP-μ
Iambic lengthening + H minimal word

Two desirable predictions result from this situation: regular lengthening is always accompanied by a minimal word that is at least bimoraic, and iambic lengthening languages and trochaic lengthening languages can both have H minimal words.

Although the lengthening constraints cannot produce disyllabic minimal words on their own, they do help to determine which type of disyllable emerges. Assuming that disyllabic minimal words have a trochaic strong–weak stress contour, we can explain the two-syllable requirement with an additional non-finality constraint, NON-FINALITY(ω), which bans stress from the final syllable of a prosodic word.[8] Once the strong–weak contour is established, lengthening constraints determine the weight of the initial syllable. NON-FINALITY(σ), which produces lengthening in both iambic feet and trochaic feet, requires that the initial syllable be heavy. NON-FINALITY(Ft), which produces lengthening only in iambic feet, tolerates a light initial syllable.

(45) a. NON-FINALITY(ω), NON-FINALITY(σ) >> DEP-μ
Iambic or trochaic lengthening + HL minimal word
b. NON-FINALITY(ω), NON-FINALITY(Ft) >> DEP-μ
Iambic lengthening + LL minimal word

[8] Plausible cases of iambic minimal words appear to be extremely rare.

This correctly predicts that either iambic or trochaic lengthening can be accompanied by an HL minimal word, but only iambic lengthening can be accompanied by an LL minimal word.

Van de Vijver (1998) and Revithiadou (2004) propose an approach to rhythmic lengthening that is similar in some respects to the non-finality approach. Although it does not rely on the non-finality formulation, it does posit two lengthening mechanisms. One lengthens stressed syllables generally, which produces both iambic lengthening and trochaic lengthening, and the other lengthens foot-final syllables in particular, which produces only iambic lengthening.

(46) *Lengthening constraints* (van de Vijver 1998)

a. STRESSED SYLLABLE LENGTH
   A stressed syllable is long and an unstressed syllable is short.
b. FOOTFINAL
   Foot-final elements are lengthened.

Since there are two sources for iambic lengthening and only one for trochaic lengthening, Revithiadou's and van de Vijver's proposals, like the non-finality approach, provide an account of the different frequencies with which the two types of lengthening occur. The advantage of the non-finality approach is that it incorporates the lengthening mechanisms into the much more general non-finality formulation, a formulation independently motivated by its ability to account for a surprisingly broad range of phenomena at different prosodic levels. (See CHAPTER 43: EXTRAMETRICALITY AND NON-FINALITY.)

5 Summary

The most interesting interpretation of the Iambic–Trochaic Law is a strong interpretation that focuses on the presence or absence of durational contrasts in disyllabic feet. Since the general typology of attested stress systems offers very little support for the strong interpretation, Hayes (1985) introduced the ITL to metrical theory under a weaker interpretation that focused on quantity-sensitivity. This also turned out to be inadequate, however, as it was soon recognized that both iambic languages and trochaic languages could be either quantity-sensitive or quantity-insensitive. Two subsequent accounts – McCarthy and Prince (1986) and Hayes (1987, 1995) – pursued a hybrid approach, combining aspects of the weak interpretation and the strong interpretation. Another, Prince (1990), returned to a strong interpretation of the ITL, but applied it, in effect, only to quantity-sensitive systems and as a preference rather than an absolute requirement.

Since the ITL is inherently quantity-sensitive, it seems more natural to employ it as a foundation for an account of quantity-sensitive systems in particular than as the foundation for an account of stress systems generally. There is, in fact, considerable support for the ITL among quantity-sensitive systems. Iambic quantity-sensitivity differs from trochaic quantity-sensitivity, as indicated by the different ways in which alternating patterns resume after encountering a heavy syllable, and the asymmetric foot inventory of ITL accounts very effectively for this difference. Standard iambs exclude heavy syllables from weak position

45 The Representation of Tone

Larry M. Hyman

1 Introduction

No issue has had a greater impact on phonological representations than the study of tone. Although receiving only passing attention in both pre- and early generative phonology, tone quickly moved away from its marginal status to occupy center stage in the development of non-linear phonology. While both level and contour tones had been traditionally transcribed with either accents or numerals, as in (1) and (2), the assumption in early generative phonology, e.g. Wang (1967), was that tones consisted of features that could be added at the bottom of a segmental feature matrix, as in (3).

(1)

	Awa		*Falam*		*Obokuitai*	
High (H)	ná	'breast'	páa	'mushroom'	kuik^{1}	'rock'
Low (L)	nà	'house'	kèe	'leg'	kuik^{2}	'insect (sp.)'
HL (falling)	nâ	'taro'	sâa	'animal'	kuik^{12}	'lizard (sp.)'
LH (rising)	pǎ	'fish'	zǔu	'bear'		
	(Loving 1966: 25)		(personal notes)		(Jenison and Jenison 1991: 85)	

(2)

Jingpho			*Ayutla Mixtec*		
H	mu^{55}	'word'	H–H	ʃi^{1}ɲuʔ^{1}	'pineapple'
Mid (M)	mu^{33}	'delicious'	H–L	ʃi^{1}niʔ^{3}	'hat'
L	mu^{31}	'to see'	M–L	ʃi^{2}niʔ^{3}	'head'
HL	mu^{51}	'mother'	L–L	ti^{3}kuʔ^{3}	'louse'
(Qingxia and Diehl 2003: 401)			(Pankratz and Pike 1967: 291)		

(3) a. H *tone* /á/

$$\begin{bmatrix} +\text{syll} \\ -\text{cons} \\ +\text{back} \\ +\text{low} \\ +\textsc{high} \end{bmatrix}$$

b. HL *falling tone* /â/

$$\begin{bmatrix} +\text{syll} \\ -\text{cons} \\ +\text{back} \\ +\text{low} \\ +\textsc{falling} \end{bmatrix}$$

A major representational problem was how to account for the properties of contour tones. Although falling and rising tones could be expressed less formally by combining accents (â, ǎ) or numerals (31, 13, etc.), features such as [±FALLING] and [±RISING] fail to capture what are known as "edge effects": a high to low falling tone acts like a H tone with respect to what precedes, but as a L tone with respect to what follows. Similarly, a low to high rising tone acts like a L tone with respect to what precedes, but as a H tone with respect to what follows. Representations such as in (4), which were occasionally entertained, would simply be incoherent in a framework in which a segment consists of a single vertical matrix of features:

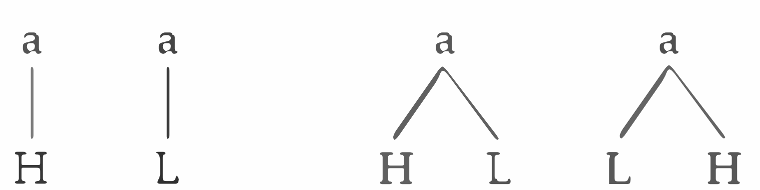
(4) a. *Falling tone /â/* b. *Rising tone /ǎ/*

$$\begin{bmatrix} +\text{syll} \\ -\text{cons} \\ +\text{back} \\ +\text{low} \\ [+\text{HIGH}][+\text{LOW}] \end{bmatrix} \qquad \begin{bmatrix} +\text{syll} \\ -\text{cons} \\ +\text{back} \\ +\text{low} \\ [+\text{LOW}][+\text{HIGH}] \end{bmatrix}$$

In order to solve this and other representational problems, Goldsmith (1976a, 1976b) proposed a theory of "autosegmental" phonology in which segments and tones appear on separate "tiers," as in (5).

(5) *Autosegmental representations of* H, L, HL, LH

a. *level tones* b. *contour tones*



By so doing, Goldsmith was able to capture the traditional intuitions implicit in the accent and numeral notations and make predictions about what should *vs.* should not be found in tone systems. Armed with the autosegmental framework, enormous strides were made in the analysis of tone as well as in other applications of the framework, e.g. segmental harmonies (Clements 1977, 1981; Hoberman 1988), feature geometry (Clements 1985; Clements and Hume 1995) and prosodic morphology (McCarthy 1981; McCarthy and Prince 1986).

The main question to be addressed in this chapter is the extent to which the key insight of autosegmental phonology, expressed in (6), is still valid:

(6) *Tones are semi-autonomous from their tone-bearing units*

a. tones are on a separate tier, but
b. they are linked to their tone-bearing units by association lines.

The chapter is organized as follows: in §2 we consider some of the predictions of autosegmental tonology in order to see how they have fared since the 1970s. In §3 we consider the issue of underspecification, while §4 addresses the issues of tone features, tonal geometry, and tone-bearing units. §5 evaluates potential limitations of autosegmental representations, while §6 concludes the chapter with a brief consideration of tone in constraint-based phonology. We will see that there is much reason to hold on to the autosegmental insight even as phonological frameworks have evolved.

2 Autosegmental tonology

One can distinguish two consequences of autosegmental phonology (see also CHAPTER 14: AUTOSEGMENTS) as applied to tone: those that follow directly from the architecture *vs.* those that involve additional principles or conventions. We take up the first of these here and postpone discussion of the second until §5.

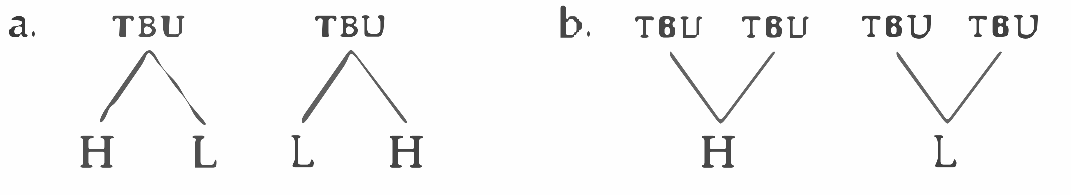
There are at least three direct consequences of the two-tier autosegmental architecture proposed by Goldsmith, as in (7):

(7) a. non-isomorphism between the tiers
  b. zero representation on one *vs.* the other tier
  c. stability effects

2.1 *Non-isomorphism*

Using TBU to represent the tone-bearing unit to which tones link (see §4), the first of these is schematized in (8).

(8)



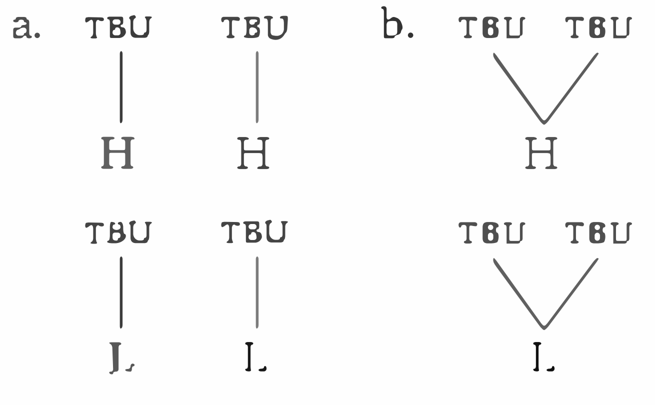
We have already seen that more than one tone can link to a single TBU, resulting in falling and rising contour tones, as in (8a). Complex contours are also attested, as exemplified in (9).

(9)	a.	falling-rising:	Iau	be^{213}	'tree fern'	(Bateman 1990)
				ba^{243}	'sticking to'	
	b.	rising-falling:	Nzadi	mwǎ̀n	'child'	(personal notes)
				dzǐ̀	'eye'	

In addition, Lomongo is said to have LHLH on one syllable derived from elision (Hulstaert 1961: 164): /èmí là wě bàsàngì/ → [èm_â w_ǎ̌sàngì] 'it's you and I who are related', where _ marks the two places where elision occurs.

The second type of non-isomorphism in (8b) shows that the same tone can link to more than one TBU. What this means is that there is a potential contrast between the representations in (10a) *vs.* those in (10b).

(10)



contrasts with /Ø/ rather than /L/.) Although a rare occurrence, the tautomorphemic version of the OCP is thereby violated.

Similar contrasts and OCP problems are found with respect to /L/ tones in Dioula d'Odienné (Braconnier 1982). In this language there is a rule of the form in (14), where pause (//) may be interpreted with a %L boundary tone:

(14) L → H / {//, L} __ H

As seen in (15), the rule is not iterative, as only one L autosegment can be raised:

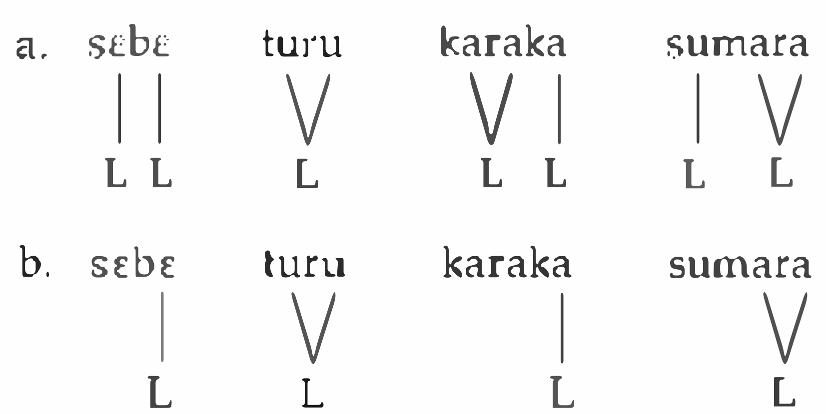
(15)	a.	/i mà dɛ̀ tá/	→	ì mà dɛ̌ tá	'you didn't take any child'
				*ì má dɛ̌ tá	
	b.	/i mà tùrù tá/	→	ì mà túrú tá	'you didn't take any oil'
				*ì má túrú tá	

However, the following examples show that not all monomorphemic L tone nouns have the same properties before H:

(16)	a.	*before pause*	b.	*before* H	
		sɛ̀bɛ̀		sɛ̀bɛ́	'paper'
		tùrù		túrú	'oil'
		kàràkà		kàràká	'bed'
		sùmàrà		sùmárá	'soumbala (a spice)'

One solution is to give the above nouns the representations in (17a), where the OCP is violated similarly to Odden's (1982) tautomorphemic Hs in Shambala.

(17)



Another solution in (17b) might be to posit a distinction between /L/ and toneless TBUs, which later become L by default. While the OCP is violable in the ways just seen, it is important to note that the autosegmental representations provide a straightforward way of encoding the contrastive tonal properties of Kukuya, Kishambaa, and Dioula d'Odienné. Other frameworks would have to resort to ad hoc junctures or diacritics.

2.2 *Zero representation*

The second consequence that directly flows from the autosegmental architecture is the possibility that a tone can exist without a TBU, and vice versa. When a morpheme consists solely of a tone, it is referred to as a tonal morpheme (see also CHAPTER 82: FEATURAL AFFIXES). An oft-cited example is the associative (genitive) marker in Igbo (see Williamson 1986 and references cited therein), which is most transparently observed when preceded and followed by a L–L noun. As seen in (18), the H tonal morpheme is assigned to the preceding TBU in Central Igbo and to the following TBU in the Aboh dialect:

(18) a. *Central Igbo* àgbà + ´ + èŋwè → àgbá èŋwè 'jaw of monkey'
b. *Aboh Igbo* ẹ̀gbà + ´ + èŋwè → ẹ̀gbà éŋwè 'jaw of monkey'

Floating tones can also be part of a lexical morpheme. In Aghem, the nouns [kífú] 'rat' and [kɨ́wɔ́] 'hand' are both pronounced with H–H tones in isolation (Hyman 1979). However, as seen in (19), they have different effects on the following word (the [kí-] prefix drops out when the noun is modified):

(19) a. fú kɨ̂a 'your (SG) rat' b. fú kɨ́n 'this rat'
H L H H
wɔ́ kɨ̀a 'your (SG) hand' wɔ́ ꜜkɨ́n 'this hand'
H L L H L H

In (19a), the H of the stem /-fú/ spreads onto the /L/ of /kɨ̀a/ 'your SG (class 7)' creating a HL contour. As seen, the floating L of /-wɔ́`/ 'hand' blocks the spreading. When followed by the /H/ tone demonstrative /kɨ́n/ 'this (class 7)' in (19b), 'this rat' is realized H–H, while 'this hand' has a downstep conditioned by the same lexical floating L of /-wɔ́`/, which was originally due to a historically lost syllable (cf. Proto-Bantu *-bókò 'hand').

Corresponding to floating tones, which lack a TBU, are TBUs that lack tones. Such toneless morphemes may receive their tonal specification by context or by default tone assignment (see §3). An oft-cited example of the former comes from Mende (Leben 1973, 1978):

(20)

	base noun			+hu 'in'	+ma 'on'
a.	/H/	kɔ́	'war'	kɔ́-hú	kɔ́-má
b.	/L/	bɛ̀lɛ̀	'trousers'	bɛ̀lɛ̀-hù	bɛ̀lɛ̀-mà
c.	/HL/	mbû	'owl'	mbú-hù	mbú-mà
d.	/LH/	mbà	'rice'	mbà-hú	mbà-má
e.	/LHL/	njàhà	'woman'	njàhá-hù	nyàhá-mà

As seen, the tone of the two locative postpositions is the same as the last underlying tone of the nouns to which they attach. The /HL/, /LH/, and /LHL/ "melodies" are linked one-to-one to the noun + postposition constituent.

2.3 *Stability effects*

The third consequence of autosegmental representations, stability, is related to the second: when a TBU is deleted, its tone may still remain, and vice versa. An example of this comes from Tangale, which Kenstowicz and Kidda (1987: 230) cross each other. The representation of L as /Ø/, on the other hand, allows for such long-distance processes without requiring further complications.

Just as in the case of single *vs.* multiply linked tones, underspecification potentially allows for more distinctions than fully specified representations. Limiting ourselves first to languages that have only two tone heights, (23) summarizes the possible analyses:

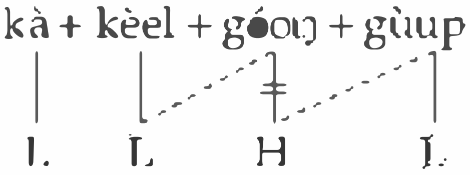
(23) a. /H/ *vs.* /L/
  b. /H/ *vs.* /Ø/
  c. /L/ *vs.* /Ø/
  d. /H/ *vs.* /L/ *vs.* /Ø/

As seen, the tonal contrast may be binary, with /H/ contrasting with /L/; privative, with either /H/ or /L/ contrasting with /Ø/; or both, in the case of where a ternary system of /H, L, Ø/ is required. Thus, the central question concerning any such system is to determine which of the above representations best accounts for the properties of the surface [H] *vs.* [L] contrast.

A /H, L/ system is required when both features are phonologically active (see also CHAPTER 4: MARKEDNESS for more discussion of markedness). This is seen in Kuki-Thaadow, which has both H- and L-tone spreading (Hyman 2010):

(24) a. /kà + zóoŋ + lien + tʰúm/ [kà zòoŋ líen tʰǔm] 'my three big monkeys'

  b. /kà + kèel + góoŋ + gùup/ [kà kèel gòoŋ gûup] 'my six thin goats'



Not only do both /H/ and /L/ spread onto a following /L/ and /H/ syllable, respectively, but the result in final position is a rising (LH) or falling (HL) contour tone. Both spreading and contour tones would be difficult to represent if one of the tones were underspecified. The same would be true of a language which has both floating H and L.

While /H, L/ systems are those in which the phonology refers to both tone values, in a privative tone system only one of the two tones is phonologically active. Many Bantu languages have a /H, Ø/ system, as was seen in the Giryama examples in (22). A few have a /L, Ø/ system, such as Ruund, for which Nash (1992–94) gives the following arguments:

(25) a. Hs are by far more numerous than Ls, hence "unmarked."
  b. Floating L exists, while floating H does not.
  c. Morphological rules assign L tones, not Hs.
  d. Phonological rules manipulate L tones, not Hs.

Athabaskan languages are also known for having H- *vs.* L-marked tone systems (see the various studies in Hargus and Rice 2005). The closely related South American dialects, Bora (Weber and Thiesen 2000) and Miraña (Seifart 2005), have

(1988) propose that Yoruba has the system in (27b), where M tone is not only unmarked, but underspecified. Among the arguments is the fact that Yoruba allows only HL and LH contours, but none involving M tone (*MH, *LM, *HM, *ML). If M = /Ø/, it follows that Ø cannot form a contour with either H or L. Another argument derives from alternations in which H or L overrides M tone. While all of these properties naturally follow from the underspecification of M, the latter can be set up as /M/, as long as other mechanisms are put in place to capture the recessiveness of M tones. Pulleyblank (2004), for instance, proposes an account within Optimality Theory in which, essentially, M tones need not be preserved in outputs to the same degree as H or L. An argument for a /H, Ø, L/ system comes from Peñoles Mixtec (Daly and Hyman 2007), which has an OCP constraint disallowing successive Ls, or Ls which are separated by any number of /Ø/ TBUs. The result is the L-tone deletion rule in (28a).

(28) a. L → Ø / L __
b. ɨ̈^{N} di̱i-ni-kwe-ʃi kada-kwe-ʃi ɨ̈^{N} ɨ̈^{N} ʧi̱u^N (^{N} = nasalization)
L (under di̱i) … L (under ʧi̱u) ↓ Ø
'only one of them will do each of the jobs'

As seen, this rule is responsible for the loss of the second L on /ʧi̱u^N/ 'work' in (28b), which is separated from the first L by twelve toneless TBUs. That the two L tones can 'see' each other over long distances is strong evidence for the underspecification account.

Returning to the systems in (27), (27c) and (27d) seem to be rare or non-occurring. Paster (2003) proposes /H, M, Ø/ for Leggbó, with /Ø/ alternating between H and L in the verb morphology (cf. §4). If correct, the relatively few short-vowel LH, HL, and LM contours would have to be exceptionally marked: [èggǔ] 'catfish (sp.)', [gēppjôn] 'afternoon', [lèssò¯] 'last year'. While I am unaware of any three-height tone system being analyzed as /Ø, M, L/, the system in (27e) seems at first appropriate for Yatzachi Zapotec (Pike 1948). Although this language has only the three surface tones H, M, L (and HM and MH contours on monosyllabic words), there are two kinds of L tones: those that alternate with M *vs.* those that do not. Pike identifies these, respectively, as class A *vs.* class B. For example, a class B L will become M when followed by a M or H within or across words, while a class A L tone will not be affected. This is seen in the minimal pair in (29).

(29)	a.	L_a	[bìa]	'cactus'	bìa gōlī	'old cactus'
	b.	L_b	[bìa]	'animal'	bīa gōlī	'old animal'

A natural interpretation would be to recognize L_a as /L/ and L_b as /Ø/. Where the /Ø/ tone is not realized M, i.e. when not occurring before a /M/ or /H/, it will be realized with a default L tone, hence merging with class A /L/. However, it is hard to evaluate this proposal without considering what the featural representation is of all of the tones in the language (see Hyman 2009). It is likely that Yatzachi Zapotec has two kinds of L tone because it originally contrasted four tone heights. The L_b /Ø/ could therefore have been a tone level between M and or binary and hierarchized (Clements 1983). Anderson (1978) provides a comprehensive appraisal of the different feature proposals up to that date. If assimilations are assumed to spread individual features such as [UPPER] and [RAISED], these latter must occur on independent tiers. This then raises the question of where these tiers link up, e.g. to a laryngeal node or directly to the TBU? There have been numerous proposals in the literature (see the surveys and discussion in Yip 1995, 2002; Bao 1999; Snider 1999; and Lee 2008). The advantage of the first proposal is that tones frequently interact with other laryngeal properties. Halle and Stevens' (1971) system in (35) – an early attempt to capture the relation between tone and obstruent voicing – fails, however, to characterize more than three tone heights:

(35)

	tones			*voiceless obstruents*	*sonorants*	*voiced obstruents*
	H	M	L	p t k f s	m n l w j	b d g v z
stiff	+	–	–	+	–	–
slack	–	–	+	–	–	+

Clearly, one wants to account for the relation between tone and (non-modal) phonations, or the interference of obstruent voicing with tonal assimilations, but not at the expense of losing the generalization that tones are distributed by TBUs. While tones have an autosegmental independence, they ultimately must be realized on something, e.g. a vowel or syllabic consonant. A language may consistently assign tones by mora, such that a CVV syllable receives two tones, or it may assign tones by syllable. Sometimes it is difficult to distinguish between the two. The complexities and corresponding representational possibilities are many. Both Clements *et al.* (2009) and Hyman (2009) have expressed doubts that tones should be analyzed in terms of features at all.

5 Possible limits of autosegmental representation

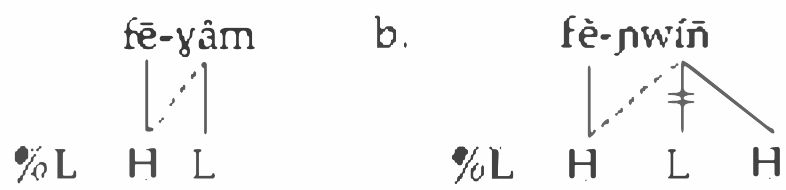
Two general conclusions can be drawn from the preceding sections. First, there is still much merit in the autosegmental insights on tone. Second, there is much more work to do. In this section we first address real or apparent problems for autosegmental tonology. The arguments for autosegmental tonology were enumerated in §2. Some of the evidence concerned the non-isomorphism between the tones and their TBUs: more than one tone can link to a TBU, in which case we get a tonal contour or cluster; conversely, one tone can link to more than one TBU. Contrasting representations such as those in (12a) and (17a) were said to be needed. The question here is whether they ever get in the way: are there cases where it is disadvantageous to represent a tautomorphemic H–H or L–L as a single tone linked to two TBUs?

One such awkward case would seem to arise in Kom, which has an underlying contrast between /H/ and /L/, but a surface contrast between H, M, and L. All M tones are derived by a rule that lowers a single H TBU to M when preceded by a L or initial phrase boundary (which can be represented by a %L boundary tone). This produces outputs such as the following:

(36) a. /fe-ɣam/ → fē-ɣâm 'mat' [M–HL]
H L
b. /fe-ɲwin/ → fē-ɲwíň 'bird' [M–HM]
H LH
c. /fe-buʔ/ → fē-búʔ 'gorilla' [M–H]
HHL
d. /fe-tam/ → fē-tám 'fruit' [M–H]
H H

As in these examples, most nouns in Kom have a /H/-tone prefix followed by a monosyllabic stem that can have any of the four tone patterns exemplified in (36). As schematized in (37), the H of the prefix spreads onto a following L or LH stem:

(37) a. b.

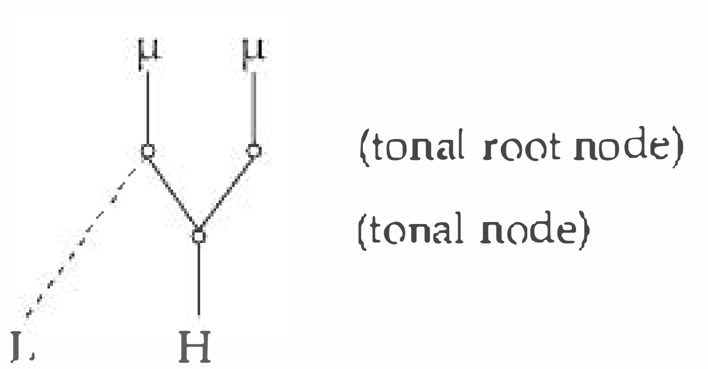


As seen in the transcriptions, the output is M–HL in (37a) and M–HM in (37b). The M tones in question are conditioned by the rule that lowers a H to M after a (linked, floating, or boundary) L. In both forms the prefix is thus lowered to M; in addition, in (37b), the (delinked) stem L lowers the following H to produce the HM contour. Since the prefix lowers to M without affecting the stem, the lowering rule cannot be written as a single-tier rule, as in (38), or we would get the wrong outputs *M–ML and *M–M:

(38) H → M / L __ (cf. the Kukuya rule in (13))

It is clear that the doubly linked H representation is not useful, but it is not fatally contradictory to the autosegmental approach. At least four responses come to mind. First, assuming that the TBU is the mora and that stems are bimoraic, the M can be derived by delinking a H from the first TBU (mora) that immediately follows a L. Second, one can complicate the tonal geometry to include a tonal root node, as in (39), to which the preceding L can link as a register feature, perhaps [–RAISED] (cf. the surveys of similar proposals in Bao 1999 and Snider 1999):

(39)



Third, assuming that floating tones persist into the output, one might argue that the M outputs are derived by phonetic implementation, where the M may be interpolated as part of the aligning of output tones with their segmental supports. A fourth possibility is to spread the L to form a LH TBU, which is phonetically interpreted as M.

(50) a. ne fe-ɣam -fe → nè fè-ɣǎm̄ -fè° 'with a mat' [L–L–ML–L°]
L H L H → L H L H

b. ne fe-ɲwin -fe → nè fè-ɲwīn -fé 'with a bird' [L–L–M–H]
L H L H H → L H L H H

c. ne fe-buʔ -fe → nè fè-búʔ -fē 'with a gorilla' [L–L–H–M]
L H HL H → L H HL H

d. ne fe-tam -fe → nè fè-tám -fé 'with a fruit' [L–L–H–H]
L H H H → L H H H

As seen, Kom has both H- and L-tone spreading. In (50a), L-tone spreading causes the following H to delink (producing a level L° tone on the postposition), while H-tone spreading does not cause the following L to delink. With a single H TBU lowering to M after L (cf. (37)), the noun stem /-ɣàm/ 'mat' surfaces with a ML contour tone. Similarly, the stem /-ɲwìn/ 'bird' surfaces as M, each of the two linked H tones being lowered to M by a preceding L. The important examples are (50c) and (50d). As seen, when the L of /nè/ spreads and delinks the H of the noun prefix /fé-/, the latter's H tone floats. As a result, the floating H shields the roots /-búʔ`/ 'gorilla' and /-tám/ 'fruit' from lowering to M. (The floating L of /-búʔ`/ is responsible for the lowering of the postposition /-fé/ to M in (50c).) Since the H to M lowering process is a late one for which we have even entertained the possibility that it applies in phonetic implementation, it should be clear that the floating Hs must persist into the surface representations. The alternative, that L-tone spreading does not delink a following H, but rather creates LH rising tones that are simplified in phonetic implementation, is perhaps suspect, if not ad hoc. If, on the other hand, the floating tones are allowed to occur in surface representations, the solution is straightforward.

Such a conclusion would also seem to have consequences for other analyses. Particularly within OT, the question arises whether a surviving, delinked floating tone should be able to satisfy MAX(Tone). Data from Kuki-Thaadow suggest maybe not. In this largely monosyllabic Tibeto-Burman language, words are underlyingly /H/, /L/, or /HL/ (Hyman 2010). As seen in (51a), however, a rising tone results from L-tone spreading:

(51) a. /hùon + zóoŋ/ → hùon zǒoŋ 'garden monkey'
L H

b. /hùon + zóoŋ + gùup/ → hùon zòoŋ gûup 'six garden monkeys'
L H L

In (51b) we see that Kuki-Thaadow also has H-tone spreading, and the H of /zóoŋ/ is delinked. This is because rising (LH) and falling (HL) tones are permitted only phrase-finally. Thus, the L of /hùon/ 'garden' is realized on /zóoŋ/ 'monkey', and the H of /zóoŋ/ is realized on /gùup/ 'six'.

Now consider the forms in (52).

```
(52)  a.  /hùon + zóoŋ + thúm/ → hùon zóoŋ thúm    'three garden monkeys'
            |      |       |
            L      H       H

      b.  /hùon + zóoŋ + gîet/  → hùon zóoŋ gîet   'eight garden monkeys'
            |      |       |
            L      H       HL
```

As seen, L-tone spreading does not occur when the targeted H tone is followed in turn by a H or HL tone. The question is: Why not? To answer this we have but to consider what the output would have been if L-tone spreading had applied in (52). The H of /zóoŋ/ would necessarily have had to delink, since a LH rising tone is well formed only in phrase-final position. As a result, the underlying /H/ would, at best, have to float. The question, then, is why this would not be well formed. It cannot be that an input link must remain as such in the output, since the H does delink in (51b). Instead, what seems to allow L-tone spreading to apply in (51a) and (51b) is that the input /H/ of /zóoŋ/ is preserved in the output: It is realized within the LH contour on its own syllable in (51a) and as part of the HL contour on the following syllable in (51b). In other words, Max(H) is satisfied. We must suppose, therefore, that if L-tone spreading applied in (52) and delinked the /H/ of /zóoŋ/, the resulting floating H would not satisfy Max(H). By contrast, H-tone spreading applies whether or not the targeted L remains linked on the surface (see Hyman 2010). We therefore can establish the ranking in (53).

(53) Max(H) >> Spread(H,L) >> Max(L)

In Kuki-Thaadow all input H tones make it to the surface, *vs.* closely related Hakha Lai, where the opposite ranking Max(L) >> Max(H) results in all input L tones being realized on the surface (Hyman and VanBik 2004). It should be noted that the non-application of L-tone spreading in (52) results more straightforwardly from the ranked constraints in (53), rather than from a requirement on recoverability: had L-tone spreading applied in (52a), the output L–L–H sequence would have unambiguously pointed to underlying /L–H–H/, since /L–L–H/ would have been realized as L–L–LH. (The same is not true of (52b), since L-tone spreading does not apply to a following HL tone.) If (53) is correct, OT will have made a unique contribution in providing a constraint, Max(H), which is responsible for the non-application of L-tone spreading in (52). By contrast, a rule-based approach would have to stipulate that L-tone spreading occurs to a L–H sequence when the H is followed either by pause or by a L tone, and would not provide any motivation for why the rule does not apply when the following tone is H or HL. Whether this is an indication that OT is on the right track – and can hence offer more improvements over the pre-OT conceptions of tonology – remains to be seen. In fairness, it must be said that the blocking of an otherwise general L-tone spreading process in (52) is unique to Kuki-Thaadow. As pointed out by Hyman (1973b: 157), we expect L–H–H to be a better target for L-tone spreading than L–H–L. Except for Kuki-Thaadow, this is true whether the H–H sequence is from two /H/ tones or from one /H/ that is doubly linked.

Where does this leave the representation of tone? To summarize the foregoing sections, although the well-formedness and mapping conventions in (44) have been superseded in subsequent work, most of the essential representational insights of autosegmental tonology are still intact. The above discussion has only touched on a small part of the vast world of tone and of the growing constraint-based literature treating tone. Whatever the outcome of ongoing OT interpretations of tone, it is likely that questions of representation will remain central.

46 Positional Effects in Consonant Clusters

Jongho Jun

1 Introduction

It is commonly observed across languages that phonological processes may apply only in certain ("non-prominent") positions. In contrast, elements in other ("prominent") positions typically resist or trigger these processes. Such prominent *vs.* non-prominent positional distinctions are further applicable to more general patterns of licensing and neutralization of phonological contrasts; namely, featural/segmental contrasts are likely to be licensed in prominent positions, whereas these contrasts are likely to be neutralized in non-prominent positions. Pairs of prominent and non-prominent positions include word-initial *vs.* non-initial, stressed *vs.* unstressed, root *vs.* affix, and prevocalic *vs.* preconsonantal positions. Among the positional effects involving these pairs, this chapter is mainly concerned with those involving the two members of intervocalic consonant clusters. See Beckman (1998) and Barnes (2006) for recent extensive investigations of other positional effects; see also CHAPTER 104: ROOT–AFFIX ASYMMETRIES and CHAPTER 102: CATEGORY-SPECIFIC EFFECTS. In intervocalic C_1C_2 clusters, the preconsonantal C_1 is more likely to undergo phonological processes such as voicing and place assimilation, in contrast with the prevocalic C_2, which is rarely subject to such processes. I will refer to this asymmetric positional effect as the C_2 dominance effect.

This chapter discusses empirical data patterns which display positional effects. Its focus will be on how to explain the C_2 dominance effect. I will begin with a discussion of typical data patterns of the C_2 dominance effect and proceed to less common, somewhat exceptional, patterns which are nonetheless crucial in comparing the previous approaches. Specifically, I will concentrate on the comparison between prosody-based approaches (Itô 1986, 1989; Cho 1990; Goldsmith 1990; Rubach 1990; Lombardi 1995, 1999, 2001b; Beckman 1998; Kabak and Idsardi 2007) and cue-based approaches (Steriade 1993, 1995, 1999, 2001, 2009; Flemming 1995; Jun 1995, 2004; Padgett 1995; Boersma 1998; Hume 1999; Côté 2000; Wilson 2001; Blevins 2003; Seo 2003). It will be shown that current evidence is mixed. Much of the commonly observed data, to be discussed in the following two sections, can be equally well accommodated in the two approaches. However, there exist less common patterns which can be understood under only one of the two approaches. Evidence exclusively supporting the cue-based approach will be discussed in §4, and evidence for the prosody-based approach in §5.

2 C_2 dominance effect

Assimilation occurs in consonant clusters when one of two neighboring consonants takes on some property of the other. I will call the former (i.e. the undergoer of assimilation) the target, and the latter (i.e. the source of the assimilating property) the trigger. With respect to the assimilation in C_1C_2 clusters, it is cross-linguistically true that C_1 and C_2 are the target and the trigger, respectively, and thus the direction of assimilation is regressive. To illustrate this C_2 dominance effect, I will first consider patterns of voicing assimilation and then patterns of place assimilation. Finally, patterns of consonant deletion will be discussed.

As can be seen in (1), in Catalan, Polish and Russian, voiced and voiceless obstruents are separate phonemes, and they may occur unhindered in prevocalic position. But in clusters composed of obstruents, the first constituent of the cluster must agree in voicing with the following constituent. As shown in (1.i), underlyingly voiced obstruents in C_1 become voiceless before a voiceless obstruent in C_2 whereas underlyingly voiceless obstruents in C_1 become voiced before a voiced obstruent in C_2, as in (1.ii). Thus, voicing assimilation occurs in clusters, targeting C_1. This C_2 dominance effect in voicing assimilation can be seen in other languages, including Dutch, Yiddish, Sanskrit, Romanian, Serbo-Croatian, Ukrainian, Hungarian, Egyptian Arabic, and Lithuanian. Steriade (1999) and Beckman (1998) provide in-depth discussion of voicing assimilation, i.e. a type of laryngeal neutralization, in these languages, emphasizing that it is normally regressive, and thus its C_2 dominance effect is quite robust.

(1) *Regressive voicing assimilation*

	back track	*ba[t] track	*back [k]rack

This C_2 dominance effect in casual speech assimilation can also be seen in other languages, such as German (Kohler 1990, 1991a, 1991b, 1992), Malay, Thai (Lodge 1986, 1992), Toba Batak (Hayes 1986), Spanish (Harris 1969), and Ponapean (Rehg and Sohl 1981); see also CHAPTER 79: REDUCTION on assimilation as a casual speech phenomenon.

The C_2 dominance effect is not limited to assimilation in consonant clusters, but extends to consonant deletion in clusters. Consonant deletion occurs in clusters when one of two adjacent consonants, i.e. the target, deletes. It has been observed and emphasized in the literature (Côté 2000; Wilson 2001; Jun 2002; McCarthy 2008) that C_1, as opposed to C_2, is always the target in such deletions. For instance, as shown in (4), stops in C_1, not C_2, delete in Diola Fogny, West Greenlandic, and Basque.

(4) *Consonant deletion: C_1 is the target*

a. *Diola Fogny* (Sapir 1965)

/let+ku+jaw/	[le kujaw]	'they won't go'
/kutεb sinaŋas/	[kutε sinaŋas]	'they carried the food'
/εkεt bo/	[εkε bo]	'death there'

b. *West Greenlandic* (Rischel 1974; Fortescue 1980)

/qanik+lerpoq/	[qani lerpoq]	'begins to approach'
/ukijuq+tuqaq/	[ukiju tuqaq]	'old year'
/anguti+kulak/	[angu kulak]	'he goat'

c. *Basque* (Hualde 1987)

/bat+paratu/	[ba-paratu]	'put one'
/bat+kurri/	[ba-kurri]	'run one'
/guk+piztu/	[gu-piztu]	'we light'
/guk+kendu/	[gu-kendu]	'we take away'

[1] In Korean, which has a three-way laryngeal contrast among obstruents, i.e. lenis, aspirated, and tense, lenis obstruents become tense after an obstruent (Post-obstruent tensing), and voiced between sonorants (Inter-sonorant voicing). See Kim-Renaud (1986) and Ahn (1998) for details of these automatic processes.

In addition to those shown above, consonant deletion with a C_1 target can be found in Akan (Lombardi 2001b, citing Schachter and Fromkin 1968), Axininca person prefixes (Lombardi 2001b, citing Payne 1981), Carib (Gildea 1995), and Tunica (Wilson 2001, citing Haas 1946).

Consequently, as summarized below, the cross-linguistic generalization which is common to the three phonological processes (voicing assimilation, place assimilation, and consonant deletion) is that C_1 in intervocalic C_1C_2 clusters is the target, whereas C_2 is the trigger.

(5) *The C_2 dominance effect in voicing assimilation, place assimilation, and consonant deletion*

In intervocalic C_1C_2 clusters, C_1 is a typical target, and C_2 is a typical trigger.

Let us consider how to capture this C_2 dominance effect. It is not difficult to derive patterns with the C_2 dominance effect within the framework of previous theories such as classical generative theory, autosegmental phonology, and underspecification theory. For instance, regressive assimilation can easily be characterized by a rule of the type shown in (6a). However, progressive assimilation can also be formulated with equal complexity, as shown in (6b), and its absence, or at best rarity, in the typology would be a surprise. Representational theories such as autosegmental phonology, feature geometry, and underspecification theory would be no better in this respect than classical generative theory, as there is no plausible reason to differentiate in the complexity of the representation between the two members of a consonant cluster. (See Jun 1995 for the relevant discussion.)

(6) *Rules for consonant place assimilation*

a. $C \rightarrow [\alpha\text{place}]$ / __ $[C, \alpha\text{place}]$ (regressive assimilation)
b. $C \rightarrow [\alpha\text{place}]$ / $[C, \alpha\text{place}]$ __ (progressive assimilation)

Compared to the rule-based theories with a focus on the correct formulation of the language-specific phonological processes, Optimality Theory (McCarthy and Prince 1995; Prince and Smolensky 2004) is more concerned with universal patterns, thus being in a better position to explain positional effects such as the C_2 dominance effect and understand the motivation behind processes showing the effect.

Along with the development of Optimality Theory, there have been two major lines of approach to the analysis of the positional effects, Licensing-by-cue and Licensing-by-prosody (in Steriade's 1999 terminology). The prosody-based approach explains positional asymmetries by reference to prosodic structure. It attributes the C_2 dominance effect to the coda-onset asymmetry since C_1 and C_2 are usually syllabified as a coda and an onset, respectively. The C_1 in the coda is likely to be targeted in the processes since the coda is phonologically non-prominent and marked. In contrast, the C_2 in the onset resists these processes since the onset is phonologically prominent and unmarked. For an analysis of the data of the C_2 dominance effect, either greater faithfulness to the onset and/or dispreference for the coda or (marked) properties in the coda have been called on. Specifically, within the framework of Optimality Theory, positional faithfulness constraints for the onset or/and positional markedness constraints for the coda have been adopted in the literature. (See Casali 1996, 1997 and Beckman 1998 for positional faithfulness analyses, and Zoll 1998 for the comparison between positional faithfulness and positional markedness.)

In contrast, the cue-based approach (Flemming 1995; Steriade 1995, 1999, 2001, 2009; Boersma 1998; Côté 2000; Wilson 2001; Blevins 2003; Jun 2004) explains the C_2 dominance effect by relying on the perceptual factors involved. The C_1 has low perceptibility since it is preconsonantal and thus may lack important perception cues, such as release bursts and C-to-V formant transitions, to laryngeal/place features and segmenthood under overlap with C_2 (Lamontagne 1993; Wright 1996). In contrast, the C_2 is perceptually prominent since it is prevocalic, being able to maintain such perception cues. (See Wright 2004 for a detailed discussion of perception cues.) From the assumption that change in perceptually prominent positions would cause drastic input-output difference, and thus be greatly dispreferred, whereas the comparable change in non-prominent positions would cause less difference, and thus be less dispreferred, it is derived that non-prominent C_1 is more likely to be modified, i.e. targeted in phonological processes, than prominent C_2. Thus, the cue-based approach attributes the C_2 dominance effect to higher perceptibility of C_2 over C_1.

The two approaches under consideration differ in whether the constraints (and rules) adopted to explain positional effects should be expressed as prosody-based or string-based (more precisely, cue-based) statements. However, the empirical data presented thus far will not distinguish the two approaches, since the preconsonantal C_1 which is expected to be the target of the phonological processes in the cue-based approach is normally syllabified as a coda, which the prosody-based approach also expects to be the more likely target. In §4 and §5, I will present the data patterns for which the two approaches make distinct predictions.

3 Non-assimilatory neutralization

Assimilation can be considered as a case of contrast neutralization. As shown in the previous section, assimilation is primarily regressive (i.e. C_1 is the target), and thus potential contrasts of the assimilating feature are neutralized in C_1 position. For instance, in regressive voicing assimilation, consonants in C_1 with distinct voice feature values in their underlying form would have identical phonetic realization with respect to voicing, i.e. they are voiced before a voiced segment and voiceless before a voiceless one. Non-assimilatory neutralization of voicing, as well as other laryngeal features and place of articulation features, targets the C_1 and word-final position. In languages which have voicing assimilation in consonant clusters, the word-final position is the only available target of non-assimilatory neutralization, and in fact languages with voicing assimilation mentioned in the previous section show final devoicing, as in (7) (see also CHAPTER 69: FINAL DEVOICING AND FINAL LARYNGEAL NEUTRALIZATION).

(7) *Final devoicing in languages with voicing assimilation*

a. *Catalan* (Beckman 1998, citing Hualde 1992)

		__V		__#	
i.	/t/	['gatə]	'cat (FEM)'	['gat]	'bad (MASC)'
	/k/	['pɔkə]	'little (FEM)'	['pɔk]	'little (MASC)'

(9) *Place assimilation and final place neutralization*

a. *Spanish* (from Harris 1984)
   i. Homorganic NC clusters: ca[mp]o, ma[ns]o, ma[ŋk]o, á[ɱf]ora, ma[n̪t]o
   ii. Final [n] in standard varieties: e[n] Chile, ta[n] frío, u[n] elefante
   iii. Final [ŋ] in non-standard varieties: e[ŋ] Chile, ta[ŋ] frío, u[ŋ] elefante

b. *Japanese* (Vance 1987; Yip 1991; Itô *et al.* 1995; Kager 1999)
   i. *Geminates*

kap.pa	'a legendary being'
kit.te	'stamp'
gak.koo	'school'

   ii. *Homorganic nasal + obstruent*

tom.bo	'dragonfly'
non.do	'tranquil'
kaŋ.gae	'thought'
/jom + te/ → jonde	'reading'
/ʃin + te/ → ʃinde	'dying'

   iii. *Final mora nasal*

hoN	'book'
zeN	'goodness'

There are also languages in which place neutralization occurs only in a non-assimilatory fashion. As discussed in Lombardi (2001b, citing Rice 1989), non-sonorant consonants in Slave (Athabaskan) are realized as /h/ syllable-finally, as shown in (10a). Sonorants are like obstruents in having no place distinctions, although the exact final neutralization patterns are not the same. Syllable-final nasals delete, nasalizing the preceding vowel, and /j/ is the only possible coda among non-nasal sonorants. Another example of non-assimilatory place neutralization is from the Kelantan dialect of Malay (Teoh 1988). Final stops /k t p/ are realized as [ʔ], and final fricatives like /s/ as [h], as shown in (10b).

(10) *Final place neutralization* (from Lombardi 2001b)

a. *Slave*

i.	/ts'ad/	ts'ah	-ts'ade	'hat'
ii.	/xaz/	xah	-ɣaze	'scar'
iii.	/seeɣ/	seeh	-zeeɣe	'saliva'
	/tl'uł/	tl'uh	-tl'ułe	'rope'

b. *Kelantan Malay*

i.	/ikat/	ikaʔ	'tie'
ii.	/səsak/	səsaʔ	'crowded'
iii.	/dakap/	dakaʔ	'embrace'
iv.	/tapis/	tapih	'to filter'

In these languages, contrasts of some features other than place can be maintained finally, for instance obstruents *vs.* sonorants in Slave and stops *vs.* fricatives in Kelantan Malay. But there are also many languages like Burmese in which all consonants are neutralized to [ʔ]. (See Lombardi 2001b and references therein for more details.)

In summary, as stated below, the preconsonantal C_1 is not only the typical target of assimilation, but also the typical target of the non-assimilatory neutralization. The word-final position is an additional typical target of the neutralization.

(11) *The C_2 dominance effect in (assimilatory and non-assimilatory) laryngeal and place neutralization*

Preconsonantal C_1 and word-final positions are common target positions.

It is usually the case that preconsonantal C_1 and word-final positions form a natural class, i.e. coda. Thus it is obvious that the prosody-based approach can provide a unified account of positional neutralizations of C_1 and word-final positions, attributing both cases to the coda-onset asymmetry. The cue-based approach also provides a somewhat unified account for the two common target positions based on the fact that the word-final position lacks C-to-V transition cues, just as preconsonantal C_1 does, and thus it has lower perceptibility compared to the prevocalic C_2 position. Consequently, the relatively common positional neutralization patterns presented thus far do not significantly distinguish the two approaches. In the remainder of this chapter, I will consider the patterns which crucially distinguish them.

4 Evidence for the cue-based approach

4.1 *Neutralization sites ≠ syllable positions*

According to the prosody-based approach, neutralization contexts should be described in prosodic terms: for instance, "codas are the target of laryngeal neutralization." But, as discussed by Steriade (1999), there are cases in which there is no consistent connection between neutralization sites and syllable structure.

First, there are languages in which neutralization targets only C_1, not word-final, positions. Languages in which laryngeal neutralization occurs only in C_1, not at the end of the word, include Yiddish, Romanian, Serbo-Croatian (Lombardi 2001b: 269), French, Hungarian, and Kolami (Steriade 1999). In addition, place neutralization of nasals occurs only in C_1, not at the end of the word, in Diola Fogny (Sapir 1965) and the Souletin dialect of Basque (Hualde 1993). Under the prosody-based approach, it is not clear why word-medial and final codas behave differently, and even less clear why medial codas are more likely to be targeted in the neutralization than word-final codas (see CHAPTER 36: FINAL CONSONANTS for more discussion). In contrast, in the cue-based approach, the asymmetry between preconsonantal C_1 and final positions may be derived from their relative perceptibility difference. C_1 may be considered less perceptible than word-final position, because stops in C_1, which overlap with consonants in C_2, are more likely to be unreleased, thus lacking the release burst and closure duration cues, than those in word-final position.[3]

[3] Blevins (2006: 143) discusses data from Dhaasana, Chadic Arabic, and Maltese in which devoicing occurs exclusively at the end of the word, not in C_1 position. This word-final, but not syllable-final, devoicing can be a problem not only for the prosody-based approach but also for the cue-based approach.

Second, laryngeal neutralization targets C_1 only before obstruents, not before sonorants, regardless of its syllabic assignment in many languages, including Lithuanian, German, Russian, Greek, Sanskrit, Polish, Hungarian, and Kolami. Notice that it is possible that C_1 in intervocalic C_1C_2 clusters is syllabified as a coda when sonorant consonants occupy C_2, and its voicing contrast is then expected to be neutralized in the prosody-based approach. Also, it is usually the case that an obstruent is syllabified as an onset when it occurs as the first constituent of the word-initial clusters composed of obstruents, and then its voicing contrast is expected to be licensed in the prosody-based approach. These two expectations of the prosody-based approach are not satisfied in the languages mentioned above. For instance, in Lithuanian, where consonant clusters are heterosyllabic regardless of composition (e.g. /'auk.le/), voicing of obstruents may be contrastive in the coda when they occur before sonorants, as in (12c). The voicing of an obstruent is neutralized in the onset when it precedes another obstruent, as in (12b). Consequently, it is difficult to provide an adequate description of neutralization contexts in syllabic terms.

(12) *Lithuanian obstruents in clusters* (Steriade 1999)

		voiceless		*voiced*	
a.	licensed onsets	sam'gus	'cheerful'	žmo'gus	'man'
b.	neutralized onsets	spalva	'color'	'lizdas	'nest'
c.	licensed codas	aug.muo	'growth'	ak.muõ	'stone'
d.	neutralized codas	daũ [k]	'much'		

In contrast, to explain the difference in the likelihood of the neutralization between pre-obstruent and pre-sonorant positions, the cue-based approach may still rely on the perceptibility difference of the two positions. Specifically, the pre-obstruent position lacks the main contextual cues (VOT and other release-related cues), and thus is less perceptible than the pre-sonorant position, where the main cues can be maintained.

Finally, there are languages in which neutralization patterns are fixed despite the variable syllabification. As discussed by Steriade (1999), for both Sanskrit and Ancient Greek syllable divisions in obstruent–sonorant clusters were variable, depending on "the dialect, the period, the literary style and the juncture separating the consonants." In contrast, there was no variation in the pattern of laryngeal neutralization: in styles or dialects where $VC_1.C_2V$ divisions were the norm for all clusters, laryngeal neutralization did not take place before heterosyllabic sonorants. This indicates that laryngeal features in these languages are neutralized irrespective of the syllabic affiliation of clusters, and thus the neutralization patterns cannot be adequately described in syllable terms.

The above patterns indicate that syllable positions like codas are neither a sufficient nor a necessary condition for the occurrence of neutralization. Codas are not a sufficient condition in the patterns in which only word-medial, as opposed to final, codas and pre-obstruent, as opposed to pre-sonorant, codas are neutralized. Codas are not a necessary condition in the patterns in which an obstruent onset in word-initial clusters is neutralized. Codas would be totally useless in describing the Sanskrit and Greek patterns with variable syllabification but fixed neutralization patterns. Consequently, all these patterns can be taken as evidence against the prosody-based approach and in favor of the cue-based approach.

C_2 in Murinbata. Miriwung is just like Murinbata, in that the apical contrast is maintained in C_1, but neutralized in C_2. Apical neutralization additionally occurs at the beginning of the word in which only alveolars, not retroflexes, are allowed to occur.

Consequently, the typical targets of apical neutralization may be summarized as below:

(15) *The C_1 dominance effect in (assimilatory and non-assimilatory) apical neutralization*

Postconsonantal C_2 and word-initial positions are common target positions.

This is therefore the complete opposite of the C_2 dominance effect in the neutralization patterns of laryngeality and major C-Places of articulation. Given that C_2 is usually an onset, the prosody-based approach cannot explain the C_1 dominance effect in apical neutralization in the same way as the C_2 dominance effect summarized in (13). In contrast, in the cue-based approach, the C_1 dominance effect may be derived naturally from the perception fact that cues to the apical distinction lie primarily in the V-to-C, not C-to-V, transitions, and thus C_1 is more prominent in the perception of the apical contrast than C_2. As discussed by Steriade (2001), citing Ladefoged and Maddieson (1986), Dave (1976), Stevens and Blumstein (1975), and Bhat (1973), the formant transitions into retroflexes in C_1 show distinctively low F3 and F4 values, compared to those of denti-alveolars, whereas the transitions out of retroflexes in C_2 are not distinct from those of denti-alveolars. This acoustic asymmetry originates from the characteristic articulation of retroflexes, in which the tongue tip moves forward during the closure and releases from the same constriction location as apico-alveolars.

Consequently, both the C_2 dominance effect in major C-Place assimilation and the C_1 dominance effect in apical assimilation may be derived from the main argument of the cue-based approach, i.e. the neutralization targets positions which lack prominent perceptual cues to the contrasts in question. Thus, the apical neutralization typology may form very strong evidence for the cue-based approach by showing a case of contrast-specific neutralization. (See Zhang's 2004 discussion of contour tone typology for an additional case of contrast-specific licensing/neutralization.)

5 Evidence for the prosody-based approach

5.1 *Obstruent–sonorant clusters in Catalan*

The cue-based approach provides a string-based, not prosody-based, account for positional neutralizations. If two sequences are segmentally identical, and thus not significantly different in the perceptibility involved, the cue-based approach expects the two to behave similarly with respect to neutralization even when they have different prosodic structures. Suppose that in obstruent–sonorant C_1C_2 clusters, the C_1 obstruent may be syllabified either as an onset or as a coda, depending on the environment. The cue-based approach expects that the C_1 obstruent will behave invariably with respect to positional neutralization, regardless of whether it is an onset or a coda. If, as predicted by the prosody-based approach, the C_1 is licensed when syllabified as an onset, but neutralized when syllabified

b. dental / __ lateral

voiced		*voiceless*
atleta [d.l]	'athlete'	*none*

Further, comparable active neutralization, which is even more difficult to explain within the cue-based approach, can be observed in the obstruent–sonorant sequences occurring across word boundaries. In Catalan, word-final obstruents assimilate in voicing to the following consonants including liquids. Word-final stops, which are voiceless before an initial vowel of the following word (18.ii), become voiced before an initial sonorant (18.i). Thus the C_1 obstruents here are neutralized with respect to voicing. This final obstruent neutralization would not be expected within the cue-based approach, since the same obstruent-sonorant sequences within a word are not subject to the voicing neutralization, as shown in (16a). So this is a case in which identical sequences behave differently with respect to neutralization, depending on where they occur. According to Wheeler (2005), the only difference between the obstruent-sonorant sequences of (16a) and (18.i) is in syllabic affiliation: the C_1 obstruents in (16a) are onsets, whereas those in (18.i) are codas. Thus, only the prosody-based, not cue-based, approaches can explain the voicing patterns of obstruents in Catalan.

(18) *Neutralized obstruent voicing in Catalan obstruent sonorant clusters*

a. non-sibilant / __ #liquid

i.	*poc logic*	/'pɔk#ə'lɔʒik/	['pɔg.'lɔʒik]	'not very logical'
ii.	*poc amable*		['pɔ.kə'mab.blə]	'not very friendly'

b. non-sibilant / __ #glide

i.	*poc whisky*	/'pɔk#'wiski/	['pɔg.'wiski]	'not much whisky'
ii.	*poc usual*		['pɔ.ku'zwal]	'not very usual'

5.2 *Obstruent–sonorant clusters in Eastern Andalusian Spanish*

Eastern Andalusian Spanish shows an additional case in which sequences with similar perception cues behave differently in contrast distribution and neutralizing processes, thus posing a problem to the cue-based approach. The discussion of this section is mostly based on Gerfen (2001).

As shown in (19), in Standard Peninsular Spanish, /s/ is allowed in preconsonantal and word-final positions. In contrast, in Eastern Andalusian Spanish, /s/ is not allowed to occur in those positions. As shown in (20a), word-final /s/ deletes and aspirates the preceding vowel. Preconsonantal C_1 /s/ also deletes but the deletion is accompanied by the gemination of the following C_2 consonant.

(19) */s/ in Standard Peninsular Spanish* (Gerfen 2001)

a.	word-final coda:	[ga.fas]	'eyeglasses'
b.	pre-C coda:	[gas.ko]	'helmet'

b. *Word-internal obstruent + liquid clusters*
   i. [a.klara] 's/he/it clears up'
   ii. [a.grada] 's/he/it pleases'
   iii. [a.plana] 's/he/it applies'
   iv. [a.trapa] 's/he/it traps'

But it is still unclear why /sl/, an obstruent–liquid sequence, does not behave like stop–liquid sequences. As shown in (20b.ii), /s/ is subject to coda deletion before /l/. Also, as shown below, /tl/, a stop–liquid sequence, behaves like /sl/, not like /kl/ and /gl/. If rich perceptual cues to C_1 before a liquid can guarantee the surface realization of stop–liquid sequences like /kl/, /gr/, /pl/, and /tr/, it is difficult to understand why /tl/ and /sl/ cannot surface as such.

(23) /tl/ *clusters in Eastern Andalusian Spanish* (Gerfen 2001)

/atleta/ [a^{h}lleta] 'athlete'

To summarize, both Catalan and Eastern Andalusian Spanish show asymmetric patterns in which only a subset of obstruent–sonorant sequences is subject to the distributional restrictions and related alternations targeting an obstruent in C_1. For the analysis of these patterns, the prosody-based approach can still attribute the difference among the obstruent–sonorant sequences to the coda-onset asymmetry, but an equally plausible, string-based, solution seems to be unavailable in the cue-based approach. See Kabak and Idsardi (2007) for an additional support for the prosody-based, as opposed to the cue-based, approach. They investigated Korean listeners' perception of non-native sequences, and argue that only syllable-based, not string-based, phonotactic constraints can explain their experimental results.

6 Conclusion

From the literature on phonological typology, we know that it is common for phonological processes not to apply in all positions, and more generally for phonological contrasts not to be licensed in all positions. Such positional effects are characterized by reference to certain pairs of prominent and non-prominent positions such as word-initial *vs.* non-initial, stressed *vs.* unstressed, root *vs.* affix, and prevocalic C_2 *vs.* preconsonantal C_1 positions. Among these, this chapter has been mainly concerned with the C_2 dominance effect in which preconsonantal C_1 in intervocalic C_1C_2 clusters is likely to be targeted for neutralization, whereas prevocalic C_2 is likely to trigger or resist such neutralization. This C_2 dominance effect is quite robust in laryngeal and place neutralization and consonant deletion. I have looked at the relevant data patterns, ranging from well known and common to less known and relatively exceptional, while comparing the cue-based and prosody-based approaches. Common data patterns can be explained equally well by both approaches. In contrast, less common or somewhat exceptional patterns may distinguish the two approaches. However, the evidence so far is mixed. Not only neutralization patterns in which there is no connection between neutralization sites and syllable positions, but also apical neutralization patterns,

47 Initial Geminates

Astrid Kraehenmann

1 Introduction

There are a number of different ways in which languages make phonemic differences between consonant segments. One, for example, is on the basis of phonological features. The groups of sounds in (1a) differ in terms of voicing (CHAPTER 69: FINAL DEVOICING AND FINAL LARYNGEAL NEUTRALIZATION), the ones in (1b) in terms of continuancy (CHAPTER 13: THE STRICTURE FEATURES), and the ones in (1c) in terms of place of articulation (labial, coronal, dorsal) (CHAPTER 22: CONSONANTAL PLACE OF ARTICULATION), etc.

(1) a. /p t k f s x/ *vs.* /b d g v z ɣ/
b. /p t k b d g/ *vs.* /f s x v z ɣ/
c. /p b f v/ *vs.* /t d s z/ *vs.* /k g x ɣ/

Another way in which consonants may contrast is on the basis of inherent prosodic structure such as sound length and/or weight.[1] This distinction is also called a difference in quantity (see also CHAPTER 37: GEMINATES; CHAPTER 57: QUANTITY-SENSITIVITY). Thus the groups of sounds in (2) differ in terms of quantity, which is generally reflected (a) phonetically as long *vs.* short articulatory duration, (b) phonologically as heavy *vs.* light, and (c) structurally in the way they are associated to syllabic and higher-level prosodic structure.

(2) /pp tt kk ff ss xx/ *vs.* /p t k f s x/

Cross-linguistically, there are some constraints and implicational relationships on the existence of such quantity contrasts. As will be shown in the next section, initial geminates – i.e. geminates that contrast with singletons at the beginning of (lexical) words – are a special case, because they are even rarer than medial geminates. In the subsequent sections we will discuss in turn some issues regarding the phonological representation, prosodic behavior, phonetic properties, perception, and word-edge effects of initial geminates. These issues will provide some interesting insight on why initial geminates are so special.

[1] In this chapter, length/quantity is transcribed by a sequence of identical phonetic symbols.

2 Typological issues

Not many languages are known to have a lexical quantity contrast at word edges as well as word-medially. As an illustration we give examples from Thurgovian Swiss German (Indo-European)[2] in (3), which are representative of the phonological quantity distinction common to the majority of Swiss German dialects.

(3) *Swiss German quantity contrast*

a.	initial	/ppaaʀ/	'pair'	*vs.*	/paaʀ/	'bar'
		/ttaŋkx/	'tank'	*vs.*	/taŋkx/	'thank'
		/kkaaʀ/	'coach'	*vs.*	/kaaʀ/	'cooked'
b.	medial	/vappə/	'crest'	*vs.*	/vapə/	'honeycomb'
		/mattə/	'mat'	*vs.*	/matə/	'maggot'
		/makkə/	'fault'	*vs.*	/makə/	'stomach'
c.	final	/alpp/	'alp'	*vs.*	/xalp/	'calf'
		/vɛʀtt/	'value'	*vs.*	/hɛʀt/	'hearth'
		/maʀkk/	'marrow'	*vs.*	/aʀk/	'bad'

In order to eventually get a better feel for the typological status of initial geminates such as the ones in (3a), it is worth taking a look at the established typological facts of geminates in general. Surprisingly little comprehensive work has been done in this area to date.

If we consult the largest extant phonological database – the UCLA Phonological Segment Inventory Database (UPSID), which is an extended and revised online version of Maddieson (1984), listing the phonemes of 451 languages – only 12 languages are coded for having at least one geminate consonant segment. But not all of them have a quantity contrast to speak of. There are only seven (less than 2 percent of the whole sample) if we discount those languages which – based on the inventories given – have either only a single geminate–singleton pair (!Xu (Khoisan), Iraqw (Afro-Asiatic), and Telugu (Dravidian)) or only geminates that come without a singleton counterpart (Inuit (Eskimo-Aleut) and Trumai (South American isolate)). Those seven are: the North Caucasian Archi, Avar, and Lak; Ocaina (Witotoan), Waray (Austronesian), Wichita (Caddoan), and Wolof (Niger-Congo).

While the general picture that emerges seems to be that quantity contrasts are rather uncommon, it is doubtful that they are quite as uncommon as that. For example, the database also contains languages such as the Indo-European Bengali, Breton, and Norwegian, as well as Finnish (Uralic), for which there is general consensus among linguists that all have quantity contrasts. However, they are not coded as such in UPSID. Thus the typological interpretation of the UPSID data – not only with respect to quantity – must be taken with the necessary pinch of salt (see also Simpson 1999, among others).

One particular piece of information missing in UPSID but of primary interest for our purposes is where within a word the geminates may occur. This information is given, albeit rather implicitly, in the survey of 63 languages with geminates by

2 Language family classification in all cases follow Lewis (2009).

Thurgood (1993). In his sample, Thurgood identifies a number of frequency facts and prerequisite conditions for geminates and proposes some implicational tendencies. For example, he finds preferences for certain places of articulation (alveolar > labial > velar > glottal)[3] and certain prosodic environments (post-tonic > pre-tonic/unstressed; after short vowel > after long vowel). But most importantly, he establishes that geminates are most favored in intervocalic position or, more specifically, if preceded by a short (and stressed) vowel and followed by another short vowel (Thurgood 1993: 129). Although not explicitly stated, these flanking vowels preferably also belong to the same word. This means that if a language has any quantity contrast at all, it will be word-medially. Thus, the existence of initial and/or final geminates implies the existence of medial geminates (see also Muller 1999). While Thurgood (1993) lists the three Austronesian counter-examples Sa'ban, Kelantan Malay, and Pattani Malay, no further explanation is given as to how it could be that they exclusively have initial geminates, which is an interesting issue that we will come back to shortly. Thurgood does not mention word-final geminates separately, let alone whether or not the languages under investigation allow word-final (i.e. syllable-final) consonants in the first place. But, based on the preference factors he identifies, we can conclude that a quantity contrast is cross-linguistically most common medially, somewhat less common finally, and least common initially.

Is there also a specific consonant class that stands out as the most preferred to display a quantity contrast? Based purely on the sonority of consonants (CHAPTER 49: SONORITY), Morén (1999: 110) answers this question negatively. He finds languages with quantity distinctions in stops, continuants, and sonorants alike (Hungarian (Uralic), Brahui (Northern Dravidian), Italian, Baloch, Gajarati (Indo-European)), only in continuants (Tartar (Altaic)), only in sonorants (Hausa (Afro-Asiatic)), and only in obstruents (Chechen, Lak (North Caucasian)), but also languages that allow geminate stops and sonorants to the exclusion of continuants (Kurdish (Indo-European)). He does not list any languages either allowing only stop geminates or excluding only stop geminates, both of which he considers to be accidental gaps. In comparison, Thurgood's (1993) generalizations are a bit more fine-grained for place of articulation and voicing within the major classes of obstruents and sonorants. He observes that geminate stops seem to be a prerequisite for geminate affricates to occur, and presents data that suggest a voiceless alveolar stop or fricative /tt ss/ or an alveolar nasal or liquid /nn ll/ to be good candidates for the prototypical geminate.

To conclude our look at geminates in general, it is very surprising to notice that 46 of the 63 languages (= 73 percent) in Thurgood's (1993) sample are also listed in UPSID, yet obviously with different phoneme analyses from the ones consulted by Thurgood. As regards language diversity, six language families figure very prominently, accounting for more than 50 percent of the whole set: namely, in descending frequency, Afro-Asiatic (10 languages), Indo-European (7), Austronesian (6), Altaic (3), Dravidian (3), and Uralic (3).

[3] This means that Thurgood (1993) finds, on the one hand, that alveolar geminates are the most frequent and glottal geminates the least frequent and, on the other hand, that if a language has, for example, velar geminates it also tends to have labial and alveolar ones. He presents his data as an overview of the phonological systems and does not use them to make any claims about preferences for the *emergence* of geminates.

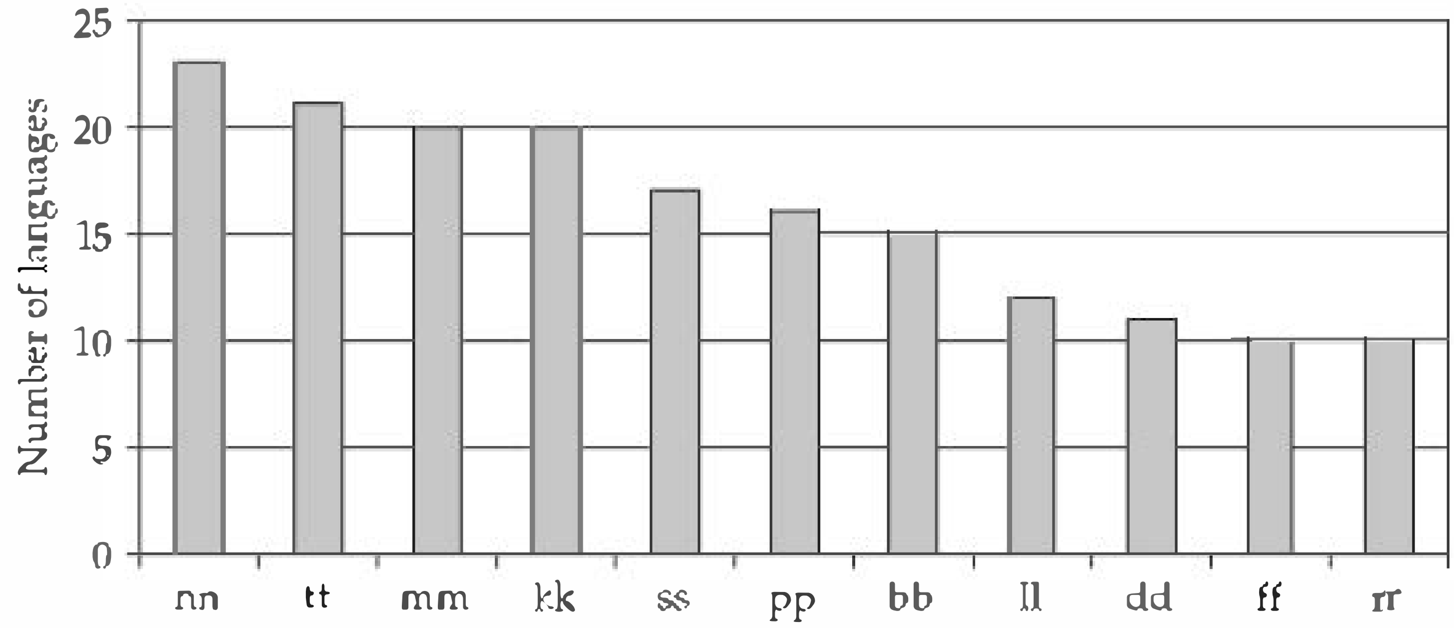

Figure 47.2 The 10 most frequent geminate phonemes in the 29 languages listed in Muller (2001: 204–233)

Looking at the frequency of initial geminate phonemes, there are some interesting observations to be made with respect to major consonant class, manner, place of articulation, and voicing.[7] But before looking at these factors, let us first consider the 10 most frequent geminates in these languages, as illustrated in Figure 47.2.

The nasals /nn mm/ and the voiceless stops /tt kk pp/ are among the most commonly occurring geminates. The voiceless fricatives /ss ff/, the voiced stops /bb dd/, and the liquids /ll rr/ are next on the top-10 frequency list. Thus, within the sonorants /nn/ is most universally present, and within the obstruents it is /tt/ for the stops and /ss/ for the fricatives. Very significantly, all these sounds follow the universal preference patterns (cf. Ladefoged and Maddieson 1996; Ladefoged 2001): they are coronal as well as voiced if sonorant and voiceless if obstruent, which is the less marked voicing characteristic within each respective class.

Considering the entire set of initial geminates, stops and fricatives together make up almost two-thirds, with nasals taking the lion's share in the last third (see Figure 47.3). Geminate fricatives imply geminate stops, except for Hatoma, which has /ff/ and /ss/, but does not allow any geminate stops or affricates. Overall, geminate affricates are least frequent and only occur in conjunction with

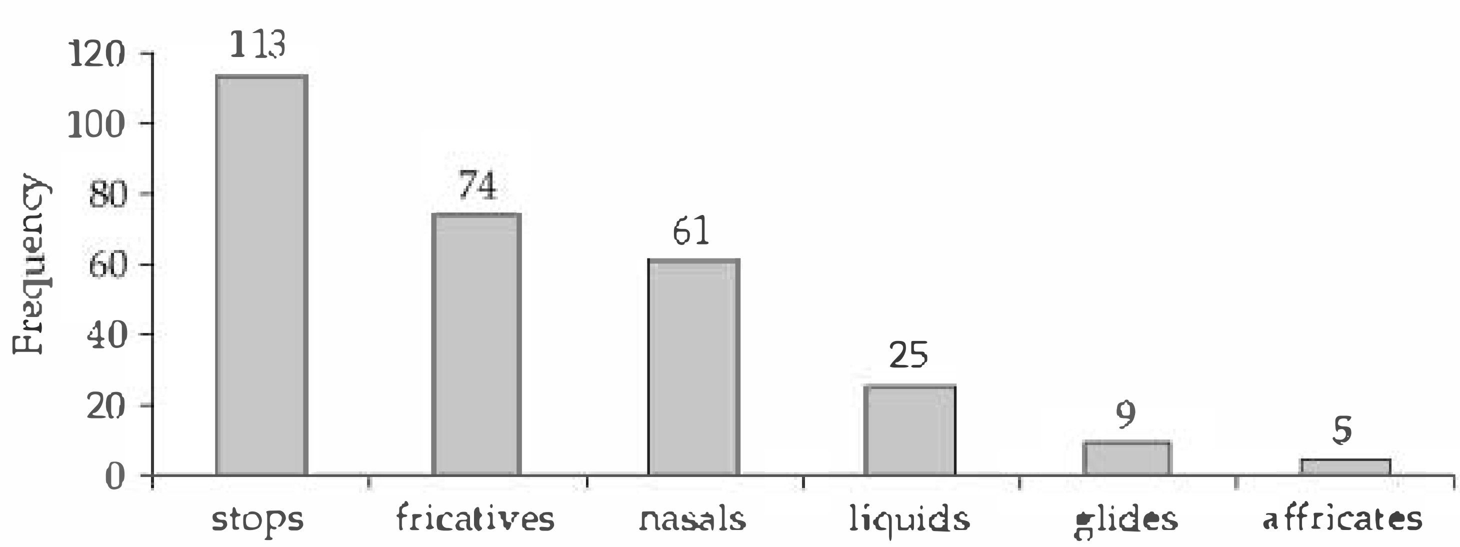

Figure 47.3 Initial geminates by manner (data from Muller 2001: 204–233)

[7] In this chapter, I refer only to *type* frequency of phonemes and members of natural classes. I have no information about *token* frequency of the sounds in the respective languages.

both stops and fricatives. As for the sonorants, nasals are a prerequisite for any other type of sonorant geminate (CHAPTER 8: SONORANTS). The only exception is Yapese, which has only a coronal lateral /ll/ and no nasal or other sonorant geminate, although it has labial, coronal, and dorsal nasal singletons.

In the complete set of languages, there are 22 that have both obstruent and sonorant geminates. However, Circassian, Lak, Bernese, and Thurgovian Swiss German allow only obstruents, while Kiribati, Piro, and Ponapean allow only sonorants. In the latter group, all three languages have geminate nasals, most often a coronal /nn/.

Figure 47.4 illustrates the frequencies of the different places of articulation[8] in the sample. As expected, the predominance of coronals over labials and dorsals mirrors the general attested cross-linguistic preferences. Finally, regarding voicing where it is contrastive, namely within the obstruents, voiceless geminates outnumber voiced ones by a little over 100 percent (see Figure 47.5). There are seven languages without voicing distinction, for which only "voiceless" geminates are listed: Atapec Zapotec, Trukese, Hatoma, Lak, Leti, Puluwat, and Thurgovian Swiss German. In three languages, there seem to be "voiced" geminates without any "voiceless" counterpart: Lugbara has /bb dd/ but no */pp tt/, Ngada has /bb/ but no */pp/, and Yapese has /gg/ but no */kk/. However, in all three cases, these phonemes are the only obstruent geminates in the respective systems. Dobel is a slightly different case, in that it lacks */pp/, with /bb/ being part of a bigger set, which includes voiceless /tt kk ʔʔ ss/.

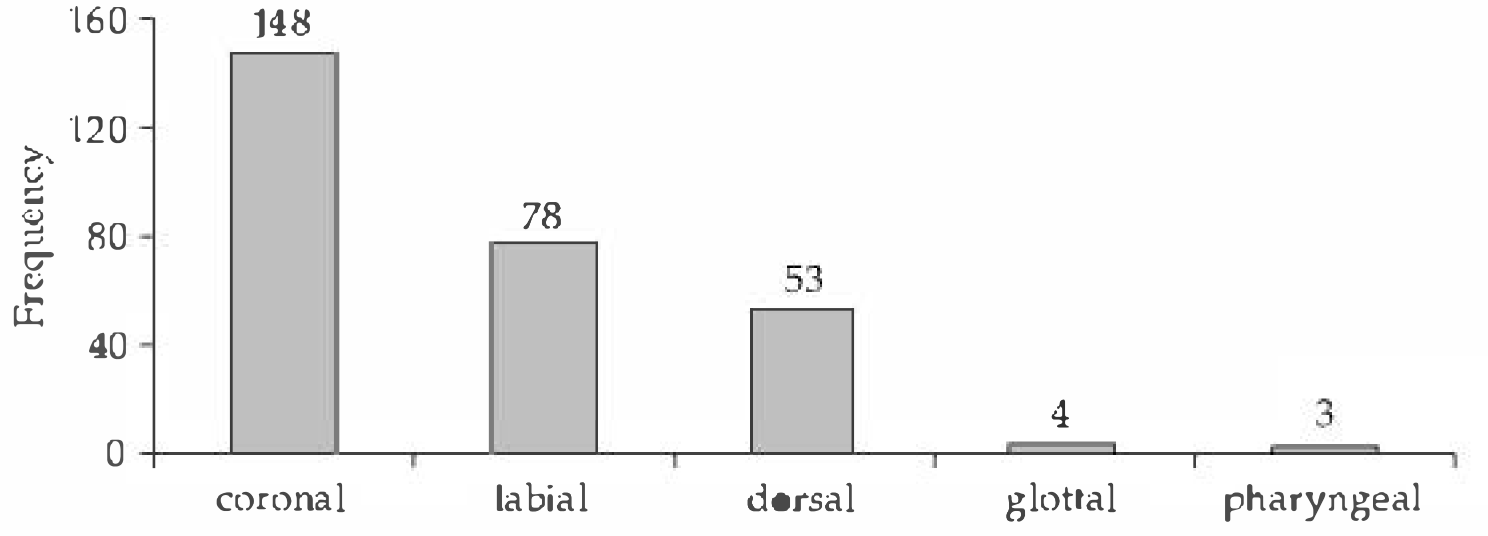

Figure 47.4 Initial geminates by place of articulation (data from Muller 2001: 204–233)

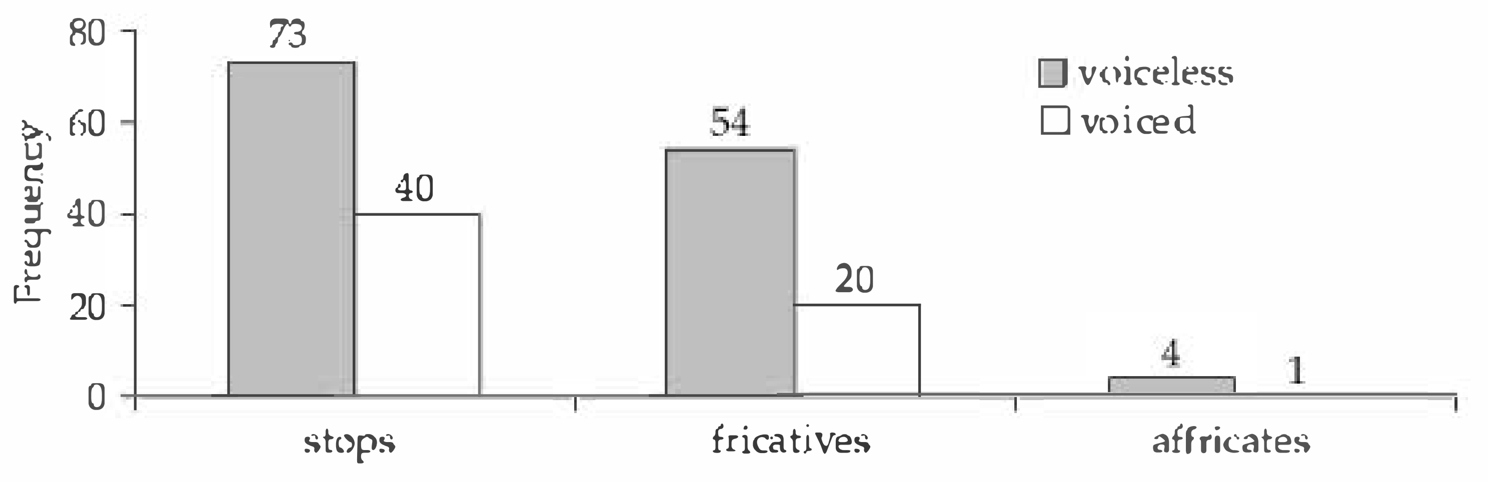

Figure 47.5 Initial obstruent geminates by manner and voicing (data from Muller 2001: 204–233)

[8] In Muller's (2001) terminology, labials comprise bilabials and labio-dentals, coronals refer to (inter)dentals, alveolars, and palatals, and dorsals are velars.

a preceding syllable and is the onset of a following syllable; see the structures in (5). As a rule, "intervocalic" is interpreted to mean "within one and the same word."

(5) *Syllabification of geminates and singletons*[9]

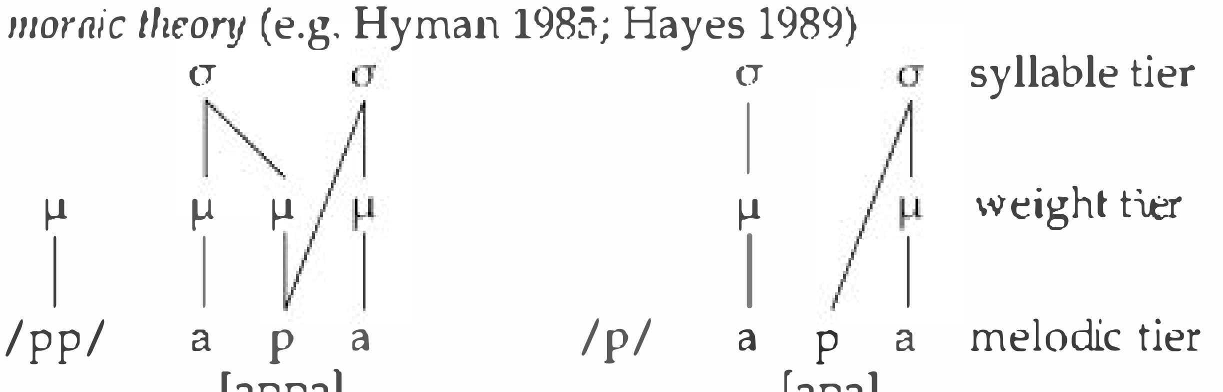
a. *ambisyllabic link: geminate* b. *tautosyllabic link: singleton*

While there is considerable agreement as to the ambisyllabic nature of geminates (but see Topintzi 2008 for a different view), theories vary in what unit they posit to link up with these syllable constituents. These assumptions have far-reaching consequences for how geminates are phonologically represented, especially so if the goal is to establish a single representation that is to capture not only language-specific but also cross-linguistic patterns of geminates (e.g. Selkirk 1990; Tranel 1991; Broselow 1995; Broselow *et al.* 1997; Ham 1998; Davis 1999a, 1999b, 2003; Muller 2001; Curtis 2003; Kraehenmann 2003; Topintzi 2008; Ringen and Vago 2010; among others).

For convenience, we briefly sketch the main tenets of the two competing theories at this point.[10] In moraic theory, a geminate is associated with a unit of weight, the mora – see (6a) – and should therefore participate in weight-related phenomena such as stress patterns, compensatory lengthening, and minimal word conditions. In skeletal theory (CHAPTER 54: THE SKELETON), though, a geminate is doubly linked to the timing tier – see (6b) – and is prosodically long without pre-association to any weight tier. As a consequence, weightless geminates pose a challenge for the former theory, moraic geminates for the latter.

(6) *Underlying representation and syllabification*

a. *moraic theory* (e.g. Hyman 1985; Hayes 1989)



[9] The segmental labels linking up to syllable nodes are shorthand for the root nodes representing these segments.

[10] See Curtis (2003) for a concise survey of the different models of geminate representation. CHAPTER 37: GEMINATES also discusses in detail the basic controversy between the weight account and the timing account, as well as the Composite Model (e.g. Hume *et al.* 1997; Muller 2001; Curtis 2003; Kraehenmann 2003; Baker 2008). A full exploration of this theory goes beyond the scope of this chapter. Suffice it to say, however, that it is a combination of the other two models: geminates are associated to two timing positions and weight, if it plays a role at all, is a consequence of syllabification, mainly one of Weight-by-Position (Hayes 1989). One worry with this view is that it runs the risk of overgeneration, since it allows for all types of combinations between length and weight, possibly even unattested ones.

et al. (1997: 393), Kraehenmann (2003: 26), and Topintzi (2008: 180), the mora cannot count for weight purposes by any measure of analysis when not associated to higher level prosodic structure. Finally, Topintzi's (2008) proposal for Trukese and Pattani Malay – and moraic onsets in general – is the one illustrated in (8d), in which the geminate mora is directly associated with the syllable node to which the following vowel belongs.

This tautosyllabic representation is striking for at least two reasons. First, it treats the geminate like a regular onset consonant by making it entirely the initial constituent within the first syllable. There is no ambisyllabic double linking, which is characteristic of geminates in all other proposals. Second, the geminate carries a mora equal in all respects to the mora of the syllable nucleus. The implications of such structures are, on the one hand, that moraic onsets are expected to occur not only word-initially but also word-medially and, on the other hand, that, to an even greater extent, moras play the double role of a unit of weight *and* length.

In support of the first implication, Topintzi (2008: 170–172) presents some intriguing data from Marshallese stress patterns and Trique compensatory lengthening processes which suggest an analysis of medial geminates with tautosyllabification (see also CHAPTER 55: ONSETS; Topintzi 2010). In the majority of cases, though, medial geminates must be analyzed ambisyllabically as illustrated in (8), cases like Marshallese being the exception rather than the rule. Regarding the length issue, Topintzi replaces the basic tenet of traditional moraic theory that onset consonants are never moraic with another, based on findings by Hubbard (1994) and Ham (1998), namely "that moras are allocated a minimum target duration" (2008: 174), the controversial proposal being that surface phonetic duration is in *direct* relation to underlying prosodic length.

To summarize this section, there are a number of different challenges that initial geminates pose for the existing theoretical models of representation. Like medial geminates, initial geminates do not present a uniform behavior across languages. In some cases it is clear that they fully participate in weight-sensitive processes (e.g. Trukese), in other cases weight is not involved at all (e.g. Leti). If, in the interest of a universal geminate representation, geminates are *not* underlyingly moraic, how do we explain the Trukese cases? And vice versa, if geminates *are* underlyingly moraic, how do we explain the Leti cases? Moreover, how can such Leti-type geminates occupy the syllable onset, *the* non-weight position? It is evident that strict adherence to the traditional concepts of the two theories is not very fruitful. A combination of the two approaches seems rather more promising but the proper balance still needs to be established (see also note 10).

4 Phonetic properties and perception

In terms of phonetic properties, initial geminates are a model case for illustrating the interdependence between articulation, acoustics, and perception because not only segmental features, such as place of articulation, manner, etc., are involved, but prosodic features representing duration also play a role.

Temporal characteristics have received most attention in phonetic studies of geminates to date. Although there is still some discussion on whether geminates are to be considered long or tense consonants, it is generally accepted that the manifestations of the tense articulation of geminates. One example is the finding that the normalized Root Mean Square (RMS) amplitude of the stop release is slightly higher for geminates than for singletons for all but one of the five speakers, who shows the reverse pattern. Another example would be the fact that geminates tend to devoice for aerodynamic reasons (cf. Ohala 1983), depending in degree on factors such as speaker, place of articulation, and position within the word. Also, voiced stop singletons have a weakish propensity to lenite, i.e. become fricatives, while geminates never do. As for durational correlates apart from the primary cue, Ridouane (2007: 129) finds that the duration of the stop release – also called "voice onset time" (VOT) or "after closure time" by other authors – shows no difference in voiceless stops but is longer for voiced geminates than for singletons.[16] None of these additional correlates, however, has yet been tested for its significance in perception. The jury is still out on whether Tashlhiyt Berber native listeners can and do rely on these cues when the primary duration cue is not available.

While VOT plays no role for voiceless stops of Tashlhiyt Berber, it is a temporal measure correlating with the quantity distinction of these sounds in Cypriot Greek. Parallel to Tserdanelis and Arvaniti's (2001) findings on medial geminates, Muller (2001, 2003) establishes that VOT is also significantly longer for geminates than for singletons in word-initial position. Like native listeners of Pattani Malay, native listeners of Cypriot Greek can distinguish voiceless stop geminates from singletons at the beginning of an utterance. Muller hypothesizes that the subjects of her very basic perception experiment thus utilize VOT as one of possibly many secondary cues to the phonological quantity distinction.

Finally, as well as Pattani Malay, Tashlhiyt Berber, and Cypriot Greek, Swiss German initial geminates have also received some attention in the literature, in particular in the Thurgovian dialect of Swiss German (Kraehenmann 2001, 2003, 2009; Kraehenmann and Lahiri 2008). Kraehenmann (2001, 2003) confirms earlier findings on other dialects, for example by Enstrom and Spörri-Bütler (1981) and Fulop (1994), that VOT does not participate in the quantity opposition: there is no difference in the duration of the stop release for geminates and singletons, be they initial, medial, or final. Since voiceless stops are the only consonants occurring in initial length opposition, the question is again whether the phonological difference is enhanced by cues other than the primary one. While lacking any corroborating perception evidence, Fulop (1994) claims to have found potential secondary non-temporary cues, namely increased intensity, movement, and clarity of post-release sonorant formants above F2 for geminates in comparison to singletons. However, anecdotal evidence in Moulton (1979) and the results of a pilot perception study reported in Kraehenmann (2003) call into question whether listeners can make use of these acoustic differences. Their listeners seemed unable to recover the quantity contrast in utterance-initial context. A crucial fact to verify especially in this case is whether the difference is actually produced by the speakers or whether contrast neutralization occurs. Using electropalatography (EPG), Kraehenmann and Lahiri (2008) set out to do just that in an articulatory study. They find that geminates are indeed articulated significantly longer (by about 85 msecs) than singletons even in absolute utterance/phrase-initial position (see Figure 47.6).

16 Exactly the same finding is reported in Mikuteit and Reetz (2007) for voiceless and voiced stops in East Bengali.

201) rightly speculates that the segmental inventory of the language in question may affect the "availability" of such acoustic cues. But the complexity of syllable structures and the degree of the functional load of the contrast must also play a significant role.

5 Edge effects

In the field of the phonology–phonetics interface, one area of investigation focuses on how the articulation of speech sounds is influenced by the position within prosodic structure they occur in. A number of effects have been established that involve the edges of prosodic domains such as the syllable (CHAPTER 33: SYLLABLE-INTERNAL STRUCTURE), the phonological word (CHAPTER 51: THE PHONOLOGICAL WORD), the phonological phrase (CHAPTER 50: TONAL ALIGNMENT), etc. What is most interesting and relevant with respect to the topic of this chapter is the fact that these domain edges – beginnings in particular – have a significant effect on sound duration. More specifically, the length of segments or particular properties of segments is greater the higher up in the prosodic hierarchy their edges are (e.g. Fujimura 1990; Byrd *et al.* 2005).

This has become known in the literature as *initial articulatory strengthening* or *prosodic strengthening*. It is important to note at this point, however, that most studies so far have been on sounds that are not in a quantity opposition. For example, in their seminal EPG study, Fougeron and Keating (1997) tested the English dummy syllable *no* in trisyllabic words with initial, medial, and final stress embedded in a carrier phrase. They found that the amount of linguopalatal contact as well as the acoustic duration of the syllable-initial nasal increased with each increasing prosodic level. Fougeron and Keating conclude that these "more extreme articulations" (1997: 3738) perform an important function for perception. On the one hand, they facilitate segmentation into higher prosodic domains, but particularly into words. On the other hand, they enhance the acoustic cues for identifying sounds and thus assist lexical access. Although the correlation between the amount of articulator contact and acoustic duration is reported as being only weak, it is there nonetheless. Because EPG studies are still few and far between, we will also use this acoustic finding as the main basis for our remaining discussion.

In a phonetic study on real words, Cho and McQueen (2005) investigated word-initial Dutch alveolar stops /t d/ in different phrasal and word-stress contexts. As expected, the closure durations of both voiced and voiceless stops were significantly longer in stronger prosodic positions. In addition, however, the VOTs of voiceless stops were cumulatively shorter in the same prosodic positions, i.e. the opposite of the findings for English /t/. Cho and McQueen argue in essence that the difference is due to the difference in how the phonological encoding of the voicing contrast is phonetically enhanced in the two languages. That is, Dutch /t/, as the phonologically unmarked member of the pair (voiceless *vs.* voiced), has the phonetic (default) specification [–spread glottis], which is enhanced by shorter aspiration; in contrast, English /t/, as the phonologically marked member of the pair (aspirated *vs.* non-aspirated), has the phonetic specification [+spread glottis], which is enhanced by longer aspiration. One of their main claims is thus that prosodic strengthening acoustically amplifies the difference between sounds in

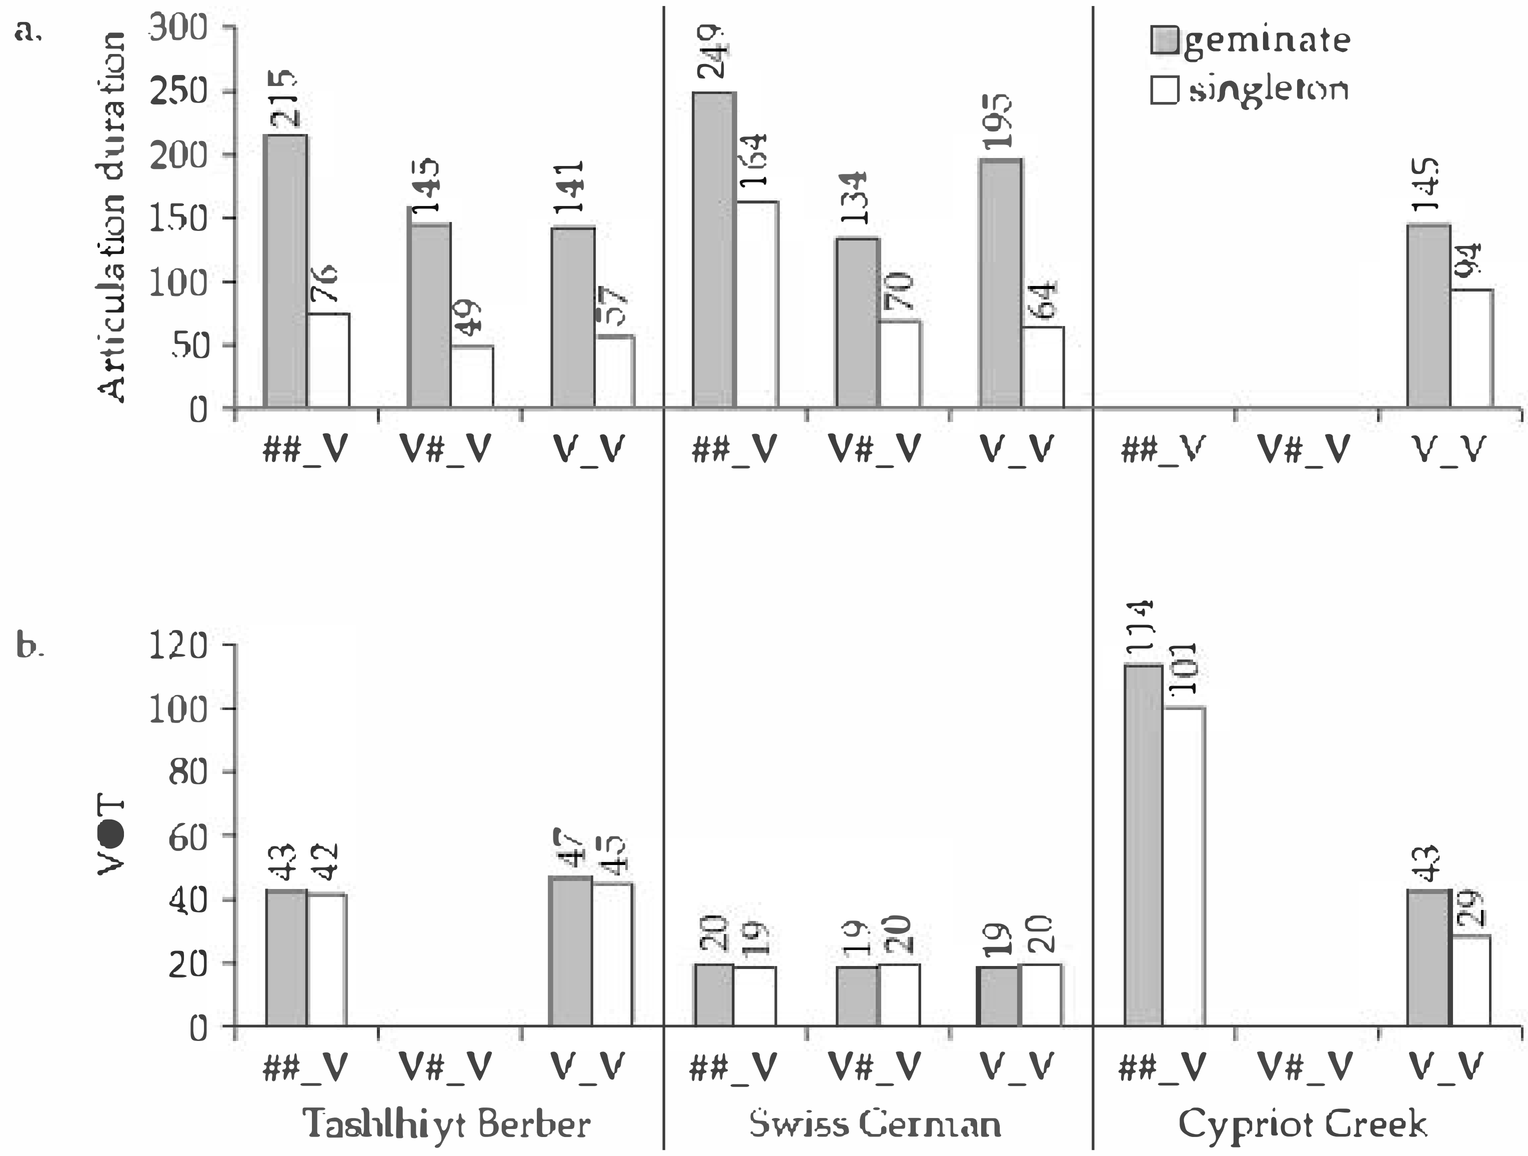


Figure 47.7 Articulation/closure duration[a] and VOT in msec for initial geminates and singletons in phrase-initial (## __ V) and phrase-medial post-vocalic (V# __ V) context and medial geminates and singletons in intervocalic (V __ V) context in three languages: Tashlhiyt Berber (Ridouane 2007: 128–129), Swiss German (Kraehenmann and Lahiri 2008: 4450–4451), and Cypriot Greek (Muller 2001: 29, 32)

[a] The measures of the medial geminates and singletons in Tashlhiyt Berber and Cypriot Greek are acoustic (closure duration); all others are articulatory (linguo-palatal contact)

phonological contrast. With respect to VOT effects, this claim seems to be supported by studies on Korean word-initial voiceless stops (Jun 1993; Cho and Keating 2001; Keating *et al.* 2003), which found that VOT measures were longest phrase initially, somewhat shorter word-initially within a phrase, and shortest word-medially within a phrase.

The question we want to ask now is whether articulatory strengthening also applies to word-initial geminates and singletons and, if so, whether it shows different characteristics. There are no studies comparable to Fougeron and Keating (1997) and their later work that directly address this issue in any depth. However, some generalizations can be drawn from the studies on voiceless stops in Cypriot Greek (Muller 2001), Tashlhiyt Berber (Ridouane 2007), and Swiss German (Kraehenmann and Lahiri 2008), by comparing medial *vs.* initial geminates and – in the latter two cases – initial geminates in different phrasal contexts.

The measures we are therefore most interested in are articulatory/acoustic closure duration and VOT. To start with the latter, we would not expect VOT to become a differentiating characteristic for initial geminates and singletons if it does not play any role for the medial contrast. This is indeed what we find. As can be seen in Figure 47.7b, Tashlhiyt Berber VOTs are only slightly but not significantly shorter when syllable, word, phrase, and utterance boundaries coincide (## __ V), compared to word-medially (V __ V). For the Swiss German data, the non-effect is even more pronounced, with basically identical measures in all three contexts. If anything had changed, longer measures would have been expected in the vocalic context (V# __ V) for initial stops and the longest ones at the phrase edge (## __ V), at least for geminates, if not for singletons. In contrast to these two languages, there are drastically longer measures in the Cypriot Greek data, where VOT is a secondary cue: geminate VOTs are longer by 71 msecs (265 percent), singleton VOTs by 72 msecs (348 percent). Although the 13 msecs difference in the phrase-initial context is still statistically significant, the differential has substantially decreased from 1.5 : 1 to 1.1 : 1, which goes against Cho and McQueen's (2005) claim of contrast amplification at increasing prosodic domain edges. Unfortunately, Muller (2001) does not provide any data for the contact/closure duration in utterance-initial or vocalic context. Thus we do not know how the primary cue is affected by prosodic strengthening.

This, however, is different for Tashlhiyt Berber and Swiss German (see Figure 47.7a). In Tashlhiyt Berber the trend seems to go in the expected direction in two of the three contexts. The geminate to singleton proportion is 2.5 : 1 word-medially and increases to 3 : 1 for word-initial stops after a vowel-final word. But at the utterance boundary, the highest prosodic domain, it decreases again to 2.8 : 1. In Swiss German we find exactly the opposite of what prosodic strengthening would predict, namely that the contrast magnitude decreases as the prosodic level increases. The difference between geminates and singletons is biggest in word-medial intervocalic context (syllable level, 3 : 1), somewhat smaller in word-initial intervocalic context (word level, 2 : 1), and smallest in utterance-initial context (phrase/utterance level, 1.5 : 1).

To conclude, there are some strengthening effects in languages with word-initial quantity contrast but only to the extent that the primary correlates lengthen substantially at the highest prosodic level, the utterance. However, this lengthening affects both geminates and singletons, resulting in contrast diminishment rather than augmentation. The segmental context, rather than the prosodic level, might therefore be the more reliable predictor of how the quantity contrast is realized, because intervocalic geminates – be they word-medial or phrase-medial word-initial – are actually not *at* a domain boundary, but contain one, because they straddle two syllables; see (6). The only time initial geminates occur at a domain edge is utterance-initially, which, as we have seen, is a very special context in many respects.

6 Conclusion

The field of word-initial quantity contrasts shows many faces and still awaits unveiling and scrutinizing investigations of a wealth of issues. A start has been made. Yet the existing disputes about phonological representation (length *vs.* weight), acoustic and articulatory properties, and perception are far from settled and promise to provide discussion material and theoretical arguments for years and decades to come. The historical question has only been hinted at in this chapter but constitutes another fertile ground and worthwhile area of research to be followed.

1 Introduction

Rhythm characterizes most natural phenomena: heartbeats have a rhythmic organization, and so do the waves of the sea, the alternation of day and night, and bird songs. Language is yet another natural phenomenon that is characterized by rhythm. What is rhythm? Is it possible to give a general enough definition of rhythm to include all the phenomena we just mentioned? The origin of the word *rhythm* is the Greek word ρυθμός, derived from the verb ρεί, which means 'to flow'. We could say that rhythm determines the flow of different phenomena.

Plato (*The Laws*, book II: 93) gave a very general – and in our opinion the most beautiful – definition of rhythm: "rhythm is order in movement." In order to understand how rhythm is instantiated in different natural phenomena, including language, it is necessary to discover the elements responsible for it in each single case. Thus the question we address is: which elements establish order in linguistic rhythm, i.e. in the flow of speech?

2 The rhythmic hierarchy: Rhythm as alternation

Rhythm is hierarchical in nature in language, as it is in music. According to the metrical grid theory, i.e. the representation of linguistic rhythm within Generative Grammar (cf., amongst others, Liberman and Prince 1977; Prince 1983; Nespor and Vogel 1989; chapter 41: the representation of word stress), the element that "establishes order" in the flow of speech is stress: universally, stressed and unstressed positions alternate at different levels of the hierarchy (see chapter 39: stress: phonotactic and phonetic evidence).

Two examples of stress alternation are given in (1) and (2), on the basis of Italian and English, respectively. The first level of the grid assigns a star (*) to each syllable, and is meant to represent an abstract notion of time; on the second, third, and fourth level, a star is assigned to every syllable bearing secondary word stress, primary word stress, and phonological phrase stress, respectively.

```

Guinevere will arrive with Oliver tomorrow morning with a transatlantic

Indeed, these examples clearly show that in the two languages there is a similar alternation of stresses ranging from secondary word stress to primary word stress to phonological phrase stress.

The level that is problematic in the metrical grid is the basic level, i.e. the level corresponding to the syllable. This representation does not show any alternation, or any element that establishes order in movement: if we restrict our attention to this level, all syllables are represented with equal prominence. It is clear, however, that grids that are identical at all levels, as in the two following Italian and English sentences, may represent very different rhythms. In particular, the first level – which represents an abstract notion of time for syllables – does not represent important differences between languages, precisely because it is abstract: simple syllables and very complex ones receive identical representations.

Tomorrow Albert will return

There are thus empirical differences in rhythm between languages that are not represented in a metrical grid. Long before the metrical grid theory was proposed, phoneticians (e.g. Pike 1945) had proposed the existence of *rhythmic classes* to account for the rhythmic differences between languages like English or German, on the one hand, and languages like Spanish or Italian, on the other.

3 Linguistic rhythm as isochrony

The idea that languages have different rhythms was first advanced by Lloyd James (1940), who observed that the rhythm of Spanish recalls that of a machine gun languages, adjacent primary word stresses constitute a stress clash and are eliminated in much the same way (Liberman and Prince 1977; Nespor and Vogel 1979, 1989).

That languages vary in their rhythm is a fact. However, from these studies it can be concluded that it is not different rhythms that trigger different phonological phenomena. Rather, different rhythms arise as a consequence of a series of independent phonological properties (cf. also Dasher and Bolinger 1982).

4 Infants' sensitivity to rhythmic classes

Linguists were not alone in investigating rhythmic classes. The discovery in developmental psychology that newborns are capable of discriminating a switch from one language to another (Mehler *et al.* 1987; Mehler *et al.* 1988) triggered further experiments to explore which cues were responsible for this early human ability. In particular, the grouping of languages into different rhythmic classes attracted the attention of cognitive scientists interested in understanding how language develops in the infant's brain. Mehler *et al.* (1996) relied on the classification of languages into syllable-timed, stress-timed, and mora-timed to advance a proposal as to how infants may access the phonological system of the language they are exposed to. In particular, they proposed that the rhythmic class of the language of exposure determines the unit exploited in the segmentation of connected speech: infants exposed to stress-timed languages would use the stress foot (that is, the interstress interval), those exposed to syllable-timed language the syllable and those exposed to a mora-timed language the mora (Cutler *et al.* 1986; Otake *et al.* 1993; Mehler *et al.* 1996).

Most convincing are a number of experiments carried out with French newborns, which show that they are able to discriminate English from Japanese, but not English from Dutch, in low-pass filtered sentences, that is, in sentences whose segmental information is reduced, while prosodic information is largely preserved (Nazzi *et al.* 1998). In order to show that rhythm – rather than any other property of the test languages – is responsible for this discrimination ability, Nazzi *et al.* also tested newborns on a set of randomly intermixed English and Dutch sentences, and showed that they discriminate these from a set of randomly intermixed Spanish and Italian sentences. However, the discrimination ability disappeared when the newborns were tested on a set of English and Spanish sentences *vs.* a set of Italian and Dutch sentences. Thus the intuitions that many phoneticians shared about different rhythms in English and Italian, for example, are confirmed by newborns' sensitivity to this distinction. It is thus clear that some physical property must be present in the signal to account for this difference, but until recently it has not been clear what this property was.

5 Rhythm as alternation at all levels

If isochrony is not responsible for the machine-gun and Morse-code effects, we should ask which characteristics in the signal are responsible for it. That is, what is there in the signal that would account for the clear rhythmic differences of languages belonging to different classes? Or what is the element that establishes order at this level? Ramus *et al.* (1999) answered this question starting from the hypothesis that newborns hear speech as a sequence of vowels interrupted by unanalyzed noise, i.e. consonants; this hypothesis is known as the *Time-Intensity Grid Representation* (TIGRE; Mehler *et al.* 1996). Ramus *et al.* (1999) proposed that, at the basic level, the perception of different rhythms is created by the way in which vowels alternate with consonants. It is thus the regularity with which vowels recur that establishes alternation at this level: vowels alternate with consonants. Starting from the observation that as we go from stress-timed to syllable-timed and then to mora-timed languages the syllabic structure tends to get simpler – and the observation that simple syllables imply the presence of proportionately greater vocalic spaces – vowels would occupy less time in the flow of speech in stress-timed languages than syllable-timed languages. Likewise, in syllable-timed languages vowels would occupy less time than in mora-timed languages, which have the largest amount of time per utterance occupied by vowels. This difference is clear from the rough division into Vs and Cs in the three sentences in (5)–(7). Notice that, in agreement with Ramus *et al.* (1999), glides are treated as Cs if prevocalic and as Vs if post-vocalic.

(5) *English*
The next local elections will take place during the winter
CVCVCCCCVVCVCVCVCCCVCCCVCCVVCCVVCCVCVCCV

(6) *Italian*
Le prossime elezioni locali avranno luogo in inverno
CVCCVCCVCVVCVCCVCVCVCVCVVCCVCCVCCVCVVCVCCVCCV

(7) *Japanese*
Tsugi no chiho senkyo wa haruni okonawareru daro
CVCVCVCVCVCVCCVVCVCVCVCVVCVCVCVCVCVCV

Ramus *et al.* (1999) tested this idea on a corpus of eight languages: English, Polish, and Dutch, representatives of the stress-timed category, French, Italian, Spanish, and Catalan, representatives of the syllable-timed category (Abercrombie 1967), and Japanese, representative of the mora-timed languages (Ladefoged 1975). They observed that languages from the same rhythmic class had similar values for %V – i.e. a similar amount of time occupied by vowels in the speech stream – as compared to languages from different rhythmic classes. The computation of %V was carried out on the basis of a careful segmentation, on the basis of both auditory and visual cues from the spectrogram (cf. Ramus *et al.* 1999). Given the assumption that newborns do not retain the difference between individual Cs and individual Vs, for each sentence only the vocalic and consonantal intervals were measured. Adjacent vowels and adjacent consonants are thus treated as vocalic and consonantal chunks, respectively. A second measure that clusters the languages into three groups is the standard deviation of the duration of consonantal intervals (ΔC), i.e. a broad measure of the regularity with which vowels recur (see Figure 48.1). Both measures are related to syllable structure. A high %V implies that the repertoire of the possible syllable types is restricted, thus also that the consonantal intervals do not vary a great deal, given that there are no languages in which all

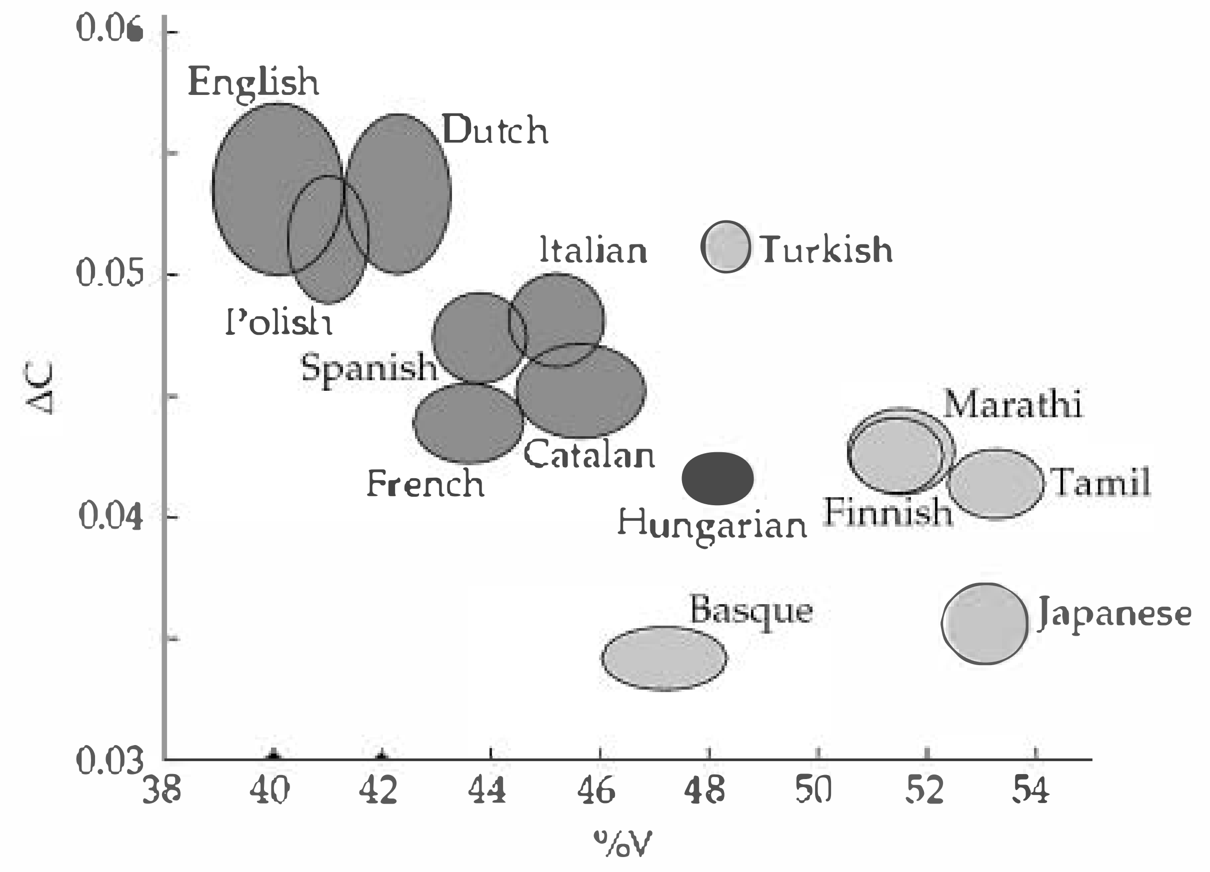

Figure 48.1 ΔC, the standard deviation of the consonantal intervals, *vs.* %V, the amount of time per utterance spent in vowels, for 14 languages. The widths of the ellipses along the two axes represent standard errors of the mean along the axes. Dark ellipses represent head-initial languages, and light ellipses head-final languages. Turkish, Hungarian, Basque, Finnish, Marathi, and Tamil are from unpublished results. Data for the remaining languages are from Ramus *et al.* (1999)

syllables are complex. Rather, even in languages with the greatest variety of syllable types, the basic syllable type – CV – is the most unmarked (Blevins 1995; Rice 2007).

Thus, according to this proposal, rhythm is alternation at all levels: of consonants and vowels at the basic level and of stressed and unstressed syllables, feet, and words at subsequent levels. This order in the flow of speech is always established by the alternation of more and less audible elements.

6 Other proposals

The analysis proposed by Ramus *et al.* (1999) is not the only one to rely on a purely acoustic-phonetic description of the speech stream in trying to understand the basis of linguistic rhythm. In Ramus *et al.* the %V and ΔC variables do not consider the relative ordering of long and short intervals inside an utterance. That is, sequences like CCVː.CCVː.CV.CV and CCVː.CV.CV.CCVː (where Vː is a long vowel, as opposed to VV, which denotes two different adjacent vowels) will yield identical values for their two variables.

Grabe and colleagues therefore chose to examine the *pairwise variability indices* (PVI) in the vocalic and intervocalic intervals in speech (e.g. Low *et al.* 2000; Grabe and Low 2002). This measure is meant to capture a little more of the (local) temporal patterns in speech by considering the variability of all *pairs* of vocalic or intervocalic intervals.

classes differ in their syllabic structure: going from a low %V to a high %V, languages go from having more complex to having simpler syllabic structures. Typologists have in fact observed that various morphosyntactic properties are correlated with the complexity of syllables in a language (Gil 1986; Fenk-Oczlon and Fenk 2004) and, in addition, with its rhythmic patterns (Donegan and Stampe 1983). The computation of %V might therefore offer cues to very different properties of the language of exposure.

Shukla *et al.* (in progress) hypothesize that the correlates of linguistic rhythm, %V and ΔC, have consequences for acquiring correlated morphosyntactic properties like agglutination and word order. These researchers extend the results from Ramus *et al.* to a larger and more varied set of languages. The results indicate that there is a tendency for languages with a low %V to differ from languages with a high %V in head direction, degree of agglutination, richness of the case system, and flexibility of word order (see Figure 48.1). Thus, it is proposed that a simple syllabic structure is correlated with agglutination: if many suffixes can be attached to a word, complex syllabic structure would make these words excessively long and possibly hard to parse.

The question remains why agglutination is found almost exclusively in head-final languages. Two different reasons, both syntactic in nature, have been given. In van Riemsdijk (1998), the explanation for the correlation between head-finality and agglutinative morphology is based on head adjunction, the syntactic device that assembles independent, phonetically realized morphemes in complex words. A principle states that head adjunction can take place only between linearly adjacent heads; since heads are adjacent in head-final languages, while they are separated by intervening specifiers in head-initial languages, head adjunction – and thus agglutination – is expected to take place in OV languages only.

More recently, Cecchetto (forthcoming) assumes that morphological conflation, responsible for fusional morphology, requires that a direct syntactic dependency be established between a selecting head and a selected one. However, in head-final languages this dependency would go backwards, since the selecting head linearly follows the selected one, and backward dependencies are disfavored, for processing reasons (e.g. Fodor 1978). As a consequence, in head-final languages affixes cannot be fused, and result in agglutination instead.

If there is indeed a syntactic explanation for the correlation between head direction and agglutination, the identification of the rhythmic class of the language of exposure would be one of the mechanisms that would assist the infant in the bootstrapping of both the favored morphological operations and word order in the language to which they are exposed.

8 Concluding remarks

In conclusion, linguists' intuitive notion of stress-timed and syllable-timed rhythm is most likely a consequence of the phonological organization of different languages, which can be captured by two relatively simple acoustic-phonetic cues, such as %V and ΔC. Languages appear to be grouped into three rhythmic classes: one corresponding to so-called stress-timed languages, one to so-called syllable-timed languages, and one to so-called mora-timed languages. The rhythmic class to which a language belongs appears also to determine the segmentation unit used by its
